HANFORD'S RADIOACTIVE MIXED WASTE DISPOSAL FACILITY

D. E. McKenney
Westinghouse Hanford Company

ABSTRACT

The Radioactive Mixed Waste Disposal Facility, is located in the Hanford Site Low-Level Burial Grounds and is designated as Trench 31 in the 218-W-5 Burial Ground. Trench 31 is a Resource Conservation and Recovery Act compliant landfill and will receive wastes generated from both remediation and waste management activities.

On December 30, 1994, Westinghouse Hanford Company declared readiness to operate Trench 31, which is the Hanford Site's (and the Department of Energy complex's) first facility for disposal of low-level radioactive mixed wastes. As part of their startup approval process, the Department of Energy is currently conducting a line management review of the facility and it's operating basis.

INTRODUCTION

The Department of Energy and it's contractors have taken an important step forward in their program for management of mixed wastes at the Hanford Site. The completion of construction of Trench 31 in the low-level waste burial grounds provides the Site with it's first disposal facility for mixed waste.

An aerial view of Trench 31 is shown in Fig. 1.

This facility not only provides a disposal pathway for qualifying waste currently in storage at the Site, but also provides a disposal pathway for residues from planned mixed waste treatment facilities.

The facility also provides near-term disposal capacity for Site remediation activities. Long-term disposal capacity for remediation wastes may be provided by a larger facility (currently in regulatory review and development). Trench 31 operations will provide valuable operating experience and data (bulk remediation waste handling, leachate generation and disposal) that will aid development and planning for this larger facility.

FACILITY DESCRIPTION

Trench 31 is Resource Conservation and Recovery Act (RCRA) compliant, with a double composite liner and leachate collection and removal systems. The landfill is rectangular, with approximate base dimensions of 76 meters by 30 meters. The side slope ratio for the landfill excavation is 3 horizontal to 1 vertical. The bottom of the landfill excavation slopes slightly to facilitate leachate collection, giving a variable depth of approximately 7.6 meters to 9.1 meters. There is a recessed section at the eastern end of the landfill excavation that houses the sumps for leachate collection and removal. Access into the landfill is provided by a vehicle ramp (8% slope) along the southern perimeter.

From top to bottom, the liner system incorporates the following layers (see Fig. 2):

Operations layer - The bottom and sides of the landfill are covered with a 0.9 meter deep layer of soil to protect the liner system during waste placement operations.

Primary Leachate Collection System - This layer consists of geotextile, drainage gravel, geonet/geotextile geocomposite, primary high density polyethylene (HDPE) geomembrane, and a 0.5 meter soil and bentonite clay (eight to ten percent) admix layer.

Secondary Leachate Collection System - This layer consists of geotextile, drainage gravel, geonet/geotextile geocomposite, secondary HDPE geomembrane, and a 0.9 meter soil and bentonite clay admix layer.

The primary leachate collection system is composed of drainage gravel and perforated drainage pipes that lie along the centerline of the trench bottom, at the base of the side slopes, and down the "upslope" side if the access ramp. A secondary leachate collection system is installed above the secondary liner system. The leachate collection systems are designed to direct leachate to the sump area located at the east end of the landfill. Pumps are located in the sump area, and provide for removal and storage of leachate in a 37,850 liter storage tank sited at the eastern crest of the landfill.

The landfill was designed with consideration for the 24 hour, 25 year peak precipitation event (>4 centimeters precipitation). This 24 hour event is conservatively estimated to result in a maximum of 400,000 liters of liquid collected. The layout of the facility as described is shown in Fig. 3.

Construction of a second landfill lobe has been completed and is currently going through the operations acceptance process. The design of this lobe is nearly identical to Trench 31. It is currently planned that this second lobe will not be used until Trench 31 is filled and capped with an interim cover, in order to minimize volumes of leachate requiring management.

WASTE SOURCES

The predominance of the wastes to be disposed of in the facility will be remediation wastes. Remediation alternatives for waste sites along the Columbia River are being developed through the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) process and/or Resource Conservation and Recovery Act (RCRA) past-practice corrective measures actions. When developed and selected, these alternatives may involve relocation of wastes to a location more central to the Hanford Site (further separated from the river and groundwater). Trench 31 is intended to provide disposal capacity to support such a relocation alternative for remediation waste. Trench 31 will also provide sufficient disposal capacity for remediation waste to "span the gap" until a larger centralized disposal facility, the Environmental Restoration Disposal Facility, comes on line as proposed in September, 1996.

It is anticipated, based on historical knowledge and characterization data from the remediation sites, that the remediation wastes to be disposed of in the landfill will be predominantly soils or debris with very low concentrations of radionuclide and hazardous constituents. The facility operating basis has been developed to support packaged or unpackaged (bulk) waste receipts.

A small relative volume of the landfill capacity (less than 2000 cubic meters) will be used for disposal of wastes generated through waste management activities. Some of the containerized waste currently stored within the Hanford Central Waste Complex may qualify for disposal in the landfill without treatment. Evaluations are underway to determine what portion of the stored wastes may be disposed of directly without further treatment. Trench 31 will provide disposal capacity for some of these stored wastes, as well as for other newly generated wastes, which qualify for disposal.

WASTE ACCEPTANCE

Primary waste acceptance criteria have been developed for mixed low-level radioactive disposal in this landfill. These waste acceptance criteria for the landfill are included in the "Hanford Site Solid Waste Acceptance Criteria" document. Procedural requirements for waste sampling and analysis, waste receipt, and certification prior to acceptance into the landfill will be based on these waste acceptance criteria.

Waste acceptance criteria currently include prohibitions on acceptance of certain wastes. Prohibited wastes include, but are not necessarily limited to, such items as free liquids, reactive wastes, greater than Class C wastes as defined in 10 CFR 61.55, RCRA land disposal restricted wastes, transuranic wastes (there are quantifiable limits applied to many of these).

The waste acceptance criteria also address the compatibility of the accepted wastes with the landfill liner materials, with the RCRA permits for all affected facilities (including those that will handle the leachate), and with other applicable regulatory documentation (e.g. the delisting petition for the facility that will eventually treat and dispose of the leachate). Testing for liner compatibility (9090 testing) has been completed for a limited number of constituents, additional testing is underway and will likely expand the range of compounds found to be compatible with the liner system.

These waste acceptance criteria will likely continue to evolve as the regulatory processes are completed for the remediation sites (ie. Record of Decision outcomes may influence criteria), as additional waste characteristic information is obtained as remediation progresses and field observation information is obtained, and as ongoing tests to supplement liner compatibility data are completed.

LEACHATE GENERATION AND DISPOSAL

Leachate handling and disposal is an important consideration once landfill operation begins. The facility will be operated to insure that leachate generated is consistent with treatment/disposal facility requirements and that leachate generation is avoided or minimized to the maximum extent possible.

The characteristics of solid wastes accepted in the landfill for disposal will be have to be carefully managed to remain consistent with permits, regulatory requirements and process parameters for facilities which will be involved with

handling, storage, treatment and disposal of the leachate. Of particular concern, waste codes assigned to the solid wastes accepted for disposal will have to be managed in order to comply with current permitting documentation for leachate handling facilities. If multiple listed waste codes are accepted into the facility, the F039 waste code ("multisource leachate") will apply to the leachate per RCRA requirements. Modifications to the applicable permits and other regulatory documentation (i.e. delisting petitions) are being pursued to support as much flexibility in waste receipt as possible. The list of acceptable waste codes will likely continue to evolve as needed and as regulatory requirements allow.

The scheduling of waste receipts at the facility is important in limiting the volumes of leachate requiring management. It is desirable to minimize the length of time between start of operations and closure of the facility (placement of interim cap or final closure) in order to minimize the volume of leachate generated. Requests for forecast waste volumes and schedule information have been sent to the generators. These will be used to develop operating scenarios for the facility which will minimize leachate volumes.

Modeling of leachate production was conducted using the Hydrologic Evaluation of Landfill Performance (HELP) model. Using conservative assumptions (such as the facility is open for 10 years, minimal operating cover layers, etc.), the average annual leachate production of leachate was estimated to be about 590,000 liters. Experience at nearby commercial hazardous waste disposal facilities and at Hanford indicate that this is a conservative estimate and that actual volumes may be somewhat lower.

It is planned that leachate collected from the operating landfill will initially be transferred to the Hanford double-shell tank system for storage. Treatment and disposal of the leachate once received in tank farms will be as for any other dilute tank farm waste stream. Disposal will be facilitated through the use of existing tank farm and liquid effluent facilities, such as the 242-A Evaporator, the Liquid Effluent Retention Facility (LERF) and the 200 Area Effluent Treatment Facility (ETF).

The transfer of the leachate to the tank farms supports operation of the landfill in the near-term, but may not represent the best long-term alternative. Tank farm space is a limited and valuable commodity, and is best reserved for higher priority, less dilute, liquid waste streams. In the interest of limiting the volumes of waste sent to the tank farms, direct transfer of the leachate to the 200 Area Effluent Treatment Facility (ETF) is being pursued.

CONCLUSIONS

The Department of Energy has been in a mode of interim storage of mixed wastes at Hanford, this facility represents the first step towards a final solution (disposal). Qualified wastes currently in storage at Hanford can now be disposed of, and development and implementation of waste treatment processes can continue to proceed with the knowledge that a facility exists which can receive mixed waste residues. Trench 31 will also allow disposal of mixed wastes resulting from remediation activities, and thus supports the Hanford Restoration mission. This facility can also serve as an important pilot test of disposal operations to be used to support full scale remediation activities.

APPLICATION OF BINARY MIXING MODELS TO THE INTERPRETATION OF NITRATE AND RADIONUCLIDE FLUCTUATIONS IN THE VADOSE AND SATURATED ZONES, SOLAR EVAPORATION PONDS, ROCKY FLATS ENVIRONMENTAL TECHNOLOGY SITE, GOLDEN, COLORADO

Ron L. Schmiermund
Richard L. Henry
Phil A. Nixon
Parsons Engineering Science, Inc.
Denver, Colorado

ABSTRACT

The Rocky Flats Environmental Technology Site (RFETS) has utilized surface impoundments (Solar Evaporation Ponds or SEPs) for the storage of high nitrate, liquid plutonium- and uranium-process wastes since 1953. Emptying of the ponds is now nearly complete and decommissioning is underway. The Interim Measures/Interim Remedial Action (IM/IRA) proposes to place all SEP-contaminated wastes beneath an engineered cover constructed of natural materials and to demonstrate long-term

protection of the environment. A critical aspect of the IM/IRA design is an assessment of the environmental threat posed by sub-SEP vadose zone soils if left in place. Excavation of the soils significantly increases the volume of waste required to be covered and thus the extent of the engineered cover. Simple binary mixing models are derived and used to interpret existing groundwater data collected since 1989, and to evaluate the extent of on-going contaminant leaching from the vadose zone which serves as the basis of a predictive model for future performance. Data analysis indicates that nitrate and radionuclides are mobilized from both vadose zone pore waters related to old (ca. 1960) liquid pond wastes, and from vadose zone solids during seasonal high groundwater stands. The mixing model is also used to implicate sorption control of uranium and colloid-facilitated transport of americium and plutonium. The study supports the decision to excavate vadose zone soils down to the mean seasonal high groundwater table and install a drainage layer (to limit groundwater rise) as a base for soils and other SEP wastes scheduled for inclusion beneath the engineered cover.

INTRODUCTION

Liquid process wastes from plutonium and uranium operations at the Department of Energy's, Rocky Flats Plant near Golden, Colorado (now known as the Rocky Flats Environmental Technology Site or RFETS) were discharged into various surface impoundments beginning in 1953. Collectively these ponds are known as the Solar Evaporation Ponds (SEPs). Details of the site are contained in numerous documents including DOE (1) and illustrated in Fig. 1. The nature of the plutonium refining process involved large quantities of nitric acid for dissolution of the fissionable metal. Prior to the incorporation of adequate refluxing equipment, the highly acidic spent nitric acid wastes with traces of unrecoverable plutonium and uranium were placed in the SEPs along with other industrial wastes. Documented SEP leakage is known to have been responsible for unquantified releases of nitrate to groundwaters and surface waters. Direct discharges of process wastes to the SEPs largely ceased by the mid 1980s but various contaminated waters have remained in the impoundments until recently.

As of this writing, all SEPs have now been deactivated and all but one are completely emptied of liquids and sludges. A proposed action under the negotiated Interim Measures/Integrated Remedial Action (IM/IRA) is to construct a "dirty" closure whereby all contaminated materials from SEP activities (sludges, liquids, liners etc.) would be enclosed on-site beneath an engineered cover designed to be protective of the environment and human health for 1000 years. Additional contaminated materials considered for inclusion beneath the engineered cover are those vadose zone soils previously exposed to SEP leakage. Inclusion of these soils with the other wastes beneath the engineered cover represents a significant increase in volume. As part of the IM/IRA design, the
extent of ongoing groundwater contamination due to leaching of contaminants from vadose zone soils was investigated as a predictor of future behavior and as a basis for justifying their disposition relative to inclusion with the other wastes beneath the engineered cover.

Absolute contaminant concentrations in groundwater proximal to the SEPs reveal long (4 to 6 years) and short (quarterly) term variability. All or part of such variability may be attributed to 1) a changing contaminant sources (e.g., cessation of leakage, decreased contaminant concentration in leakage, or exposure to contaminated soils due to water table rises) and/or 2) changing dilution factors with uncontaminated groundwater. In order to sort out the relative contributions of these factors to the observed contaminant concentration variability, and to determine if vadose zone soils are actively supplying contaminants to the groundwater (and thus might be a liability in the future if allowed to remain in place), it was first necessary to evaluate the effect of dilution. Following the method described by Whittemore (2) and others, groundwater concentrations of two components, both assumed to be conservative (chloride and nitrate), were ratioed and compared to the predicted ratios for various mixtures of background groundwater and SEP waters. Correspondence of observed data with predicted values offers support for a simple mixing hypothesis.

Averaged over several years, groundwater in the most nitrate-contaminated OU4 monitoring wells appears to be a product of mixing of background groundwater with SEP water compositions intermediate between ca. 1963 and 1991 pond waters. Groundwater in monitoring wells as close as 30 meters to the nearest SEP have

experienced very little dilution to date, apparently due to low groundwater flow rates. More proximal wells have become more dilute with time and indicate a shrinking contaminant plume. On a more detail time scale (seasonal), however, the degree of dilution appears to be affected by groundwater table fluctuations and suggests that during normal seasonal rises, groundwater may encounter labile nitrate sources in the vadose zone, presumably in the form of trapped SEP leakage in soil pores. Uranium/chloride ratios also vary with water table elevation and suggest that a net increase in groundwater uranium mass occurs during seasonal high water stands. These observations indicate that the vadose zone soils above the mean seasonal high water table pose a risk if allowed to remain in place and if groundwater rises further.

HISTORY OF SOLAR EVAPORATION PONDS (SEPs)

A brief history of the SEPs is useful for interpreting mixing curves presented later in this paper. Unlined (briefly) and lined impoundments have occupied an eight acre site in the northeast portion of RFETS since December, 1953. Current capacity is 10.7 million gallons. Their purpose was initially to provide temporary storage for low-level radioactive liquid process wastes and ultimately long-term waste reduction by evaporation. Existing ponds are collectively known as the SEPs and the entire area, including remnants of previous ponds, is being treated as Operable Unit (OU4). The history of SEP utilization is complex based on construction, maintenance and sparse discharge records. Process knowledge also suggests complexity because discharge compositions would have changed over time as plutonium and uranium refining procedures improved, but unfortunately. very little data exists on pond water compositions, especially during the period from 1963 to 1991.

Primary process waste discharges to the 207-B Ponds ceased in 1974 and to 207-A and 207-C in 1986. Treated sanitary waste water, recovered downgradient contaminated groundwater and minor industrial wastes were added to various ponds in later years. Removal and treatment of water and sludge has been on-going over the last five to ten years and currently only 207-C has not been emptied. A comprehensive pond water sampling and analysis program conducted in 1991 revealed that the water present at that time was dramatically less contaminated relative to water in the same ponds in 1963.

Evidence of leakage of pond liquids to the underlying vadose zone is abundant, both in the form of SEP operational records and compositions of downgradient groundwaters and surface waters. Although improvements in pond construction techniques were implemented and frequent repair measures taken documented leakage events were common through 1970 and sporadic thereafter. No estimate of volumetric leakage from the SEPs is available. A large Interceptor Trench System (ITS) was installed and upgraded to collect contaminated groundwater and return it to the ponds. High nitrate (2500+ mg/L NO_3^- + NO_2^- as N) concentrations have been observed in downgradient monitoring wells since their installation in 1989.

At present, contaminated materials resulting from SEP activities in OU4 include liquids stored in tanks, consolidated (cemented) sludges, unconsolidated sludges, pond liners and vadose zone soils. A proposed action under the terms of the IM/IRA negotiated for the site, is to excavate contaminated soils, further consolidate liquids and sludges, and to place all solid materials on an engineered drainage layer positioned above the water table and to cover the entire volume with an engineered cover constructed of natural materials. The design criteria include no unacceptable impact to groundwater for 1000 years.

HYDROGEOLOGIC SETTING AND GROUNDWATER CONTAMINATION

The site is located on a low interfluve pediment between North and South Walnut Creeks (Fig. 1). Surface geologic units are composed of thin accumulations (2-5 meters) of complexly interbedded silts and silty clays of the Quaternary Rocky Flats Alluvium (RFA) and derived colluvium. The RFA unconformably overlies bedrock which consists of nearly flat-lying claystones, shales and local fine sandstones of the Cretaceous Arapahoe/Laramie formations. Operationally, the entire thickness of the RFA, colluvium, the weathered top of bedrock and bedrock sandstones present at the unconformity are considered to constitute the Upper Hydrostratigraphic Unit (Upper HSU). Laboratory-determined hydraulic conductivities in the RFA exhibit a large range (7×10^{-2} to 1×10^{-9} cm s^{-1}) but are generally taken to be low (1×10^{-7} cm s^{-1}), as are overall hydraulic gradients (0.03), indicating very low Darcy velocities (1×10^{-3} m/yr). Effective hydraulic conductivity, based on well recovery data, appear to be significantly higher (1.4×10^{-4} cm s^{-1}) perhaps due to macropores, and

gradients in the vicinity of plumes (see Fig. 1) are higher (0.07) and may have been higher still in the past due to pond leakage. Conservative Darcy velocities therefore may be as high as 3 m yr-1. Overall groundwater flow directions are indicated on Fig. 1 but in detail are highly complex due to natural lithologic variability, earth moving disturbances, and extensive buried pipelines, drains and foundations.

The mean seasonal high groundwater table is generally within a few meters of the base of the SEP structures and locally may contact the liners. In general, leakage from SEPs is thought to have locally saturated the vadose zone, mixed with the groundwater and migrated to the north and northeast toward North Walnut Creek. The ITS was installed in such a way as to intercept and capture this flow path although current data suggest some component of the flow may pass beneath the ITS trenches locally.

Figure 1 also illustrates the location of monitoring wells proximal to the SEPs that have been completed in the Upper HSU and are sufficiently saturated for normal quarterly groundwater sampling. Coverage is sporadic for a variety of reasons but is sufficient to reveal downgradient groundwater contamination. Distributions of average 1992 groundwater nitrate concentrations (values represent NO3- + NO2- as N averaged over four quarters) are also shown on Fig. 1. A contaminated plume defined by monitoring wells H, I and J issues from the northern ends of 207-A and the 207-B series SEPs and is shown truncated by the ITS. A stylized plume is also shown downgradient of 207-C but data to support its existence is circumstantial. Minor nitrate contamination is present to the southeast of 207-B South and appears to be responding to a minor southeasterly component of groundwater flow.

Identifying uncontaminated, upgradient (background) monitoring wells is problematic at OU4 because the bulk of the RFETS industrial complex lies upgradient. A detailed examination of all available data (not presented here) using trilinear diagram analyses indicates that only groundwater in monitoring well A is similar to site-wide background groundwater and does not appear to have been affected by SEP leakage or other industrial contamination. This well is taken to represent background for all subsequent analyses but in reality, groundwater upgradient of OU4 and therefore groundwater which received SEP leakage may already have been contaminated to some extent by other industrial activities.

DERIVATION OF CONSERVATIVE COMPONENT MIXING EQUATIONS AND PLOTS

Simple 2-component conservative mixing equations have been presented by Whittemore (2) and others and applied to the identification of brine sources in contaminated surface waters and groundwaters. In these cases, dissolved chloride and bromide ions are assumed to be unaffected by heterogenous (aqueous-solid) processes and are thus considered "conservative". If multiple potential sources of brines exist (e.g., separated oil field brines and road salt runoff) and each possesses a different [Br/Cl] ratio, then it can be shown that each source will produce a unique mixing curve relative to a common diluent in [Br/Cl] vs. Cl space. By comparing an observed contaminated water composition with the mixing curves, it is possible to identify the source of the brine. For the purposes of this study Cl- and (NO3- + NO2-) reported as N, hereafter denoted simply as NO3-(N) were selected as the two conservative components as no Br- data exists and nitrate is of obvious interest. The extreme solubility of nitrate salts (>100,000 mg/L NO3-(N)) and abundance of dissolved nitrate (up to 2800 mg/L NO3-(N)) indicates that nitrate may be safely considered conservative. A mixing curve for two solutions (A and B), each containing two conservative components (1 and 2) is derived as follows:

Solution A (e.g., a concentrated brine)
C1A = concentration of 1 in solution A (e.g., Br- or NO3-(N))
C2A = concentration of 2 in solution A (e.g., Cl-)
VA = volume of solution A in mixture
Solution B (e.g., a background water)
C1B = concentration of 1 in solution B (e.g., Br- or NO3-(N))
C2B = concentration of 2 in solution B (e.g., Cl-)
VB = volume of solution B in mixture
Mixture (e.g., contaminated groundwater)
C1 Mix = concentration of 1 in mixture
C2 Mix = concentration of 2 in mixture
VA + VB = VMix
RV = VA / VB

See Eq. 1
Figure 2 illustrates a generic mixing curve calculated as described above. Note the relative sensitivity to mixing ratios at various points along the curve.
NITRATE IN GROUNDWATER
Figure 1 illustrates the distribution of nitrate in groundwaters only in the immediate vicinity of the SEPs. The sparse data reveal a significant nitrate plume extending northwest from SEP 207-BN to the point where it should be truncated by the ITS. This plume is consistent with the principal groundwater flow direction toward North Walnut Creek. Historically, data suggest the existence of another major plume emanating from SEP 207-C but no monitoring wells exist in that area. Nitrate groundwater contamination is also present outside the area of Fig. 1 and downgradient of the ITS at a distance of more than 300 m from the SEPs. Assuming the estimated effective Darcy velocities (3 m yr-1) in the RFA it is clearly impossible to explain the overall distribution of groundwater nitrate. It is apparent that overland flow of contaminated water, sourced in springs and seeps and possibly hidden drains, is partially responsible for the observed overall distribution. To interpret the source(s) and pathways contributing to the nitrate observed in the most contaminated monitoring wells (H, I and J on Fig. 1), a binary mixing model as described in the previous section was used.
OU4 Binary Mixing Model
Figure 3 illustrates various mixing curves developed for groundwater beneath the SEPs. All curves were constructed as described previously. Theoretical mixing curves are shown for a single upgradient groundwater (A) mixed with waters from four SEPs as they existed in 1963 and 1991. The dilute end-member groundwater represents a mean of water quality data collected from monitoring well A, the most defensible candidate for "local" background groundwater at OU4. Site-wide background groundwater contains, on average, less Cl- than well A but similar [NO3-(N)/Cl] ratios. Meteoric precipitation would also be expected to contain less Cl- than A and potentially lower [NO3-(N)/Cl]. Reddy and Caine (3) give 0.152 mg/L and 0.507 for Cl- and [NO3(N)/Cl], respectively, for precipitation at a site 32 km northwest of RFETS. Given this information, the dilute end-member of the mixing curves might be best considered to be an area on the plot rather than a point.
Six concentrated end-members are identified according to source SEP and year. Although substantial differences existed between pond compositions in 1963, as a group, the 1963 waters are clearly distinctive from the 1991 pond waters and consequently result in distinctive theoretical mixing curves. The curves describe where groundwater compositions would plot if they originated from mixing various proportions of background groundwater and a specific pond water. Given the period of time spanned by the two sets of curves and the complex evolutionary history of the ponds as described above, it is entirely possible that some undocumented intermediate pond water compositions might better represent the concentrated end-members for the majority of groundwater/pond water mixes.
All available quarterly groundwater nitrate and chloride data collected during the period 1987 to 1993 from monitoring wells H, I, and J are also shown on Fig. 3. Note that over this period groundwater from wells I and J each exhibit limited variability in [NO3(N)/Cl] - Cl space, indicating a stable groundwater chemical regime at those locations. The plotting positions of I and J data between the group of 1963 mixing curves and the group of 1991 curves suggest that some intermediate pond water composition was the source of the nitrate contamination in those wells. Additionally, the similar [NO3-(N)/Cl] ratio of I and J groundwaters suggests a common contaminant source and the lower Cl- concentrations in I well groundwaters indicates greater dilution at that location. The fact that groundwater at neither well I nor well J (located 20 and 60 m downgradient of the nearest pond margin, respectively) appear to represent dilutions of contemporaneous pond water (i.e, 1991 pond water) may be explained by the slow groundwater flow rates and their distances from the ponds. Greater dilution at the more source-proximal well I location may be evidence that the source has abated and the maximum contaminant concentrations have passed that location - analogous to a decaying breakthrough curve.
Monitoring well H is located immediately adjacent to SEP 207-BN but appears to be lateral to the main body of the groundwater nitrate plume. Groundwater from well H shares a similar [NO3-(N)/Cl] ratio with I and J, suggesting a common contaminant source, but exhibits a much wider range of Cl- concentrations and, by inference, a much wider range of dilutions of that source. A consistent decrease in Cl-

concentrations in well H groundwater (from >300 to <50 mg/L) with time is also seen, indicating a relatively rapid increase in source dilution. Such temporal behavior would be consistent with position of well H relative to the main axis of the plume where the affects of a waning source would occur most rapidly.

A mixing curve passing through the plots of groundwater compositions from wells H, I and J may be constructed as shown in Fig. 3 by calculating the compositions between a hypothetical intermediate pond water X and a hypothetical background groundwater Z representing the mean of all site-wide Upper HSU groundwaters (see previous discussion of background variability). This hypothetical mixing curve may then be used to estimate the dilution factors necessary to produce the observed groundwater compositions. (Note that the dilution factor is very sensitive to the chloride concentration selected for the brine endmember.) For example, well J groundwaters appear to be a 1:1 mixture (background groundwater:pond water), well I groundwaters about 2:1 and well H groundwaters ranging from 2:1 to 80:1.

Temporal Variations in Groundwater Nitrate

Figure 4a illustrates the nitrate and chloride concentration history of monitoring well H. With the exception of the final sampling period (which may reflect damage to the well casing which resulted in abandonment of the well), nitrate concentrations have decreased steadily and dramatically since mid-1987. By comparison, [NO3-(N)/Cl] has remained nearly constant over the same period, ranging from 3.3 to 5.2. The contrast between these two quantities supports the important conclusion that the source of nitrate contamination is remaining essentially constant in composition and only the flux of that source to the groundwater is changing (i.e., a changing dilution factor). Recall that pond water compositions are known to have changed over time and that 1991 SEP sampling reveals that the pond water present during the period shown in Fig. 4a was more dilute. In the absence of [NO3-(N)/Cl], one might conclude that pond leakage rates have remained constant and improving groundwater quality is due to improved pond water quality. Rather, it would appear that the "old" pond water source is diminishing but continues to affect present-day groundwater quality.

Figure 4a also shows that the groundwater elevation in monitoring well H. High [NO3-(N)/Cl] ratios appear to occur during periods of high groundwater stands. Although simple correlation analysis does not support this apparent relationship, close examination reveals that quarterly samples for water quality measurements were not collected consistently with respect to peak groundwater elevations. Other monitoring wells in the vicinity of the SEPs exhibit similar trends but in all cases the groundwater table elevation fluctuates at a higher frequency than that at which water quality samples were collected. It is apparent that monthly sampling would be required to directly quantify this relationship. If high groundwater stands are indeed associated with elevated [NO3-(N)/Cl], such a relationship would support the existence of a concentrated "old" pond water reservoir in the form of residual vadose zone pore water. In this scenario, groundwater rising into the vadose zone would mix with vadose zone pore water, acquire some of the dissolved contaminants and transfer those contaminants to the saturated zone as groundwater recedes. A simple mixing model, based on assumptions of effectively infinite nitrate solubility, saturated vadose zone porosity and field capacity predicts the decay of nitrate concentrations with successive seasonal flushing events.

RADIONUCLIDES IN GROUNDWATER

Behavior of radionuclides in the OU4 subsurface is a point of obvious concern but data is limited spatially and temporally, in part due to the large volumetric requirements for water analyses and low-yield nature of most monitoring wells. In the case of monitoring well H, damage to the well casing resulted in its removal from service in early 1992. Figure 4b illustrates the fluctuation of U-238 and U-238/Cl in monitoring well H. (As expected, U-235 and U-233/234 and the respective chloride ratios behave similarly.) Dissolved uranium concentrations appear to be depressed in Fall 1991, roughly coincident with a period of relatively high groundwater surface elevation. This decrease in dissolved uranium is initially associated with a sharp increase in U-238/Cl, followed by a decrease.

Applying the same mixing equations described earlier (substituting dissolved uranium for NO3(N)), and the uranium concentrations in the same hypothetical background and pond water necessary to explain the behavior of nitrate, the data presented in Fig. 4b can be tested against the predictions of a simple mixing model. A mixing plot containing the measured groundwater U-238 and U-238/Cl data (analogous to Fig. 3 but

not presented here) reveals that observed groundwaters do not fall on the mixing curve and actually describe an inverse curve relative to the hypothetical mixing line. The different behavior of uranium as compared to nitrate and the failure of the simple mixing hypothesis to explain the observed uranium concentrations is expected since dissolved uranium is unlikely to behave conservatively due to sorption and/or precipitation processes. Figure 4b indicates that during the initial rise of the groundwater into the vadose zone, dissolved U-238 decreases. Chloride also decreases during this period (as can be determined by the [U-238/Cl] ratios) but to a greater extent than does U-238. An equivalent decrease in both quantities would be consistent with simple dilution and result in a constant [U-238/Cl] ratio. It is evident, however, that the [U-238/Cl] ratio increases. This observation indicates that U-238 was added to the groundwater during the high water stand, probably as a result of transferral (dissolution or desorption) from the vadose zone stationary solid phase to the aqueous phase. Subsequent depression of the U-238/Cl ratio may represent the reverse process in the saturated zone. In support of a solid/liquid partitioning mechanism, a range of Kd values (approx. 15 to 30 L kg-1) was calculated using U-238 groundwater activities (as shown in Fig. 4b) and activities for vadose zone soils collected from the H borehole (1.5 - 2.0 pCi/g). Such Kd values are close to the preferred value of 43 L kg-1 proposed by Looney et al. (3), indicating the reasonableness of sorption control of U-238 groundwater activities.

A very limited amount of Am-241 data exists for groundwater from monitoring well H. Am-241 is present in the OU4 environment as a daughter product of Pu-241 (half life = 14.4 yr), a component of weapons-grade plutonium (Shefelbine (5)). Such a short half life would allow significant in-growth of Am-241 from plutonium contamination within the time frame of SEP operations and could remain proximal to the parent plutonium in the vadose zone. The fluctuation trends of Am-241 and [Am-241/Cl] in well H closely resembles that of NO3(N) and [NO3(N)/Cl] and thus suggesting extensive americium solubility. This is significant in view of the fact that americium is generally thought to have Kd values greater than those for uranium (Looney (4) recommends 100 L kg-1) and may be solubility limited in carbonate-rich environments (Triay et al. (6)). Mobility or apparent solubility of a species with a recognized affinity for solid phases may imply an association with suspended matter and/or colloidal matter. Colloid-facilitated transport of plutonium is generally considered to be potentially important and has been tentatively demonstrated for plutonium and americium elsewhere at RFETS by Harnish et al. (7). Consequently, the behavior of americium in the OU4 vadose zone may be a function of plutonium behavior which is influenced by colloidal matter.

CONCLUSIONS

Simple binary mixing models for conservative groundwater constituents (Cl- and NO3-) have been usefully applied to the interpretation of groundwater-vadose zone interactions in the vicinity of the SEPs at RFETS. Data demonstrate that recent groundwater compositions were mixtures of background groundwater and older, more concentrated, pond water rather than dilute contemporaneous pond water. This implies the retention of older pond leakage as vadose zone pore water. Temporal correlations of [NO3-(N)/Cl] ratios with groundwater elevation indicate that trapped pore water is contacted by and mixes with groundwater during seasonal high water stands resulting in periodic pulses of nitrate to the saturated zone. Limited data also suggests that radionuclides are mobilized from the vadose zone during high water stands. Uranium isotopes respond to groundwater fluctuations but do not obey the mixing model derived from nitrate and chloride concentrations. Uranium appears to be influenced by sorption processes characterized by a Kd in the range of 16 to 26. Americium, a daughter of weapons-grade plutonium, resembles the behavior of nitrate implying high (apparent) solubility but is likely associated with colloidal plutonium and is therefore more mobile than might be expected from literature Kd values. In the case of this site, the vadose zone appears to have the potential to act as a long-term contaminant source after elimination of leakage from the surface ponds. Excavation of contaminated vadose zone soils is recommended followed by isolation from rising groundwater.

J. Derald Morgan
New Mexico State University
Waste-management Education and Research Consortium

ABSTRACT

The Waste-management Education and Research Consortium (WERC) is a consortium of three universities, a community collge, and two national laboratories with the mission of generating resources to address issues associated with all aspects of environmental management.

For the past four years, WERC has implemented an environmental design contest for competition by institutes of higher education. This is the only environmental design contest of its kind in the world. The contest is structured to give university student groups an opportunity to exchange information via a national contest for design, development, and testing of an environmental control process. Each year a practical environmental problem is presented to the competing teams approximately nine months prior to the actual competition. Each team prepares a total plant design for the solution of the environmental problem. The design stresses not only the technical solutions but also includes such factors as economics, risk analysis, health, regulations, public policy and communications. Some participating teams have used the contest problem as a part of a capstone design course. The judging is performed by experts from academia, industry, and government agencies.

In April 1994, twenty-five teams from throughout North America, including one team from Mexico, competed in the contest which focused on remediation of a contaminated site followed by reclamation of the remediated site using water harvesting as one of the techniques. The 1995 contest focuses on a waste handling and removal, as well as, a waste remediation/stabilization process. The program has continued to accomplish its objectives of providing a design challenge and a medium of exchanging information in the environmental area between various participating teams, industry and government.

This paper presents the 1994 Design Contest problem statement; what is expected from the participating universities; deliverables; as well as the list of participating teams and the list of 1994 award winners.

INTRODUCTION

The Waste-management Education and Research Consortium (WERC) was created in 1990 by the U.S. Department of Energy as a partnership between New Mexico State University, the University of New Mexico, and the New Mexico Institute of Mining and Technology in collaboration with Los Alamos National Laboratory and Sandia National Laboratories; the Navajo Community College joined as an affiliate in 1991. More than 2000 students (pre-college, college, and professional) receive these educational benefits, and more than 40 technology development projects are progressing on all aspects of waste management and environmental restoration. Currently, there are undergraduate and graduate educational programs throughout the world on environmental management and engineering. However, there has been no vehicle to bring students from various universities together for discussions and solutions of major environmental issues. Consequently, for the past four years, a unique and innovative environmental design contest for universities throughout the Americas (including Canada and Mexico) has been conducted by WERC. Practical environmental problems are presented to the competing teams approximately 9 months prior to the actual competition. The design contest is co-sponsored by industrial organizations, the Department of energy and other governmental agencies. The contest is structured to give university student groups from all over America an opportunity to exchange information and participate in an international contest for design, development, and testing of a realistic environmental control process. The judging, is performed by experts from academia, government, and industry and is based on technical, as well as other criteria such as economics, risk analysis, health regulations, public policy and communication.

1994 DESIGN CONTEST

In April 1994, twenty-five teams from throughout North America, including one team from Mexico, competed in the contest which focused on remediation of a contaminated site followed by reclamation of the remediated site using water harvesting as one of the techniques.

The issue was described in realistic terms in a simulated letter from the company management to an engineer who had recently joined the company. The young engineer is asked to form a group to design and construct a bench-scale working model and demonstrate the pollution control process. The engineer is given the following four tasks:

1) A written two-part report, one for remediation and the second a reclamation process. The report was to include:

- a process design
- a detailed total plant design
- the engineering basis for the design
- the economics of the process
- a discussion of the legal and health implications\
- a plan for presentation to the community for public acceptance so that problems are minimized after construction

2) A practical bench-scale working model of the process to demonstrate functionality of both the remediation and reclamation processes.

3) A brief oral presentation of the design including economics, health, business development, regulatory, and other related issues.

4) A poster presentation containing highlights of the design, economics and other issues.

In addition to trophies, the participating teams received cash awards in several categories which exceeded $ 30,000.

1994 DESIGN CONTEST STATEMENT

Introduction: A large area (hundreds of square miles) in an arid region of the Pacific-Northwest has been contaminated with fallout from a neighboring manufacturing region. The site is to be both remediated and reclaimed. Remediation will be defined as reducing the concentration of identified contaminants below the threshold values listed below. Reclamation will include the use of a water harvesting system to enhance the growth or natural vegetation or agricultural crops on the site.

Water harvesting is an ancient concept that has been applied to increase biomass production in arid and semi-arid lands. Water harvesting concepts currently applied in arid lands continue to be somewhat primitive technically and small in scale. The desire to improve the technical state of water harvesting by finding, selecting, designing and/or testing sealants for catchment areas and by developing equipment

that can apply the sealants on very large areas (hundreds of miles) in relatively short times (a few years) in a cost effective manner. These water harvesting catchments (sealed areas) may be tied into no drainage growing strips.
The design team is given the following three tasks:
1). Develop and demonstrate a bench scale process to remove the identified contaminants from a 5kg sample of the soil. Develop a conceptual design of the process applicable to the field scale project.
2) Develop and demonstrate a non-geomembrane, UV resistant, water repellant, erosion resistant, sealant that can be applied to the soil surface as an aid in water harvesting.
3) Develop a conceptual design for a machine capable of applying the sealant developed in task 2, to the surface of the remediated area.
Regional and Soils Description: The area to be remediated is located adjacent to a large river in an arid climate. Natural vegetation is desert shrub and bunch grasses. Soil material is the result of catastrophic flooding followed by deposition of river alluvium. The resulting material is a mixture of cobbles and sandy loam soil material. The following particle size description is typical of the material at the remediation site.
Soil (see insert a):
To approximate this material with a soil from New Mexico, we have chosen the soil series Casito (Petrocalcic Ustollic Paleargrid). This soil is formed in alluvium at the base of mountain watersheds. It is found on alluvial fans and terraces. It contains a similar mixture of cobbles and fines as the remediation site; however, the source of the alluvium is storm runoff rather than catastrophic flooding and river deposition. Provided below is some additional information on the contaminants in this soil.
Contaminants:

Category	Concentration per kg of soil
1) Pesticides, herbicides, insecticides	
Lindane (C6H6Cl6)	150 mg
Methoxychlor (Cl3CCH(C6H4OCH3)2)	150 mg
Endrin (C12H8OCL6)	150 mg
2) Metals	
Cadmium (Cd)	350 mg
Silver (Ag)	100 mg
Copper (Cu)	100 mg
3) Organic Compounds	
Ethyl Benzene (C6H5C2H5)	75 mg
Methyl ISO-Butyl Ketone (CH3CO-CH2-CH(CH3)2	100 mg
4) Halogenated Compounds	
Chloroethene (CH2CHCl)	75 mg
Tetra Chloroethylene (C2Cl4)	100 mg

The contamination is a surface type contamination (<1' deep) and must be removed to the following levels:

1) Pesticide, herbicides, insecticides	
Lindane (C6H6Cl6)	10 mg
Methoxychlor Cl3CCH (C6H4OCH3)2	10 mg
Endren (C12H8OCl6)	10 mg
2) Metals	
Cadmium (Cd)	15 mg
Silver (Ag)	15 mg
Copper (Cu)	15 mg
3) Organic Compounds	
Ethyl Benzene (C6H5C2H5)	10 mg
Methyl ISO-Butyl Ketone CH3-CO-CH2-CH-(CH3)2	10 mg
4) Halogenated Compounds	
Chloroethene (CH2CHCl)	14 mg
Tetra Chloroethylene (C2Cl4)	14 mg

Detailed Discussion of Tasks and Evaluation Criteria:
Task 1: The remediation demonstration will only deal with the fraction of soil material with particle diameter <2mm. This is because of the logistical trouble in transporting samples containing large cobbles. Therefore, each team will be supplied with a 5kg soil sample containing particles <2mm diameter. Contest rules will stipulate that the presence of the cobbles will not inhibit any process developed from removing contaminants from the fine fraction of the soil. However, teams must consider the logistical problems posed by the presence of large cobbles. For example, insitu processes must account for problems of surface roughness, wear and tear on equipment, etc, that the cobbles would create. Batch processes must handle the presence of the cobbles or account for their removal.
Task 2: Utilizing current knowledge of water harvesting sealants, select and test a nontoxic sealant for catchment areas. The test should be conducted at the bench scale per ASTM D5093-90. The sealant should have the maximum possible UV resistance. (The tests are subject to verification at an independent lab by the judges.) The sealant should be the lowest possible cost per unit gallon.
The sealant developed must not be a geomembrane or other "liner" material. It must be a non-toxic, UV resistant chemical formulation that is applied to the soil surface in a mechanized fashion. Literature and/or experimental data must be presented to document the UV resistance. The sealant must have water-repulsive properties to facilitate water harvesting, and be resistant to erosion on slopes up to 30. Demonstration of sealant properties and application must include soil with cobbles. Samples of the complete soil mixture with cobbles will be provided at the contest location. Practice by the design team must be done on samples created locally from the soil information provided here.
Sealant testing must conform to ASTM D5093-90 standards. Demonstration of sealant properties at the contest site will include water shedding and erosion resistant properties. Each design team will apply their sealant to a sample 2' wide x 3' long x 1' deep posed at 30. Each sample will have a standard amount of water applied at a standard intensity and total runoff of soil, sealant, and water will be measured, and used in the evaluation of the design. Amounts of water applied and application intensities will be provided at a later date. Water infiltrating into the soil and seeping from the bottom of the sample container will be measured separately and count against the design.
Task 3: Prepare a conceptual design of machine to apply the sealant on catchment areas. The catchment areas can be assumed to be nonvegetated, compacted beds of sand, gravel and cobble, or mixtures of the same that have been pregraded to remove gullies and rills.
The machine developed to apply the sealant chosen must be able to work on slopes up to 30. Evaluation criteria include: 1) cost, 2) speed of application (e.g. acres/day) and 3) reliability.
The design problem does not involve design of the water harvesting system. The team is not responsible for estimating the topography of the harvesting area, size of the area to receive sealant, etc. The only job for the team is to design a machine capable of applying the sealant over large areas of up to 30% slope.
The conceptual design should include sketches or mockups, and conceptual drawings. The conceptual design should also include an estimate of the capital cost to design, develop and test a full-scale machine along with estimates of amount of area that can be sealed per day (8 hours), number of operating days per month and number of downdays per month for maintenance and repair.
RESULTS AND CONCLUSIONS
The participating teams competed in a three-day event containing the paper design and presentation, as well as the bench-scale demonstration. 1994 Design Contest participating teams are listed in Table I. The winners of awards are shown in Table II. The top four solutions are presented following this paper. The winning designs are being examined by DOE for possible application to actual site remediation. If selected, the DOE will work with the individual schools to work out the contractual arrangements.
The 1995 contest focuses on a waste handling and removal, as well, as waste remediation/stabilization process. The program has continued to accomplish its objectives of providing a design challenge and a medium for exchanging information in the environmental area between various participating teams, industry and government.

Michigan State University
East Lansing, MI

ABSTRACT

The WERC Corporation requested proposals for harvesting water from 100 square miles of arid land and for remediation of five acres of contaminated soil. The Michigan State University (a.k.a. Spartan Environmental Technologies or SET) design was selected as the best in the international competition held in Las Cruces, NM in May of 1994. This paper outlines Spartan Environmental Technologies' proposal. SET evaluated nine alternatives for water harvesting and selected one based on the use of fly ash as technically feasible and most economical. Ten site remediation alternatives were investigated. Solvent extraction with water rinsing was selected as the best alternative. SET considered legal and regulatory issues, health standards, and community concerns in selecting the design alternatives for proposal to WERC.

INTRODUCTION

Each year, the Waste-management Education & Research Consortium sponsors an international design contest under the auspices of the Department of Energy. The contest invitation is in the form of a request for proposals from a hypothetical company called the WERC Corporation. In 1994, the contest required the contestants to prepare two designs: (1) water harvesting and (2) site remediation of a contaminated soil. Michigan State University students formed a design team composed of 27 students from five departments: civil, environmental and, chemical engineering, crop and soil science and resource development. They formed a "company" called Spartan Environmental Technologies (SET) to investigate the problem and alternative solutions. The following discussion is a summary of their investigations and proposals.

WATER HARVESTING

The theory of water harvesting is to collect water over a large area and to utilize this water for irrigation. Sealing of the surface to minimize infiltration increases the runoff and the potential volume of water that can be collected. As requested by WERC, SET's proposal addresses only the process for sealing the terrain and does not cover the methods for water collection. The alternatives shown in Table I were considered for possible use.

Based on initial cost estimates, expected effectiveness and toxicity, three alternatives were selected for further study: water softening sludge, water based siliconates and fly ash. The results of infiltration studies are shown in Tables II, III and IV. Six tests were conducted using fly ash mixed with water. No significant amount of water infiltrated the fly ash treated soils in a 60 minute period. These data indicated that the fly ash incorporated into the soil with water yielded the least infiltration. Optimization studies on the proportions of fly ash, soil and water were conducted by measuring the surface runoff compared to a control surface of geomembrane (Table V.)

Several processes were investigated for the application of the fly ash: surface application of a fly ash/water slurry, incorporation of a fly ash/water slurry into the soil, and incorporation of the fly ash into the soil followed by the addition of water. Incorporation of the fly ash followed by the application of water yielded the most satisfactory results. A thick sealant layer is created by mixing the fly ash into the soil. The application of water will "set" the surface of the soil/fly ash mixture to form a strong, impermeable layer. If cracking occurs, subsequent precipitation events will provide water that will react with lower layers of the soil/fly ash mix and a new impermeable layer will form. Thus, the sealant is self-repairing. Should gross erosion occur, this system is easily repaired by incorporation of another fly ash/water layer.

The proposed full scale design involves a four step process. The site initially will

be prepared by removing any obstacles and vegetation that would inhibit vehicle travel. Then dry fly ash will be applied to a depth of approximately 1/2 inch using a commercially available dry material applicator. Next, a cultivator will be utilized to incorporate the fly ash into the top two inches of soil. In the final step, approximately 1/8 inch of water will be sprayed onto the soil/fly ash mixture to activate or harden the mixture.

REMEDIATION

WERC Corporation identified five acres of their southwest operation that required remediation. The soil contained unacceptable levels of lindane, endrin, methoxychlor, cadmium, silver, copper, ethylbenzene, methyl iso-butyl ketone (MIBK), chloroethene (VC), and tetrachloroethylene (PCE). These contaminants were in the top foot of soil. The initial concentrations provided by WERC Corporation and the remediation criteria are listed in Table VI.

In preliminary screening SET investigated the alternatives shown in Table VII. Using the method of Jury et. al., it was found that the volatile compounds would be removed from the soil within 15 days. (1) Because of the large safety factor in actually applying the model (i.e., the implementation of the remediation project would take more than 20 times the time for volatilization), SET determined that no treatment would be required for thee compounds. Based on the screening study, solvent extraction followed by water rinsing was selected as the treatment alternative to be investigated in the laboratory.

The extraction process designed by SET is a five stage batch extraction employing two different solvents. The first four stages utilize a one molar solution of di(2ethylhexyl) phosphoric acid (DEHPA) in hexane. The DEHPA, acting as a liquid ion exchange agent, extracts the metals while the organic compounds four stages are followed by a water rinse in the fifth extraction.

The process flow diagram is shown in Fig. 1. The contaminated soil enters the process through a trommel screen to remove oversized material. The DEHPA in hexane is added to the contaminated soil at a solvent:soil ratio of 1:1, volume/weight (V/W). The mixture is blended rapidly for thirty minutes and then allowed to settle for thirty minutes. The liquid fraction is decanted off and sent to the solvent recovery unit. This process is repeated three additional times. After decanting the fourth time, water is added as a final rinse at a water:soil ratio of 1:1 (V/W). The process generates the following waste streams: 1) spent DEHPA, 2) spent hexane, 3) decanted water, and 4) soil raffinate. These are further treated prior to discharge to the environment as shown in the process flow diagram.

The spent DEHPA solution will have a relatively high concentration of metals. This flow is pumped to a gravity separator. The DEHPA fraction from the separator is pumped to an acid stripper/settler. In the stripper, the liquid ion exchange reaction will be reversed. Metals will be dissolved in the acid and the DEHPA will be regenerated for reuse. Thus, a majority of the DEHPA will be recovered and reused. The silver may be recovered from the stripping solution through electrolysis using a parallel plate alternating electrode system. The remaining metals are removed from the solution by precipitation, solidified and disposed of in a RCRA Subtitle C landfill.

The spent hexane solution containing the pesticides is regenerated in a batch distillation unit. The recovered hexane is reused. The residual organics from the distillation process will be disposed of in a RCRA Subtitle C incinerator. The off-gases from distiller will be treated by chemical oxidation.

The decanted water will also be treated in the silver recovery and precipitation units. Once this stream is treated it will be discharged to a public owned treatment works. The residual solids are disposed of in a RCRA Subtitle C landfill.

The soil raffinate will be processed in a thermal desorption unit. The thermal desorption unit, operating between 120 -130 C, will volatilize the hexane. The hexane gas is recovered in a condenser. The off-gases are treated by chemical oxidation. The soil from the desorption unit will be placed back on the site.

IMPLEMENTAION ISSUES

Federal legislative and regulatory requirements, as well as New Mexico Environmental Department rules , were reviewed to determine WERC's responsibilities in implementing these projects. For the reclamation project, the requirements of the National Environmental Policy Act (NEPA), Safe Drinking Water Act, Clean Water Act (CWA), and Occupational Safety and Health Act (OSHA) must be met. For the remediation project, the requirements of NEPA, Comprehensive Environmental Response,

Compensation and Liability Act, Resource Conservation and Recovery Act, CWA, Clean Air Act, and OSHA must be met.
Health issues are a major concern to anyone working at the job sites and to the surrounding community. SET proposed that all employees be trained in legal, materials safety, emergency response and equipment operation aspects of each project. Protective equipment will be readily available on site. For the remediation site, access will be limited by security measures and engineering measures will be taken to control and monitor contaminant migration. Risk management techniques will be used where contaminants and treatment chemicals are used.
Community relations committees and public hearings are recommended to keep the public informed.

ABSTRACT
The first part of the 1994 Environmental Design Contest sponsored by the Waste-management Education and Research Consortium required teams to remediate contaminated soil to specified cleanup levels. MSC selected a process in which contaminants are removed from soil by heating with dilute nitric acid and air sparging. Aqueous effluent is treated by carbon adsorption and cation exchange. The basic idea for the process came from a participant's experience with plutonium processing at a DOE facility. MSC's application of this approach to the contest problem represents a first step in successful technology transfer from DOE to the private sector. The second part of the contest required teams to develop a sealant for application to soil to promote water harvesting in an arid area. MSC selected bentonite as a sealant because of its low cost, availability, and its acceptance as a natural material. The team then developed a simple method of applying the material to the land surface using conventional farm equipment.
PREFACE
Twelve students from the Environmental Restoration and Waste Management program at Mesa State College (MSC) in Grand Junction, Colorado participated in the 1994 Environmental Design Contest. Since 1991, MSC has offered an Associate of Applied Science degree in Environmental Restoration Engineering Technology. A Bachelor of Science degree in Environmental Restoration and Waste Management has been offered since Fall 1993. Participating for only the first time as a four-year program, the MSC team finished in fourth place overall.
An abridged version of the team's report is provided below.
INTRODUCTION
The Students for Environmental Awareness, Research, Compliance, and Health (SEARCH) team members from Mesa State College located in Grand Junction, Colorado, are pleased to have joined the Environmental Assurance Group of WERC Corporation. We, the SEARCH members, fully support the ethics of social responsibility expressed by management and place great importance on conduct of operations in a manner that ensures protection of human health and the environment as well as full compliance

with all legal and ethical requirements.
Our proposal responds to your request for support to deal with one of your WERC site operations located in the Dona Ana County area just outside of Las Cruces, New Mexico. This extensive site has received surface contamination from fallout originating from a neighboring manufacturing region. Contamination includes specific pesticides, metals, organic compounds, and halogenated organic compounds. The contamination is of sufficient magnitude that the soil must be remediated and contained in order to prevent more serious problems in the future. In addition to remediation of contaminants to concentrations below threshold values, reclamation of the site must also be accomplished. Reclamation should include use of a water harvesting system to enhance growth of natural vegetation or agricultural crops on the site in the future.

SOIL SEALING

Technical approach

The SEARCH team investigated several options for addressing WERC Corporation's request for the use of a sealant to reclaim its 100 square mile site. Although we have selected what we believe to be the most viable sealant option, we urge WERC to reconsider its plans to use a sealant for site reclamation. We believe that use of institutional controls and/or other less drastic actions (e.g., treatment through a revegetation program or construction of small catchment basins) will be more effective and much more publicly acceptable. We make this recommendation because the intended purpose of WERC's reclamation efforts is to enhance the growth of natural vegetation or agricultural crops on the site in the future. Any engineering solution (i.e., application of sealant) will do extensive environmental damage to the site that will likely be counter to this objective. The New Mexico site is located adjacent to a large river and ground water exists beneath the site at depths ranging from 8 to 10 feet. Given the availability of water and the aforementioned concerns, we hope that consideration is given to other reclamation options. Many such options can probably be applied at costs considerably less than any sealant option available.

SEARCH team members identified five criteria to be used in evaluating potential sealant materials. The sealant must: 1) exhibit water repellency to prevent both infiltration of water into the soil and erosion of the soil surface; 2) be resistant to decomposition from exposure to ultraviolet light; 3) be non-toxic to plants, animals, and humans; 4) be easily handled and capable of being applied to the land surface in an efficient manner; and 5) not be a geomembrane, as specified by the WERC corporation. Three materials were identified for detailed consideration: an asphalt-bentonite emulsion, a liquid polymer, and bentonite clay. The bentonite clay was selected as the sealant that best met the performance criteria. Bentonite-treated soil was demonstrated to have excellent water repellency and is known to have minimal toxicity and good UV durability. Bentonite is also available at low cost. The liquid polymer was rejected after extensive testing because it failed to meet the water repellency criterion. The polymer formed a hard crust on the soil surface that cracked following the initial tests. The asphalt-bentonite emulsion was rejected because of the presence of hydrocarbons and reports that water collecting in catchments lined with asphalt-bentonite will turn a black color. Difficulties with the emulsion binding up in a sprayer and being difficult to apply were also reason for rejection.

We propose to use standard agricultural equipment for application of the bentonite to the land surface at a rate of 1.5 pounds of bentonite per square foot. A widely-available seed and fertilizer applicator pulled by a tractor of at least 50 horsepower will be used to distribute the bentonite. The hopper on the applicator will be 10 feet wide with openings on the bottom spaced 3 inches apart. Flow rate can be adjusted by a lever on the applicator and by the speed of the tractor. The optimum speed for the applicator is 5 miles per hour, which will allow a single machine to cover one acre in 40 minutes. The hopper can hold 800 pounds of bentonite, which will be applied at a rate of 1.5 pounds per square foot. In order to reduce or eliminate refilling time, a truck and auger system will be driven alongside the applicator to provide continuous delivery of bentonite to the hopper. Simultaneous use of 5 applicators in this fashion will allow the 100 square mile area to be covered in 266 work days.

After application of bentonite to the land surface, a culti-packer will be used to incorporate the bentonite into the top 3 inches of soil. The culti-packer is a

common piece of farm equipment that uses a system of tines and rollers to break up, till, and smooth the soil. A 120-horsepower tractor is required to pull the culti-packer.

The equipment described here is widely available, both new and used. The known durability of the equipment should minimize depreciation and preserve value for resale at project completion.

Testing

The different sealants were tested according to the following procedure. Dried, sifted, and homogenized samples of local soil conforming with WERC's specifications were placed in one square foot pans. The liquid polymer was applied by spraying onto the soil in several thin coats; four different dilutions with water were tried. The bentonite (Swell Seal #10) was mixed with in different proportions with soil, then distributed as a three-inch layer on top of the soil. A pressurized sprayer was used to add water at a rate of 0.5 gallons over a 9 minute period to simulate a hard, heavy rainfall. The soil pan was inclined at a 30 degree angle for this operation. The mass of soil washed into a catchment was measured to determine the degree of erosion. The volume of water washed into the catchment was measured to determine water repellency. Test results are shown in Table I.

Soil without any sealant suffered a great deal of infiltration and erosion. Application of bentonite sealant decreased both infiltration and erosion. The best results were observed when part of the bentonite was incorporated into the top three inches of soil and the rest was applied in a thin layer on the soil surface. Bentonite can limit infiltration to as little as 17 percent of applied water. The polymer was as efficient as bentonite in the initial tests, but was rejected because of later cracking. Although bentonite also cracked upon drying, it softened and resealed upon becoming wet again.

Cost

The unit cost for sodium bentonite sealant is $23 per ton. At the selected application rate of 1.5 pounds per square foot, the cost for the sealant is $753 per acre or $48.2 million for the entire 100 square mile site. This cost includes a 5 percent waste allowance for over-application and spillage. Information from the "Means Site Work Cost Data" reference book indicate that operational costs will be approximately $36 per acre, including support operations. The equipment and labor costs sum to $2.3 million for the entire site. Including roughly 2 to 3 percent for overhead, total cost for soil sealing is $52 million. Assuming an average annual precipitation of 6.5 inches and 20 percent infiltration, the volume of water collected per acre per year is 132,286 gallons. The cost per gallon of harvested water (after one year) is $0.006 per gallon.

SOIL REMEDIATION

Technical Approach

SEARCH members investigated, researched, and compiled information on possible technical solutions. Several meetings were held to evaluate and select the most promising remediation processes. At the conclusion of our feasibility study, we conceptualized the Pollutant Extraction/Cation Exchange (PECE) process as our preferred alternative. We have determined that the PECE process is the most effective alternative in terms of processing rate and yield, equipment setup time and reliability, operating cost, and functionality. The PECE process complies with technical and regulatory requirements and is a safe and publicly acceptable process.

In the PECE process, contaminated soil is placed in a dissolution vessel containing nitric acid (0.1 M) at a mass ratio of 5:2 (acid solution to soil). Heat is applied to the vessel and a gentle air sparge is introduced. The temperature is held at 90 C for forty-five minutes, allowing soil contaminants to become dissolved. Vapors are collected and returned to the dissolution vessel through a condenser system. After cooling, the solution is drained through a primary filter. The soil is rinsed, dried, and sampled; clean soil is returned to the site.

The filtrate is then pumped bottom-to-top through a granular activated carbon (GAC) unit to remove dissolved organics. Sampling is conducted to verify removal of the organics. The pH is also measured and adjusted to a value greater than four to ensure effective cation exchange in the next step of the process. Technical grade Chelex-20 resin was selected for cation exchange. Chelex-20 is a coarse mesh resin useful for large-scale cleanup. The clean effluent produced by this process is sampled and collected in a basin for use in reclamation and water harvesting

activities.
Two secondary wastes are created by the PECE process: (1) contaminated activated carbon and (2) metals loaded onto the cation exchange column. The activated carbon will be transported to a treatment, storage, and disposal (TSD) facility. The metals loaded onto the cation exchange column will be sold through one of several regional "waste exchanges" to companies that has expressed interest in recovery of these metals.
PECE equipment will be truck-mounted in order to minimize setup time and expedite site remediation. System components will be constructed of stainless steel with a corrosion-resistant coating. Each component will be bolted to a flatbed trailer and supplied with an impact-resistant cover. Additionally, the entire trailer will be covered for transport.
Our research determined that the dissolution and cation exchange technologies have been successfully applied for many years in the defense nuclear industry to destroy contaminants and recover various metals for further production. By incorporating several modifications of these widely-accepted technologies, we have successfully demonstrated that this technology transfer can be effectively utilized to address WERC's current environmental restoration concern at its New Mexico operation; the PECE shows great promise for application to future environmental restoration needs as well.
Bench-scale testing
A one-liter three-port distilling flask was used as our dissolver vessel and three ground glass stoppers were fitted with rubber corks. The first contained a thermometer; the second contained the air sparge tube, constructed of bendable glass tubing; the third, the center port, contained the 13-inch condenser unit. Tygon tubing was attached to the fill and drain openings in the condenser and a cooling water source was added. Tygon tubing was also attached from the air sparge unit to the air compressor. The distilling flask for the dissolution unit was placed in an electric heating mantle.
Seventy-five grams of contaminated soil were weighed and placed in the dissolution unit with 400 milliliters of 0.1 M hydrochloric acid were added. The heating mantle and air compressor were each activated and the mixture was heated and circulated for 1 hour after reaching the optimum temperature of 90 C.
Following filtration, the dissolved phase solution was placed in a flask which held 10 grams of granular activated carbon. A magnetic stir rod was installed and the flask was placed on the magnetic stirring device, stirred for 10 minutes, and filtered to a third flask. The pH of this solution was approximately 6.20.
A 50 mL graduated buret was used as an ion exchange column. The buret was filled with 10 grams of Chelex-20 resin. The resin had been hydrated 3 times with deionized water (150 mL). The dissolved phase solution was processed through the cation exchange column at the rate of one drop per second.
Treated effluent samples were analyzed for pesticides by gas chromatography using laboratory standard operating procedure (SOP) U.S. EPA SW-846, Method 8080. The determination of cadmium, copper, and silver was done by inductively coupled plasma-atomic emission spectrometry. The determination of volatile organic compounds by gas chromatography-mass spectrometry was done using laboratory SOP U.S. EPA SW-846, Method 8240. All laboratory quality control requirements were met.
Under acidic conditions and high Eh, metal contaminants in this study's soil are soluble. If the soil is allowed to come to equilibrium with the amount of fluid used in the PECE process, no undissolved metal contaminants should remain. Agitating and heating the acidic solution enhances the rate at which equilibrium is attained. The conditions that the organics are exposed to, high Eh and low pH, are highly oxidizing. Any organics not oxidized to carbon dioxide and water are dissolved in the acid solution. The organic contaminants can then be concentrated onto activated carbon because of its strong affinity for organic contaminants. Volatile organics that are not condensed back into the reaction mixture are collected on a carbon filter placed at the outlet of the condenser.
Concentrations of metals and pesticides in the extract from the dissolution process ranged from hundreds to thousands of milligrams per liter. The efficiency of metal removal from the soil was low, ranging from only 1 percent for copper to 25 percent for cadmium. No residual pesticides were detected in the soil. Results for the volatile organics were ambiguous. Careful consideration of the chemistry of this process led us to believe that replacing hydrochloric acid with nitric acid would

improve performance for metals. Nitric acid was used during the contest, apparently with considerably better results.
Following GAC treatment, pesticide concentrations in the dissolution extract were reduced to 1.6 ug/L for lindane, 0.23 ug/L for methoxychlor, and 0.1 ug/L for endrin. After treatment by cation exchange, silver was reduced to non-detectable levels, cadmium to 5.9 ug/L, and copper to 16.3 ug/L.
Costs
In the full-scale implementation of PECE, we estimate that 21,600 pounds of soil can be treated per day. Approximately 925 work days would be required to remediate the estimated total weight of contaminated soil. We recommend that three treatment units be used simultaneously to reduce processing time.
For three treatment units, total capital costs were estimated to be $306,071. Operating costs are estimated at $2,601,074, which includes costs for incineration of spent activated carbon.
NON-TECHNICAL CONSIDERATIONS
Community Relations
Establishing an open, two-way relationship with the community is critical to the success of any remediation project. It is our ethical responsibility to ensure that such a program is in place prior to beginning any site activities and that the program establishes mechanisms for communication that will prevent misconceptions between WERC Corporation and local citizens. Because numerous recent environmental issues have received bad publicity and received increased public involvement, we propose appointment of a public relations official to oversee our community relations program. Our public relations representative will be knowledgeable about environmental remediation/reclamation and will exhibit strong communication skills. These capabilities will be essential in dealing with government officials, private citizens, and advocate groups to create win /win situations.
Our community relations plan will emphasize the successful technology transfer being applied to the Las Cruces site. Technologies similar to our PECE process were used in the defense nuclear industry during the cold war. We have demonstrated that this existing technology can be economically and effectively converted to new, positively-perceived applications in the areas of environmental restoration and waste management.
SEARCH members will ensure that the community relations plan emphasizes the following reclamation and reclamation activities:
Performance of environmental monitoring throughout remediation and reclamation activities to ensure that contaminants are controlled on site and that the surrounding environment is protected from spread of contamination;
Performance of post-closure monitoring;
Evaluation and controls to eliminate any potential public hazards; and
Full cooperation of WERC Corporation and the SEARCH team with all Federal, State, and local authorities.
We will establish several mechanisms to encourage public participation and to obtain public input; these activities will be designed to ensure that the community understands and does not oppose our remediation approach. Planned activities include public meetings with measures in place to facilitate attendance (e.g., selecting meeting locations particularly accessible to the general public; advance distribution of public notices; press releases provided well in advance to local radio, newspaper, and television stations). Special efforts will be made to supply visual aids and information to a representative of KRWG, University of new Mexico, since it serves as the television station exclusive to the Las Cruces area. Special efforts will also be made to work with the local newspapers, Las Cruces Sun News and the weekly Bulletin. Our public relations official will be our single point-of-contact and will be responsible for contacting the media. We will establish schedules and a special telephone line to ensure that our public relations official can be easily contacted.
We must make genuine efforts to identify and understand community perceptions and concerns and must demonstrate sincerity and compassion when addressing public concerns. The SEARCH team will seek to identify any potentially affected interests (i.e., individuals or groups who may, in any way, perceive that our reclamation or remediation activities may impact them). Potentially affected interests include local media; key community leaders; local government officials; local environmental groups including the Sierra Club, the Mesilla Valley Club of Audubon, the Native

Plant Society, and the Natures Park Group; and the Concerned Citizens of Sunland Park, who have recently been involved with hazardous waste issues in New Mexico.
Our community relations plan will address the history behind the site contamination and will express the mission of the WERC Corporation related to both the Las Cruces remedial action and overall corporate endeavors. The goal will be to establish and maintain public confidence in the company without over publicizing the issue.
We will ensure that our remediation and reclamation mission and its importance are clearly expressed at the public meeting and that the public understands the risks involved if no remedial action was performed on the site. We will openly address any aspects that may considered potential risks and precautions taken to address them. Activities that may be perceived as risks include potential for air pollution from dust raised during excavation; effluent produced in the process and effluent discharge; and use of hydrochloric acid in the PECE process.
Our community relations plan will directly address Emergency Plan and Community Right to Know Act (EPCRA). Key issues that will be addressed include procedures for responding to releases, procedures for notifying the pubic, process to evaluate releases and their impact on the area and population, MSDS information for all chemicals present, and conduct of periodic emergency drills.
Our public meetings will encourage involvement. Because approximately 40 percent of the Las Cruces community is Spanish-speaking we will ensure that our public relations official is bilingual and that bilingual facilitators are available at each meeting. Our remediation and reclamation processes will be explained in non-technical terms that will promote understanding and allow for questions and input. Sufficient time will be allowed for all to openly express suggestions, questions, and concerns.
SEARCH will promote public acceptance by emphasizing economic benefits and jobs for the community and future land use for the community once remedial action and restoration activities are complete. We will provide information regarding our employees' qualifications and expertise and explain the measures taken to ensure worker safety.
Health & Safety and Regulatory Considerations
A standard, site-specific health and safety plan was prepared for the proposed operations. The plan included provisions for training, medical surveillance, hazard communication, site operations, and emergency response.
Major environmental laws and regulations were analyzed for their effect on the proposed operations. Of particular concern is the proposed discharge of treated water from the soil remediation process to a basin for subsequent use in site reclamation. It is anticipated that a permit under the National Pollutant Discharge Elimination System (NPDES) may be required for this discharge. However, if the basin is less than 1 acre in area, an exemption from this requirement may be possible. New Mexico does not have NPDES authority, so application will have to be made to EPA Region VI in Dallas, Texas.
CONCLUSIONS
The SEARCH team urges the WERC Corporation to consider reclamation options other than application of a sealant. We believe that suitable options could be identified that would be less costly, less harmful to the environment, and more publicly acceptable.
The SEARCH team did, however, research several options and selected bentonite as the sealant of choice on the basis of extensive testing and the acceptability of results according to guidelines provided by WERC. We have demonstrated the ability of bentonite in limiting infiltration and erosion, and have found bentonite to be widely available at reasonable cost.
The SEARCH team believes that the Pollutant Extraction/Cation Exchange (PECE) process is an excellent process to treat WERC Corporation's contaminated soil and that test demonstrations to be held in Las Cruces in April will support our claims. We have developed and tested a bench-scale model of our process that represents successful transfer of technology developed in the nuclear weapons complex and applied it to this environmental restoration problem.
We carefully reviewed and verified each detail in calculating the effectiveness of our process. However, we recognize that several improvements to optimize performance can be made after additional testing. For example, tests with different molarities of acetic acid could be conducted since acetic acid is considered to be safer for use in environmental restoration. As always, field testing is recommended prior to

full-scale operations.

INTRODUCTION
WERC Corporation requested that a remediation plan be developed for a site that is contaminated with hazardous materials. A five acre portion of the site is contaminated with heavy metals, halogenated organics, nonchlorinated organics, and pesticides to a depth of one foot. Target remediation goals range between 82% and 96% removal of the initial concentration depending on the compound.
REMEDIATION
ECoWVU conducted a thorough investigation of treatment options. Emphasis was placed on maximizing clean soil yield, minimizing costs and waste generated, and complying with all federal, state, and local regulations. After extensive literature review and laboratory testing, soil washing was determined to be the best type of remediation system available.
Soil washing of all soil size fractions is the only technology capable of removing both heavy metals and organic contaminants while satisfying the goal of maximizing clean soil yield. In addition, soil washing can remediate the soil within the one year deadline and is generally cost-effective. ECoWVU tested several soil washing agents to determine their effectiveness in removing the soil-bound contaminants. Based on these experiments, sodium dodecyl sulfate (SDS), a biodegradable, nontoxic, anionic surfactant, exhibited high removals of the organic contaminants, and 1N HNO3 was effective in removing the metal contaminants.
Therefore, ECoWVU recommends a treatment train consisting of excavation and dry separation, followed by soil washing with both an SDS and 1N HNO3 wash. In Fig. 1, a schematic of the chosen treatment process is presented for a soil processing rate of 100 tons/day. This alternative utilized a two phase soil washing process that is capable of treating soil to the desired contaminant levels at a cost of $575/ton. The system was designed to remediate 11,000 tons of contaminated soil in 42 weeks (including construction and startup). A clean soil yield near 100% is expected. Using an innovative system of SDS and 1N HNO3 reuse and regeneration, and treatment of ancillary wastewater, minimal residuals are produced.
Excavation and Storage
A 50,000lb track excavator will be used to excavate the 11,000 tons of dry soil at a rate of 500 yd3/day. Four hundred tons of soil will be excavated per week and placed in a 100 foot by 100 foot air-tight building, which also contains the dry size-separation unit. Earthwork can be completed in about 24 days.

Soil Washing Process
Each day, 100 tons of contaminated soil will be fed into an inclined trommel unit, enclosed in the airtight building, for dry separation. Volatilization of the volatile and semi-volatile contaminants should occur as the soil particles >2 inches (5cm) are separated. Because of the likelihood of the contamination of sands with heavy metals and pesticides, it was decided that all particles <2 inches would undergo soil washing.
About 50% of the soil will be greater than 5cm, and will be fed by conveyor belt to a high pressure spraying unit, which flushes any remaining fines from the cobbles. The clean cobbles are swabbed to ensure successful removal of the contaminants and returned to the site. The material <5cm will be made up of approximately 66% sands and 34% silt and clay. This material will be transported to two 40,000 gallon soil washing tanks (referred to as SWU-1) where a 2.5% SDS solution, with a 5:1 liquid:soil ratio (by weight), employing a 4-hour mixing and 4-hour settling schedule. Following settling, the supernatant is decanted and fed to the second soil washing unit
(SWU-2) to repeat the aforementioned process with a new batch of contaminated soil. Then, 1N HNO_3, at a 5:1 liquid:soil ratio, is added to the half-washed soil in SWU-1, utilizing a 2-hour mixing and 4-hour settling schedule. Following settling, the 1N HNO_3 supernatant from SWU-1 is decanted and transferred into two 30,000 gallon holding tanks and later used to acid wash the soil in SWU-2. The process is staggered so one batch of soil is being washed with surfactant while the other is washed with nitric acid, maximizing the amount of soil treated per week and adding operational flexibility. Before each wash, the appropriate amount of SDS, water, and concentrated HNO_3 will be added to the unit to restore the original liquid:soil ratio and maintain wash solution concentrations. Washing solutions will be regenerated after two complete cycles. The SDS solution is renegerated using a liquid exchange column containing methylene chloride. The HNO_3-metal waste water is treated using flocculation/coagulation followed by settling.
Following the SDS and nitric acid washes, the soil is transferred to a smaller tank where a 2:1 clean water rinse is performed to remove the wash solution residuals. The soil slurry settles briefly to remove the sand fraction. The supernatant, containing silt and clay, is mixed with a nontoxic polymer to promote settling and fed to a high speed centrifuge to ensure maximum separation of fines. Each batch of clean soil will be tested to ensure sufficient contaminant removal. The used water is pumped to a holding tank, where a portion of it is used to replenish the liquid streams. The remaining used rinse water is fed through two 10' by 2' diameter ion exchange columns (11) for metal removal and through a granular activated carbon column for organic contaminant removal. (12) The resultant metal and organic contaminant concentrations will be much less than 1 mg/L and thus, will be suitable for discharge to the local POTW. (13) A portion of this water will be recycled to the high pressure cobble wash step.
Further Research Requirements
Before final implementation of the remediation process, ECoWVU strongly recommends that additional research be conducted. Also, the soil washing process should undergo the pilot and field-scale testing according to the USEPA's Three-Tiered Approach for Site Remediation. (15) Results from pilot and field-scale tests will be used to optimize process performance, determine possible process modifications, and develop better cost data.
Materials and Methods
ECoWVU conducted extensive laboratory testing to select the most effective extracting solutions and to optimize their use in the treatment process. Based on literature reviews and preliminary lab tests, the following three washing fluids were identified as having the potential to remove the contaminants of concern: anionic surfactants, NaOH, and HNO_3. Pesticides, because of their hydrophobic nature, are tightly bound on the soil. Surfactants are able to transfer soil-bound hydrophobic, oily compounds into a water based emulsion by reducing the interfacial tension between the soil and water phases. (16) Sodium dodecyl sulfate (SDS), an anionic, biodegradable, nontoxic surfactant, removed over 90% of soil-bound pesticides and organics at ten times the critical micelle concentration (0.25%). (5) Because its effectiveness had been demostrated, SDS was selected for further testing. NaOH was selected because pesticides hydrolyze at high pH values. (17) Metal-removal using acids is well-documented. (17) HNO_3 was selected for further

study over other acids, such as HCl and H2SO4, because they have the potential to form precipitates with metal contaminants. Following the literature review and initial metal removal experiments, a series of soil washing experiments were conducted to determine: 1) the effectiveness of each solution in removing contaminants, 2) the optimal liquid:soil ratio and reaction time, and 3) the effect of the wash solution order. Table I provides a list of the soil washing experiments. Clean soil from the WERC site was contaminated to the prescribed levels using WERC's contamination recipe. Vinyl Chloride was excluded from the testing procedure because it was difficult to obtain and because it is improbable that it would remain on soil samples, due to an extremely high vapor pressure. For each soil washing experiment, a predetermined amount of contaminated soil was placed in a Nalgene container and a specified volume of washing fluid was added. The soil slurry was then placed on a shaking table for a predetermined period. After shaking, the soil slurry was centrifuged for 5 minutes at 7000 RPM to separate the liquid from the solids. The supernatant liquid was saved and analyzed for metal content on a Perkin Elmer Atomic Absorption (AA) unit. The concentration of orgainc contaminants on the washed and centrifugal soil were determined using EPA Method 8080 (Pesticides) and Method 8240 (VOC/SVOC). An unwashed, contaminated soil sample was analyzed to ensure the contamination method successfully placed the specified amounts of the compounds on the soil. Spiked matrices and several levels of recoveries were also carried out to ensure the required level of quality control/assurance.

Settling tests were performed with the wash solutions to determine the time required to separate the soil from the wash solution, allowing ECoWVU to evaluate the need for centrifuges in the process design.

Soil Washing Results

A summary of the experimental soil washing conditions, the final soil contaminant soil concentrations (mg/kg), the initial contaminant concentrations, the WERC proposed cleanup targets, and the analytical detection limit for each contaminant are presented in Table I.

Volatile and semi-volatile concentrations were below detectable limits for all soil solutions tested. Based on volatilization studies on the contaminated soil, researchers at ECoWVU believe that VOC/SVOC removal occurred predominantly through the volatilization of these compounds, and the dry separation unit was designed accordingly. SDS HNO3 met all of the target levels except Ag. Based on results in Table I, ECoWVU researchers concluded that an initial 2.5% SDS wash at a 5:1 ratio for 4 hours, followed by a 5:1 1N HNO3 for 2 hours would meet all cleanup goals for the contaminants. With optimization of the system, even the target level for the lowest scoring contaminant should be reachable.

BUSINESS PLAN AND ECONOMIC ANALYSIS

For the effective evaluation of alternatives, an economic analysis was conducted, and our remediation and reclamation solutions were chosen. Costs are presented in March 1994 dollars and are considered accurate to within +50/-30 percent. The total cost of the 1 year remediation plan is $6.3million ($575/ton).

ECoWVU has chosen an innovative technology called soil washing to solve the remediation problem. The total cost of the project will be $6.3 million ($575/ton), using 82 BTU/kg of contaminated soil. Fixed and variable costs are $2.2 million and $4.1 million, respectively. A further cost breakdown may be found in Table II.

Some benefits of the chosen process are the maximization of clean soil yield, the meeting of cleanup goals, and the minimization of secondary waste. Generally, soil washing costs range from $50 to $250 per ton. (17) However, most commercial vendors do not treat the fine fraction, and therefore have less yield and more waste. For example, if soil particles <2mm were disposed off-site, the cost would be $4.0 million, but the clean soil yield would be only 50 percent.

Also, because of the 1-year duration, several pieces of equipment may be sold for a depreciated value. A seven-year life (20) is assumed for the equipment, and a potentially profitable option is the reuse of the process for other remediation projects or the marketing of these services to other corporations in need of remediation technology. ECoWVU strongly recommends that WERC consider these options further.

LEGAL, HEALTH, AND REGULATORY CONSIDERATIONS

Operation of ECoWVU's proposed treatment train and sealant application for the remediation of the contaminated site requires compliance with specific Federal, State, and local regulatory standards. In 1992, New Mexico readopted the sections of

the Resource Conservation and Recovery Act (RCRA) and the Comprehensive Environmental Response, Liability, and Compensation Act of 1980 (CERCLA) as the New Mexico Hazardous Waste Management Regulations (NMHWMR). (7) New Mexico state regulations are consistent with Federal regulations unless otherwise noted.
Under RCRA, ECoWVU's TSD facility would be considered a generator of hazardous waste. A generator of hazardous waste is "any person, by site, whose act or process produces hazardous waste...or whose act first causes hazardous waste to become subject to regulation" (40 CFR 260.10(a)).(22) The soil washing process requires that the soil be transferred from the soil matrix to the liquid/gaseous matrices; therefor, WERC is considered a generator of hazardous waste.
The proposed TSD facility that ECoWVU will manage must comply with one of the following two air emission limits for volatile organic compounds. The facility must either limit total organic emissions with process vents to less than 1.4 kg/h (3 lb/h) and 2.8 Mg/yr (3.1 tons/yr), or reduce its total organic emissions by 95 percent (40 CFR 264.1032).(22)
Discharge limits for pH and the metal contaminants in the WERC soil are specified by the local Publicly Owned Treatment Works (POTW) in Table III.
The organic compounds that may be present in the liquid effluent are not directly regulated (with respect to specific discharge limits) by federal, state, or local statutes. Representatives from the Las Cruces POTW indicate that an Industrial Discharge Permit would be required and would likely be attained for the treatment project. The waste stream from the remediation process will be checked for compliance on these limits at least once a year by the Las Cruces POTW.
Under EPCRA, ECoWVU must report unplanned releases of any hazardous materials and the quantity released to each environmental medium (soil, air, and/or water). ECoWVU must notify a 911 operator if a release occurs on-site or during transportation to the licensed disposal facility. EPCRA requires that ECoWVU provide a material safety data sheets (MSDSs) to the local fire department and state and local emergency response commissions. If an employee is being treated at a health care facility for an on-site injury, the MSDS information must be provided to the health care professionals. Under the Occupational Safety and Health Administration (OSHA), ECoWVU must maintain an accurate record of on-site deaths, illnesses, injuries, and exposures to toxic substances that are incurred by its employees. (21)
The most basic duty of ECoWVU under OSHA with respect to worker safety is to furnish its employees with an environment that is free of hazards that are likely to cause serious physical harm or death. The hazard communication standards (HCS) under OSHA requires the following safety procedures of ECoWVU: 1) A MSDS for each hazardous substance that employees will be exposed to must be easily assessable to all facility workers, 2) A hazard communication program containing provisions for labeling of containers, MSDSs, and an employee training program must be written and implemented, and 3) OSHA certified employee training must be provided to employees by ECoWVU. Under OSHA regulations employees must be educated as to the engineering safety controls, work practices, and the proper usage of the personal protective equipment (PPE). The PPE that is required based upon OSHA's specifications in 29 CFR 1910.120 must meet the most stringent requirements of Level C protection. ECoWVU feels that with standardized training in the use of all Level C PPE, there should be minimal threat to employee health and safety. To mitigate the problem of heat stress that may result from working in a full body suit at the given site temperatures, cooling vests will be available for all employees.
To control air emissions of VOCs that may result from agitation of the contaminated soil during excavation, the soil should be excavated into a dump truck and then covered with a heavy canvas sheet while transporting the soil to the on-site storage facility. (7) ECoWVU will not have to comply with transporter standards as outlined in 40 CFR 263 when engaging in on-site transportation of the contaminated soil. (1) ECoWVU will hire a licensed transporter to remove the waste (in the form of solid and/or liquid residuals) from the site. The transporter will come on-site to get the waste after ECoWVU has properly labeled, marked, and contained the hazardous waste. The manifest reporting requirement must be signed by ECoWVU and given to the transporter at the time the waste leaves the site. The transporter must keep the manifest with the hazardous waste at all times and the document must show any transfer of the hazardous waste to another transporter or to the disposal facility. The final manifest signed by all parties should be returned to and kept by the generator for at least three years. (21)

ECoWVU's must obtain a final RCRA permit as stated in 40 CFR 270 as adopted in the NMHWMR part IX, sections 901 and 902. (7) Additionally, ECoWVU's TSD facility must obtain an EPA identification number for purposes of record keeping (40 CFR 264.11). Under RCRA, ECoWVU may only store hazardous waste on-site for a period of 90 days (40 CFR 262.34(a)). In order to store hazardous waste on-site for more than 90 days, ECoWVU must obtain a permit from the New Mexico Environment Department. (7) At the close of the TSD facility's operation, RCRA and CERCLA closure requirements must be met. ECoWVU must prepare a written closure plan to be submitted to the EPA with the initial permit application.

COMMUNITY RELATIONS

A Community Relations Plan (CRP) is extremely important for any project, particularly one that deals with hazardous wastes. The CRP may be used effectively to help establish a good working relationship with the community. A successful CRP allows the public to be involved in all steps of the process, from the initial screening of alternatives to the final selection of the treatment plan. WERC should designate an independent, experienced spokesperson to create information repositories and inform the public of all actions undertaken. The most important steps necessary to involve the public are putting articles in the local newspaper(s), posting signs at local establishments, hold interviews with community leaders and interested parties, and to place informational ads in the newspapers, radio, and television for at least 50 days.

CONCLUSIONS

ECoWVU's team has designed a dual unit, multi-phase soil washing system that meets contaminant removal goals and achieves a clean soil yield approaching 100 percent. After excavation and soil separation, the fines are washed in a 2.5% sodium dodecyl sulfate solution (5:1), followed by a 1N HNO_3 solution (5:1). The cleaning solutions are then recycled to minimize waste. The system is designed to process 100 tons of contaminated soil per day at an approximate cost of $575/ton and complete the remediation of the five acre site in 42 weeks (including construction and processing).

EXECUTIVE SUMMARY
The WERC Corporation has requested that Environmental Consultants of West Virginia University (ECoWVU) develop a remedial plan for a site contaminated with several hazardous substances. A five acre portion of the site is contaminated with heavy metals, halogenated organics, nonchlorinated organics, and pesticides to a depth of one foot. Target remediation goals range between 82% and 96% removal of the initial concentration depending on the compound.
ECoWVU conducted a thorough investigation of treatment options in order to select the most effective treatment that would fulfill WERC Corporation's stated criteria. Emphasis was placed on maximizing clean soil yield, minimizing costs and wastes generated, and complying all federal, state, and local regulations. ECoWVU selected a dual unit, multi-phase soil washing system that met contaminant removal goals and achieved a clean soil yield of about 100 percent. The system is designed to process 100 tons of contaminated soil per day at an approximate cost of $575/ton and can remediate the five acre site in 42 weeks (including construction and processing).

ABSTRACT
This work concerns the remediation and reclamation of soils from a hypothetical site contaminated with lindane, methoxychlor, endrin, cadmium, silver, copper, ethyl benzene, methyl iso-butyl ketone, chloroethylene and tetrachloroethylene. An ex-situ soil washing process involving batch addition of sodium dodecylsulfate, ethylenediamine tetraacetic acid (EDTA) and sodium thiosulfate was designed for treating the soil. The liquid effluent from the soil washing process was treated with granular activated carbon (GAC) to remove metal-EDTA complexes and organic pollutants, while a cementation bed was used to recover the silver. GAC also was used to treat gas-phase effluent. A bench scale study showed that the remediation process was capable of reducing all but one of the contaminants in the soil to target levels. The bench scale design was scaled up on a mass basis to design the full-scale remediation system. Estimated remediation time for the 12.95 km2 site was 90 days.
Site reclamation involved the application of a two-layer, impermeable sealant to the remediated and surrounding 259 km2 -area for the purpose of water harvesting. The first layer is composed of a cellulose xanthate slurry to be prepared on site. The purpose of this slurry is to enhance the structural integrity of the soil. The second layer is a spray mixture of unrefined paraffin wax and an anti-stripping agent to provide impermeability. The sealant was shown to be non-toxic, UV resistant, and erosion resistant. Bench-scale tests did not produce the predicted

runoff yield of 87%. However, only minor adjustments in the mixture are needed to achieve the desired yield. A modification of an agricultural tractor with additional insulation, heat tracing and exhaust re-routing will be used for the application of the sealant. The sealant application for the proposed 259 km2 area is projected to be completed in one year and five months.

INTRODUCTION

In August 1993, the Waste-Management Education & Research Consortium (WERC) invited a team of students at Michigan Technological University to participate in an international environmental design competition. The goal of the 14-member team was to develop processes for the remediation and reclamation of a hypothetical, contaminated site near Las Cruces, New Mexico. The site was contaminated by industrial fall-out from a neighboring manufacturing region which had deposited lindane, methoxychlor, endrin, cadmium, silver, copper, ethyl benzene, methyl iso-butyl ketone, chloroethene and tetrachloroethylene. The extent of the site to be remediated was 12.95 km2 in area and 0.3 m in depth, which translates into a total of 8.2 million kg of soil to be treated. Design of a remediation process for the soil was challenging because of the mixture of organic and metallic compounds, the wide range of contaminant chemical properties, and the chemical characteristics of the native soils. Design of the reclamation process also was difficult because of the physical characteristics of the site, the stringent efficiency criteria, and the requirement of using a non-geomembrane material. Two objectives were designated for solving these problems: 1) design a process for remediating the contaminated soils from the initial concentrations to concentrations specified for clean closure of the site, and 2) design a non-geomembrane sealant and a machine for sealant application to produce site suitable for water harvesting.

SOIL REMEDIATION

Background

The design approach was dictated by the major aspects of the problem: the large volume of soil to be remediated, the shallow depth of contamination, the composition of the Casito series soil, the 24-hour bench-scale testing time constraint, and the chemical properties of the contaminants. Ex-situ soil washing was the technology selected for remediating the contaminated soil.

common process in ex-situ soil remediation is the separation of oversized materials. Most of the contaminants are preferentially adsorbed onto the soil organic matter and are equally distributed on a surface area basis. This means that more contamination will be present on the smaller fraction due to the large surface area per unit mass. The larger soil fractions, which account for 50% of the total mass of contaminated soil, contains a very small potion of the contamination.

Chemical extraction is defined by the U.S. Environmental Protection Agency as a separation process that uses additives to remove insoluble pollutants from the soil. (1) The additives used in our remediation process were the surfactant sodium dodecylsulfate (DS) and the complexing agents ethylenediamine tetraacetic acid (EDTA) and sodium thiosulfate. The technique most frequently used for the extraction of metals is acid washing. However, the 1-8% percent carbonate content of the native Casito soils would make an acid wash difficult and expensive for low pH metal extraction. Removal of metals from soil by the addition of EDTA has been shown to be an effective alternative to acid washing for metals extraction. EDTA is a strong chelating agent which forms highly stable metal ion complexes with stability constants greater that 107 in stoichiometric 1:1 ratios. (2) The metal ions of concern in this case were Ag+, Ca2+, Cd2+, and Cu2+ with stability constants of 7.3, 10.7, 16.5, and 18.8, respectively. Although EDTA will form copper and cadmium chelates, only slight amounts of calcium will be complexed because calcium has a low solubility (0.14 g/ml) and low stability constant and the fact that the EDTA solution will be slightly basic. (3) Adaptation of a photo processing technique using sodium thiosulfate was chosen to remove the residual silver from the soil. A 2:1 molar ratio of sodium thiosulfate to silver was found to be optimal. (4) The addition of a surfactant effectively reduces the distribution coefficient between the soil and liquid (5) through the formation of micelles. This causes the equilibrium concentration of the contaminant in the micelle pseudophase to increase, and the time to reach equilibrium is shortened. Studies done by Jafvert (6) using DS as a surfactant and the pollutant pyrene were used to design a process for removing pesticides from the soil. The time required for equilibrium was calculated from a first-order rate equation. In this system, DS was chosen because its properties are

well known, it is easily obtained, and is non-toxic, non-recalcitrant, and anionic. In comparison to cationic or nonionic surfactants, DS should not adsorb appreciably to the soils (7).
GAC was chosen for removing the EDTA metal complexes (8) and the DS micelles (9) from the soil processing water and for treating the gas phase captured from the soil treatment unit. The Polanyi potential theory was used to determine the Freundlich parameters for liquid phase adsorption (10). Gas phase GAC parameters for the removal of volatiles were estimated from the Dubinin-Redushkevich equation (11). A software package was used to determine component break through times and reactor volumes. Carbon usage rates and GAC columns were sized accordingly.
A cementation process which incorporates scrap iron or iron wool was selected to remove silver from the liquid effluent. Gould et al. found that this process was effective for removal and recovery of the pure metals as an amalgam. (4)

Process Design Summary

Figure 1 shows a schematic summary of the soil remediation process. The following steps are performed in the application of the soil remediation design.
Step 1. Excavated soil is screened through a 4.76 mm sieve, and all over-sized material is returned to the site.
Step 2. Soil is placed into a constantly stirred batch reactor and washed four times. EDTA is utilized during the first wash to remove cadmium and copper. During the second wash, the silver is removed by sodium thiosulfate while DS is added to remove the more soluble organics. The third wash implements DS to remove the less soluble organics. Clean water is then flushed through the system as a final rinse. The reactor is covered and vented to gas phase GAC during mixing operations due to stripping of the volatile components MIBK, ethyl benzene, chloroethene, and tetrachloroethylene.
Step 3. Upon completion of the soil washing process, the tank is drained, allowing the effluent to flow through a rotary drum filter. The separated liquid is then pumped through storage tanks to allow for the optimal flow rate through the liquid phase GAC system. Liquid phase GAC is used to remove lindane, endrin, methoxychlor, EDTA-metal complexes, and tetrachloroethylene from the process water streams. Silver is separated from the thiosulfate-silver complex by passing the solution through a cementation tank containing scrap iron.
Step 4. The treated soil is dried using a decanting-type, paved, drying bed. Since the contaminants concentrations in the treated soil are not zero, an application for an innovative technologies permit will be submitted for in-situ biological remediation to zero concentrations if the soil is returned to the site.

Testing Results

Individual processes were evaluated in the laboratory prior to a bench-scale demonstration. Jar tests were performed with varying concentrations of surfactant to maximize the removal of radio labeled (C14) surrogate organic compounds, which were measured with a scintillation counter. Batch runs with EDTA and sodium thiosulfate established optimum concentrations. Metals concentrations were analyzed by atomic absorption spectrophotometry. GAC and cementation experiments were not run prior to bench-scale testing. A sieve analysis and a Walkley-Black analysis for total organic carbon content for each size fraction were performed. The results showed that the large size fractions could be left untreated.
Full-scale processes were approximated in the laboratory by bench-scale models in order to optimize remediation techniques. A bench-scale model was constructed and tested during the spring 1994 WERC Design Competition. Five kg of contaminated soil was placed in an 11.5 L bucket. The first 10.1 L soil wash consisted of 8 g of EDTA (10% excess) to produce a 2.36 mM solution. 233 g of DS solution (15 mM) and 1240 g of sodium thiosulfate solution (495 mM) were added for the second wash. DS was again added at the same concentration for the third wash. Clean water was used as a final rinse. The times for individual washes were 0.66, 1.11, and 1.66 hours, respectively. In place of the rotary drum filter, a centrifuge and buchner funnel were used to separate the clean soil from the wash water. The clean, dewatered soil was transferred to an aluminum pan and dried on a hot plate. The wash water was passed through glass tubing packed with GAC and the bucket was periodically vented to gas phase GAC to ensure VOC removal. A simulation of the cementation was performed by placing the final waste water in a beaker containing steel wool.
Table I. shows the concentrations of the soil contaminants used as remediation targets for the bench-scale remediation, as reported by an analytical laboratory.

The results show that only lindane was not removed to the soil contaminant criteria. During the bench-scale demonstration, only two surfactant washes were performed due to unforeseen filtering problems caused by frothing. This may explain why the lindane exceeded the final concentration criteria. Application of reduced surfactant concentrations may overcome the filtering problems by reducing froth formation. The silver cementation process appeared to produce positive results, although no laboratory analysis was performed.

Estimated Full-Scale Costs

A full-scale design was devised on a mass basis by scaling the bench-scale results to treat 12.95 km2 of soil in less than 90 days. Table II shows the breakdown of costs for full-scale remediation.

SOIL RECLAMATION

Background

Selection of the optimal sealant for water harvesting was based on a number of independent factors which may be loosely grouped into efficiency criteria and site-specific criteria. Efficiency criteria are the physical and chemical properties of a material which determine its suitability for use as a water harvesting sealant. The efficiency criteria used during sealant selection were:

1. impermeability
2. non-geomembrane or other "liner" type material
3. low toxicity
4. high resistance to failure by ultra-violet (UV) light exposure
5. color
6. ease of application
7. cost

Once a sealant meets the efficiency requirements, its usefulness was evaluated with respect to unique conditions at the site of application. These site-specific criteria include:

1. stability on slopes up to thirty degrees
2. durability in freeze/thaw cycling
3. high temperature resistance
4. compatibility with Casito soils, especially large cobbles and clays.

Based on these criteria, a feasibility study was conducted to determine the best sealant for the hypothetical site. Due to the large scale of the proposed water harvesting system, particular emphasis was placed on the cost of the sealant material. For this reason, the scope of research into potential sealants was limited to readily-available, commercial compounds which have been pre-engineered for cost-effectiveness and reliability. The sealants which were considered for the site include: aromatic and aliphatic urethanes, silicones, high molecular weight acrylate monomers, rubberized asphalt waterproofing compounds, and petroleum-based waxes.

The results of a feasibility study indicated that the optimal sealant was a petroleum-based wax. Waxes are highly impermeable when applied in a continuous layer due to their non-polar nature. They are also light-reflective; relatively easy to apply in liquid spray, liquid brush or solid chip form; and they exhibit low enough toxicity to be used in food products. (12) Waxes range in price from $0.46 per kg for highly refined paraffin to $0.35 per kg for unrefined wax, which is a byproduct of oil refining processes. A variety of waxes are available with differing melting points to accommodate the required resistance to high temperatures.

The most important factor in the success of a water harvesting sealant is sustained impermeability. The impermeability of the waxes results from their hydrophobic nature. Petroleum-based waxes are simply straight chains of hydrocarbons, meaning that they have single bonds between all carbon atoms in the molecule. (13) Therefore, if a uniform, continuous layer of petroleum wax is applied to soil, the theoretical water penetration should be near zero. However, real world applications of wax sealants suffer from loss of water repellency from UV light or ozone exposure, lack of structural stability due to erosion from freeze/thaw cycling, and lack of sealant continuity due to uneven application.

Published runoff efficiencies of early field experiments using paraffin alone at an application rate of 1.0 kg/m2 averaged better than 90% in the first year and 87% over the following seven years. (14) Unfortunately, due to weak Van der Waals type binding forces, wax alone does not exhibit stability from erosion and freeze/thaw cycling. However, these qualities can be improved by supplementing the wax with an antistripping agent and/or soil stabilizer. (15) Similar results have been published

using the residual wax/antistripping agent and soil stabilizer combination, at an application rate of 0.25 kg/m2, in an identical configuration to that proposed for the hypothetical site. In published studies, increasing the wax application rate from 0.25 to 1.0 kg/m2 had no noticeable effect on water repellency. (15) All of the cited studies tested sealant designs on soils which were relatively uniform in grain size and contained little pore space in comparison to the Casito series. The combined factors of a good rating against the selection criteria and the accessibility of previous wax-based water harvesting results made a petroleum-based wax the optimal sealant for the hypothetical site.

Reclamation Design Summary

The proposed sealant for the site is comprised of two application layers: a soil stabilizer and a heated mixture of residual wax/antistripping agent. The sealant will be applied after the remediation of contaminants. To enhance the structural integrity of the sealant, a cellulose xanthate soil stabilizing solution is first be applied to the site. Because cellulose xanthate has a very short storage life, acquisition of the stabilizer is accomplished through on-site production. Production is relatively simple; it is based on the following reaction, called xanthation, in which the cellulose chain is abbreviated as cell: (8)

cell-O- + CS2 = cell-O-CS2-

High purity cellulose, required for production, is obtained by repulping high quality, post-consumer, de-inked office paper. (16) The waste paper is shredded and chemically repulped using a batch process in which the paper and an 18% (by weight) NaOH solution will be mixed. Chemical repulping was chosen instead of mechanical repulping, because mechanically generated pulp would hinder the efficiency of the xanthate stabilization. (17)

After the reaction equilibrates, the repulped waste paper is treated with a commercially manufactured "dump chest" to remove the colloidal coatings on the paper. (16) Once the cellulose has been regenerated and purified, the slurry is rerouted to the batch reactor tank. In the tank, a 1:1 molar ratio of carbon disulfide is added and mechanically stirred to form cellulose xanthate. Subsequently, the xanthate is diluted with water to attain a 0.4% solution. Cellulose xanthate has a shelf life of only a few days, however the solution may be refrigerated to extend the possible storage time to about one year. (17) Following on-site production, the 0.4% xanthate solution is spray-applied directly to dry soil at a rate of 1.5 L/m2 of soil. (15) The soil stabilizer is allowed to air-dry prior to the next phase of sealant application.

The antistripping agent/unrefined wax mixture is applied after the soil stabilizer. The wax will be placed in the heated tank of the application machinery and allowed to melt. Asphalt antistripping agent will be added to form a 2% (by weight) solution. The melted mixture is spray-applied over the stabilized soil using a rubber-tired agricultural machine at a rate of 0.25 kg/m2. A representation of the soil/sealant interface is presented in Fig. 2.

The most efficient application of sealant occurs when the soil is dry. Therefore, it is recommended that both phases of the sealant application be conducted on warm, clear days when the moisture in the top 7 to 8 cm of soil is minimized. Accounting for weather-induced down time, both phases of the reclamation would be anticipated to be completed in approximately one year and five months.

As part of the reclamation design, a machine modification was designed to facilitate application of the sealant using ordinary agricultural equipment. A rubber-tired tractor with a tank and spray bar was modified. Additional heat tracing and exhaust rerouting was provided so that the sealant is applied at the appropriate temperature and rate.

Bench-Scale Testing

To test the sealant application, the proposed reclamation process was simulated using a bench-scale model. The bench-scale model included a soil testing box that was mounted at an angle of 30 degrees. The box interior was lined with polyethylene to ensure accurate measurement of infiltration during testing. The lowest seam of the box was left with a small gap to direct any infiltration water to an open-top 5.0-cm PVC collection pipe. The test box was filled with soil to a depth of 30 cm. De-inked, non-gloss office waste paper was hand-shredded and repulped by mixing with an 18% (by weight) NaOH solution for ten minutes in a glass beaker. The pulp was removed, drained and padded with paper towels. In a closed top container, the cellulose pulp was mixed with carbon disulfide in the following ratio: 2.5 g of

cellulose per 1.5 mL of carbon disulfide. (17) The solution was allowed to equilibrate for four hours and then diluted to a 0.4% solution with distilled water. The cellulose xanthate was applied uniformly to dry soil in the test box at a rate of 1.5 L/m2 using a hand-pump spray container. The xanthate solution was allowed to air dry for one hour.

The combination of 98% (by weight) unrefined wax and 2% (by weight) antistripping agent was melted together and mixed in a large beaker over a hot plate/magnetic agitator. The wax/antistripping agent mixture was brushed uniformly onto the soil surface at a rate of 0.25 kg/m2. Subsequent to application of the soil stabilizer and unrefined wax/antistripping agent, the soil test box was exposed to normal site weathering for a period of 24 hours.

After completion of the 24-hour weathering, the test box was exposed to a simulated precipitation event. The precipitation was simulated by applying a known volume of water using a standard shower mechanism for a period of one hour. During the simulated rainfall, run-off water was collected and compared to the known volume of precipitation applied, and a run-off efficiency value was established. The run-off efficiency was found to be less than 10%. At such a poor efficiency, it appears that the sealant had little effect on the water repellency of the soil. It is anticipated that this poor performance may be attributed to two causes: the soil conditions of the Casito series, and the effects of high temperature.

In addition to runoff testing, the sealant was submitted to toxicity testing using the Microtox testing method. Photobacterium Phosporium, a microbial bioassay, was exposed to run-off water and infiltration water from the sealant for periods of five and fifteen minutes. No toxicity effects were observed.

Full-Scale Implementation and Cost Estimates

From the bench-scale testing results, it is suspected that the residual wax/antistripping agent adhered only to the walls of large voids in the Casito soil matrix, leaving a portion of the void uncoated and open for water infiltration. With even a small number of voids open for infiltration, water was channelled into the open pores, thus causing infiltration into the soil. For the full scale application, a larger unrefined wax/antistripping agent application rate is recommended, perhaps 1.0 kg/m2 or more. The higher application rate will overcome the presence of the larger pore spaces.

High temperature tolerance is another important physical property of the sealant. The temperature tolerance of a wax is a function of its congealing/melting point. For the purpose of this problem, the wax must persist in solid form at air temperatures expected in a semi-arid climate. The manufacturer's congealing point value for the proposed sealant is 64 degrees C, therefore it was expected to remain functional for normal site conditions.

However, at temperatures near 27 degrees C, the sealant experienced unusual softness of texture. By nature of their high oil content, unrefined waxes are not brittle, as are refined waxes, at normal ambient temperatures. Instead, they are more semi-solid and very pliable at normal temperatures. This textural softness and pliability led to slow flow of the sealant into the upper layer of soil. With such flow, the sealant did not act as an impermeable film atop the soil. Rather, it melted to fill the interstitial space of the top portion of soil, and compromised the continuity of the sealant cover.

Prior to full-scale application, it is recommended that further testing of the unrefined wax/antistripping agent and soil stabilizer combination sealant be conducted in a semi-arid environment and with soils having large pore spaces. Recommended modifications to the proposed sealant design for future testing include increasing the application rate, and selecting a petroleum wax with a higher, laboratory-verified congealing point. Both of these proposed modifications for further testing will lead to a substantial cost increase for full scale application. In utilizing this sealant system, the proposed 259 km2 application can be completed in a one year and five month time frame. Estimated capital, operating and labor costs for the full site are summarized in Table III. The unit cost is estimated as $146,426/km2.

DESIGN, ECONOMICS, AND IMPACT OF SOIL REMEDIATION AND RECLAMATION AT THE WERC CORPORATION SITES

ABSTRACT

A large contaminated area was discovered on a site owned by the Waste-management Education and Research Consortium (WERC) Corporation in an arid region of southern New Mexico. Contaminants included: 1) Pesticides; 2) Metals; 3) Organic compounds; and 4) Halogenated Compounds. In response to a request by the WERC Corporation, a team of Montana Tech environmental engineers assembled to conduct research and to formulate an innovative, economical, and successful method of cleaning up this contamination. All the requested tasks, and an investigation of subsequent legal, health, and economic issues, were completed and outlined in a proposal.

A two-step approach was developed to effectively treat the combination of organic and metal contaminants that exist in the soil. In the first step, soil is heated to volatilize the organic contaminants. Vapors are captured for off-site treatment. In the second step of the remediation process, soil washing and chemical extraction remove the metals from the soil matrix, transferring them to a liquid solvent. The clean soil can then be reapplied to the site.

Cost is an important consideration as WERC only generates an annual revenue of $7-$8

million dollars. The remediation system processes 4.8 tons per hour at a cost of $222 per ton; cleanup will be completed in 130 days. The total remediation project cost is $2,659,537.

SITE DESCRIPTION/DESCRIPTION OF CONTAMINANTS

The site is located in an arid region of New Mexico; vegetation consists largely of desert shrub and bunch grasses. Catastrophic flooding of a nearby river deposited cobbles and sandy loam in the upper soil strata. Contaminated soil is contained on a five (5) acre site, is limited to the top one (1) foot of soil, and is the result of fallout from a neighboring manufacturing region. Contaminants include: 1) Pesticides, Herbicides, Insecticides; 2) Metals; 3) Organic compounds; and 4) Halogenated Compounds.

It is assumed that the neighboring industrial activity was shut down before November 19, 1980, and thus, contaminants at this site are governed by the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA). Because these wastes are deemed to be a threat to human health and the environment, they must be addressed. However, removal and treatment must be conducted such that the safety of workers is assured.

REMEDIATION

Process Design

In order to remove the contamination from the soil, a multi-phase approach was taken. The organic constituents are removed in the first step, followed by metals removal and recovery in the next. The first step consists of an innovative approach to a proven technology: low temperature thermal desorption. The second step utilizes countercurrent soil washing to remove all metals followed by precipitation of those metals from the process water with lime kiln dust. The following flowchart describes the combined process chosen for this design. (See Fig. 1.)

Fig. 1. Process Flowchart.

Step One

The low temperature thermal desorption process has been used by some companies to remove small amounts of volatile or semivolatile organics. (1) This design uses the desorption process to remove the organics, halogenated organics, and also the non-volatile pesticides. The system consists of three main units; the thermal processor, the baghouse, and the condensing system; each of which are described below.

The thermal processor consists of four intermeshed hollow flight augers which are heated internally with hot oil. Each auger measures 30 inches in diameter and 28 feet long and sits in an enclosed heated auger housing. Both ends of the housing have close wall to auger tolerances to prevent air from entering the processor (less than 30 percent of the gas stream). The processor is fed by a conveyor which discharges through a vibratory screen into a surge hopper located above the thermal processor. The hopper continuously feeds the augers which will heat the soil to approximately 450 degrees Fahrenheit, removing the contaminants. The contamination is drawn through an insulated hood in the center portion of the auger housing and routed to the condensing system. The soil is then discharged from the augers into a conditioner where they slide down a ribbed heat exchanger to cool the soil and heat process water for the metals removal process. Some additional water is misted at the end of the conditioner to control dust emissions from the exiting soil. Figure 2 on the following page, shows this portion of the desorption system.

Fig. 2. Thermal Processor.

The coarse fragment which is screened off at the beginning of the process falls to the side where it is stockpiled and later reincorporated into the final clean soil (studies documented by the EPA have shown that in contaminated soils of varying particle size, the coarse particles--those over two millimeters in diameter--typically contain less than one tenth of one percent of the total contaminant). (2) The larger fragment will be tested occasionally to determine the amount of contamination it contains. If the levels are below those required on the WERC Cleanup, the material will be reincorporated into the final clean soil. If the coarse fraction does not meet these levels, it will be remediated in one of three methods:

Washing in a single cell batch reactor where the water can be captured and treated within the condenser or disposed of off-site;

Crushing and reincorporation into the feed material; or

Reintroduction to the hot fine soil stream inside the conditioner near the exit of

the thermal processor to strip the organics; it will then be screened off again and treated separately for metals.
This design will assume that under normal circumstances, treatment of the coarse fraction will not be necessary. Often, the highest concentration of metal and organic contaminants can be found in the fine fraction of any soil. This fact coupled along with the Environmental Protection Agency's (EPA) precedence of allowing minimally contaminated coarse fractions to go untreated is the basis for our assumption. Discussion with EPA project managers reaffirmed this assumption and the presented alternatives.
The contaminant vapors from the thermal processor are then routed via insulated duct through a pulse-jet baghouse to remove particulate material. Based on the expected gas flow rate, the baghouse will measure eight feet wide, nine feet long, and ten feet tall. It will house two compartments each capable of handling the gas flow rate in the event of a breakdown. The fabric filters selected were six feet long Teflon bags; they were chosen for their high temperature and corrosion resistance. The dust will be periodically blown off of the fabric filters using compressed air when the automatic pressure sensor reflects too large of a pressure drop across the baghouse. Depending upon the characteristics of the dust collected on the fabric filters, the material may be reprocessed, incorporated with the cleaned soil, or stored for off-site disposal. The performance aspects of the baghouse are presented in the Technical Assessment section.
The still hot vapors are then directed to the condensing system which consists of two condensers, a carbon adsorption bed, and the fan. A stainless steel air cooled condenser is first used to remove most of the pesticides and some organics. The gas then passes through a refrigerated condenser that will remove the remaining organic contaminants. The temperature within the second condenser is designed to be approximately 230F lower than the inlet temperature. This is a fairly high temperature to be condensing contaminants which will result in short term cost savings in equipment and long term cost savings in power consumption. The condensate is run through a simple oil-water separator and the organic contaminants are barrelled for off-site disposal. The water that is recycled, will be used for dust suppression of the raw untreated soil and for soil conditioning prior to treatment.

A small carbon adsorption bed is placed before the fan outlet to polish the exiting gas stream. Because of the relatively small flowrate, not much bed area would be necessary. An approximate three foot depth of 6 x 16 mesh activated carbon will be used; this should only contribute an additional three inches of pressure drop (see the Technical Assessment).
Step Two
The metals removal process utilizes soil washing and chemical extraction technologies to remove the metals from the soil matrix and dissolve them in the acidic solvent The process transfers the contamination to a liquid medium that is easily treated. The removal efficiency of the process is dependent on the soil: solvent ratio, the solvent characteristics, and contact time.
Metal contaminated soil exits the thermal processor and enters the five-chamber washing system. The soil is agitated in each tank and settled to the bottom where it is collected and sent to the next tank. At the same time, water is moving from tank to tank in the opposite direction. This will yield the cleanest soil at the end of the fifth tank. Metals are then removed from the water through precipitation using lime kiln dust. (See Fig. 3.)
Fig. 3. Counter Current Soil-Washing System.
The tanks will be constructed of stainless steel to avoid the corrosion effects of the acid. Likewise all pumps and tubing will be constructed to withstand the corrosive nature of the acid solvent. The soil will be mixed with .50 M nitric acid for a residence time of five minutes per tank to allow the acid solvent to dissolve the metal contaminants. The rationale behind the counter-current washing system design is to wash the cleanest soil with the cleanest solvent, thus ensuring the optimum contaminant removal from the soil. The soil will be removed from the bottom of the tanks and slurried to the top of each consecutive tank. Pneumatic mixing will allow the soil to mix with the acid as it slowly settles to the bottom of the tank. The clean soil will be removed from the bottom of the last tank of the counter-current soil washing system and slurried to the rotary drum vacuum filter. This drying system will consist of a rotary drum wrapped in filter fabric and

situated in a trough containing the soil slurry. As the drum rotates, it will pick up the slurry. A vacuum located inside the drum will draw the acid through the filter fabric. This recovered acid will be combined with the contaminated acid exiting the counter-current soil washing system and will be pumped to the acid treatment process. The dried soil will be removed from the drum by a stationary scraping knife. From this point, the clean soil will be conveyed to a height of eight feet and allowed to stockpile for several hours. A clean front end loader will be used to remove the clean soil to a storage location. When all of the soil is remediated, a small bulldozer will be utilized to spread the soil over the site.
The contaminated acid will be remediated by the precipitation of the metals as hydroxides. To accomplish this, the pH of the acid will be raised to 5.5 at which point the metals will form hydroxides and fall from the solvent in a solid phase. Kiln dust--a by-product of cement plants--has been chosen as the agent to adjust the solvent pH, allowing the utilization of one waste product (the kiln dust) to remove another waste product (the metals).
The kiln dust will be fed with a front end loader into covered hoppers located on top of the tanks. The precipitation step will take place in a double batch reactor system to allow for the necessary mixing time to sufficiently raise the pH. While one tank is filling with the appropriate amounts of solvent and kiln dust, the solution in the second tank will be mixed with a turbine mixing system and drained. The drained slurry will be transferred to a second rotary drum vacuum filter system which will recover the clean acid solvent and produce a waste sludge of kiln dust and metal hydroxides. This waste sludge will be removed from the site and disposed of at the nearest hazardous waste facility in West Moorland, CA.

TECHNICAL ASSESSMENT

Unit Operations

The thermal processor consists of a four-screw auger and trough with each auger measuring 30 inches in diameter and 28 feet long. Each auger is hollow and has high temperature oil continually flowing through it to heat the soil. Using the results from the bench scale runs in conjunction with HoloFlight heat transfer modeling, the feed rate of the soil was set at 4.8 tons per hour, or approximately 3.2 cubic yards per hour. Soil moisture will be maintained at approximately 20% by volume using recycle water separated in the condensing unit. The retention time of 20 minutes was necessary for the soil to reach the required remediation temperature of 440 degrees Fahrenheit. The bench scale testing indicated that a 20 minute retention time was more than adequate to reduce the contaminants to the required levels; therefore, with further testing of the full scale and better heat transfer, the retention time could possibly be decreased, and the feed rate could possibly be increased.
In the pulse-jet baghouse, air is filtered from the outside of the bags to the inside. A cage in each bag prevents them from collapsing. The bags are cleaned by short (30-100 millisecond) blasts of high pressure air from a compressed air manifold at the top of the baghouse. The shock wave from the compressed air blast shakes the dust off of the bags. Each bag is pulsed every few minutes. The advantage of this type of baghouse is that it does not have to be shut down for the bags to be cleaned; air-stream treatment can continue while the bags are being cleaned. The design utilizes high temperature Teflon bags and a maximum filtering velocity of ten feet per minute. With the expected dust loadings, the pressure drop is predicted to be less than ten inches of water using Leith and First's pressure drop model. (3) Particle removal efficiency for this type of pulse-jet baghouse is typically 99.9% or better.
The condenser consists of a stainless steel air cooled condenser followed by a low temperature refrigerated condenser. The use of the air condenser should reduce the amount of power consumed by the system while removing a large portion of the contaminants. The refrigerated condenser was designed with a U-value of 2.0 and should reach temperatures around 230F below the inlet temperature. Stainless steel refrigerated coils will be used to prevent corrosion. The condenser system (both condensers) will occupy approximately a ten feet by ten feet square area. A simple oil water separator will be used to reduce the volume of the condensate waste stream. The treated water is then reused on site for soil conditioning while the organic contaminants are barrelled for off-site disposal.

Prototype

A prototype thermal processor was developed to mimic the operating conditions that will be present in the full-scale unit. This was done by creating a small batch

reactor that heats and agitates the soil in a similar manner to that of the thermal processor. The contaminated air from the heated reactor is then drawn through a condensing unit and carbon adsorber before entering the atmosphere. (See Fig. 4.)
Fig. 4. Bench Scale Prototype.
The prototype is constructed of an eight inch diameter aluminum cylinder, 18 inches long, 1/8 inch thick. Aluminum was chosen because of its strength, low weight, and ability to with stand high temperatures. One end is sealed with a 1/2 inch thick aluminum plate that is connected through a coupling to a stationary electric motor by a 1/4 inch steel shaft.
The other end of the cylinder is sealed with a removable 1/2 inch thick aluminum plate. The air-tight seal for this cap consists of high temperature silicone o-rings. The center of this end plate is drilled and threaded to accept a 1/2 inch steel pipe that will draw off the contaminated vapors. On the inside of the cap, this pipe will have a small filter placed over it to prevent dust from entering the gas stream. A quick-couple slip fitting will be placed on the protruding steel pipe that will allow the cylinder to turn freely while still permitting air-tight gas flow. Following treatment, this end may be quickly removed, the motor can be uncoupled, and the cylinder may be lifted out and emptied. Heat is provided externally to the cylinder by a propane heating element fixed to the frame.
The contaminated vapors are drawn through the filter, the steel pipe, and into a short section of insulated copper tubing which leads to a condensation/adsorption unit. To simulate the condensers on the full scale design, three ice-bath condensers are placed in series to cool the vapors and condense the organics. Each condenser will contain cooled water to provide as much cooling surface area as possible. As a polishing step, the gas stream enters an activated carbon packed impinger. Finally, the gas passes through an adjustable vacuum pump and enters the atmosphere.
EXPERIMENTAL RESULTS
Gas chromatography/mass spectrometry (GC/MS) in conjunction with Soxhlet Extraction (EPA methods 3540 and 8240) was used to assess the technical feasibility of the prototype unit. The mass spectrometer was set up for ion selective detection to increase sensitivity. Three known concentrations of each contaminant were used to generate the calibration curves used for the quantitative and qualitative assessment. Unfortunately, due to improper extraction techniques, data for ethyl benzene was not obtained. However, it is the design team's consensus that the most difficult contaminants to remediate should be the non-volatile pesticides. It can also be noted that tetrachloro-ethylene and chloroethylene were not detected in any of the samples analyzed. It is assumed that the very small amount that was added to the soil had evaporated due to the volatility of these compounds.
Two different experiments were conducted in order to determine the optimum temperature and retention times for the thermal processor. Preliminary experiments were carried out using a temperature controlled oven with a gas exhaust port. Final experimentation was conducted on the bench scale prototype using a propane fuel source and revolving at approximately 10 to 15 revolutions per minute.
Three experimental runs were conducted to find the lowest (i.e. most cost efficient) temperature to run the thermal processor at while still getting an acceptable amount of degradation. The first half of Table I below shows the results of these runs. Even at the lowest temperature attempted, all of the contaminants are removed. To be safe, the temperature for the thermal processor will be set at 230C. This temperature may be adjusted based on further research; however, it is a likely possibility that the temperature can be reduced or the residence time decreased resulting in greater cost savings in the long run.
To determine the soil feed rate, the residence time for the soil would be necessary. A second experiment was conducted in which the residence time was varied while the temperature remained constant at 230C. The second half of Table I above shows that there is a notably smaller reduction of pesticide concentration in the 15 minute sample when compared to the 30 minute sample. When the 30 minute sample is compared to the 60 minute sample there is a small reduction in some concentrations, but not enough to warrant doubling the retention time. Even in the 15 minute sample, all contaminants met the required cleanup guidelines. Therefore, to be safe, the retention time can be set near 20 minutes.
Through assessment of the experimentation, the lowest--most cost effective--temperature was set at 230C and the optimum retention time was determined to be 20 minutes. When both of these conditions are met, the soil will be remediated

to the required levels. However, statistically valid experiments varying both retention time and temperature should be conducted in the future to account for any interaction between the two variables.
For the soil washing process, three parameters required investigation to determine the optimum system: the soil:solvent ratio, mixing time required, and solvent characteristics. A soil:solvent ratio was estimated based upon the amount of water needed to dissolve the amount of copper sulfate that would exist in one kilogram of soil. The ratio of 30 grams of soil to 150 ml of solvent was used for all subsequent experimentation.
The success of the metals extraction was studied by measuring the metal concentration of the washing solvent after washing with an atomic absorption (AA) analyzer for each of the three metal contaminants. A laboratory test was set up to determine the optimal mixing time and acid concentration using nitric acid as the washing solvent. Contaminated soil was washed with three different solvent concentrations: .01 M, .10 M, and 1.0 M HNO_3. The washing periods included: five, ten, and fifteen minutes.
The optimal mixing time in all cases was five minutes, and .01M acid was the optimal washing solvent for removing the silver and cadmium. Based on percent reduction, five washes would be necessary to remove the silver and cadmium. Also, .01M acid was not strong enough to remove copper in five washes; therefore, the optimum soil washing system would include five washing steps with .5 M nitric acid.
Table II depicts the removal efficiencies resulting from the experiment. The data show that copper would not be removed to the necessary 15 ppm with the .10 M HNO_3 solvent. The .50 M HNO_3 reduces the copper content to acceptable levels in five washings.
The metal hydroxide precipitation test was based on the following assumption: when adding kiln dust to the contaminated solvent, the pH of the solution would remain constant during the period in which the metals were precipitating. Upon precipitation of all metals, the pH would again begin to rise. For the experiment, three 450 ml samples of .10 M HNO_3 were directly contaminated with the amount of metals that would exist in 90 grams of soil. Kiln dust was added in increments of one gram. The pH was recorded when it stabilized and more kiln dust was added. It was determined that 5.25 grams of kiln dust to 450 milliliters of acid was the optimum ratio for metals removal from the solvent.

OPERATING PLAN

The plant must run 24 hours a day if all material is to be processed in one summer. Also, this will minimize the amount of heat and power lost due to shutdown cooling and startup reheating of the auger oil. Three shifts of four to six people will be necessary to run the operation. A safety officer will be on site at all times to enforce safe work techniques and conduct all sampling procedures. One or two bulldozers will push the soil from the five acre site to the centralized plant. From here, one man operating a small loader can load contaminated soil onto the feed conveyor. When the surge bin is full, he can move the accumulating coarse fraction with the same loader to the nearby stockpile location. On the exiting end of the soil washing process, another operator can use a different non-contaminated loader to move the accumulating clean soil into a stockpile for its future reapplication to the site. Upon full drying of the accumulated material, a bulldozer will be used to push the soil over the site. One of the employees will serve as shift supervisor. At a soil feed rate of 4.8 tons per hour, the full 12,000 tons of soil will be remediated in 2500 hours or about 105 days. Assuming approximately 80 percent utilization to account for mechanical failures and upkeep, the job time is estimated at 130 days or 3125 hours.

ECONOMIC ASSESSMENT

Table V illustrates the total cost for remediation equipment, labor, and operation and maintenance. Hours and rates along with operation and maintenance systems for this project have been estimated based on the time invested and current competitive wage estimates. Capital equipment is estimated to cost $400,500; Pre-operations labor is estimated at $170,025; and Operations and Maintenance over the project life is estimated at $2,089,012. The total Remediation Project Costs are $2,659,537 or $221.63 per ton (assuming approximately 12,000 tons of soil).

CONCLUSION

A unique remediation and reclamation plan was designed to remediate contaminated soil at the WERC site. Montana Tech environmental engineers have designed a

multistep system that includes a thermal desorption unit followed by a counter-current soil washing unit. This system can efficiently reduce contamination in the soil to acceptable levels while minimizing cost and waste streams. The remediation system first vaporizes the contaminants from the soil using heated augers and then condenses them out of the gas stream for off-site disposal. The metals are then washed out of the soil using an acidic solution. Contaminated soil is processed at 4.8 tons per hour and the WERC site can be completely treated within a four month period by a small work crew. The total cost for soil remediation is $2,659,537, or $222 per ton; however, it should be noted that the majority of this cost is due to the disposal of pure contaminant waste streams. There is, however, a high probability that the process would have a commercial value to the WERC Corporation. After the initial project costs and may even provide additional revenue in the future.

Health and safety issues are being addressed through the creation of a site safety and health plan which addresses worker safety, personal protective equipment, and emergency procedures. Legal issues regarding site remediation have been addressed including the regulations associated with any releases of wastes which will occur at the remediation plant.

Our design creatively address all of the WERC Corporation Management's concerns regarding the effectiveness, implementability, and cost of our Low Temperature Thermal Desorption/Soil Washing Project. Not only will the surrounding community benefit from a cleaner environment, but the WERC Corporation will also benefit from a safe, effective remediation and reclamation process that shall provide future economic benefits.

ABSTRACT

A detailed, dynamic simulation model of the entire high level radioactive waste complex at the Savannah River Site has been developed using SPEEDUP(tm) software. The model represents mass transfer, evaporation, precipitation, sludge washing, effluent treatment, and vitrification unit operation processes through the solution of 7800 coupled differential and algebraic equations. Twenty-seven discrete chemical constituents are tracked through the unit operations. The simultaneous simulation of concurrent batch and continuous processes is achieved by several novel, customized SPEEDUP(tm) algorithms. Due to the model's computational burden, a high-end workstation is required: simulation of a year's operation of the complex requires approximately three CPU hours on an IBM RS/6000 Model 590 processor. The model will be used to develop optimal high level waste (HLW) processing strategies

over a thirty year time horizon. It will be employed to better understand the dynamic inter-relationships between different HLW unit operations, and to suggest strategies that will maximize available working tank space during the early years of operation and minimize overall waste processing cost over the long-term history of the complex. Model validation runs are currently underway with comparisons against actual plant operating data providing an excellent match.

INTRODUCTION

Process Overview

The mission of the Savannah River Site (SRS) High Level Waste (HLW) System is to receive and store radioactive high level wastes in a safe and environmentally sound manner, and to convert these wastes into forms suitable for final disposal. The planned forms are: borosilicate glass to be sent to a Federal Repository; saltstone grout to be disposed of on-site; treated wastewater to be released to the environment; and benzene for destruction by incineration. Also, the tanks used for storage of the wastes must be left in a state such that they can be decommissioned and closed in a cost-effective manner under the applicable Federal Facility Compliance Agreement.

The operations (Ref. 1) required to fulfill the above mission are illustrated in Fig. 1, with the processes indicated in rectangles and the coupling connections between the processes shown as numbered streams. Incoming high level wastes (stream 1), consisting primarily of insoluble metal oxides and hydroxides (sludge) suspended in aqueous solutions of sodium salts (supernate), are received into HLW Storage and Evaporation (Tank Farm). The majority of the waste is from nonradioactive process chemicals. Fission and activation products, and actinide components, are mainly present in the sludge phase, except for cesium which has a high solubility and remains in the supernate. The purpose of the Tank Farm is to safely store these wastes until downstream processes are available for further processing. Most of the supernate is evaporated to solid saltcake to reduce its volume and mobility. Incoming decontaminated overheads from the separations evaporators are sent to the Effluent Treatment Facility (ETF) (stream 13).

Insoluble sludges that settle to the bottom of the waste receipt tanks in the Tank Farm are transferred (stream 2) to Extended Sludge Processing (ESP) via hydraulic slurrying techniques. In ESP, sludges high in aluminum are processed to remove previously insoluble aluminum compounds. All sludges are washed with water to reduce their soluble salt content. The spent washwater from this process is sent back to the Tank Farm (stream 3), while the washed sludge is sent to Vitrification (stream 4).

Saltcake (primarily crystallized sodium, potassium, and cesium salts) in the Tank Farm is redissolved using hydraulic slurrying techniques and sent to In-Tank Precipitation (stream 5), where the salt solution is processed to remove radionuclides, which are concentrated into an organic precipitate. The precipitate is filtered, washed with water to remove soluble salts, and sent to Vitrification (stream 7). The decontaminated filtrate is sent to Solidification (stream 6).

In Vitrification (Defense Waste Processing Facility - DWPF), the precipitate (stream 7) is catalytically decomposed and separated into two streams: a mildly contaminated organic stream which is sent to storage and eventual destruction in the Consolidated Incineration Facility (stream 11); and an aqueous stream containing virtually all of the radionuclides which is combined with the washed sludge from ESP (stream 4) and sent to the glass melter. To prepare feed to the melter, the washed sludge from ESP has been chemically adjusted, stripping out a significant amount of mercury which is purified and sent to mercury receivers (stream 12). The precipitate and sludge are mixed with glass frit and sent to glass melting. The glass melter drives off the water and melts the wastes into a borosilicate glass matrix which is poured into a stainless steel canister. The canistered wasteform (stream 9) is sent to on-site interim storage, and will eventually be disposed of in a Federal Repository.

The water vapor driven off from the melter along with other aqueous streams generated throughout Vitrification are sent to the Tank Farm for evaporation, storage, and eventual further processing (stream 10).

Overheads (i.e., the fraction which is evaporated off) from the Tank Farm evaporators are combined with overheads from separations processes and other low-level streams and sent to the ETF (stream 13). In the ETF, these low-level wastes undergo further decontamination. The treated effluent becomes outfall which

flows to the site environment (stream 14), while the contaminants removed in the treatment process are concentrated and sent back to ITP (stream 15) where they are mixed with the decontaminated salt solution from ITP. This mixture of low-level waste is then sent to Saltstone (stream 6) where it is combined with cement formers and pumped as a wet grout to a vault (stream 16). In the vault, the grout hydrates and cures, forming a grout monolith that will eventually be closed as a landfill.

Model Overview

The Integrated Flowsheet Model (Ref. 2), the subject of this paper (hereafter referred to as the "IFM"), was designed to capture the processes described in the previous section via the use of the SPEEDUP dynamic simulation package (Ref. 3). The first phase of the IFM focuses on predicting the available Tank Farm space over the next five to ten years. Thus the current emphasis is on performing accurate dynamic volume balances for 30 of the 51 tanks, with simplified models of many of the facilities outside the Tank Farm. Succeeding phases will add detail to the models as the need for such is identified.

SPEEDUP is a comprehensive plant modeling package which offers steady-state and dynamic simulation capabilities in a flowsheeting environment. The user need only create sets of differential-algebraic equations to describe a particular process (e.g., conservation and rate equations) and then define how the various processes are coupled together (e.g., "output 2 of tank_48 is input 1 of tank_49"). The equation syntax is an intuitive one illustrated in Eqs. 1-3. The differential equations are primarily statements of the time-derivative of mass for various constituents. The algebraic equations are state equations (e.g., density as a function of composition), logical IF-THEN-ELSE constructs determining process control, and intermediate expressions which are used to compute elements of the differential equations (e.g., reaction rates).

SPEEDUP carries out a symbolic translation of the equations created by the user and automatically generates a FORTRAN solution algorithm for the dynamic problem. Automatic timestep selection is used during the integration of the equations. Discontinuities (e.g., a transfer flow turning on or off) are automatically detected, and at that precise time the solution re-initializes itself to continue the time integration on the other side of the discontinuity. Thus all discrete events are accurately captured. The user of the IFM need only define the applicable process equations and instruct SPEEDUP to solve the equation set. Process changes are almost trivially implemented in the IFM: the user need only modify the basic equations, and SPEEDUP automatically regenerates the necessary solution algorithms.

Each of the "boxes" in Figure 1 is broken down in the IFM into a series of unit operations, with many additional streams coupling those unit operations internal to the "box" . Generally, a single unit operation is associated with an identifiable part of the HLW complex (e.g., a particular tank, evaporator, etc.) or a process control operation (e.g., a diversion box that switches transfers from one tank to another). Currently, approximately 7800 differential-algebraic equations are used to represent 72 distinct unit operations coupled by 172 streams, each carrying 27 chemical compounds. The computation burden is variable, dependent on the number of discontinuities encountered during the simulation and on fundamental process time scales. Typically, a one year simulation of the HLW complex requires 2-3 CPU hours on a IBM RS/6000 Model 590 workstation. About 10000 problem variables are viewable from the analysis results, with an intuitive point-and-click plotter being available within the SPEEDUP environment.

We found that the SPEEDUP environment (Refs. 4,5) lent itself naturally to the rapid and efficient development of this rather complex dynamic model. The discipline imposed by the SPEEDUP modeling language allowed a multi-disciplinary team gathered from several SRS divisions to work effectively in a concurrent fashion. Once the fundamental model interfaces were agreed to by the team, the individual modelers were able to proceed independently in developing and verifying their assigned unit operation models. As individual models were completed, they were smoothly integrated into the growing overall model. The entire modeling process (design, implementation, integration, final checkout, and documentation) required less than one year with the equivalent of five full-time modelers.

The IFM will be used by process engineers to simulate in a dynamic fashion the response of various parts of the HLW complex to varying operational strategies and to study the integrated effects of one part of the complex upon another. From another perspective, the IFM will be used by production planners to study the

dynamic effects of various feed strategies, optimal batching sequences, the impact of varying the start-up of various parts of the complex, etc., all from the viewpoint of best utilizing the available resources over a projected thirty year future for the site's high level waste complex.

UNIT OPERATION MODELS

The major elements of the Integrated Flowsheet Model (IFM) will be described in this section, which is organized to be consistent with the logical and material flows shown in Figure 1. Currently, the IFM consists of 32 models of 72 unit operations (a unit operation being, for example, a single sludge washing tank). There are fewer models than unit operations due to the replication feature in SPEEDUP: more than one unit operation may be described by the same model as long as the form of the process equations are identical for the operations (while the parameters in the equations may differ in the individual unit operations). There is insufficient room to describe such a number of models in detail (see Ref. 2), so we restrict ourselves to the general types of processes modeled. In addition, we will discuss the techniques which allowed us to employ a fundamentally continuous process modeling tool to treat cyclic, batch processes. The chemical compounds tracked in the IFM are: H2O, NaNO3, NaNO2, NaOH, KNO3, CsNO3, NH4NO3, NH4OH, NaAlO2, Na2U2O7, Fe(OH)3, Al(OH)3, Sr(OH)2, C6H6, C6H6O, CsOH, KOH, CsB(C6H5)4, NaB(C6H5)4, Na2(C6H5)BO2, KB(C6H5)4, NH4B(C6H5)4, NaTi2O5H, NaTi2O5.Sr(OH)2, NaTi2O5.Na2U2O7, miscellaneous soluble salt, and miscellaneous insoluble sludge.

Waste Generators

SRS liquid waste, as received in the waste tanks, is made up of many waste streams generated in the separations process during the recovery and purification of transuranic products and unburned fissile material from spent reactor fuel elements. To prevent corrosion of the carbon steel waste tanks, these wastes are neutralized to excess alkalinity (pH > 12) before transfer to the Tank Farm underground storage tanks. The two incoming streams shown in Figure 1 are subdivided into five streams in the IFM. The separation process details are considered to be external to the IFM and are thus represented as external boundary conditions to be imposed upon the model: the user defines time-dependent flows and compositions for the five input streams into the IFM.

Storage and Evaporation

SRS operates a Tank Farm consisting of 51 waste tanks (ranging in volumetric capacity from 2700 m3 to 4900 m3; i.e., up to 1.3 million gallons) and three evaporators. Radioactive waste, as received in the Tank Farm, can be reduced to about 25% of its original volume and immobilized as crystallized salt by successive evaporation of the liquid supernate. Such dewatering operations have been carried on routinely at SRS since 1960 and have allowed the site to avoid the need to build an additional 70 storage tanks.

In the IFM, each tank is individually represented through basic equations representing a simple, lumped parameter, perfect mixing mass balance:

```
$tank_mass = Sin (stream_in_density * stream_in_flow) -
                                    tank_density * Sout (stream_out_flow)
                (1)

$tank_mass * tank_massfrac(1:nocomp) +  tank_mass * $tank_massfrac(1:nocomp) =
              Sin (stream_in_density * stream_in_flow * massfrac_in(1:nocomp)) -
              tank_density * tank_massfrac(1:nocomp) * Sout (stream_out_flow)   (2)

tank_density = function(tank_massfrac)  (3)
```

where the above is written as an example of the actual SPEEDUP syntax with "$" denoting the time derivative and "a:b" a vector operation over the elements "a" to "b", with "nocomp" being the number of chemical compounds being tracked. The summations are over the number of streams into and out of the tank, each of which would be written out explicitly and named uniquely in the SPEEDUP implementation. The variables are typically given names that make their significance obvious. The density function is based on experimentally measured data for the SRS Tank Farm compositions: it is written as a simple algebraic form in the equation set. The volumetric flow rates are determined by the batch control logic described in a later sub-section. Eqs. 1-3 represent nocomp+2 simultaneous differential-algebraic

equations. In SPEEDUP, the unknowns may be on either or both sides of the equation: the translator is able to parse the equation and identify which variables are to be solved simply from the structure of the equations and the given input.
For a salt tank, the above set of equations would be written once for the supernate region and once for the saltcake region, with additional coupling terms in the equations to reflect the dissolution or crystallization processes. In order to minimize the computational burden, the vector equations for each region only span the compounds normally present in that region. Currently, the simple salt tank process model compares the tank supernate density against a reference specific gravity. If the density exceeds the set point, salt precipitates at a given rate, thereby removing mass from the supernate balance and adding it to the saltcake balance via the new coupling terms. If the opposite is true, the mass exchange proceeds in the other direction until the reference specific gravity is attained in the supernate.
Similarly, a parametric pseudo-steady state model is employed for the evaporator. The evaporator overheads are given as a function of the specific gravity of the evaporator feed tank. The evaporator itself is defined to produce concentrate at a prescribed specific gravity, with the concentrate delivery rate equal to the evaporator feed rate minus the overheads. The remaining degrees of freedom in the formulation then uniquely specify the feed and delivery rates, and the composition of the concentrate delivered to the salt tank.
Extended Sludge Processing
Neutralizing the waste from the separations processes produces a mixture of insoluble sludges, primarily iron, manganese, aluminum, and uranium hydroxides in a salt solution. Although the sludge has settled and compacted in the various waste tanks for 5 to 40 years, that settled volume contains a significant fraction of interstitial liquid bearing dissolved sodium salts. If this salt were not removed, the vitrification process would require a larger frit-to-waste ratio (to control the rheology of the molten glass), which would greatly increase the number of glass canisters to be produced and stored, and hence the cost of the overall process. These soluble salts are removed from the interstitial liquid by repeated dilution in processing tanks in the Extended Sludge Processing (ESP) facility. In addition, some of the sludge inventory contains large amounts of aluminum (with a negative impact on the product glass rheology) which is dissolved by heating the sludge in a high caustic concentration. The supernate containing the dissolved aluminum is then decanted before the start of the salt washing process.
A variation of the standard IFM tank model described in the previous section is used to model the sludge washing process. If needed, the aluminum dissolution is treated via additional mass transfer terms in the supernate and sludge mass balance equations (much like the salt precipitation and dissolution is handled in the salt tank model of the previous section). The batch process control algorithms set the aluminum dissolution mass transfer terms nonzero during the appropriate time interval, and then back to zero when completion of the process is detected.
The volumetric dilution which reduces the salt content during ESP washing is already handled by the basic tank mass balance algorithms. But the process control becomes more complex. After the wash water is added to the tank, the sludge solids are suspended and agitated for a period of time using slurry pumps, after which the slurry is undisturbed for another interval of time to let the sludge settle. The subsequent decant is designed to remove supernate down to a level just above the settled sludge interface (whose position and settling rate change with time). A FORTRAN procedure which encodes an empirical, four-region sludge settling model is linked into the SPEEDUP tank model in order to compute the time dependent sludge settling level. That level is then passed to the batch process control algorithms to control the turning on and off of the tank flow which represents the decant. The dynamic model in IFM couples all these varying time-dependent processes into a consistent tank response.
During the dynamic simulation, the IFM monitors the sodium content in the sludge washing tank and will automatically terminate the washing process when the desired end-point is reached and go on to the next phase of operation. In addition, during the washing process, the IFM will add corrosion inhibitors at the appropriate time and in the correct amount to maintain the tank within the specified corrosion limits. Both operations mimic the actual events that would occur in the real facility and are controlled by the batch process algorithms.

The sludge washing process can move large amounts of wash water as decant throughout the HLW complex: a typical wash cycle can utilize 1300 m3 (one-third of a million gallons) of wash water, with three or more washes to process each batch of sludge. A co-washing strategy is usually adopted which utilizes two tanks in tandem, with the wash water from one cycle in one tank being used for the next wash cycle in the other tank. Any decant can be diverted to a number of different tanks. All this flexibility is also provided in the simulation with the IFM. With the tank models having high and low level set points built into them, the IFM analyst can make a number of different strategy choices in managing tank volumes and clearly see the outcome as success or grid-lock in the Tank Farm. The IFM captures all the significant system dynamics of the actual plant.

Salt Processing

The saltcake in the Storage & Evaporation portion of the HLW complex is redissolved for pumping to the In-Tank Precipitation (ITP) process where the solution is decontaminated in a batch process. The soluble radioactive metal ions (soluble cesium and the soluble fraction of strontium, uranium, and plutonium in part per million levels) are precipitated with sodium tetraphenylborate or adsorbed on sodium titanate to form insoluble solids. The resulting precipitate, which contains most of the radionuclides, is filtered to concentrate the solids and then sent to the vitrification process. The remaining decontaminated salt solution is transferred to Solidification following benzene stripping.

This part of the IFM represents yet another variation on the fundamental mass balance algorithms in which new terms appear in the appropriate tank model equations in order to represent the dynamics of precipitation chemistry, dissolution of solids, solubility of tetraphenylborate compounds, adsorption onto sodium titanate, benzene formation via radiolytic decomposition, and benzene evaporation. Benzene stripping is represented with a steady-state model: the user specifies the benzene concentration in the effluent flow of the stripping column, and the model performs overall and component mass balances to obtain the flows and compositions of the top and bottom streams leaving the column.

Detailed descriptions of this particular model may be found in the References (2,4) and will not be repeated here. The main impacts on the overall IFM are the stiff, non-linear behavior now imposed on the equation set due to the reaction rate stoichiometries, and the additional discontinuities introduced in the solution by having another batch process cycling through its discrete steps (i.e., in addition to the ESP batching). Both new elements have the effect of significantly increasing the computational burden, but are crucial to an accurate representation of the overall process.

Vitrification

The Defense Waste Processing Facility (DWPF) consists of several facilities: Late Wash, the Vitrification process, and Saltstone. Late Wash receives washed precipitate from ITP and reduces the nitrite concentration (used for corrosion inhibition) by filtration and dilution. During the process, the slurry is reprecipitated to capture cesium (which may have returned to solution in ITP) and then reconcentrated. The filtrate produced during the filtering process is stripped of benzene, chemically adjusted, and transferred back to ITP for reuse.

In the IFM, the Late Wash precipitation reactions are assumed to be instantaneous and complete. Just as in the ITP model, the Late Wash model adds 150% of the sodium tetraphenylborate required to stoichiometrically react the incoming nitrate salts. The precipitate is assumed to be continuously washed to reduce the nitrite concentrate to the prescribed value. Simple mass balance equations are used to model the processes.

In the Vitrification process, the liquid HLW which is processed in ITP/Late Wash and ESP is immobilized as a glass solid. The operations include chemically treating the two quite different waste streams, mixing them with ground borosilicate glass (frit), heating the mixture in a melter, and pouring the molten mixture into 3 m tall by 0.6 m diameter stainless steel canisters to harden.

In the IFM, the Vitrification process is approximated as a simplified, continuous (rather than a batch) process for the purpose of translating the outputs from Late Wash and ESP into waste product streams: glass, organic waste, and recycle to the Tank Farm. The model has been shown to give the same material distributions in the output flow streams as those in the reference steady-state design analysis when the model input matches the design input stream compositions.

Vitrification proceeds through three processing cells. In the Salt Processing Cell (SPC), the precipitate slurry is acid hydrolized and steam stripped in order to remove the aromatic organics from the melter feed. Formic acid used in the SPC is absent in the IFM, thus the reaction representation is necessarily simplified: the formulation is designed to reproduce the main output of interest at this stage, the organics. At this point the hydrolized precipitate is transferred to the Chemical Process Cell where washed sludge enters from ESP. Nitric acid is added to react components and provide the required reduction-oxidation balance. Frit is added and the final mixture is sent to the Melt Cell (which is not explicitly modeled in the IFM). In the IFM, ten simplified oxidation equations are used to apportion a fraction of the components to the recycle stream and the oxides that all go to the glass. All reactions are assumed to be instantaneous and complete. Distribution parameters (e.g., fraction of sludge components transferred to the recycle stream) are user-defined constants. While mass is preserved in the model, the densities of the oxides are not known, so the density of the glass is not calculated. Glass canister production in IFM is based on a volumetric flow rate that results from a volume balance. The mass of the glass is based on a nominal density taken from the reference design calculation. The IFM controls the vitrification process by adjusting the sludge flow to meet the sludge weight fraction criterion, by adjusting the precipitate flow to meet the prescribed precipitate mass fraction in the glass, and by adjusting the frit flow to make up the balance of the nominal glass production rate. Mercury production is not treated in the current version of the IFM. Neither is the Consolidated Incineration Facility currently represented in the IFM.

The Vitrification part of the IFM computes two of the four major outputs of the HLW complex: glass canisters and recovered organics.

Solidification

In the Saltstone Production Facility, aqueous salt solution is received from ITP and then combined with a blend of cement, fly ash, and blast furnace slag to generate nonhazardous, low level waste, saltstone grout.

The grout is pumped to a covered cell of an above-grade, concrete vault where it solidifies. In the IFM, the saltstone model computes the salt solution feed from ITP based on the nominal cement premix flow rate, and calculates the volume of dilution water required to bring the feed into compliance with limits set on strontium, sodium, and hydroxides. From the resulting mass balance and the given grout density, the model will compute the volumetric production of grout, which is then translated into the number of vaults filled.

The Solidification part of the IFM computes the third of the four major outputs of the HLW complex: wet grout.

Wastewater Treatment

The Effluent Treatment Facility (ETF) decontaminates the influent wastewater through a series of steps consisting of pH adjustment, sub-micron filtration, heavy metal and organic adsorption, reverse osmosis, and ion exchange. The treatment steps concentrate the contaminants into a smaller volume of secondary waste which is further concentrated by evaporation. The clean, treated effluent is discharged to the on-site environment, while the contaminated evaporator bottoms are pumped back to ITP for eventual disposal in Saltstone. In the IFM, the ETF model takes as inputs the time-dependent flows from the five evaporator overheads tracked in the IFM. Perfect mixing of the input streams is assumed. The user defines a split fraction for the volume going to the outfall, which is taken as pure water. The mass balance relation then computes the flow rate and composition of the concentrate and returns it to ITP.

This Wastewater Treatment part of the IFM computes the final of the four major HLW complex outputs: treated effluent.

Batch Process Control

SPEEDUP was initially developed as a continuous process simulation tool. In its language constructs, no integer arithmetic is allowed. There is no way to easily store "previous timestep" values of variables, and it is difficult to recognize when a variable has changed for the first time in order to initiate some new action. Thus it is somewhat more awkward to use SPEEDUP to simulate cyclic, batch processes than for continuous ones. Fortunately, SPEEDUP has a facility for linking customized FORTRAN into the continuous model via its External Data Interface (EDI), and we have done all our batch process control in the IFM via that facility (Ref.

6). Since process control is a key part of the IFM, it will be described in some detail.

EDI consists of a set of ordered, dummy subroutine calls that are always available in a simulation. All the user has to do is recognize the call order and fill in the dummy subroutines with customized FORTRAN which carries out the desired set of operations. This is where we have located the IFM batch control. Each batch process is set up as a "recipe" consisting of several steps. For example, the ESP washing process consists of 14 steps during which aluminum dissolution, decants, inhibitor additions, wash additions, agitation, settling, and time delays occur. We have used the EDI subroutines to encode these batch recipe steps, primarily via manipulations of integer and real arrays to identify when a process is on or off. Within the continuous SPEEDUP model, we have set up unit operations which represent junction boxes coupling M tank outputs to N tank inputs. These input/output streams in the couplers contain "logical valves" (i.e., scalers between 0.0 and 1.0) which are turned off and on by the EDI interface. These scalers are used to compute the current values of stream_out_flow and stream_in_flow in Eqs. 1-2. Thus SPEEDUP calls the EDI FORTRAN when a batch operation initiates; the FORTRAN changes the appropriate scaler to begin the batch operation and computes the time at which the batch operation will be complete (so that SPEEDUP knows when to call EDI again for the next step in the recipe); control returns to SPEEDUP so that the continuous model can respond to the batch operation changes via a change in a coupler state; and the simulation proceeds onward in the operation.

The EDI FORTRAN is broken down into six modules. One controls the ESP batch process and another the ITP batch process. A third controls the sludge feed from ESP to DWPF. Two more are used to dynamically alter model parameters such as tank operating limits, evaporator utility, or feed stream flow and composition from waste generation. This module is also used to simulate transfer line availability so that even though a batch recipe step may call for an operation, the user can define that transfer line to be down for a particular time interval and thus delay the operation. The sixth module is used to carry out manual transfers which the user may choose to define in addition to the normal automated processes: e.g., the user can choose to let the normal model control the evaporator system recycle operations, or alternatively use this sixth module to prescribe all the evaporator control via detailed input. The modular structure allows the coding to execute only those code blocks that are appropriate to the processes which are currently underway.

As a result of our implementing batch process control through EDI, the IFM has great flexibility in modeling both continuous processes (e.g., evaporator operations) and discrete batch processes (e.g., sludge washing) simultaneously. The entire waste complex model consists of many different sorts of processes with varying natural time constants and sequence patterns. In the IFM, each process can be operating simultaneously and independently, and still couple to other processes when the time comes for an interaction between the processes. The power of such generality is required in order to run the full spectrum of scenarios necessary to simulate thirty years of operation of the entire HLW complex.

Model Verification and Validation

The IFM is undergoing a formal verification and validation process. In the verification phase (which has been completed), each individual model was subjected to an independent review (by a modeler not involved in its creation) in order to verify that the correct equations were properly encoded, and that the model execution satisfied the formal definitions in the detailed Software Requirements Specification document (Ref. 7). The verified individual models were then tested en masse in an integrated form to verify that the Software Requirements Specification continued to be satisfied in the whole.

The second part in determining the pedigree of the IFM, validation, is currently underway. This consists of comparing the simulation results against actual plant operating data. The results of one such comparison are presented in Fig. 2, where a 130-day operating history of one of the evaporator systems is shown. The darkened points are the actual plant data, while the open points are the results calculated by the IFM. The lower curve shows the tank volume changes in the evaporator feed tank which is coupled to this particular evaporator, while the upper curve shows the tank volume changes in the concentrate receipt tank to which that evaporator delivers material.

The feed tank volume decreases as supernate is fed to the evaporator, and increases

as supernate is recycled from the concentrate tank or fed in from other tanks. The concentrate receipt tank volume increases as it receives output from the evaporator, and decreases as it feeds recycle to the evaporator feed tank. In addition, within the concentrate tank, mass transfer occurs between the supernate and saltcake regions as the salt precipitates out upon cooling of the concentrate. The saltcake volume effects the times at which recycle occurs since as the cake builds up, less supernate volume is available for recycle. Thus precipitation effects are implicitly shown in the total volume results in Figure 2 via the transfer times. Clearly, the agreement between the plant data and the simulation model is very good. The main discrepancies are in the slopes of some sections of the lower curves which indicates that in some modes of operation, the idealized volume transfer rate in the IFM does not precisely duplicate the actual transfer rate in the plant.

Similar validation is planned for all the other parts of the IFM where plant data is available. Where the model is to simulate those parts of the HLW complex which are not yet operational, the comparisons will of necessity have to be against the best available design data, against other independent computer models, or against the cognizant expert's engineering knowledge.

Data Visualization

For a model of the IFM's complexity, one concern is how to best comprehend the results of a simulation. Through SPEEDUP's plot capability, any of the 10000 variables in the simulation result may be plotted (as in Figure 2). This is effective if the analyst knows what is important and what to expect. However, in order to obtain a more global understanding of a simulation's results, we are also developing graphical user interfaces (GUI) which will present the output in a dynamic "movie cartoon" fashion, in essence a dynamic representation similar to the form of Figure 1 in which individual streams will take on a color keyed to the current flow rate, in which tank levels will visibly rise and fall, in which "gauges" will display parameter values, etc. We have prototyped one such GUI designed on site and interfaced to the standard SPEEDUP output, and are currently evaluating a commercial package (SL-GMS) which promises even greater flexibility. In addition, the input preparation phase requires a large amount of operations-type information to fully specify multi-year scenarios. To ease this burden, we have developed a simplified, text-based input language to the specifications of the customers for the IFM. This allows the user to focus only on preparing the input in a familiar environment and leaves the preparation of the actual recipe files discussed in the Batch Process Control section to the software.

Our intent is to provide the user full convenience in accessing and understanding the results provided by the long time-scale, comprehensive, high level waste complex modeling capabilities provided in the Integrated Flowsheet Model.

CHANGES IN CHEMICAL COMPOSITION OF TETRAPHENYLBORON SLURRY DURING PRETREATMENT FOR VITRIFICATION

Lee A. Clamp

Daro M. Ferrara
Westinghouse Savannah River Company

ABSTRACT

This paper presents results from a study of changes in the composition of a high-level waste (HLW) stream at two stages of its treatment. The waste stream that was studied was a tetraphenylborate precipitate slurry of a HLW supernate from a storage tank at the Savannah River Site. Changes to the slurry composition were studied prior to treatment (a hydrolysis process) and then again after hydrolysis of the slurry. In addition, the success of the hydrolysis is briefly discussed.

This study showed that prior to hydrolysis, the solubility of cesium-137 and potassium increased significantly under the influence of the beta and gamma radiation from cesium-137 decay. This was due to radiolytic decomposition of the tetraphenylborate precipitate. The concentration of soluble boron was also expected to increase. Although the boron concentration did seem to increase, the change could not be considered statistically significant.

Composition of the hydrolysis product also changed. Concentrations of soluble mercury, calcium, and magnesium all increased by more than 2X in a six month period following the hydrolysis. Concentrations of soluble copper, boron and zinc decreased by more than 2X. The concentrations of the most soluble species in the sample, sodium and potassium, did not change significantly.

Comparisons of results from four hydrolysis demonstrations with radioactive precipitate slurry indicated that the elemental composition of the hydrolysis product did not vary greatly even when the process was scaled down. The one exception was the concentration of soluble copper. This concentration was significantly lower in two of the four studies.

INTRODUCTION

The 130 million liters of radioactive waste currently stored in the Savannah River Site (SRS) Tank Farm consist of caustic sludges and supernates. After treating the wastes, radionuclides from the sludges and supernates will be immobilized into a borosilicate glass at the Defense Waste Processing Facility (DWPF). (1) Before vitrifying the radionuclides, they will be removed from the supernate by precipitating the cesium-137 as tetraphenylborate (TPB) precipitate and adsorbing less soluble radionuclides on sodium titanate. In April 1983, this precipitation process was successfully demonstrated on HLW supernate in Tank 48 at the SRS Tank Farm using the In-Tank Precipitation (ITP) process. (2)

To avoid feeding organic material to the melter, the cesium TPB precipitate will be treated using the Precipitate Hydrolysis Process (PHP) to remove the organic portion of the TPB precipitate. The Precipitate Hydrolysis Process (PHP) was developed to hydrolyze the TPB using formic acid. Hydroxylamine nitrate (HAN) was also added to mitigate production of high-boiling compounds caused by nitrite in the slurry. The late wash flowsheet was later developed when HAN was found to cause ammonium nitrate formation which created a safety concern. (3,4) As part of this development, the PHP has been demonstrated with nonradioactive TPB precipitate slurries expected from the late wash flowsheet. (5)

The SRS operates a shielded cells facility which has the capability to perform each of the DWPF-related processes on a labscale using actual radioactive waste from the SRS Tank Farm. This facility was used to demonstrate the PHP with a sample from the Tank Farm ITP demonstration. In this PHP study, the ITP slurry was successfully hydrolyzed, showing that the process could be used on actual radioactive waste from the SRS Tank Farm.

The purpose of the work described in this paper was to use the results from the initial PHP study and results from more recent studies to identify the effects of radiation on the TPB slurry and on the precipitate hydrolysis aqueous product (PHA). Because this work is ongoing, the results presented here will focus primarily on the elemental compositions of the radioactive slurry and the products from hydrolysis of this material.

At the time of the initial radioactive studies, the slurry had aged for nine years, and some of the TPB precipitate had been destroyed releasing cesium-137 to the supernate. To prepare for the PHP, the slurry was reprecipitated and washed so the

slurry fed to the PHP had the same nitrate, nitrite, sodium, hydroxide, and solid concentrations as slurries expected from late washing. (3) Two PHP tests were performed using this washed Tank 48 radioactive slurry. (6,7)
Later two more PHP tests were performed using the same Tank 48 radioactive slurry which had now aged for ten years. Once again, the slurry was reprecipitated and washed to adjust the concentrations of the soluble salts to the levels compatible with the PHP. The second set of tests were identical to the first except that they were performed in a hastelloy vessel rather than glass, and they were performed with 50 mL of Tank 48 radioactive slurry rather than 200 mL.
Most of the data included in this paper has not been published elsewhere. Some of the data used in this paper has been, but it was included with this work to compare data sets which had not been discussed together previously. This allowed additional conclusions to be made. For example, the effect of radiolysis on the solubility of some species in the Tank 48 radioactive TPB slurry was determined.

EXPERIMENTAL

Information presented in this paper is the result of several studies which have been performed over the last ten years. A summary of significant steps in the studies of Tank 48 radioactive precipitate is given in Table I. The results presented in this paper are primarily from the characterization of the precipitate and of the products of the hydrolysis.
Approximately 1.4 L of radioactive precipitate slurry from the ITP campaign completed in April 1983 was obtained for the demonstrations. To collect the 1.4 L sample, nineteen 100 mL bottles were individually lowered to the bottom of Tank 48, which contained approximately 20,000 gallons of radioactive precipitate slurry. After each bottle was filled, it was pulled out of the slurry and capped remotely. The bottles were delivered to SRTC in two batches, one on September 24, 1990 and the other on November 3, 1990. On November 14, the samples were combined to form the 1.4 L sample. (8)
By the time the first PHP tests were started (in April 1992) the precipitate slurry had received a dose of approximately 1.4 x 108 rad from the cesium-137. The slurry contained approximately 4 Ci of cesium-137/gallon of slurry.
Because the slurry was nine years old, much of the cesium and potassium had been released to the supernate. Prior to washing the precipitate, it was essential that the cesium-137 in the supernate be reprecipitated to avoid losing it in the washing process. Sodium tetraphenylborate was added to the precipitate slurry to reprecipitate the cesium and potassium prior to the hydrolysis tests. To determine the amount of sodium tetraphenylborate to add, a sample of the slurry was filtered and analyzed for potassium and cesium by atomic absorption spectroscopy, and for ammonium by ion chromatography. The resulting mixture was stirred and allowed to settle.
Initially, the sodium concentration in the slurry was 3.8 M, and the nitrite concentration was 0.38 M. These high concentrations were the result of sodium hydroxide and sodium nitrite additions to the waste in Tank 48 at the Tank Farm to inhibit corrosion of the tank. In an attempt to reduce the concentrations of sodium and nitrite to levels acceptable for glass production and for hydrolysis, the precipitate slurry was washed with 0.015 M sodium hydroxide. The late wash flowsheet requirement for nitrite is that the concentration be below 0.01 M. To reach this concentration, the slurry was washed several times. After washing the slurry, the sodium and nitrite concentrations dropped to 0.12 and 0.011 M respectively.
Prior to performing the hydrolysis, the amount of formic acid to be added was calculated. This calculation was made based on an algorithm for determining the amount of acid necessary to hydrolyze the TPB, neutralize the caustic and any buffers in the solution and to produce a solution of 0.25 acid equivalents/liter in the hydrolysis product. This algorithm has been presented elsewhere. (9)
The first two PHP tests were made with a 2 L glass reaction vessel which was heated with a hot plate/stirrer. Mounted on top of the reaction vessel was a decanter, and on top of the decanter was a condenser. During the test, water at 15oC was circulated through the condenser. Water that evaporated from the solution was condensed in the condenser and trapped in the decanter. Organic compounds that evaporated during the PHP were trapped in the decanter and collected in the organic arm. In addition to the port for the condenser, the top of the reaction vessel had three additional ports where a pH electrode, a thermocouple, and an addition tube were located. The purge gas, argon, was introduced through the same port as the

thermocouple and flushed from the reaction vessel through the decanter.
The other two PHP tests discussed in this paper were performed using a much smaller (approximately 200 mL) hastelloy apparatus. Hastelloy was used to allow us to study interactions of the slurries with the vessel material. The only difference other than the size and the material of construction between these two sets of studies was that the hastelloy vessel had a hastelloy "cold finger" which allowed cooling of the vessel upon completion of the PHP.
The procedure followed was identical to that used in larger scale studies with nonradioactive precipitate slurries. (10) The procedure has been discussed in a previous report. (6) The procedure called for the formic acid and copper formate (copper nitrate in the last two studies) to be added to the reaction vessel. The mixture was then heated to 90oC, and the precipitate slurry was added. The reaction vessel temperature was then kept at 88 to 92oC for five hours. After this five hours, the reaction mixture was boiled for five hours. Finally, the apparatus was cooled to room temperature, the purge gas was stopped, and the gas chromatograph was turned off.
For the hydrolysis to be a success, essentially all of the boron-phenyl bonds must be cleaved and the resulting benzene distilled from the solution. Using the conditions described in the previous paragraph, three of the four boron-phenyl bonds could be cleaved. To cleave the final boron-phenyl bond, a catalyst must be used. The copper catalyst was added as a hydrate of copper formate in the original two tests and as copper nitrate in the last two. Sufficient catalyst was added to produce a PHA with 950 ppm copper.
After the tests, samples were taken from the shielded cells, and analyzed by such methods as atomic absorption (AA), inductively coupled plasma-atomic emission spectroscopy (ICP-AES), and inductively coupled plasma-mass spectroscopy (ICP-MS). Analysis of the organic species is in progress for the last two tests. Therefore, this data will not be discussed in this paper.
Because the material used in these studies is very radioactive, the work could not be carried out in a laboratory or even a glovebox. Except for some of the analytical operations, this work was performed remotely using a shielded cells facility.

RESULTS AND DISCUSSION

The compositions of the radioactive TPB slurry and hydrolysis products changed with time. For the TPB slurry, the primary changes were from the radiolytic decomposition of the precipitate. The mechanism for the changes to the hydrolysis product is not as clear, however some of these changes have been reported for nonradioactive product.

Compositions of Tetraphenylborate Slurries

The tetraphenylborate slurries are primarily TPB salts, titanates, sludge solids, soluble salts, and small concentrations of products from the irradiation of the TPB. After ITP and before hydrolysis, the composition of the insoluble material changes only slightly. On the other hand, these small changes in the insoluble material significantly alter the composition of the soluble material. The effect of reprecipitation and washing on the Tank 48 slurry has been shown in previous work (6,7,11) and is outside of the scope of this paper.
After the Tank 48 slurry was reprecipitated and washed, the resulting tetraphenylborate feed was 9.0 wt % solids. Approximately 1 wt % was soluble solids, e.g. sodium hydroxide and sodium nitrite. The remainder was an insoluble mixture of TPB precipitate, sodium titanates, and sludge solids.
As the concentrations in Table II show, the most abundant elements in the insoluble material were

- aluminum and iron from sludge solids in the slurry
- potassium and boron present in the precipitate as the potassium salt of TPB
- titanium from sodium titanate used to remove strontium, uranium, and plutonium

The concentrations given in Table II also indicate that the largest contribution to irradiation of the slurry is from decay of cesium-137. For high-level-waste sludges at SRS, most of the dose comes from decay of strontium-90. Finally, sufficient uranium was present on the sodium titanate to produce 2.4 mCi/g insoluble solids.
The soluble solids in the Tank 48 slurry were made up of

- sodium salts which did not vary significantly with irradiation
- products from radiolysis of the TPB precipitates

As expected, no measurable change was observed in the concentrations of the sodium salts as a function of dose (Table III). Nitrate and nitrite concentrations can be

reduced by radiolysis, (12,13) however the doses of the slurries were not large enough to cause a significant change in these concentrations. The high aluminum concentration after 1.5x108 rad has been included but this value is under further investigation.

Potassium and cesium-137 were released to solution by radiolytic decomposition of TPB salts. The concentrations of these species were expected to increase as the slurry dose increased. Although the composition of the slurry after receiving 1.5x108 rad was not significantly different than it was after 1.4x108 rad, the concentrations of potassium and cesium (Table III) were significantly higher after 1.7x108 rad. The boron concentration was also higher after 1.7x108 rad, but this difference may not be statistically significant. Since potassium, cesium, and boron are all released to the supernate with radiolysis, soluble concentrations are expected to increase with dose. Release of cesium to the supernate is the motivation behind reprecipitating the slurry.

Solids in the Tank 48 TPB slurry were a complex mixture of species from reprocessing efforts at SRS (such as sludge solids, cesium-137, and uranium), corrosion inhibitors (such as sodium hydroxide, and sodium nitrite), material added during the In-Tank Precipitation demonstration (such as TPB, and sodium titanate), and products from radiolysis (such as soluble boron). The insoluble material was primarily sludge solids, potassium and cesium TPB, and titanates. The soluble solids were mostly soluble sodium salts and products from the irradiation of the TPB precipitate.

Compositions of Hydrolysis Products

During hydrolysis, much of the insoluble material in the TPB slurry becomes soluble. Concentrations of soluble species are significantly higher when compared to soluble solids in the original TPB slurry. These concentrations seem to change after the hydrolysis.

The insoluble solids from two of the hydrolysis tests were dissolved at high temperatures using both a nitric acid dissolution method and a sulfuric acid method. As the concentrations given in Table IV indicate, values from the nitric acid dissolutions seem to have been more precise.

Comparisons of concentrations presented in Table III and Table IV indicate that the concentrations of titanium did not change significantly during hydrolysis. Studies have shown that although the titanium may change form (perhaps to titanium dioxide), it is still not soluble in the supernate. (13)

While the insoluble titanium concentrations remained constant, insoluble copper concentrations increased because copper was added as a catalyst for the hydrolysis. Most insoluble species were increased by hydrolysis. Concentrations of cesium are not yet available but the decrease in the amount of insoluble solids, especially in potassium and boron suggests the cesium was released to the solution.

The concentrations given in Table V indicate that the hydrolysis products from the four tests were similar. Variations among the products include

- fluctuations in the manganese concentrations perhaps due to inhomogeneities
- high zinc concentrations in two tests which might also be inhomogeneities
- lower copper concentrations in the last two tests

The difference in the copper concentrations was similar to differences seen in nonradioactive hydrolysis tests. The remainder of the copper in the last two tests was present as insoluble copper as indicated by the high concentrations shown in Table IV.

The concentrations of soluble species significantly changed when the PHA from the first two tests were stored. This can be seen by comparing the concentrations at completion of hydrolysis to those six months after the hydrolysis (Table VI). The concentrations of potassium and sodium ions did not change significantly. Concentrations of mercury, calcium, magnesium, and zinc increased, while concentrations of copper, boron, and cesium decreased significantly.

CONCLUSIONS

In our studies of the Tank 48 radioactive tetraphenylborate slurry and the PHA which results from hydrolysis of this material, much has been learned about the effect of radiation on these materials, about the properties of the materials and about the success of the hydrolysis process. We have determined

Potassium and cesium became soluble as the Tank 48 slurry was irradiated by the decay radiation from cesium-137.

PHA composition changed with time. These changes may be due to a physical process, e.g. adsorption to the glass sample bottle, or to a chemical interaction.

Concentrations of the soluble sodium salts in the slurry did not change significantly as the material was irradiated.

Preliminary indications are that the TPB salts were hydrolyzed during the PHP. Success of the hydrolysis will be determined by analysis of the PHA organic species.

PHP tests using similar equipment and volumes gave very similar results, as expected.

PHP can be performed with as little as 50 mL feed in glass or hastelloy vessels without compromising the process or sample integrities.

Hydrolysis caused the solubility of all the major components in the insoluble phase to increase except titanium. Although the concentration of insoluble copper increased, the copper was added during the hydrolysis process.

Nitric acid dissolution was more compatible with our PHA solids and analytical methods than sulfuric acid.

Insoluble solids in the Tank 48 sample were TPB precipitates, titanates, and sludge solids

Currently, efforts are underway to collect more information on these materials by

Determining the Tank 48 supernate composition at higher doses.

Determining the PHA supernate composition at extended periods after hydrolysis.

Confirming the composition of insoluble material in the Tank 48 slurry using the nitric acid dissolution.

Determining the concentrations of organic species in the remaining slurry and PHP products.

Determining the composition of the insoluble solids in the first two PHA samples.

ACKNOWLEDGMENTS

The authors are extremely thankful for the advice and guidance given by N. E. Bibler and B. C. Ha. Without their expertise and experience, this study would not have been possible.

We are also thankful for the work of the Savannah River Technology Center Shielded Cells Operations group especially Alda Enlow, Ronald Blessing, and Jeannine Mills. Their outstanding skills at performing the necessary tasks remotely and the insight they used to design the reaction vessels were essential to the completion of this study.

This paper was prepared in conjunction with work done under Contract No. DE-AC09-89SR18035 with the U. S. Department of Energy.

THE CIRCULATING AIR BARRIER: INNOVATIVE CONFINEMENT OF LIQUID CONTAMINANT PLUMES

William Overbey
BDM Federal, Inc.

ABSTRACT

The environmental cleanup task facing the United States Department of Energy (DOE) presents enormous technical, planning and institutional challenges, including the need to develop new technologies that are faster, better, safer, and cheaper, in order to expedite site cleanup. Through its support services contract with the Morgantown Energy Technology Center (METC), K&M Engineering and Consulting Corporation, supported by BDM Federal, Inc., has developed an innovative subsurface barrier concept, the Circulating Air Barrier (CAB), for potential application at the DOE's Hanford Site. Characterization of contaminated sediments resulting from past tank leaks, continued safe operations of the tanks, total confinement of leaking materials, secondary waste minimization, and final closure of the single shell tanks are five of the many facets of the storage tank issue at Hanford and elsewhere in the nation. Each of these issues are considered in the development of the CAB system.

Hanford contains 149 single shell underground storage tanks that have exceeded their original design lifetimes of 30 years, some by more than 20 years. The single shell tanks range in capacity from 55,000 to 1,000,000 gallons. The total estimated liquid volume is 6.8 million gallons, with a maximum drainable volume of 413,000 gallons in a single tank. As of April, 1994, 67 of the tanks have been identified as assumed leakers. K&M was tasked to evaluate current options for establishing a subsurface confinement barrier to prevent the migration of contaminant plumes toward the groundwater.

The Circulating Air Barrier System is a desiccant-type barrier designed to prevent the movement of liquid contaminants toward the groundwater by using an air circulation and processing system to lower the water saturation in a targeted subsurface zone below the saturation level required for liquid flow through that zone. The barrier can be installed using either vertical or horizontal wells, establishing a pattern of air injection and production so that the injected air moves from the injection wells through the target barrier zone to the production wells. The circulating air vaporizes water in the zone and carries the Water vapor and other volatile or entrained contaminants to the production wells. The production stream is then processed in a surface facility to remove the water, contaminants and particulates. In time, the circulating air reduces the water saturation in the target zone, and continues to remove, by evaporation, liquids that move into the zone. In the event of a tank leak, the system serves as a tool for early detection and provides a means to withdraw volatile contaminants to the surface for treatment.

The CAB system offers several important advantages, including the fact that it is a non-physical confinement technology; it has an active monitoring and leak detection capability; it is based on proven, commercially available oil and gas technologies and equipment; it has excellent potential for emergency response and rapid deployment capability; and offers high potential for integration with other remediation technologies. Demonstration- and full-scale CAB systems have been designed for the Hanford Site. This includes chemical and geologic characterization; model development, sensitivity analysis and performance optimization; subsurface configuration and surface processing equipment design; and development of a test program with associated cost estimates.

INTRODUCTION AND BACKGROUND

The Hanford Site, located near Richland, Washington was used by the former Atomic Energy Commission, later succeeded by the Department of Energy, to manufacture materials for use in nuclear weapons systems. Hanford contains 149 single shell underground storage tanks; as of April, 1994, 67 of the tanks have been identified

as
assumed leakers. The single shell tanks range in capacity from 55,000 to 1,000,000 gallons, with a maximum drainable volume of 413,000 gallons in a single tank. C-Tank farm was one of the first tank farms, constructed in 1943, and at the time of construction, functional design life for the tanks was 30 years. All of the single shell tanks are now well beyond the original design life and DOE has established a program to address this problem as quickly and safely as possible.

K&M Engineering and Consulting Corporation (K&M) supported by BDM Federal, Inc. (BDM), completed a study in June, 1993, for DOE's Morgantown Energy Technology Center (METC). In the study, the K&M/BDM team evaluated alternative drilling technologies and subsurface confinement barriers for application at the Hanford Site, specifically targeting the C tank farm in the 200 East area. The drilling assessment focused on the ability to drill in unconsolidated soils, provide good horizontal and vertical position control, facilitate subsurface characterization and monitoring, and permit installation of subsurface barriers beneath waste storage tanks. The study explored the possibility of cross-deployment of commercially available technologies found in the oil and gas industries to accomplish these objectives.

Another facet of the study included investigation and concept development of barrier systems which could be installed beneath and around the tank farms with a minimum of excavation. The barrier concepts included existing, commercially available technologies which were suitable for the variety of soil conditions found beneath the Hanford tank farms. The evaluation of the drilling and barrier technologies culminated in the development of seven integrated subsurface barrier systems and associated implementation plans.

Following the completion of that study, K&M was assigned a task to further evaluate two of the most promising barrier systems identified, including the Circulating Air Barrier (CAB). In this more recent study, K&M was supported by BDM Federal, Inc. and Arctech, Inc. The CAB system is designed to function as a confinement barrier to prevent contamination of the water table located approximately 200 feet below the base of the C-Tank-Farm underground storage tanks. This task addressed the need to design a CAB system for cold testing in uncontaminated soils at Hanford in order to gain regulatory acceptance from the U.S. Environmental Protection Agency and the Washington State Department of Ecology. Objectives of the task included design development and optimization, modeling, selection of drilling and surface processing equipment, and development of test procedures and cost estimates for conducting a cold test demonstration of the CAB process. The demonstration configuration is designed to be scaled to a prototype CAB system designed specifically for the C Tank Farm at the Hanford Site. The design methodology is also applicable to design of the CAB system for application at other sites within the DOE Weapons Complex.

The Circulating Air Barrier System is a desiccant-type barrier designed to prevent the migration of liquid contaminants toward the ground water by using an air circulation and processing system to lower the saturation in a targeted subsurface zone below the saturation level required for liquid flow through that zone. The barrier can be installed using either vertical or horizontal wells (Fig. 1), establishing a pattern of air movement from the injection wells through the targeted barrier zone to the production wells. The dry injected air circulates through the targeted zone vaporizing in-situ water and other volatile or entrained contaminants to the production wells. The production stream is then processed in a surface facility to remove the water, contaminants and particulates. In time, the circulating air reduces the water saturation level in the target zone, and continues to remove, by evaporation, liquids that move into the zone. In the event of a tank leak, the system serves as an early detection tool and provides a method to withdraw volatile contaminants for surface treatment.

The CAB system offers several important advantages, including the fact that it is a non-physical confinement technology; it has an active monitoring and leak detection capability; it is based on proven, commercially available oil and gas technologies and equipment; it has excellent potential for emergency response and rapid deployment; and offers high potential for integration with other remediation technologies. Demonstration- and full-scale CAB systems have been designed for the Hanford Site.

PROJECT DESCRIPTION

The technical approach to designing both the prototype and cold demonstration CAB

systems includes the following elements:
- selection and use of a simulator to predict and optimize performance of the CAB;
- detailed geologic characterization of the sites;
- detailed chemical characterization of the potential contaminants which may leak from the single shell tanks and enter the CAB zone;
- selection of a drilling system for installation of the CAB wells;
- finalizing subsurface configuration and design of the surface processing equipment;
- development of test program and schedule;
- investigation of applicable environmental, safety and health issues; and
- estimation of costs for program/application.

An overview of each of these elements, as applied to design of the CAB system for deployment at the DOE's Hanford Site, is provided below.

The CAB design methodology included detailed analysis of candidate system configurations (well patterns, orientation and dimensions) and issues of scale between the prototype and small-scale designs. The full scale prototype CAB for a single-tank application utilizes three horizontal wells (1 injection, 2 production) to create the CAB zone 100' x 100' x 60', with the top of the 60' thick CAB zone located 60 feet below the surface. The CAB prototype is designed to confine the maximum drainable liquid in any C tank farm tank (48,000 gal) if it leaked instantaneously.

The demonstration design is for a quarter-scale CAB system and utilizes four vertical wells (2 injection, 2 production) to create the 25' x 25' x 15' CAB zone; the top of 15' thick CAB zone is located 15 feet below the surface. The five-spot configuration upon which the design is based was evaluated using classical potential flow theory in addition to the detailed numerical modeling. Extensive analysis was also conducted on a full scale CAB for a single-tank application utilizing four vertical wells (2 injection, 2 production) to create the CAB zone 100' x 100' x 60', with the top of the 60' thick CAB zone located 60 feet below the surface. Each of these configurations are shown in Fig. 2.

The prototype is designed to utilize horizontal wells to establish and maintain the CAB zone. Horizontal wells are preferred for this particular application for the following reasons:
- obstructions between and beneath the tanks such as transfer lines, which will interfere with vertical well drilling;
- improved likelihood of regulatory acceptance, as the horizontal wells can be drilled from outside the tank farm and contact with contaminated soils will be minimized;
- higher efficiency/effectiveness when using horizontal wells; and
- horizontal wells may improve air flow paths if regions of extremely low and/or complex permeabilities, such as dikes, are encountered.

BVAP MODEL SELECTION

After establishing the objectives for barrier design, a validated, commercially available black oil reservoir simulator, BOAST3-PC, was selected, modified, and used to simulate the CAB process. BOAST3 is a finite-difference, implicit pressure / explicit saturation (IMPES) numerical simulator designed for use on a personal computer. It includes options for both direct and iterative techniques for use in the solution of systems of algebraic equations. The program simulates isothermal, multiple-phase fluid flow in three dimensions. It assumes that modeled fluids can be described by a maximum of three fluid phases (oil (in this case, the "leak" phase), gas, and water) with physical properties that depend on pressure only. The program can simulate movement and/or production of fluids by fluid expansion, displacement, gravity drainage, and capillary imbibition mechanisms. Some problems which have been accurately simulated by BOAST3 include primary oil and water depletion studies, pressure maintenance by water and/or gas injection, and evaluation of secondary oil recovery operations.

The design of the CAB required an understanding of air-flow patterns in the sediment layers at the leak site, the estimation of the volume of air required to dry the sediment and the maximum air volume that could be injected without disturbing the storage tanks such as those in the single shell Tank Farms at Hanford. In order to model the specific problems encountered in the non-oily, highly-porous, highly permeable, very dry environment at Hanford, BOAST3 was modified to account for the phase changes that will be encountered at the Reservation problem

sites. The result was a new simulator program, BVAP, with the capability to quantitatively track the vaporization, transport and removal of subsurface moisture through the proper use and control of injection and production wells. The simulator was used to predict CAB performance for each of the three modes of operation:

initial drying: the CAB system operates at up to full capacity to create the CAB zone of reduced water saturation;

leak response: the CAB system operates at up to full capacity in order to contain and produce a leak; and

monitoring and barrier maintenance: the CAB system operates at reduced capacity to provide continuous or intermittent monitoring and maintain the target level of water saturation in the zone.

The key simulator output is the length of time and volumetric air flow rate required to dry and maintain the CAB zone, and the air flow rates and pressures required to confine any simulated leak. These volumetric air flow rates become the critical parameters for design of the subsurface configuration and injection and production stream processing facilities.

GEOLOGIC CHARACTERIZATION

A detailed analysis was then performed of aspects of the depositional history, stratigraphy, and sediment properties which may affect CAB operation at the Hanford Site, using geophysical well logs; tank farm maps and drawings; and RCRA and ERA-VOC well data. For prediction of CAB performance at Hanford, the complex geology had to be characterized and converted to 22-layer BVAP grid format. In the C tank farm, studies of four RCRA wells drilled since 1989 indicate 10 easily-grouped soil units of relatively constant grain size and appearance. These beds are grouped into three stratigraphic units; the upper, middle, and lower Hanford Formation, based on correlation with wells drilled for the ERA-VOC project in the 200 West area, which were cored and extensively sampled and studied. The range of variability of the geologic characteristics are summarized below:

materials range from fine sand and clay to gravel;

thickness of the various subsurface layers ranges from 2 to 85 feet;

porosity ranges from 20 to 55%

vertical and horizontal permeabilities range from 24 to 9785 millidarcies; and

initial water saturation ranges from 6. to 10% of pore volume.

Potential geologic complications were identified, including regions of extremes in permeability such as systems of sedimentary dikes. Effective CAB design, most importantly well orientation (horizontal v. vertical)/placement and pressure differentials, will ensure improved performance in these types of soils.

SENSITIVITY ANALYSIS AND PERFORMANCE OPTIMIZATION

This geologic characterization data was used to predict CAB performance using the BVAP model. A preliminary sensitivity study was performed using a 25' x 10' x 20' simulated CAB cross-section; these results were then used to target specific areas of focus for the detailed, three-dimensional sensitivity analysis.

A detailed sensitivity study was then performed to evaluate the effect on CAB operation of site-and process-specific parameters, based on a five-spot vertical well pattern for a single-tank application. Evaluated parameters included, but were not limited to:

volumetric air flow rate horizontal and vertical permeabilities leak fluid viscosity

leak volume minimum water saturation required for fluid flow soil porosity

initial water saturation high and low permeability zones completion interval

depth to CAB zone leak rate and volume well orientation

CAB thickness

The data obtained from each analysis included:

time history of water production;

maximum vertical and horizontal extent of the leak plume;

maximum injection pressure and the minimum production pressure;

number of blocks with water saturation equal to Swr (irreducible water saturation level) at the end of the drying phase;

number of blocks with water saturation equal to Swr, above Swi (initial water saturation level), and equal to Swm (minimum water saturation level required for flow) at the end of the leak phase and at the end of the analysis;

time required for leak containment (the time required for all grid block water saturation levels to be constant or decreasing); and

evaporation efficiency.

The sensitivity analysis was used to optimize practical operating ranges for volumetric flow rates, operating pressures, and water production levels:

The CAB reduced the maximum vertical penetration depth of the leak plume. The maximum vertical penetration of the leak plume was found to be directly related to soil porosity, initial liquid saturation level, minimum liquid saturation level required for flow, and the volume of soil available for leak containment. The CAB decreased the maximum vertical penetration depth of the leak plume by two methods.

The dry injected air withdrew volatile liquids and reduced the initial liquid saturation level.

The combined effects of the injection and extraction wells induced a horizontal pressure gradient within the subsurface. As a result, modeled leak fluids migrated along the pressure gradient from the injection to the extraction wells and reduced the maximum vertical penetration of the leak fluid.

Figure 3 indicates the significant effects of the addition of a CAB within a soil of porosity 0.43, horizontal permeability of 10,000 md, vertical permeability of 5,000 md, initial water saturation of 8%, and minimum water saturation required for flow of 20%. A 96,000 gallon leak occurring over 20 days remained within 130 ft. of the surface when the CAB was used. Without the use of the CAB, 57,000 gallons of the leak plume remained above the water table with the remaining 39,000 gallons of the leak contaminating the groundwater table. With the use of a CAB, the maximum amount of leak contained above the water table increased from 57,000 gallons to 150,000 gallons.

Following the sensitivity analysis, the input data files were then modified from a homogenous region approximating C Tank Farm soils to the actual permeability and porosity distributions detailed in the geologic characterization. Optimized parameters, including horizontal well configuration, were used to predict performance of both the prototype CAB system and the quarter-scale demonstration.

CHEMICAL CHARACTERIZATION AND PROCESSING DESIGN

The site chemical characterization effort details the chemical evaluation of a possible leak from the C Tank Farm storage tanks in order to design the air production stream processing equipment. Sources of characterization data for the C Tank Farm contents included waste characterization sample data for tanks 103, 104, 105, and 106, TRAC model predictions, and a PNL comparison of waste stream feed characteristics for single-shell tank waste treatment. Potential rates of removal for radon gas, radioactive and non-radioactive particulates, volatile organics, and tritiated water vapor were estimated. While the production processing system is designed to filter each of these potential contaminants, estimated quantities were minimal.

The facility design includes subsurface configuration and surface processing facility for both the full-scale prototype and the quarter scale demonstration CAB systems. The single-tank prototype system (Fig. 4), designed for C tank farm application, consists of a three-horizontal well (one injection, two production) subsurface CAB approximately 100 ft2, 60 feet thick with the top of the CAB zone 60' deep. The surface processing injection components include (two-train redundancy) a blower/aftercooler, a desiccant dryer and associated filtration. The production-side components include (dual train) an initial heat exchanger, roughing and HEPA filter units, vacuum blower/aftercoolers, desiccant dryer/filter, and activated carbon/HEPA units. Both sides are equipped with adequate, redundant instrumentation.

The quarter-scale cold test is of vertical well configuration (two injection, two production), and is 25 ft2, 15 feet thick, with the top of the CAB zone 15 feet deep. Injection-side components are (single train) a blower/aftercooler, a desiccant dryer and associated filtration. The production-side components (single train) include an initial heat exchanger, roughing and HEPA filter units, vacuum blower/afiercoolers, and a desiccant dryer/filter. The carbon filter/HEPA unit is not necessary for demonstration of the CAB concept at a clean site.

DRILLING TECHNOLOGY REVIEW

An assessment was performed in parallel with other design activities to provide an update of the analysis of alternative drilling technologies which was completed during the previous study. Of particular importance was an assessment of the various types of drilling equipment that might be used to install horizontal wells in the

difficult Hanford geologic media while providing safe working conditions for the drill rig employees. Because of the severe problems associated with effluent control for drill cuttings and air returns for air drilling operations, a review of the state-of-the-art in compaction boring equipment and operations was completed.
Other important components of the drilling systems review were:
  directional drilling systems: air rotary, sonic, coiled tubing, compaction boring, river crossing;
  directional control (measurement-while-drilling) systems: hard-wired, mudpulse-telemetry, electromagnetic; and
  modified oil field drilling equipment bits: roller cone, drag, and hammer.
The directional drilling required to support the Circulating Air Barrier system does not require pinpoint accuracy in the location of the horizontal wellbores. The sonic rig can place a vertical wellbore within a one foot diameter circle at a depth of ninety (90) feet. Heavy duty coiled tubing directional drilling units in conjunction with air motors should be able to deploy the drill bit system at the proper elevation and orientation. These systems still have not been tested with directional indexing air hammer bits which would be required to drill through boulders often encountered in the Hanford geologic media. These systems have been tested in deep petroleum and natural gas drilling operations in moderately hard drilling conditions. The study team recommended the sonic drill rig for installation of the cold test vertical wells, and additional testing for compaction boring units for installation of prototype horizontal wells.
TEST PROGRAM DEVELOPMENT AND COSTS
The proposed test program for demonstrating the CAB design concept in an uncontaminated area (Washington Public Power Supply System (WPPSS) site) includes the following objectives:
  demonstrate the CAB system concept and operability;
  validate and update the BVAP model by comparing field performance with model-predicted performance of the demonstration design;
  provide data for scale-up to hot-test and detailed cost estimates;
  demonstrate CAB system capability to comply with applicable environmental health and safety regulations; and
  demonstrate CAB system potential as a monitoring system for potential use in conjunction with other barrier and/or remediation technologies
The Cold Test as proposed consists of drilling a system of four process wells (2 injection and 2 production) and seven monitoring wells that demonstrate the air cimulating and drying process, including demonstration of the equipment required to remove all particulates and liquids that will be removed from the subsurface environment.
The demonstration as planned would verify the ability to contain any material leaked from a tank by vapor phase transport of the liquid component of that material to the surface, where it will be contained and stored in suitable containers until testing of the material can be accomplished and it can be disposed of in accordance with the proper regulations.
The test program duration is two years, including permitting; drilling and soil analysis; model modification and process design verification; detail engineering and procurement specification; procurement; subsurface equipment installation; system commissioning and check-out; cold test operation; and site restoration.
Costs were estimated for installation and operation of the demonstration CAB and capital costs for the prototype. The total cost of the demonstration test program is $3,304,000, with the largest cost components being system equipment installation ($989,000), contingency ($762,000), and cold test operation ($744,000).
Capital cost for the full-scale prototype is $13,772,000. The largest cost components are system equipment installation ($5,862,000), contingency ($3,178,000), and drilling and soil analysis ($1,474,000).
A preliminary overview of the regulatory environment for demonstration testing of the CAB system was performed. A general overview of applicable federal regulations includes DOE Order 5400.0, "General Environmental Protection Program"; the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA); the Emergency
Planning and Community Right to Know Act; the Resource Conservation and Recovery Act (RCRA); the Clean Air Act; the Clean Water Act; and the National Environmental Policy Act (NEPA). An overview of the Hanford Site-specific regulatory issues were

developed from the WHC-CM-7-5, the Hanford Site Environmental Compliance Manual, and it addresses the following as related to the CAB system:

- Environmental Compliance
- Requirements for New Facility
- Regulatory Permitting Requirements

FUTURE WORK

Activities recommended to complement the CAB demonstration at Hanford include laboratory studies of soil characteristics and CAB performance, which will also serve to validate the BVAP model predictions; a survey/characterization of other candidate sites for CAB deployment; continued testing and demonstration of horizontal drilling technologies; and a study of instrumentation and monitoring options for the CAB system in varying contaminant environments. The potential of the CAB system to function as both a monitoring tool and barrier in conjunction with other physical barriers and/or remediation operations is a great incentive for further study.

ACKNOWLEDGMENTS

A CASE STUDY: A PROCESS IMPROVEMENT TO SURVEILLANCE AND MONITORING ACTIVITIES AT HANFORD TANK FARMS

Theodore B. Smith
BDM Federal

ABSTRACT

This paper describes an improvement to the process of collecting surveillance and monitoring data from high-level waste underground storage tank instrumentation. This process improvement uses conventional operating system (DOS) pen-based computers to improve manual acquisition methods and overall data management for tank farm surveillance and monitoring.

The Department of Energy's (DOE) concerns with demonstrating tank safety, in anticipation of continually increasing regulatory requirements and increased public participation, have resulted in the need for timely, accurate, and valid physical data describing tank farm conditions. In the face of an increasingly constrained annual budget, DOE's challenge is to provide a cost-effective, versatile, safe, and efficient method for collecting, validating, storing, distributing, and analyzing this data.

BACKGROUND

The Hanford Reservation was acquired by the United States government in 1943 as the location for the nation's first full-sized plutonium production reactors. Nuclear fuel production operations began on the 560-square-mile Hanford site in 1944 as part of the United States Department of War's secret Manhattan Project. Since that time, the Hanford Site has operated nine reactors and six processing or finishing facilities.

In 1992, a DOE Secretarial Decision terminated fuel reprocessing activities associated with the nation's weapon complex, and the Hanford mission was formally changed from defense production to waste management and environmental restoration. As a result of prior processing operations, an estimated 60 million gallonsa (230,000 cubic meters) of radioactive hazardous waste from the processing facilities has been stored in 177 underground storage tanks located in 15 different farms at the 200 East and 200 West areas of the site.

The age of and conditions that exist in the waste tanks demand that adequate

surveillance and monitoring of tank and waste physical conditions be performed until final remediation is completed. Tank waste remediation is scheduled to be completed in 2018 for single shell tanks, and 2030 for double shell tanks.

EXISTING METHOD

The existing radioactive waste storage tank surveillance and monitoring system at Hanford was developed before the capability existed for a more efficient and thorough data collection process. The existing tank farm data collection method is completely manual; that is, schedule generation, task assignment, collection, verification, validation, storage and retrieval are done manually (using logbooks, paper files and typed lists) across the site.

Data management in the existing monitoring system begins with scheduling, which is developed based on supervisor data requests and procedural requirements. The operators' schedule to perform all required surveillance and monitoring activities is established manually on a weekly basis.

Data is collected by parameter (temperatures, liquid level, pressure, etc.) and written onto procedurally approved paper forms. Each parameter has an associated procedure, which defines how to collect that type of data. Tank-farm procedures are developed to ensure that all state, federal, and local requirements are met. Procedures require additional data collections one, and sometimes two, when the recorded values are outside an expected normal operating or safety range. These requirements are enforced to confirm the out-of-range condition. Managers must be notified when out-of-range conditions are confirmed. When completed, the data sheets are submitted to managers for review and verification of the collected data.

The review typically includes comparing a sample of collected data with historical records or logbooks. The manager performs a spot check of collected data for validity and then approves and signs the entire data sheet. The approved data is then routed for trending, analysis and manual file storage.

Any subsequent analysis of collected data requires data to be retrieved from paper file storage, manually entered into a computer, and routed to the analyst for use in computations.

See Fig. 1.

STATEMENT OF NEED

DOE requiresb surveillance and monitoring activities to be: timely, legible, accurate/correctable, reviewable, storable for the life of the facility and retrievable.

The need for improved manual data-acquisition methods and better overall data management of underground storage tank surveillance and monitoring has been identified by the Tank Farms Operations and the Tank Waste Remediation System Division. For example, data on paper forms must be transcribed to an electron format for analysis. This process is time-consuming and may introduce errors. The existing system includes many such inefficient and quality-affecting data management practices. Process evaluations consisting of document evaluation and personal interviews with key operations personnel and direct observation of monitoring operations show that the process problems for tank surveillance and monitoring arec,d:

  Establishing task schedules
  Security of data
  Physical data collection
  Managers' primary review
  Access to historical data
  Data transfer and storage

Attributes of a Process Improvement

A valid process improvement should be characterized by the following attributes:

  Simplified operations
- Better support with fewer people
- Simplified maintenance
- Simplified quality assurance
- Simplified process control
- Simplified materials management
- Simplified data processing
- Further process improvements easy to implement
  More involvement by participants
  Increased efficiency

Increased flexibility
Clearly defined responsibilities
Improved quality control and fault cause analysise,f,g.

PROCESS IMPROVEMENT OPTIONS

These process improvement attributes and DOE operational requirements were applied to three potential solutions to Hanford's tank farm monitoring and surveillance problems. Full automation, partial automation, and no automation are considered below.

FULL AUTOMATION: Full automation of the data collection process, including electronic instrumentation and centralized collection of all tank farm data. The system would require new instrumentation and data lines or transmitters to be installed for each data collection point.

It was determined that full automation is not cost effective or desirable. The high expense of designing, developing, installing, maintaining and upgrading a completely automated system is cost prohibited for the foreseeable future. In those few cases where continuous monitoring is required for safety reasons, a fully automated data-acquisition system can be installed without significantly affecting overall complexity and control. Worker action needed to perform monitoring and surveillance activities would be greatly simplified, but at the sacrifice of flexibility and a decrease in oversight and control of the tank waste system. For example, operators would not need to visit the tank farms, and thus not observe the physical condition of instrumentation (corrosion, damage, etc.). The oversight and control is reduced by the complex and sometimes unique equipment needed to achieve full automation, and by the elimination of direct observation by operators. Full automation violates one of the basic principles of automation; do not install equipment in locations where humans are needed to think and solve problems and can ensure sufficient process consistency. Operators are needed to observe tank farms conditions and identify possible trouble. Equipment should be considered a problem and labor an opportunity. The main advantage derived from installing automation equipment is a decrease in process variability. That is, the process is more consistently performed without making changes due to extenuating circumstances.

PARTIAL AUTOMATION: Partial system automation to improve identified problems; schedule, security, data collection, data review, access to historical data and data handling validated by comparison to industry expectations of process improvements. Partial automation was found to be the most cost-effective process improvement solution. Subsequently, a fully implementable partial automation system was developed jointly by BDM Federal and Westinghouse Hanford Company. The resulting system, named the Pen-Based Computer for Handheld Data Acquisition of Tank Farms (PC-HDAT) is briefly described in the following section.

NO AUTOMATION: Revise existing manual system without automating to ameliorate deficiencies.

Revising the existing manual system was determined to be insufficient. Adequate improvements to the existing process could not be determined; the existing process was not designed to meet the existing demands for tank farm data. It is anticipated that this solution would also result in higher overall expense in long-term operations.

SYSTEM DEFINITION

The PC-HDAT system consists of standard PC workstations, dockable pen-based computers, conventional software, the existing Hanford computer local area network, and BDM Federal-developed PC-HDAT software to automate the Hanford tank farm surveillance and monitoring process.

PROCESS COMPARISON

PC-HDAT has been signed to correct the six process problems Hanford has identified. Each section contains a description of PC-HDAT system functions. The comparison is divided into the six Hanford identified problem areas in the existing method. Each section contains a brief description of the existing problems, followed by a description of PC-HDAT system functions developed in accordance with DOE requirements and process improvement attributes (8,9).

SCHEDULING

Existing Method

Procedure based surveillance and monitoring schedules specify the frequency of data collection, and in some cases, the work shift during which work is to be performed. Surveillance and monitoring data collection done by parameter rather than by

physical location is inefficient since more operator time must be spent to reenter a tank farm, which is a radiological controlled area.
In addition, a manually established schedule results in an unbalanced work load. For example, all quarterly mandated monitoring operations occur on the first day of the quarter rather than distributing the monitoring operations across the quarter. Until 1992, all scheduling was performed manually, resulting in data collections at times being delinquent by days or weeks. During 1992, a document was developed to establish a controlled scheduling process. While the written scheduling document reduces the number of missed collections, errors still persist. The daily work load also remains highly variable and the collections are still inefficiently taken by data type.
PC-HDAT Process
The purpose of scheduling surveillance and monitoring operations is to assign qualified personnel to perform specific surveillance and monitoring operations. These operations are scheduled at designated facilities at specific times and with required monitoring frequencies. For Hanford tank farm operations, the scheduling function must ensure regulatory-driven monitoring frequencies are met.
The PC-HDAT system automatically established a daily work list by comparing a detailed list of required monitoring frequencies and collection preferences with the last data collection date for each data point. The task list is sorted by tank farm, tank, location, and instrument to minimize operator exposure time in a radiation area. A "To Do List" is generated listing each location, component and instrument to be monitored. A separate "Urgent" To Do List is generated for any scheduled maintenance that is within a specific time period (grace period) of going overdue. The lengths of grace periods are established to coincide with the monitoring frequency for a given instrument.
The schedule is automatically transferred (along with other necessary configuration) to the handheld unit installed in the docking station. PC-HDAT audits all information exchanges between handheld units and the managers' workstation. The task list is then assigned to the next shift operator that logs onto the PC-HDAT system. The manager may adjust the scheduled monitoring and surveillance in several ways. The manager may balance the schedule by changing the monitoring preference (i.e. collect farm A data on Mondays, Farm B data on Tuesdays, etc.) The manager may easily schedule expedited surveillance and monitoring for either a specific instrument or for all instrumentation in a specific tank. The manager may increase the monitoring frequency above procedural requirements. PC-HDAT will allow the monitoring frequency to be easily changed for an instrument or tank while ensuring that the frequency is not allowed to be less than procedural requirements.
The PC-HDAT scheduler clearly simplifies operations. Automated scheduling eliminates the need for an individual to develop schedule with the attendant human error. The only maintenance required for PC-HDAT scheduling is an update of the required monitoring frequencies list when these are changed. The quality of the scheduling process is improved by decreasing the variability of the schedule building process and allowing balanced work tasking. Scheduling process control is improved by the use of grace periods to warn the operator when monitoring is nearly overdue, reducing overdue data collections. In addition, separate documents to control scheduling are no longer needed. Managers have more control over the periodic monitoring schedule and urgent monitoring requests. The scheduler is more efficient and flexible than the existing manual method while providing clear task responsibilities are greater quality control. Scheduling process quality control is expedited by audit trails built during data modifications and transfers.
DATA SECURITY
Existing Method
Current data security relies on strict procedural compliance. Human interaction is necessary to ensure that only properly trained operators are assigned and allowed to collect tank data. The increasing importance of data security is driven by increased potential of defending the validity of data in a court of law. Data security is also needed to ensure that collected data is not distributed until approved by a manager to ensure all accessible data has been properly reviewed in accordance with DOE Order 5480.19.
PC-HDAT Process
PC-HDAT provides data security through encrypted computer accounts and passwords. PC-HDAT provides seven different user access levels, allowing control of system

function access. Only managers are allowed to perform certain functions, and only registered operators are allowed to collect data using PC-HDAT. To prevent ambiguous or duplicate entries, collected data is maintained in a separate, controlled data file until it is approved by a manager. Logbooks and paper files are no longer needed. All data collections list the name of the operator collecting the data and the manager that approved the data. All applicable surveillance and monitoring procedures are available for viewing within the PC-HDAT system. Operators can access all procedures applicable to surveillance and monitoring at the touch of a button. Operators are automatically notified when procedures have been revised. All data collection entries are automatically date and time-stamped at time of data entry, and automatically transferred from the handheld computer to the manager's workstation upon return to its docking station. Audit trails and conservative data transfer protocols are used to ensure data is not lost during transfers and data can be tracked from the instant of collection.

Under the manual surveillance and monitoring system, data security only established a case-by-case basis when considered necessary. Under PC-HDAT, data security is built into the system from the lowest levels up, simplifying the establishment of data credibility. Data quality is improved by tracking the data from the moment of collection. Robust software design ensures that data quality from the source is not inadvertently lost during loss of power or surges.

PHYSICAL DATA COLLECTION

Existing Method

Manual methods of data collection presents many difficulties. The problems may be classified into three categories: environmental conditions, human error, and lack of complete information.

Environmental Conditions

Operators are limited by what they can carry into radiation areas due to necessary protective clothing. Anti-contamination clothing is cumbersome and may prevent operators from easily carrying in various tools, measurement devices, procedural documentation and other needed information. The operating environment often has high winds, dust, rain, low lighting, and large variations of temperature. Paper forms are prone to being lost or rendered unusable by adverse environmental conditions.

Human Error

Data quality checks cannot be performed in the field, leading to frequent rechecks. Data entries may be illegible due to ink smears or poor handwriting. Manual transcription errors may be introduced during data collection, and data processing, while entering data from paper into an electronic format for subsequent analysis. Additionally, errors may be introduced during data transcription into managers logbooks.

Document control is uncertain during corrections and editing of data sheets. Multiple copies of data sheets may exist with differing editing and corrective marking.

Lack of Complete Information

There is not clearly defined forum for operator feedback. This may result in not communicating important operator observations, or ambiguous or indecipherable operator markings on data sheets. Range checking of data may not be completed until return from the field, resulting in one or two rechecks at a later time. Data range rechecks are inconsistent with ALARA (As Low As Reasonably Achievable) radiation exposure policy.

Operators do not have the flexibility to collect different parameter data. Operators are limited to collecting data only for the assigned data sheet. Additional data cannot be taken since collection procedures are not available. The time lag between data collection and time of data availability electronically is unnecessarily long, delaying corrective actions.

PC-HDAT Process

PC-HDAT allows the operator to carry all necessary documentation in one handheld unit. Current tank farm surveillance and monitoring procedures are available on PC-HDAT at the touch of a button. The system is flexible in that the "To Do List" may be completed in any order desired by the operator. PC-HDAT also allows the operator to collect any additional data determined necessary while in the tank farm. Paper data forms are eliminated. The handheld computer is environmentally rugged, able to operate in a wide range of temperatures, withstand extremely wet or rainy conditions and endure drops onto a hard surface without failure or data loss.

PC-HDAT automatically checks each data entry against procedural normal operating, safety, and data quality ranges. Any range violation will result in one or more automatic data recollections, with indicating messages.
Operator feedback is provided through the use of commenting functions and instrument condition indicators. Operators may provide comments specific to a data collection or instrument. The comments can be selected from an established set of comments, for clarity, or a customized, handwritten comment may be provided. The commenting function serves to provide more detailed, specific feedback about operating conditions and operator observations. Comments are reviewed by managers during data review and approval. Out-of-service instruments or equipment that is operating in a standby mode may be easily indicated as such. Since all data transfers are automatic, transcription errors are eliminated and document control is improved.
PC-HDAT simplifies the data collection process by shortening the path and reducing the amount of extra effort required to make data available to end users. Maintenance operations are simplified by use of comments, and Out-of-Service/Standby indicators. Quality assurance and data processing is improved by the elimination of data transcription and paper filing. Quality is achieved at the source by completing a variety of range checks at the time of data collection. The ruggedness nd amount of required materials is reduced, with a flexibility to eliminate more equipment and improve the process in a full implementation of the system. Maintenance departments can easily access instrument condition information, for determination of optimum maintenance requirements. Process efficiency is increased by the determination of optimum maintenance requirements. Process efficiency is increased by the elimination of unnecessary data handling steps and the elimination of cumbersome data transcription and use of automatic data transfers. Because PC-HDAT uses commercially available hardware and software, a number of improvements and changes can be readily made. Pen-based computers will continue to have the capability to implement existing and emerging technologies, such as Global Positioning Satellite (GPS), digital video systems, and bar-code readers.
PRIMARY REVIEW
Existing Method
A primary review is conducted by the manager to verify data collection results, in an effort to overcome errors introduced during collection. Corrective actions may require recollection of data, resulting in additional time spent in a radiological controlled area (RCA) in violation of ALARA practices.
The primary review also involves cross correlation of a sample of data sheet entries to a number of initial quality-check documents that include: procedural range sheets, historical records, and logbooks. Data sheets are signed by the manager verifying that it was checked. The current manual data review process does not provide a 100 percent check of procedural requirements.
PC-HDAT Process
PC-HDAT performs a 100 percent check of collected data, indicating any data which is outside procedurally allowed normal operating, safety or quality check ranges. The manager is prompted to individually approve each out-of-range data collection. The manager may choose to approve compliant data by page or individually. At the touch of a button, the manager may access all operator comments and historical data (in tabular or graphical form, as desired). If desired, the manager may initiate an additional data collection during this review. The time required to conduct primary reviews is reduced increasing process efficiency by reducing the amount of manager time required to review data. Moreover, primary reviews are simplified, allowing the manager to perform a more thorough review.
HISTORICAL DATA ACCESS
Existing Method
Historical data is only available at the shift operations office, or in file storage. Thus, operators have no access to historical data in the field. Managers must rely upon independent logbooks of historical data to conduct data sheet reviews. The use of logbook data introduces another possible source of error, and data will only be as complete as managers' efforts provide.
PC-HDAT Process
PC-HDAT provides archival access to historical data to all registered PC-HDAT users at the touch of a button, tubular and graphical. A variety of standard and customized reports are available for hard copy or electronic reporting. Recurring reports can be established to automatically build and transfer customized data

reports on specified frequency.
DATA TRANSFER AND STORAGE
Existing Method
The existing data transfer system relies on filing offices and a conventional mail system to ensure data is properly stored and routed. In such a manual transfer system, the time delay for transfer reduces the time available if an urgent response is necessary Additionally, there is a higher likelihood of data error or loss than is achievable in the existing Hanford electronic mail system. Manual filing and routing systems do not provide quick or as reliable access to stored data, and paper records are more subject to misfiling, loss, damage, wear, and destruction than a well-organized and secure data information network.
PC-HDAT Process
Once data has been accepted into the handheld computer, no additional data transfer action is necessary to ensure that approved data is available to all registered data users on the HLAN system. All data transfers are automatic upon completion of the required prerequisites (i.e data is not sent to HLAN until after manager review and approval), thus eliminating unnecessary delays. All data is electronically stored and archived as part of the HLAN system.
PC-HDAT simplifies the data collection process by shortening the path and reducing the amount of extra effort required to make data available to end users. Manually filing systems are eliminated, reducing the number of people required for support while improving support capability. Maintenance is simplified since computer archiving of data is performed in accordance with existing archival systems. Storage facility requirements are greatly reduced since the data can be archived in an electronically compatible format, such as tape or CD-ROM.
CONCLUSIONS
Changes to working, albeit inefficient, operations in the nuclear field must be made with careful consideration and great discretion due to the inherent risk and potential consequences of failures. However, the PC-HDAT system resolves all Hanford identified problems in the waste tank-farm surveillance and monitoring operations, while at the same time providing a simpler, more controlled process that is more efficient to operate, results in lower exposure, easy to implement, and flexible to meet the current and future needs of the DOE.

QUENCHING OF HYDROGEN-AIR FLAMES BY CRUSHED SALT AS BACKFILL MATERIAL
Eike Barnert
Forschungszentrum Jlich GmbH (KFA)
Horst Kausen
Ralf Rben
Fachhochschule Aachen
ABSTRACT
The emplacement of radioactive wastes in salt leads to the formation of hydrogen due to radiolysis and/or corrosion. A reaction of the hydrogen with atmospheric oxygen (explosion) must be prevented in the repository. One possibility is to backfill the void space left in the drifts and boreholes with crushed salt during package emplacement. Crushed salt acts as a flame barrier.
Test series serve to determine the quenching effect of crushed salt in a hydrogen-air atmosphere. Depending on parameters such as temperature, fine particle fraction of crushed salt and ignition direction, a safe height for crushed salt beds preventing flame propagation is determined.
INTRODUCTION
The current concept for the planned Gorleben repository provides for an emplacement of high-level radioactive waste (HLW) and intermediate-level waste of the upper activity category (ILW-(Q)) according to either the drift or the borehole technique. In the case of the borehole technique, waste packages are lowered into 300 m deep, vertical boreholes drilled into the floor of drifts situated at 800 m depth. The annular space left between packages and borehole wall is backfilled with crushed salt which simultaneously covers the packages.
Crushed salt is the debris produced when driving drifts and drilling the boreholes. It is used as backfill material and, in the event of an assumed local ignition, should also prevent the formation of a propagating flame front caused by the reaction of radiolytic hydrogen released from the packages or hydrogen produced by

corrosion.
The use of crushed salt as a flame barrier in the emplacement of radioactive waste packages in boreholes in salt is described in (1).
The project "ILW-(Q) and HTGR Fuel Element Test Programme" financed by the Bundesamt fr Strahlenschutz (BfS - Federal Office for Radiation Protection) has been dealt with at the Research Centre Jlich (KFA) since mid-1993. A subtask of this programme comprises studies on the quenching effect of crushed salt.

THE QUENCHING EFFECT OF CRUSHED SALT

A bed of granular material can impede or completely prevent the formation and propagation of a flame front (explosion) in ignitable gas mixtures under certain conditions. This effect is known as quenching.
According to present knowledge, the quenching effect is based on two different processes. Chemical heterogeneous surface reactions in the flame front lead to the degradation of free radicals acting in the gas phase reaction (O atoms, H atoms, OH molecules). The uptake of thermal energy by the grain surfaces of the bed causes a near-wall temperature decrease in the reacting gas mixture, which reduces the reaction rate (2,3).
According to Deckardt et al. (2), the chemical effects are predominant in hydrocarbon flame quenching, whereas the quenching effect in hydrogen-air mixtures is primarily based on thermal losses in the flame front. The boundary condition for flame quenching can be described by the Pclet number Pe.

$$Pe = \frac{\text{heat flow dissipated on the wall}}{\text{enthalpy flow of combustion}}$$

Under certain simplifying conditions (4)

$$Pecrit = K \cdot dcrit$$

where K contains physical parameters of the gas mixture and d is the gap width or channel diameter of a flame barrier.
Since the critical Pe numbers do not differ very much for different gas mixtures, d becomes the determinant for flame quenching. In the literature, d/2 is referred to as the quenching distance. The quenching distance depends above all on the combustible gas under consideration, the mixing ratio e.g. with air, gas density and temperature. It is generally specified as a function of the combustible gas fraction in the mixture and reaches a critical minimum value at a certain mixing ratio. The minimum quenching distance is e.g. d/2 = 0.6 mm for hydrogen-air mixtures. It is reached with a hydrogen fraction of about 30 vol.% (2).
A condition for the use of crushed salt as a flame barrier is therefore that the channels left by the grains in the bed do not exceed a certain size, the double quenching distance. This can only be achieved, however, if the bed contains fractions of fine and ultrafine grains.
In order to describe the quenching effect of crushed salt in a hydrogen-air atmosphere, a safe bed height, hs, is defined (2,3,5). The bed height hS is precisely that level which prevents the ignition taking place in an ignition volume from flashing over into a reaction volume, i.e. into an adjacent space, both volumes being filled with the same hydrogen-air mixture and only separated by the crushed salt bed.
The test facility described below was set up to determine the safe bed height of crushed salt.

TEST FACILITY

The test facility is shown in Fig. 1.
Fig. 1. Schematic representation of the test facility
The main components of the test facility are the three tube segments, ignition section 1, bed section 2 and reaction section 3, which are flanged onto each other in such a way that the bed section is located between the ignition and reaction sections. The three sections can be heated by heaters HZ 1 to HZ 3.
The bottom end of the reaction section is connected to vacuum tank 5 by a sealing foil mount 4 (with sealing foil). The sealing foil is destroyed when a defined explosion pressure in the reaction section is exceeded. The gas present in the sections expands into the vacuum tank.
Sections 1 to 3 and vacuum tank 5 can be separately evacuated by vacuum pump 6. The three sections can be filled with defined hydrogen mixtures. Proportioning is effected via the partial pressure display at pressure gauge 7. Homogenization is achieved by recirculating the mixture with pump 8.
Ignition unit 9 ignites the gas mixture in the ignition section.

The test facility described above and shown in Fig. 1 permits the determination of the safe bed height of crushed salt for ignition from above the bed, i.e. in the direction of gravity. The facility can be modified for ignition from below the bed. The experimental procedure is basically the same (see next chapter).

TEST PARAMETERS AND EXPERIMENTAL PROCEDURE

The safe bed height, hs, of crushed salt in H2-air atmosphere is determined as a function of temperature, TG, and fine grain fraction, XF, of the crushed salt.

hs = hs (TG = 25C 150C) and
hs = hs (XF = 0 wt% 90 wt%)

The following was defined on the basis of earlier studies (2,3):

concentration of H2 in air K [vol.%] = 30
grain size distribution of crushed salt D [wt%] = 0 32 mm with about 60 wt%
0 2 mm
ignition volume V [dm3] = 2.5
wall roughness of the ignition section R [m] = "steel wall"
ignition direction Z [-] = from above, from below the bed
moisture of crushed salt Xw [wt%] 0.06

The crushed salt has a grain size of 0 32 mm with about 60 wt% fine grain fraction of 0 2 mm. It consists of approx. 96 wt% NaCl, 3 wt% anhydride, and 1 wt% clays and others. The test material is produced by sieving the fine particle fraction out of the unfractionated crushed salt and adding defined quantities (0 wt% 90wt%) of these particles again to the remaining material.

In order to determine the safe bed height, hs, crushed salt is filled into the bed section up to the level h1, and the section is flanged in between the ignition and reaction sections. A sealing foil is placed into the sealing foil mount so that the volumes of the sections and that of the vacuum tank are separated from each other. The vacuum tank and the sections are evacuated.

The H2-air mixture is prepared by flooding the facility with a defined amount of hydrogen (partial pressure measurement) and subsequent replenishing with air. The mixture is then homogenized by recirculation. This completes the preparations for the actual experiment.

The H2-air mixture is now ignited in the ignition section by means of piezoelectric ignition.

The pressure displayed after combustion (pressure gauge 7) and also the noise during the reaction (explosion in the reaction section, bursting of the sealing foil) reveal whether or not flame propagation through the crushed salt bed has occurred. In the event of a flame propagation, the crushed salt bed was not sufficiently high. The experiment is repeated with a greater bed height h2.

The safe bed height, hs, was defined as that level at which, for the first time, 15 consecutive experiments did not lead to flame propagation. Figure 2 illustrates a test series for the determination of hs.

Fig. 2. Test series for the determination of safe bed height hs.

EXPERIMENTAL RESULTS

Figure 3 shows the results of the experiments determining the influence of temperature on the quenching effect of crushed salt beds in H2-air atmosphere. The fine particle fraction of the crushed salt used is 60 wt%. As can be seen, slightly deviating safe bed heights are obtained for different temperatures, but an influence of temperature on hs cannot be observed in the range 25C TG 150C. The resultant differences for hs can be regarded as general experimental tolerances. It is therefore advisable for a determination of hs from this test series, as shown in Fig. 3, to proceed from the respective highest level determined, so that a safe bed height of hs = 85 mm is obtained for ignition from above and of hs = 375 mm for ignition from below.

Fig. 3. Safe bed height hs as a function of temperature TG

The differences resulting from the ignition direction can be explained as follows. Due to the explosion pressure produced during hydrogen combustion in the ignition section, the crushed salt layer is compacted by ignition from above. Any open channels present in the bed are reduced in size or clogged so that the flame front propagating into the bed is extinguished within a relatively short distance. On the other hand, the bed is loosened in the case of ignition from below. The pore volume is enlarged and the quenching effect decreases correspondingly.

The dependence of the quenching effect of crushed salt on the fine particle fraction

is shown in Fig. 4. The quantity of 0 2 mm grains contained in the crushed salt is defined as the fine particle fraction. Its grain distribution corresponds to that of the unfractionated crushed salt produced when driving the emplacement drifts and drilling the boreholes in a salt dome. The test temperature is TG = 25C.
As already mentioned above and described in the literature (2,3), the barrier effect of a granular bed against flame propagation is the greater, the smaller the grain size of the bed material. With respect to the crushed salt investigated here this means that hs should become smaller with increasing fine particle fraction. Figure 4 precisely shows this trend.
Due to the finite length (1150 mm) of the bed section of the test facility, no safe bed height can be specified for crushed salt beds without any fine particle fraction. However, the results of tests with 10 wt% fine particle fraction suggest that beds without fine particles do not have any or only a very slight quenching effect. Figure 4 also shows that the influence of the ignition direction is of minor significance for fine particle fractions below 10 wt%.
Fig. 4. Safe bed height hs as a function of the fine particle fraction XF in crushed salt
With increasing fine particle fraction hs becomes smaller. The curves show a strictly monotonous decrease. The influence of the ignition direction increases. With a fine particle fraction of 90 wt%, for example, a safe bed height of hs = 40 mm is obtained for ignition from above, whereas hs is higher by a factor of almost 10, amounting to 350 mm, for ignition from below. The corresponding values for a fine particle fraction of 60 wt% are hs = 70 mm and hs = 375 mm.
CONCLUSION
Crushed salt beds can be used under certain conditions as a barrier to the propagation of flame fronts in hydrogen-air atmosphere when emplacing radioactive wastes according to the borehole technique. An important requirement is that beds contain a defined fine particle fraction of 0 to 2 mm grain size as flowable material. Unfractionated crushed salt as produced, for example, in driving repository drifts and drilling boreholes has a fine particle fraction of about 50 to 60 weight percent and thus fulfils this requirement.
The critical ignition direction is that from below the bed, i.e. against gravity, since, in this case, the bed can be loosened. Even then, however, a bed of unfractionated crushed salt less than 500 mm in height will be sufficient to prevent flame propagation.
In the range between 20C and 150C, temperature has no influence on the quenching effect of the crushed salt bed. With a view to preventing the formation of propagating flame fronts in a repository borehole, the same technique can therefore be used for the emplacement of both ILW(Q) and HLW packages in vertical boreholes. The above statements are also applicable to the emplacement of waste packages in drifts backfilled with crushed salt.

ABSTRACT
There is an increasing need to accurately characterize "alpha contaminated" waste. The aim of this work was to develop an approach using the well known MGA code for waste characterization. To establish what changes are needed in its analysis methods, we have investigated the effects of geometry, matrix, and detectors on the ability of the MGA code to determine the isotopic composition. This has resulted in a new, improved version of the MGA code that is suited for such waste analysis. As a practical limit, we have found that the new improved version of the software is able to accurately determine the isotopic composition of less than 10 mg of plutonium in 200 L waste drums. However, this limit is affected by detector size, source distribution, drum size, plutonium isotopics, etc. This paper presents some data that indicates how important each of these factors are in the accurate determination of plutonium isotopics in waste.
INTRODUCTION
There is an increasing need to accurately characterize the "alpha contaminated" waste that is being generated in fuel reprocessing facilities, nuclear fuel manufacturing plants, and weapons facilities. For regulatory and safety reasons, the presence of plutonium is of most concern, although uranium, neptunium and curium, if present, must also be accounted for. Safe long term storage of "alpha contaminated" waste depends on the predicted build-up and decay of its activity. A reasonably accurate prediction of future activity of a waste drum can only be made with knowledge of its isotopic composition. Of all of the techniques used for waste characterisation, gamma spectrometry is the most isotope specific. However, traditional gamma spectrometric methods are limited for this application due to the complexity of the plutonium spectrum, the low emission probabilities of the even plutonium isotopes and effects caused by high atomic number materials and widely varying matrix densities.
Several other non-destructive analysis techniques exist that allow detection of sub-milligram quantities of plutonium in drums as large as 200 liters. One of these techniques, passive neutron counting detects only the sum of even mass number isotopes of plutonium and curium by measuring the spontaneous fission neutrons (1). Active neutron counting techniques measure only the sum of the fissile plutonium and uranium isotopes by inducing fissions (2). When the fission product content and the matrix density of the measured sample are low, systems based on normal gamma spectrometric techniques can also be used to obtain quantitative estimates of some alpha emitting radionuclides that also produce reasonably strong and distinct gamma lines, such as 239Pu , 241Pu and 235U (3). With calorimetric methods, the plutonium mass is estimated by measuring the total heat output of the sample.
The problem with all of the techniques mentioned above is that they are each only good for certain conditions and can quantify only some of the alpha emitting isotopes. A proper characterization of the waste requires a calculation of the total elemental masses which in turn requires precise knowledge of the isotopic composition of each element that is present. This may be available either through knowledge of prior history of the material being characterised or through measurements. For waste material, determination of the isotopic composition through measurements can be very difficult.
Measurements of isotopic compositions for total elemental mass calculations are also required in safeguards measurements. For such work, both the IAEA and Euratom

inspectors routinely measure their samples for gamma radiation, and analyze the resulting spectra with the Multi-Group Analysis (MGA) software (4). The nature of samples investigated during a safeguards inspection, however, is quite different from waste samples. Waste samples typically have a larger physical size, contain less plutonium, have widely varying matrix compositions, and may contain other alpha, beta, and gamma emitting isotopes. These differences make it very difficult to apply the traditional safeguards version of the MGA software to accurate characterization of waste. Furthermore, safeguards inspections are routinely performed by well trained inspectors. The amount of waste barrels to be characterized in many industrial nuclear sites preclude that operators investigate each drum separately. Waste characterisation is mostly done in automated installations.

The aim of this work was to define the boundaries and limitations of the existing MGA code and to make it more applicable for alpha contaminated waste measurements. In addition, we wanted to investigate how sensitive the accuracy of the results was to the detection geometry, the composition of the uranium or plutonium, the matrix density differences and the amount of uranium and/or plutonium mass in the drum. To facilitate more effective test measurements and permit us to design automated waste characterization systems, the MGA input and output needed to be simplified.

The original MGA software can only establish the isotopics for plutonium. Recently Ray Gunnink, in collaboration with Canberra, has also developed a version of the MGA code for uranium (5). However, this new version of the MGA software was not available at the time the test measurements of this study were made and was not tested for its performance.

EXPERIMENTS

The first tests were done on real plutonium samples at the CEA Cadarache facility in France. However, during the analysis it appeared that the high gamma background encountered at this location influenced some of the results. Moreover, we had some doubts about the declared isotopic compositions of some of the sources. Therefore, it was decided to repeat some of the measurements with very well characterized sources in the (relatively) low background environment of the IRMM laboratories in Geel, Belgium . At IRMM, some other limits for the applicability of the MGA code were examined.

Experimental Set-Up in Cadarache

Experiments in Cadarache were carried out with the plutonium samples in rotating waste drums. For these experiments, the drum turning table of the neutron shuffler installation "Banco" (6) was used. Due to the nearby storage of calibration sources and due to neutron activation of the inside stainless steel lining (^{60}Co), the gamma background was quite high (approximately 5 cps/cm3 of germanium). The characteristics of the high purity germanium detectors that were used for the tests are listed in Table I. Low Energy Germanium (LEGe) detector GL2020 was connected to a second amplifier, ADC and MCA with a calibration of 250 eV/channel. This way the same detector could be used as a 2000mm2 LEGe as well as a 10% high energy detector. For each experiment, 4 spectra were recorded, 2 as low energy spectra and 2 as high energy spectra. Most spectra were taken with 30 min true time. Some weaker sources were measured for a longer time. At Cadarache, some 120 spectra were taken for this work. No peak shift or degradation was observed during the two weeks that these spectra were accumulated.

The plutonium sources used are listed in Table II. All sources are small volume sources, except source 5S and 8S. The former is a 220 L reference drum filled with polyethylene (density 0.206 g/cm3) and with the plutonium distributed over 12 positions throughout the drum. Source 8S is a 110 L reference drum filled with polyethylene (density: 0.297 g/cm3) and with the plutonium and uranium distributed over 7 positions throughout the drum. The details about these plutonium sources have been reported elsewhere (7). For generating background spectra that could potentially produce interfering peaks in the critical 100 keV region, uranium, curium, ^{137}Cs, ^{152}Eu and ^{60}Co sources were used.

Experimental Set-Up at IRMM

At IRMM, two detectors were used (see Table I). The samples were placed at a distance of 25 cm from the endcaps of both detectors. The background conditions were approximately five times better than in Cadarache. We counted a background of only about 1 cps/ cm3 of germanium, mainly due to ^{40}K. The list of sources used are also listed in Table II. Apart from these, a very well characterized (NRM-446-37) uranium

source was measured with and without cadmium filters in front of the detectors.

Experimental Set-Up at La Hague

The new MGA code for waste was also tested using small plutonium sources hidden in rotating 120 L waste drums using a "normal" waste assay system at the AD2 laboratory of Cogema La Hague. The matrix in the drums was fixed at 0.3 g/cm3 (compacted pink vinyl) and the masses of the plutonium sources hidden in the drums ranged from 0.3 mg to 10 mg. The sources that were used had typical reactor grade isotopic compositions (56 - 66 % 239Pu).

RESULTS

After we started analyzing the results of the various tests it became readily apparent that the previous version of MGA (prior to the modifications made during this study) often did not give satisfactory results for the test measurements. It either stopped operating or gave wrong answers with certain sources and/or matrices. Thus it became necessary to change the code as we accumulated test data. Most of all, the code needed to be hardened so that it kept working under as many conditions as possible. Furthermore, the code was changed to tell the operator if and why the detection or source/matrix conditions are insufficient to perform a good isotopic analysis for the cases when successful analysis was not possible. It also now warns the operator that the results given may be suspect if it detects that certain source/matrix or detector conditions are not sufficient.

The error calculation was enhanced. The uncertainty for the 242Pu abundance used to be fixed at 10 %. It was quickly obvious that this uncertainty had to be larger for the smaller plutonium samples.

To accommodate the wide range of conditions likely to be encountered in waste analysis, the new MGA code needed to introduce new set-up parameters. One of these parameters allows the user to choose the minimum number of counts in the low energy spectrum before the MGA code tries to analyze the spectrum. The maximum allowed statistical uncertainty on the 129 keV and the 208 keV peak in the low energy spectrum and on the 208 keV and the 414 keV peaks in the high energy spectrum (in the dual detector mode) can be chosen in the set-up. This way, the operator can choose not to spend analysis time for spectra that would perhaps yield results but with unacceptably large uncertainties.

Other parameters that can be inputted for this new MGA code for waste to direct its calculations include the volume of the low and high energy detectors as well as the attenuators in front and between these detectors (if the two detectors are used in a telescope configuration) and the coefficients for the calculation of the 242Pu abundance.

The influence on the MGA accuracy of the source positioning in the drum was examined by measuring the reference source C45 (778.6 mg of Pu) at 5 different radii in a 110 L drum. Two sets of measurements were done this way, with the drum empty and with it filled with pink vinyl (density 0.3 g/cm3). As can be seen from the results summarized for 239Pu in Fig. 1, the results from the analysis remain correct as a function of the source placement. In the figure, the x-axis simply represents the measurement numbers (with the 0.3 g/cm3 measurement results deliberately offset from the empty drum results for clarity). The y-axis is the ratio of the weight percentage reported by the MGA code in our analysis to the declared value and the error bars indicate the uncertainty estimate of the MGA results as reported by the program. The deviation from the declared value is not statistically significant for either case. Similar results were also obtained for the other plutonium isotopes with the error bars naturally larger for the smaller weight percentages.

Fig. 1. Ratio of MGA results with their uncertainties to the declared value for 239Pu in an empty drum and one filled to a density of 0.3 g/cm3 for a source placement of 5 different radii.

The effect of the drum size was tested by measuring the same reference source at a fixed source to detector distance in a 220 L drum, a 110 L drum and a 25 L drum all filled with pink vinyl up to a density of 0.3 g/cm3. The results clearly indicate that the results are not dependent on the size of the drum and that the uncertainty estimates from MGA remain appropriate.

To determine the influence of the plutonium isotopic composition on the accuracy that can be obtained with MGA, all sources listed in Table II were measured at a fixed position in a 110 L drum. Two sets of measurements were also performed for this test, with the drum empty and with it filled with pink vinyl to a density of 0.3 g/cm3. The results indicate that there are still some problems with certain

isotopic compositions. The deviation of the MGA results from the declared values is sometimes too large. We are still investigating what kind of isotopic compositions are a problem. Source E44 , with 50 % more 240Pu than 239Pu seems to be a particularly difficult combination for the code. Most of the more "normal" compositions were not a problem.

The influence of an increased background due to the presence of gamma sources in the drum was tested in several ways. The influence of a continuous (Compton) background under the plutonium peaks is seen when the results of the IRMM measurements are compared by those from the Cadarache measurements. Also, when the 110 L drum is filled with vinyl, the continuum background under the plutonium peaks in the 100 keV region is about a factor of two larger than for an empty drum. Still lower peak/background ratios were obtained by adding the (Compton scattered) spectra of 137Cs to the plutonium spectra. The general conclusion is that the lower the continuum background the better the results.

The MGA code was also tested on how it handles spectra where photopeaks from other nuclei interfere with the 100 keV energy region where the major plutonium lines used for the MGA analysis are to be found. Therefore, plutonium spectra were summed with a spectrum from a complex source containing 143Cm, 144Cm, 243Am, 239Np and 154Eu. It was observed that even the new MGA code could not analyze these spectra properly.

Some tests were also done with non-uniform matrices. For instance, to examine how the MGA code handles waste drums that have radially inhomogeneous attenuating materials, measurements were done with a reference source in a 110 L rotating waste drum screened at one side and at two sides with a 1 cm thick steel plate.

Also the influence of the atomic number and of the density of the matrix was investigated. Therefore, a 110 L drum with the reference source in a fixed position was filled with homogeneous matrices having a low (polyethylene and paraffin), a high (cadmium and iron) and a mixed (vinyl and iron) atomic number. For these, the average matrix density varied from 0.1 g/cm3 to 1.3 g/cm3. The influence of attenuation was further tested by measuring the stationary reference source with aluminum plates of 2 cm, 4 cm and 8 cm between the source and the detector. MGA results for plutonium samples behind varying steel thicknesses of up to 1.7 cm have been reported elsewhere (8). In that experiment it was shown that the MGA results improve dramatically when strongly attenuated high burnup Pu is measured with a telescope germanium detector. Our results with high Z materials were somewhat inconclusive. One of the measurements produced a result that was not within the allowed uncertainty of the declared value. while the others were. However, the number of measurements was not sufficient to draw any real conclusions.

Spectra of plutonium samples ranging from 1 mg to 1 g (see Table II) were taken to determine the minimum plutonium mass that is needed to do the isotopic analysis with a certain accuracy.

In addition to testing the source characteristics, the variety of detectors used for every measurement in Cadarache allowed us to test several detector types, geometries and shielding arrangements to understand their influence on the MGA results. Unfortunately, it appears that a single detector and
shielding geometry is not optimum for all types of waste streams. For instance, in some cases the use of a telescope configuration or a dual detector system will result in a more precise isotopic composition determination, while in other cases a single low energy germanium detector should be used. For good statistics spectra, the results seemed to be in general agreement regardless of the detector configuration. However, in the case of a spectrum with poor statistics, such as the spectra likely to be encountered in waste applications, the results were not quite as clear.

The measurements performed at La Hague permit us to do a more comprehensive statistical analysis on the MGA uncertainty estimates since there were many more repeat measurements using the same sources. One particular set of results contained 38 spectra where we were able to compare the declared values with the measured values (and their estimated uncertainties) for 239Pu and 240Pu. The calculated test of accuracy parameter for 239Pu is approximately 45 for this set of 38 spectra, with the 5% to 95% fraction of the allowed values of the expected distribution being 25 to 53. For 240Pu, the value of the test parameter is approximately 28, with the same range of acceptable values. The fact that the value of the test parameter falls within the expected range, of course, means that the MGA results are given with appropriate uncertainties. See Fig. 2 for a summary of the 239Pu results and Fig 3.

for a summary of the 240Pu results. Similar to Fig. 1, the Y-axis is the ratio of the MGA results to the declared value, and the X-axis is the measurement number.
Fig. 2. Ratio of MGA results with their uncertainties to the declared value for 239Pu in sources containing not more than 10 mg of plutonium
Fig. 3 . Ratio of MGA results with their uncertainties to the declared value for 240Pu in sources containing not more than 10 mg of plutonium.
Taking all of the results from the La Hague experiment we can deduce the minimum plutonium masses that can be successfully analyzed under such conditions. Assuming that the plutonium source sits in the center position of a 120 L drum filled with a low density matrix up to 0.3 g/cm3, ideal counting and shielding geometries and a 30 minute counting time are used, the minimum masses together with the largest errors that can be expected are listed in Table III.

CONCLUSIONS

This project has resulted in a better understanding of the limitations and capabilities of the MGA code. We observed that the former version of the MGA code was not well suited for the measurement of "alpha contaminated" waste. It required input from an operator in the "unusual" cases that are often encountered in waste conditions that he or she is normally not trained to provide. In some cases, such input was not possible to provide through the user interface of the previous version of the program. The old code sometimes refused to analyze spectra from weak samples, or gave wrong answers and /or the errors quoted by it appeared to be out of bound. This study has led to the development of a the new version of the MGA code that is better suited for the analysis of plutonium bearing waste. Furthermore, some of the improvements also make the new version better suited for automated analysis of large quantities of waste drums.

Our studies show that when this new MGA code provides results, they are statistically accurate relative to the declared values. Furthermore, it has been shown to be able to analyze milligram quantities of both weapons grade and reactor grade plutonium in 100 L and 200 L waste drums filled with a low density (0.3 g/cm3) matrix. The errors at these low quantities are quite high (20 % range, depending on the count time).

This project has led to a better design of the counting geometry and detector configuration for particular waste characteristics, in terms of the expected mass range and composition of the uranium and/or plutonium, in terms of the expected density and composition of the matrix and in terms of the expected internal and external background conditions.

At the present time the new version of MGA that is capable of analyzing waste is available under the Canberra Genie-PC platform. Other programs on the same PC can simultaneously communicate with other computers, perform gamma (or alpha) acquisitions using the ICB NIM or InSpector electronics and do other complex calculations while performing the MGA analysis.

ABSTRACT

Clean-up of actinide effluent waste steams is of increasing importance at the Los Alamos Plutonium Facility, TA-55, and removing the actinide elements to very low levels allows less radioactivity to go the Los Alamos National Laboratory Water Treatment Facility, TA-50, thus reducing the number of drums of TRU waste. Americium (Am) is a difficult element to remove from chloride media because the +3 state is difficult to oxidize and chelating resins work better with elements such as plutonium which are more readily oxidized to the +4 and/or +6 state. Currently in hydrochloric acid (HCl) media, the acidic liquid waste is neutralized with potassium hydroxide to precipitate the metal hydroxides, before disposal to TA-50. This process is not very efficient.

The removal of Am from chloride media was compared using a series of resins, some commercial and some made in our laboratory, using different percentages by weight of octyl(phenyl)-N,N-diiso-butylcarbamoyl-methylphosphine oxide (CMPO) along with diamyl amylphosphonate (DAAP) or tributyl phosphate (TBP) as diluents. Resins were also made with no added diluent. Early comparisons using small-scale contact studies with 0.5 grams of resin in 0.1M-12M HCl, and subsequent small-scale flow experiments show a trend in which Am uptake is proportional to the amount of CMPO on the resins and the diluent plays a minor role in the uptake of Am from these solutions. Redox chemistry effects were also investigated.

From these studies , it is possible to determine the best conditions for the removal of Am from HCl media thus reducing the gross alpha content of the waste stream by a factor of 10-100 which reduces the number of barrels of waste produced at the Water Treatment Facility.

INTRODUCTION

The use of extraction chromatography is currently a very popular method for the selective removal of various metals from a variety of waste streams. This is due to the availability of selective or metal-specific extractants which can easily be loaded onto an inert substrate without the need for chemically attaching the extractant molecules to the resin backbone. We have been exploring the use of extraction chromatographic resins, both commercial and resins synthesized in our laboratory, for the removal of actinides from both nitric acid and hydrochloric acid media. (1-3) Typically these resins are coated with octyl(phenyl)-N,N-diiso-butylcarbamoyl-methylphosphine oxide (CMPO) mixed with a diluent of either tributyl phosphate (TBP) or diamyl amylphosphonate (DAAP). The removal of uranium (U), plutonium (Pu) and americium (Am) from nitric acid (HNO3) is relatively easy and the extraction efficiency or Kd's obtained from these experiments are quite high. The Kd's for removal of the same elements from hydrochloric acid (HCl) media are much lower but still quite reasonable. In fact standard ion exchange which works well for the separation of Pu from Am in nitric acid and hydrochloric acid also works well for the removal of U from HCl solutions. The most difficult species to remove from HCl solutions is americium.

The commercial (Eichrom Industries)(4) extraction chromatographic resin, TRU-Spec, containing 13% CMPO and 27% TBP, will remove Pu from HCl media down to the microcurie/L level. However removal of the Am from a similar waste stream is difficult and can be accomplished only at higher (>7M) acid molarities. In this

paper, we present some additional studies that have been completed where we examined the effect of increasing the amount of CMPO on the resin to determine if there is a correlation between the amount of Pu or Am removed and the amount of CMPO present on the resin. We have also compared similar resins made using an organic substrate with those made using a silica substrate. For comparison purposes, we have included data on the Am extraction efficiency of TRU-Spec and also in certain cases similar experiments were done using Pu solutions, in order to better define the processes that occur.

EXPERIMENTAL PROCEDURE

Resin synthesis - The procedure we adopted, uses some aspects of the Horwitz recipe found in Analytica Chimica Acta (5) and of the Barney recipe from a Westinghouse Hanford Company report (6) to make different types of solvent impregnated resins. Similar procedures using di-(2-ethylhexyl) phosphoric acid (DEHPA) for making extraction chromatography resins are outlined by Cortina and co-workers.(7) For this work, the extractants/diluents used are CMPO/DAAP or TBP. The two resins used in these experiments were Amberlite XAD-7 and XAD-16. XAD-7 contains an acrylic ester backbone, with a surface area of 160 m2/g, and a 20-60 mesh size. XAD-16 has a polyaromatic backbone, a surface area of 800 m2/g, and the same mesh size.

The first stage in making these types of resins is to clean the resin to remove all of the monomers that could affect our extraction results. Approximately 50g of the resin was first weighed into a flask and 100 mL of E-pure water (18.1 M-Ohms) was added. The flask containing the resin was swirled every 10 minutes for about an hour. The slurry was then poured into a fritted funnel and the liquid was removed using a slight vacuum to speed up the process. The resin was then washed two more times in the same manner using 50 mL of E-pure water. The pH of the rinse water was 8-9. The resin was then washed 3 times with 25 mL of methanol, using a slight vacuum on the last two washes to help remove the liquid. The pH of the wash solution was now usually < 7, which indicates that the basic monomers have been removed. The resin was then placed into a rotovap flask and vacuum dried at 50oC for 16 hours, while rotating at 120 rpm. The resin is now white in color and dry which is very different from the wet, light tan starting material.

To actually make the solvent impregnated resin, 30 grams of clean resin is weighed out and slurried in a rotovap flask with 20 mL of methanol. Specific percentages by weight of the extractants/diluents are added to the slurry. For example, to make a resin with 13% CMPO and 27% DAAP on 30 grams of resin one uses 6.5 grams of CMPO and 13.5 grams of DAAP. Since CMPO is highly soluble in both DAAP and TBP, the CMPO and diluent are first mixed together then poured into the resin/methanol slurry. To make a pure CMPO resin, the CMPO is dissolved in methanol. The slurry is stirred using the rotovap for 30 minutes at 90 rpm. After stirring, the resin is dried by rotating at 35oC and 90 rpm while under vacuum (approximate time to dryness was 24 hours depending upon the concentration of CMPO in the solution). There were no significant losses of material at this stage and yields usually were 95%.

Contact Experiments - The actinide solutions used in all of these experiments were made by dissolving either plutonium or americium oxide (PuO_2 or AmO_2) in 4-6M HCl. For each contact experiment, 0.5 grams of resin was weighed out into 25 mL Bio-Rad polyethylene columns, 5 mL of a specific molarity acid was pipetted into the column and 50-250 uL of the stock solution was added to the acid in each column. An experiment contained either Pu or Am in 1-12M HCl. The columns for each experiment were rotated on a LabQuake rotating shaker for a set period of time, typically one (1) hour. At the end of the specified time, the solution was drained from the column into a scintillation vial, the vial capped and shaken to ensure a uniformly mixed sample. A 10-250 uL aliquot was removed and placed in a scintillation vial containing 6 mL of water and 14 mL of Packard Ultima Gold-XR scintillation fluid. Each acid solution was sampled twice to provide a check on sampling technique and to avoid the complete loss of a sample for an experiment in the event that a sample was spilled. Each sample was counted for ten (10) minutes using a Packard 2550TR scintillation counter. Each experiment was repeated at least once. With each set of resin containing columns, a control column without resin but containing all the solutions was used. The solution column was treated in a similar fashion to the resin containing columns and this control was used to establish the initial actinide concentration.

Upon completion of the sampling, then either hydroxylamine hydrochloride (NH_2OH-HCl) was added as a reducing agent, or sodium chlorite ($NaClO_2$) was added as an oxidizing

reagent. This redox chemistry was done to allow for comparison of the Am data with the Pu data. Each experiment required that the solutions be sampled before the addition of the redox reagents, after the addition of NH2OH-HCl, and again after the addition of the NaClO2.

The liquid scintillation count data was entered into a spreadsheet developed by Louis Schulte. This spreadsheet calculated the Kd for each set of conditions and also plotted the Kd as a function of acid molarity. The Kd is defined as shown in Eq. 1:

$$Kd = \frac{(\text{original solution cpm} - \text{final solution cpm}) \times \text{mL of sample}}{\text{final solution cpm} \times \text{g of resin}} \quad (1)$$

DATA AND RESULTS

Experiments were first conducted with Pu samples in HNO3, using XAD-7 resin without any extractant loading. The Kd's are expected to be very low and indeed this was the case. Additional experiments with the addition of NH2OH (reducing conditions) and NaClO2 (oxidizing conditions) yielded Kd's that were quite similar to those obtained for the "no redox" conditions. (See Fig. 1)

In the next set of experiments using Pu/HCl solutions, the effect of increasing the amount of CMPO on the resin was examined. These resins were synthesized in our laboratory. The resin substrate was XAD-7 with CMPO loadings of 20%, 40% and 60%. In the "no redox" part of the experiment, all three resins gave Kd's of ~750. Upon addition of NH2OH to form Pu(III) which should not extract very well, the Kd's increase as the acid molarity increases and also as the amount of CMPO increases. The Kd for 20% CMPO is 2500, for 40% is 3000 and for 60% is 5000. Similar results were observed after addition of NaClO2 to oxidize any Pu(III) to Pu(IV). The Kd's ranged from 2500 (20% CMPO) up to 6000 for 60% CMPO loading. (See Fig. 1) These results are not very much different from the results obtained with the commercially prepared TRU-Spec resin, and the observed increases in the Kd as the acid molarity increases are consistent with our observations for experiments with TRU-Spec. It is surprising that the Kd for Pu(III) is this high and it would indicate that either the reduction is not complete or most likely that the Pu(III) formed is oxidized back to Pu(IV) during the one hour duration of the experiment.

Experiments using Am in HCl were then done using TRU-Spec. All three experimental conditions ("no redox", reducing, oxidizing conditions) were completed in order to compare the results with those obtained for the Pu solutions. The best Kd's are obtained under oxidizing conditions (addition of NaClO2). From Fig. 2, we observe that the Kd increases as the acid molarity increases (as it did in the Pu experiments).

The highest Kd was obtained at 8-9M HCl, however the Kd is approximately 100X smaller, ~53. This indicates that the Kd for Pu(III) given above is not accurate. In HCl solutions, the Pu(III) should not be as readily oxidized back to Pu(IV) if it can be stabilized with a "holding" reagent, such as ferrous sulfamate.

Fig. 2. Comparison of Am Extraction Efficiency from HCl for Resins Containing 13-40% CMPO with DAAP as Diluent.

Next experiments were performed with two other commercially manufactured "experimental" resins supplied by Eichrom Industries. These resins contained higher percentages of CMPO with DAAP as the diluent instead of TBP. The resins contained 20% CMPO with 20% DAAP (20:20 resin) and 30% CMPO with 10% DAAP(30:10 resin). The 20:20 resin performed in a similar manner to TRU-Spec with increasing Kd as the acid molarity increased. Again the highest Kd was observed after the addition of NaClO2. The Kd at 8-9M is ~200, which decreases as the acid molarity increases up to 11M.(See Fig. 2)

The experiments with the 30:10 resin (organic substrate) yielded even higher Kd's with the maximum Kd of 600-625 occurring at 8-9M HCl. The Kd's decrease as the acid strength increases past this point. (See Fig. 2) Surprisingly, there is no observed improvement upon the addition of NaClO2. Since the addition of NaClO2 should have no effect on the Am(III) in solution, the enhanced Kd's under these conditions are most likely due to trace amounts of Pu in these solutions. It should also be noted that the substrate for these commercial "experimental" resins is organic and is quite similar to XAD-7 although the bead size is smaller.

Experiments with the commercially prepared (Eichrom Industries) 30:10 resin (silica substrate) yielded results that were quite similar to the results obtained with the 30:10 organic-substrate resin. The HCl molarity versus Kd plot was similar in shape with a maximum occurring between 8-9M and bending downward to yield Kd values of 100

at 12M. (See Fig. 3) There were some differences noted, mainly that the addition of NH2OH yielded higher Kd's (850) than the Kd's (500) obtained upon addition of NaClO2.
The removal of Am from the HCl waste stream was negligible until the acid molarity was 6M. The silica substrate was a porous material, however the pore size was different than the typical pore size of the organic substrate.(8)
Four different resins were synthesized in our laboratory. They are 13:27 using 13% CMPO and 27% DAAP on both XAD-7 and XAD-16 resins. This was made to compare with the commercial TRU-Spec resin. The Am extraction data with these resins were quite similar except that the higher surface area XAD-16 yielded Kd's that were ~2/3 those of the XAD-7 resin. The XAD-7 resin had maximum Kd's (under oxidizing conditions) ranging from 75-85, (See Fig. 4) while the Kd's for the XAD-16 resin ranged from 55-60. Once again the highest Kd were observed for 9-9.5M HCl.
The third resin consisted of 35% CMPO with 5% DAAP (35:5 resin). The highest Kd's exhibited by this resin were after addition of NaClO2 and at 9-9.5M HCl. (See Fig. 2) The Kd's ranged from 600-925. Although this resin performed very well and was better than the 30:10 resin, we do not understand why the measured extraction capability or Kd is almost as high as the pure CMPO resin.
The fourth resin contained no diluent and consisted of a 40% CMPO loading on XAD-7. The Kd's for this resin ranged from 850-900 and were highest for 9-9.5M HCl after addition of NaClO2. (See Fig. 2) This resin has been investigated previously by Barney and Cowan(6) as well as the authors. Although this resin extracts Am very well, the kinetics for uptake of Am are very slow.(2,3)

DISCUSSION/CONCLUSIONS

Removal of Am is possible using either commercial resins such as TRU-Spec or using specially prepared resins such as 20:20, 30:10 or 40% CMPO with no diluent. From Fig. 3, we see that better Am extraction is obtained by using a 30:10 resin on a silica substrate. From Fig. 4, it is apparent that DAAP is a better diluent (or co-extractant) than TBP. Perhaps diluent is necessary, and therefore it would be interesting to try a 40:10 or 50:10 resin on a silica substrate.
At the present time we do not have an explanation for the reversed results upon addition of NaClO2 to solutions while using 30:10 silica substrate resin as compared to the 30:10 organic substrate resin. We expect slightly higher Kd's with the addition of NaClO2 if traces of Pu are present in the Am solutions.
The high CMPO loading on these resins should absorb Pu even better than Am. This would imply that a good primary column is required in order to remove as much of the Pu as possible prior to using one of these resins to remove any Am present in the waste stream.
Selective removal of Pu from these various resins (elution) is possible and has been demonstrated in experiments in our lab and at ANL. (1-3,9) The first step is to remove the Am using low molarity (3-5M) HCl, followed by 0.1M HCl/0.1M binoxalate to remove the Pu.

FUTURE WORK

It would be interesting to compare higher CMPO loadings containing a constant percentage of either TBP and DAAP as diluent. Is there really any difference in the extraction efficiency of resins made with these two diluents?
It would also be interesting to compare these CMPO/diluent resins with a 55% CMPO resin synthesized by simply melting the CMPO and allowing the resins to absorb it.(10) This method has been reported by the scientists at the Karlsruhe Nuclear Research Center.
It would also be interesting to determine if simple modifications of CMPO would yield a better extractant for Am from HCl media, and what would be the effect on Pu removal? This has been studied in the past by Horwitz and co-workers, (11) however the choice of CMPO was somewhat dictated by its availability and the ease with which the actinides could be removed from the resin.

ACKNOWLEDGMENTS

We would like to acknowledge the gift of the free samples of 20:20 and 30:10 resins from Eichrom Industries. Also the helpful conversation with Mike Fern and Mike Gula of Eichrom, Phil Horwitz and Renato Chiarizia of Argonne National Laboratory. We also acknowledge the help and encouragement from Keith Fife, Steve Yarbro, Gordon Jarvinen and Rob Hermes of Los Alamos National Laboratory.

BEHAVIOR OF THE CONCENTRATED PUREX HLLW FROM A HIGH BURN-UP LWR FUEL PREPARED BY A REDUCED PRESSURE EVAPORATION PROCESS

Yoshinobu Takaoku
Japan Nuclear Fuel Ltd.
Yasuo Hirose
Hitachi Works, Hitachi, Ltd.

ABSTRACT
1.5 kg of UO2 fuel irradiated in a PWR up to 47520 MWD/MTU average burn-up, cooled for 15 years, was dissolved in a nitric acid. The aqueous raffinate from solvent extraction after diluent washing, adjusted to 2.6M HNO3, and to the volume concentration of 9400 liters/MTU was concentrated in a bench scale evaporator with continuous feed under a reduced pressure maintaining the boiling temperature at 60C to give an intermediately concentrated raffinate with ca. 8M HNO3, which was successively concentrated at 50C with water feed to give 211 liters/MTU in 3.8M HNO3 solution. The concentrated active HLLW (High-Level Liquid Waste) solutions, one in 4M HNO3 and another in 2M HNO3, but with the identical volume concentration of 422 liters/MTU, were prepared by appropriate dilution procedures.
Stainless steel blocks were immersed in each concentrated HLLW solution at 50, 60 and 70C for 90 days without agitating. The blocks were weighed before and after the rinsing in a nitric acid solution to physically remove loose solids, then the soaking with a hot alkaline solution to chemically remove firmly adhesive solids. Despite no precipitation had occurred during the concentration by means of a reduced pressure evaporation process, the concentrated HLLW generated solid deposits in some extent during keeping for 90 days at the temperatures examined.
The relative amount of the Mo precipitated from the solution in 4M HNO3 (initial Mo concentration; 6.4 g/liter) was 22% at 50C, 50% at 60C and 79% at 70C. Up to 99% of

Mo precipitated from the solution in 2M HNO3 at 70C. The weight of solid firmly adhered on a unit surface area of the metal block in the solution in 4M HNO3 was 2.3 mg/cm2 at 60C. This was insignificant at 50C. Though solids adhered heavily on the blocks at 70C while the blocks were in the solution, they could be almost totally removed during the acid rinsing. Both 316L and 304L stainless steels revealed clear inter-granular attacks and the weight losses equivalent to the corrosion rate of 8-12 mm/year in 4M HNO3 and 5-8 mm/year in 2M HNO3 respectively at 70C. The corrosion rates were barely detectable, i.e., 0.2-1.4 mm, at 60C and were not depending on acidities either 4M or 2M. Neither weight loss nor local corrosion was observed on the 316L and 304L blocks with previously attached with the solid coating during the immersion in the solution in 4M or 2M HNO3 at 50C. The conceived temperature to operate the storage tanks of the concentrated HLLW, i.e., <60C was justified regarding both corrosion and solid formation points of view for either acidities of 4M or 2M HNO3.

There would be a practical incentive to simplify the reduced pressure evaporation process if the concentrated HLLW in 4M HNO3 could be discharged to the storage tanks, otherwise to produce the concentrated HLLW in 2M HNO3 at the specified fission product concentration should require an additional evaporation to a higher concentration followed by a dilution procedure.

INTRODUCTION

A reduced pressure evaporation process has been developed and established by the BNFL at Windscale in the United Kingdom to concentrate the highly active aqueous raffinate from the PUREX processing for Magnox fuel, but this did not include salt containing solution. In a typical operational condition by maintaining the pressure at 50mmHg in which the raffinate was 3M HNO3 and contained 3kg of fission products (as nitrates) per tonne of uranium processes, together with a small amount of iron, aluminum and others as alloying elements of the fuel. Under the semi-continuous operation scheme such as the continuous feed to maintain at constant volume and the batch taking-off, the acidity rose to 10M in nitric acid before dropping back about 7M as the concentration reached 80 liters/MTU, the acidity could be further reduced (typically to 4M) by water feed in place of the active feed before discharged to the storage tanks. It has demonstrated outstanding reputation to show a high mechanical reliability and a high decontamination factor for the radioactivity, in particular to reach a high evaporation factor without excessive solid precipitation, provided that the entrained and dissolved TBP were to be removed efficiently from the raffinate before the evaporation to avoid excessive precipitation of solid phosphates (1,2,3,4).

An application of a reduced pressure evaporation process to the highly active aqueous raffinate from the PUREX process for a high burn-up LWR fuel could be different from that for a Magnox fuel in the following aspects:

the relative molar abundance of fission product elements to that of residual TBP in the aqueous raffinate from the co-decontamination process increases, as TBP concentration is independent of amount of fission products.

the terminal fission product concentration in the HLLW becomes higher due to higher original concentration,

consequently the other solid forming processes rather than the formation of solid phosphates should likely gain in importance.

D.O. Campbell et al (5) have described that "The dissolver solution appears to be stable to formation of insoluble compounds for several days, provided the temperature is not too high or the acidity too low. Solids form when dissolver solution or extraction raffinate is aged at about 80C or above. From 3 to 4M HNO3 solutions, crystalline solids form which contain zirconium and molybdenum in the ratio of 1 to 2."

M.H. Lloyde (6,7) has described that "Zirconium molybdate precipitation will be more difficult to control. At an aging temperature of 100C, precipitation does not occur at all acid concentrations in the range of 1 to 7M. At a lower aging temperature (60C), precipitation does not occur at the high acid concentrations and the precipitation rate is greatly reduced at 3M HNO3." It has been also shown that the ratio of Mo precipitated after aging for 17 days at 60C was 90% in 2M HNO3, but 20% in 4M HNO3.

P.A. Anderson (8) has described that zirconium molybdate was an exclusive solid species generated during concentration of simulated HLLW under the atmospheric evaporation. T. Izumida et al. (9) have observed that the threshold temperatures to

produce solid zirconium molybdate within 10 hours were depending on acidities adjusted after the evaporation, i.e., 30-50C to 2M, 80-90C and 90-100C to 6 M in their study for the concentrated HLLW solution simulated for 33000 MWD/MTU LWR fuel prepared by a reduced pressure evaporation process.

M. Schmidt (10) has prepared zirconium molybdate ($ZrMo_2O_7(OH)_2 2H_2O$) by reflux boiling of nitric acid solutions containing Zr (1-2.7 g/liter) and Mo (1-4.3 g/liter) for 3-10 days, then measured the solubility of zirconium molybdate crystals in pure nitric acid solutions of various concentrations (1-10M) at 25C. He has described that the solubility increased steeply with increasing acidity, i.e., [Mo] was 0.5mM in 2.5M HNO_3, 2mM in 5M HNO_3 and 7mM in 8.4M HNO_3 respectively. It took more than 320 days to reach equilibrium values particularly in lower acidities than 2.5M. Schmidt suggested that the stoichiometry of [Zr]/[Mo] in his experiments might be attributed to slow kinetics.

A need to know the practical information about the behavior of the concentrated PUREX HLLW from a high burn-up LWR fuel exclusively prepared by a reduced pressure evaporation process was recognized particularly for the effect of acidity on the solid formation and on the corrosion interactions with the structural materials of the storage tank, according to the literature survey. The present study is intending to perceive a harmonized acidity for storing the concentrated HLLW, which is high enough to control the formation of solids and low enough to control the corrosion of material.

EXPERIMENTAL

Preparation of Active Concentrated HLLW

A full length Zircaloy clad UO_2 fuel rod irradiated as a part of a subassembly in the "Jose Cabreta" 153 MWe PWR (located at Zorita, Guadalajara, Spain) at an average heat rating of 9.14Kw/ft for 1334 days to give an average burn-up of 47520 MWD/MTU and the peak burn-up of 51880 MWD/MTU calculated based on the in-core power history over the fuel length, and cooled for ca. 15 years had been available at the AEA Technology's disposal and was used for the preparation of the original HLLW in this work. The fuel is called "Zorita fuel" in the paper. Details of the preparation procedure and relevant information have been published separately (11).

TABLE I, II & III

Table I shows the elementary composition of Zorita fuel calculated using FISPIN (unpublished UK code) based on the irradiation history. Table II shows simplified process flow starting from the fuel to prepare concentrated active PUREX HLLW solution by a reduced pressure evaporation process.

Despite no precipitation had been observed during the concentration by a reduced pressure evaporation process at a constant boiling temperature of 60C to produce the concentrated HLLW solution to the volume concentration of 422 liters/MTU in 8M HNO_3, a certain amount of precipitate was formed during further standing at an ambient temperature for about six months. Amount of solid collected by filtration from the concentrated solution of 36 lcm3 was 4.17g. Assuming that the chemical composition of solid was $ZrMo_2O_7(OH)_2 2H_2O$ (MW=470.2 g/mol based on the atomic weight for fission product isotopes), 41.5% of originally existed Mo could have precipitated by this stage. The solids formed were white fluffy, voluminous and easily dispersed. Gamma spectrometry of the solid showed a relatively high abundance of Te-125m. The Te-125m/Cs-137 ratio in the solid was about 16 times greater than the original ratio found in the raffinate solution (11).

The solids separated from the simulated HLLW solution evaporated simultaneously with the active runs showed the elemental composition such as Mo (55.2 at%), Zr (32.6 at%), Te (7.2 at%) and Fe (5.0 at%) by EDX analysis and the crystalline structure appeared as fluffy needles by an SEM observation as shown in Fig. 1(a), though no detail examination could have been made for the active solids. The chemical composition of the solid formed during this stage was arbitrarily assumed as $ZrMo_{1.76}Te_{0.24}O_7(OH)_2 2H_2O$ (MW=477.9 g/mol). The coordination of Fe in this compound was not understood. This could have been a reason to give a very different crystalline morphology from those previously reported for $ZrMo_2O_7(OH)_2 2H_2O$ (8,9,10). If the above assumption for the Zr-Mo-Te compound is a case, a 4.17g of solid equivalents to 15.4 mmol of Mo (1.50g of Mo) and to 35.9% of originally existed Mo in the irradiated fuel would have precipitated by this stage.

The terminal saturated acidity of the concentrate in a reduced pressure evaporation process operated with the continuous feed of an active raffinate in 2.6M HNO_3 has been known as 8M HNO_3 and it could have been reduced to 4M HNO_3 by water feed

according to the previous evaporation runs. A new mother solution concentrated at least to 211 liters/MTU should have been required in order to prepare the HLLW solution concentrated to 422 liters/MTU in 2M HNO3 by a simple dilution with an equal volume of water. A filtrate of the concentrated HLLW separated from solids was diluted to prepare the feed of 1.9 liters to the reconcentration process by adjusting HNO3 concentration to 2.6M. The continuous active feed to a reduced pressure evaporator operated to maintain at constant volume of 190ml at 50C. Two batches of 200ml water were fed at the final stage of evaporation to reduce the acidity down to 3.8M with the volume concentration of 211 liters/MTU. A vacuum drying of HLLW was also carried out at 47C as an alternative process. It is noteworthy that either reconcentration or even vacuum drying did not form any discernible solids.

Table III shows the elementary composition of the HLLW concentrated to 422 liters/MTU in the manner described above based on the results of Table I with making appropriate corrections relevant to the dissolution and the solid generation during the preparation process considering the mass balance of Mo shown in Table VIII. The total activity was 869 Ci/liter or 2.6 W/liter, though it had decreased substantially after 15 year cooling.

TABLE IV

Stainless Steel Specimens for Corrosion Tests

It has been perceived that 304L stainless steel would be more resistant to a trans-passive corrosion in a nitric acid environment but 316L stainless steel would be more resistant to local corrosion such as pitting. The corrosion tests intended to provide practical information about corrosion interaction between the concentrated HLLW and the stainless steel, both 316L and 304L.

Specimens were fabricated into an identical rectangular form, i.e., 12mm x 6mm x 4 mm, and mechanically ground to finish the surface. A 1.2 mm hole to suspend a specimen by a wire made of the same material was drilled near one end of the front. Specimens for the base metal were taken from a slab of the respective stainless steel and the front face always paralleled to the rolling direction of the original slab and the side face always represented the end grain surface, accordingly the end grain surface occupied one third of the total surface area of a specimen. Specimens for the base metal of 304L were chemically etched using HNO3-HF mixture to remove about 6 m from the surface. This chemical etching had shown effectively to remove a thin layer, which had been proved being prone to the initial dissolution (12). 316L stainless steel could not be etched under the same chemical condition as 304L had been etched effectively. The welded metal specimens were taken from the TIG arc melted section of the filler metal and the melted metal specimens (for only 316L) were taken from the TIG arc melted section of the base metal. Unfortunately, mechanical finishing of surfaces was not a high grade as expected but significant ground marks were left to be observed. Table IV shows the elemental compositions of the base materials and the filler materials for welding.

Preparation of the Specimens Attached with Solid Deposit

Those specimens to be tested at 50C were deliberately attached with solid deposits in the HLLW solution before corrosion tests by reducing acidity at the boiling temperature. The HLLW solution for this purpose was 422 liters/MTU and 1.4M HNO3 prepared by dissolving the vacuum dried HLLW in nitric acid solution. Nitric acid reduction was performed by addition of 2ml of 13M formaldehyde aqueous solution to 25ml of the HLLW under boiling condition in a glass vessel where metal specimens were immersed. This amount of formaldehyde was assumed to destruct all free nitric acid to nitrous oxide and water. The second batch of specimens was placed in the solution from which the previous batch had been removed then 25ml of the HLLW solution and 2ml of formaldehyde solution were added. The third and the fourth batch were processed in the same manner as previous. Table V shows the amount of solids deposited on each batch of process.

TABLE V

It was noted that the amount of solids adhered to the metal surface per a batch decreased along with consecutive batches, though the same amount of Mo was supplied to the solution before each batch and the same amount of solid would have been precipitated from each batch. This could be attributed to the fact in which the ratio of the surface area of metal to the volume of solution decreased along the consecutive batches, i.e., from 737cm2/liter eventually to 171 cm2/liter. Thus, it can be said that the ratio of solid adhered to the metal surface to the total solid

precipitated is proportional to the 0.4th power of the ratio of the surface area to the liquid volume, i.e., [(surface area/liquid volume)0.4].
The solid deposit from the simulated concentrated HLLW solution during the inactive preliminary runs typically showed an elementary composition such as Mo (62.2 at%), Zr (31.2 at%) and Fe (5.4 at%) but no detectable Te by an EDX analysis and showed a granular appearance by an SEM observation as in Fig. 1(b), no detail examination could be made for the active solid. Not only the chemical composition in which [Mo]/[Ze] was exactly two and no Te existed but also the crystalline morphology suggested that the solids formed in this stage were genuine $ZrMo_2O_7(OH)_2 2H_2O$.
Corrosion/Solid Deposition Tests
Experimental apparatus was made of glass and designed so as to minimize the loss of solution by volatilization during the prolonged testing period and to maximize the feasibility to remote operations in an alpha-gamma hot cell. An apparatus could contain 25ml of solution and accommodate up to six specimen blocks suspending by wires (same material as the respective stainless steel, 1mm x 1mm). Two glass apparatuses were kept at the temperature for 90 days in an aluminum block electrically heated and controlled at 1C by a thermocouple embedded in the aluminum block. The temperature of solution in each apparatus was measured by a thermocouple installed in a center tube and was recorded during the test. Fig. 2 schematically shows an apparatus.
FIG. 2 & FIG. 3
TABLE VI
After immersion for 90 days, the specimen blocks were transferred from the glass ware into a 3M HNO_3 solution and soaked for 24 hours then air dried after rinsed in water. This procedure could always enable each specimen block with a wire to move from the hot cell to the radiochemical laboratory in terms of radiation dose rate for observations and measurements. The first step of sequential procedure to measure the amount of solids was shaking each specimen block with a wire in a 1M HNO_3 solution after soaking for 24 hours to remove any loose solids physically, rinsing in water and acetone before air drying and weighing. The weight change of each specimen block including a wire from the initial weight represented the weight of solid firmly adhered on the block, though further corrections for the loss of weight due to corrosion should be made. The second step was soaking each specimen block after removing a wire in a hot 1M NaOH solution for 24 hours followed by shaking to remove adhesive solid chemically. The specimen blocks were rinsed successively in 1M HNO_3, in water and in acetone before drying and weighing. The weight change of each specimen block from the initial weight was assumed as the corrosion loss of weight. All weighing was made at a precession of 0.5mg. Corrosion loss of metal thickness was calculated based on the wetted surface area was 3.07cm2 per a block and the specific gravity of stainless steels were identically 7.9. The precession of weighing was equivalent to 0.2 mm of thickness loss and to 0.4 mm/year of corrosion rate. Fig. 3 illustrates a macrograph taken before the block was treated in a hot alkaline solution. It can be seen in the picture that this specific specimen block was covered almost entirely by the film of solid.
FIG. 4
TABLE VII & VIII
The weight change, the thickness loss and the corrosion rate for each specimen block are shown in Table VI according to the experimental varieties. Each block is identified by a code composed of (temperature)-(HNO_3 concentration)-(base: B, welded: W, melted: M)-(steel species)-(immersed totally: T, partially: P)-(block serial number). Whichever of the stainless steels showed significant weight losses at 70C, which were equivalent to 8-12 mm/year in 4M HNO_3 and to 5-9 mm/year in 2M HNO_3. The corrosion rates at 60C were barely detectable, i.e., 0.2-1.4 mm/year and did not depend on acidity. No weight loss was sensibly detected for stainless steels at 50C either in 4M or in 2M HNO_3. It has been revealed by SEM observations as shown in Fig. 4 that apparent inter-granular attacks occurred at 70C in even 2M HNO_3 solution, though they were more intense on 316L than 304L. The welded metal of 316L showed a particular attack pattern comparing others. Contrastingly no inter-granular attack was observed on any specimen immersed at 60C or 50C in either 4M or 2M. No localized corrosion other than the inter-granular attacks on the specimens tested at 70C were detected by SEM observations on the surface of specimens including end grains or those covered by the solid coating attached before testing. Specimens partially immersed in the solution at 50C did not show any irregular appearance all

over the surface of a specimen.
All solids whichever suspended or settled in the solution in each apparatus and each associated nitric acid rinsing solution were collected using 0.45 mm filter and weighed after air dried for each apparatus batch. Table VII shows the weight of solid classified into that suspended in the solution and that attached on the metal, and the latter is subclassified into that removed by shaking in an acid solution and that removed by shaking in an alkaline solution. The amount of solids totally formed in the solution generally increases with increasing temperature, particularly from 50C to 60C. Such increasing is mainly associated with the solids suspended in the solution. The amount of solids attached with the metal increases sharply from 50 to 60C. The solids attached on the metal at 70C were easily removed by the acid rinse comparing with the case at 60C. Virtually no solid attached on the metal during the tests at 50C but the solids originally attached on the specimens were kept as they had been. The effect of acidity on the total solid and on the attached solid could not be clearly judged due to lack of pertinent data, though there were general tendencies that the amount of solids increased with decreasing acidity.
A series of analysis of Mo in the filtrates separated from the suspended solids was performed using an absorption spectrophotometry method based on a thiocyanate complex formation in order to confirm the mass balance of Mo during solid formation in the solutions. Table VIII shows the results of measurement and comparison with those from gravimetric measurements of solids. Mo concentration in the original concentrated HLLW solution was assumed based on the correlation of data taken in the case of 4M HNO_3 at 50C, in which the analytical value was 4.96 g/liter and the amount of solid, i.e., 86 mg/25ml (equivalent to 1.43 g/liter of Mo). Thus, the Mo concentration in the original concentrated HLLW solution was verified as 6.39 g/liter. Analytical data suggested that very clear dependence of residual Mo concentration upon temperature and HNO_3 concentration. Discrepancies between two sets of values of Mo concentration or of Mo precipitated could attribute to incompleteness of the solid recovery from glass vessels by remote handling procedures for the gravimetric measurement. The ratio of Mo to form solids to the total Mo initially contained in the solution in 4M HNO_3 was 22% at 50C, 59% at 60C and 79 at 70C, but in 2M HNO_3 virtually all Mo tended to form solids at 70C.
DISCUSSIONS
Possibility of Loss of Mo Associated with the Undissolved Residue
Although it had been assumed previously that 41% of Mo would have been contained in the undissolved residue after the dissolution of a UO_2 fuel irradiated to 47520 MWD/MTU (11), the present work assumed that all Mo originally contained in a fuel was transferred into the HLLW after dissolution and solvent extraction. The original concentrated aqueous raffinate in 422 liters/MTU would contain 11.57g/liter of Mo if it had not been lost with the undissolved residue. 4.16g/liter of Mo has been lost from the solution in 8M HNO_3 during a long standing at an ambient temperature. Thus, the concentrated HLLW would have contained 7.41g/liter of Mo, though the Mo concentration assumed based of analysis was 6.39g/liter as shown in Table VIII. This suggested that the loss of Mo associated with the undissolved residue would have been equivalent to 1g/liter (approximately 10% of the original).
Possibility of Solid Formation during Reduced Pressure Evaporation
A fact in which a certain amount of solid precipitated from the concentrated HLLW in 8M HNO_3 during standing at an ambient temperature for six months, despite no solid had precipitated during the initial concentration of HLLW by a reduced pressure evaporation process, implied that the chemical status of the solution was under quasi-equilibrium and there might always be a possibility to initiate solid precipitation by any chance of stimulation. A strong gamma ray irradiation was reported as a stimulant by Kubota et al (13), however, an existence of seed crystals even if some extraneous nature would be effective as well. As some crystals, which have formed previously, may always exist in an industrial evaporator, it is likely that the solid precipitation is always stimulated in situ. Thus, nearly 40% of the Mo originally contained could precipitate under the practical conditions of operation according to the present experimental results.
Possibility of Solid Formation under the Storage Condition
Despite no direct evidence could be available to identify the chemical composition of solids formed in the active concentrated HLLW either in 4M or 2M HNO_3 during the tests at 50-70C, it could be reasonably suggested that the solids were zirconium molybdate and identical to those deposited compulsorily from the concentrated HLLW

at the boiling temperature by reducing acid concentration. In this stage, the solids are obviously easier to form with decreasing acidity and with elevating temperature so far enough Mo does exist in the solution. Formation of the solid exclusively depends on Mo but not on Zr, as stoichiometrically excess Zr does always exist as fission products. This can occur under the storage conditions in which the concentrated HLLW has been reduced in acidity prior to be transferred into the storage tanks. The maximum total amount of solid zirconium molybdate to be accumulated in the concentrated HLLW under storage will depend upon the total Mo contained in the irradiated fuel. The less solids form under the evaporation condition, the more solids form under the storage condition. Existence of solids would cause no notable problem in the storage tanks because they are always facilitated with an agitation capability to make solids being suspended.

Possibility of Solid Deposition and Adhesion on the Metal Surface

It would be a matter of concern if significant amount of solids would sediment from the concentrated HLLW and adhere on the cooling surface in the storage tanks. In compulsory solid deposition by reducing acidity at the boiling for 45 minutes the average solid deposition density on the metal surface was about 1mg/cm2 while all of Mo originally existed were precipitated. The average solid deposition density on the metal surface from the concentrated HLLW in 4M HNO3 after keeping at 60C for 90 days was 2.3mg/cm2 while 59% of Mo originally contained were precipitated under the similar ratio of surface to volume to the above case. The slow kinetics in solid formation seemed to increase adhered solids on the surface of metal. No data about the solid adhering for the solution in 2M HNO3 at 60C were available, therefore no direct statement about a preference of 4M HNO3 to 2M HNO3 could be done in the solid adhesion point of view.

In a conceived industrial storage tank of the concentrated HLLW operating at 60C, 120M3 in volume, ca. 1100kg of the solid is supposed to be formed during storage in addition to ca. 1200kg of the solid transferred from the evaporator, which have been already being suspended in the solution. At a presumed wetted surface area of 400m2, the ratio of surface to volume is 33.3 cm2/liter, which is smaller than the present experimental condition in a factor of 18. Thus, the ratio of solid adhered on the metal surface to the total solid precipitated will decrease to 5% from the experimental result of 15.5% based on the proposed empirical dependency on (surface area/liquid volume)0.4. Conclusively, the possible amount of solid adhered on the metal surface will be 55kg, the solid density is to be 14mg/cm2 and the thickness is to be 0.4mm based on the crystalline density of $ZrMo_2O_7(OH)_2 \cdot 2H_2O$ as 3.25g/cm3 reported by Anderson (8).

Not only gravimetric measurements but also visual observations on the specimens immersed in the HLLW solution at 70C did not show a notable amount of solid firmly adhered on the metal surface. A significant dissolution of the metal surface such as 2-3 mm during the immersion for 90 days might affect to loose solid coating on the metal, and make solids easily removable. No solid adhesion in addition to the previously attached solid was observed at 50C. Thus, to maintain the operating temperature of a storage tank at 50C or less may effectively limit the solid adhesion on the metal surface.

Effect of Acidity and Temperature on Corrosion of Stainless Steels in HLLW

Stainless steels showed notable weight losses equivalent to the corrosion rates of 8-12 mm/year in 4M HNO3, while 5-8 mm/year in 2M HNO3 and anyhow definite inter-granular attacks in either acidity at 70C. At 60C, the corrosion rates were as low as 0.2-1.4 mm/year and no inter-granular attack was detected regardless of acidities. At 50C, weight changes of stainless steels specimens before and after immersion in the HLLW solution were well within an experimental error considering of residual solid materials even after the hot alkaline treatment. Pertinent SEM observations have revealed that the crystalline morphology of residual solids was modified after the alkaline treatment, in which modifications from zirconium molybdate crystals to zirconium oxides crystals were shown.

A particular pattern of local attacks on the melted filler metal section of 316L specimens was observed. This revealed a kind of selective dissolution of metal at the grain boundaries of the ferrite phase precipitated in the melted filler metal of 316L stainless steel. As the deposition of the ferrite phase from melted 316L stainless steel is preceded by the gross solidification of the austenitic matrix phase, segregation of impurities such as sulfur tends to occur along with the grain boundaries of the ferrite phase and this causes a characteristic local corrosion.

Lower content in impurities in the 316L base metal than the filler metal could attribute to the absence of local corrosion along grain boundaries of the ferrite phase.
The environment underneath an intact solid layer could be deficient in nitric acid due to radioloysis to sustain the passivity of stainless steels. Thus, local corrosion such as pitting could have been concerned. It has been demonstrated that a local corrosion due to simple deficiency in nitric acid would not be a case under the present experimental conditions, i.e., an immersion of specimens attached with a layer of solid as thin as 3 mm in the concentrated HLLW solution in either 4M HNO3, or 2M HNO3 at 50%C. Some specimens attached with a solid coating were suspended to immerse partially in the HLLW solution at 50C for 90 days, and showed no irregularity on the observations. There was no distinction between 316L and 304L in terms of the above behavior so far as the present experiments were concerned.
Though any positive fact has not been available, in which 4M HNO3 was preferable to 2M HNO3 for the acidity of the concentrated HLLW before transferred into the storage tanks in either solid deposit or corrosion point of view, the choice of 4M HNO3 will have a practical advantage. The concentrated HLLW in 4M HNO3 can be produced straightforwardly by the water feed in place of the active feed at the terminal stage of concentration procedure in a reduced pressure evaporation process, on the other hand, to produce the concentrated HLLW in 2M HNO3 should require an additional evaporation to a high concentration before diluting with the considerable amount of water.

CONCLUSIONS

The concentrated PUREX HLLW from a high burn-up LWR fuel exclusively prepared by a reduced pressure evaporation process was studied in terms of the solid forming during either the concentration process or the storage process, the solid adhering on the metal surface and the corrosion interaction with stainless steels in the storage process. The concentrated HLLW adjusted acidity in 4M HNO3 was not particularly superior to that in 2M HNO3 regarding the solid formation or the solid adhesion, but it was not particularly inferior to that in 2M HNO3 regarding a corrosion point of view so far the temperature was kept at 60C or less. The solid adhesion on a metal surface was insignificant at 50C regardless of acidities in 4M or 2M. The conceived temperature to operate the storage tanks of the concentrated HLLW, i.e., <60C, was justified regarding both corrosion and solid formation points of view for either acidities of 4M or 2M HNO3. There would be a practical incentive to simplify the reduced pressure evaporation process in the concentrated HLLW in 4M HNO3 could be discharged to the storage tanks, otherwise to discharge the concentrated HLLW in 2M HNO3 at the specified volume concentration should require an additional evaporation to a higher concentration followed by a dilution procedure.

ACKNOWLEDGEMENT

All experimental work in this paper was performed at the Remote Handling Wing, Building 220, Harwell Laboratoy by the AEA Technology under a contract to Hitachi, Ltd. Authors wish to acknowledge the contributions made by Mr. CE Lyon, Mr. J.G. Hensley, Mr. R.J. Pateman, Mr. W.P. Stanaway, Mr. A.L. Mills and J.W. Harrison of the AEA Technology.

ABSTRACT

Alternative SYNROC production technology using the melting in high frequency induction melter - "cold crucible" is proposed. SYNROC-A, B and C compositions have been produced. The process of SYNROC-B and C production by melting, phase composition and structure of materials were studied in detail. SYNROC-B and C were produced at 1650-1800 and 1600-1700 oC respectively on lab-scale and scale-up levels. The melt capacity is widely varied (4-15 kg/h). An average specific melt capacity is 690-1062 kg/(m2 h) and depends on melt composition and melter type. It is greater than one for glassmelt at the same condition by a factors of 3 to 5. At SYNROC-C melting the total cesium loss from the crucible was estimated as 3-5%.
Melted SYNROC-B consisted of zirconolite, perovskite, hollandite and minor rutile. Crystal dimensions in quenched and annealed (slowly cooled) SYNROC-B were from 0.05 to 0.7 mm and from 0.05 to 1.5 mm respectively.
Quenched SYNROC-C samples contained zirconolite (45-50%), hollandite (35-40%), perovskite (10-15%) and minor powellite (<1%). The latter was formed due to oxidizing melting condition. Their crystal dimensions were 0.07-0.2, 0.05-0.15, ~10-2 and ~10-3 mm respectively. The mineral composition of the upper part of the slowly cooled block is similar to quenched sample. In the center of the slowly cooled block of SYNROC-C the crystal dimension can reach 1 mm.
In SYNROC-C cesium enters hollandite (58% of total content), powellite (25%) and zirconolite (17%), strontium distributes between powellite (40%), perovskite (36%) and hollandite (24%), REE enters zirconolite (55-70%) and perovskite (30-45%), most of molybdenum enters powellite under existing melting condition. The leach rates of the most of elements are at the same level as hot-pressed SYNROC-C except cesium, strontium and molybdenum. Their elevated leaching are connected to powellite formation.
The main problems observed during SYNROC production through melting stage were as follows: dry batch dusting, melt sputtering, formation of cavities and large crystals as well as undesirable phases such as powellite. A demonstration plant is being under development now. To avoid the above-mentioned problems some methods of waste and batch preparation are proposed. Pilot plant for SYNROC production was suggested to be 160 kW output power operated at 1.76 MHz with expected melt capacity 25-40 kg/h at operating temperature of 1400-1500 oC.

INTRODUCTION

SYNROC is titanate-based ceramics developed in Australia for immobilization of high

level waste (HLW) containing mainly alkali earth, transition, rare earth and actinide elements (1-5). The basic method of SYNROC production is hot-pressing (2). In that case the principal demand is to be ensured a vigorous conduction of solid phase reactions in the batch to form a desirable mineral assemblage. It requires a careful preparation of precursors, application of high temperature and pressure to consolidate the product.

SYNROC melting process was also being considered in Australia (1) and Germany (6). SYNROC melting point has been established to be high (1350oC and higher) (2). There was a problem of an unavailability of small reliable safe and remotely operated melters with long life time being able to operate at high temperatures. This problem has been partially solved in the beginning of 1980's. Developed in France and Russia so-called "cold crucible" - high frequency induction melter does not contain any refractories and electrodes. The crucible is manufactured from metal (usually copper or steel) tubes. Electromagnetic field is induced in the melt. To start up the process it is necessary to form an initial melt by means of heating of conductive material charged in the crucible together with batch. These can be, for example, graphite (as pieces), metal powder, etc. Moreover, the initial melt may be produced by heating of non-conductive batch from external source such as fuel burner, plasmatrone, microwave generator, pyrophore species etc. Principle of so-called "skull melting" excludes the contact of aggressive melt with the crucible metal walls. A layer of the partially melted batch protects the metal pipes from corrosion. The thickness of this layer depends on the melt composition and properties. For the "short" melts such as tintanate-based this layer is very thin. For the "long" glassmelts it can reach of several millimeters. Operating temperatures are limited only the thickness of the protecting layer depended on the cooling water flow rate. A lot of materials such as silica, alumina, zirconia, thoria, spinels, garnets and other minerals were easily melted in cold crucible since the beginning of 1970's (7).

The material corresponding to SYNROC formulation as well as another mineral-type materials potentially suitable for nuclear waste immobilization were produced in small crucibles operated at frequency of 5.28 MHz (8). A detailed investigation of the materials produced has not been performed.

Since 1985 works on an application of high frequency inductive melting are being conducted in SIA "Radon" in cooperation with St.-Petersburg University of Electric Engineering. The works on SYNROC production by the melting in cold crucible were started in 1990. The first samples of SYNROC-A and B formulations were produced in the same year. The melter charged by 1 dm3 of melt, operated at 1.76 MHz and energized from 60 kW high frequency generator was applied. The materials produced corresponded to SYNROC mineral assemblage and their properties were approximately the same as hot-pressed SYNROC (9). A process flexibility has been demonstrated. Any periodical, semi-continuous and continuous modes of operation were realized. Preliminary experience of Radon in the field of SYNROC melting was reported in (9-11). In this work recent advances of Radon in SYNROC melting process development are presented.

LAB-SCALE SYNROC PRODUCTION AND CHARACTERIZATION

The aim of the first step of work is to prove a possibility of SYNROC formation through the melt crystallization stage. So, SYNROC-B and SYNROC-C formulations (2,3) were chosen as basic materials for the study. Calculated materials compositions in wt.% as follows

SYNROC-B: 60.3 TiO_2, 10.8 ZrO_2, 6.3 Al_2O_3, 16.2 CaO, 6.4 BaO (2);
SYNROC-C: 54.6 TiO_2, 11.1 ZrO_2, 6.1 Al_2O_3, 13.5 CaO, 6.1 BaO, 1.0 CeO_2, 2.8 Nd_2O_3, 0.4 Eu_2O_3, 1.0 FeO, 1.6 MoO_2, 0.8 Cs_2O, 0.6 SrO, 0.3 NiO (3).

A basic laboratory works are being performed as follows:

- experimental study of SYNROC production through melting in lab-scale cold crucibles (1-5 dm3);
- evaluation of process variables and operation stability;
- characterization of product to determine the correspondence of phase composition of SYNROC produced to calculated and reference data;
- investigation of radionuclide distribution between co-existing phases;
- determination of the melted SYNROC properties;
- a comparison of phase composition and properties of melted SYNROC and hot-pressed SYNROCs known from reference data;
- modification of SYNROC formulation taking into account radwaste composition in

Russia and former USSR.
Lab-scale cold crucible is vessel of round or elliptic cross-section with 50-100 mm in inside diameter and 70-200 mm in height formed from the stainless steel or copper water-cooled tubes. It is surrounded by copper inductor. The crucible dimensions, a gap between the pipes and the number of the inductor turns are calculated from electrophysical properties of the melt and power and frequency of the generator used. However, because of difficulty of the measurement of the "short" melt electrophysical properties the crucible dimensions are selected experimentally. Commercially available high frequency generators with output power 60 kW operating at frequency of 1.76 or 5.28 MHz was used as power source. Crucible with inductor was placed in process box supplied by off-gas tube connected to gas purification system. This system consists of sleeve filter, glass fiber filter and reactor for catalytic decomposition of NOx.
The SYNROC-B batch was prepared in the vessel equipped by agitator. Screw feeding of SYNROC-B batch was conducted. The SYNROC-C batch preparation was conducted as follows. Simulated HLW components as well as Ca, Ba and Al were taken as nitrate solutions. Titania and zirconia were admixed to this solution as crystalline oxides at the mixing. Suspension prepared was dried in rotary evaporator and fed into the crucible by screw. In both cases the titanium powder was employed for starting heating and initial melt production.
The main process variables (average values) are presented in Table I.
Powdered batch was melted with high rate. However, active hydrodynamic condition resulted not only in the vigorous melt agitation but the sputtering as well, because of very low melt viscosity (<1 Pa s) and surface tension. This is a troublesome phenomenon are able to lead to ejection of the melt droplets from the crucible. Therefore, it is necessary to maintain a certain melt level in the crucible.
Very high process temperature leads to an evaporation of easy volatile components such as cesium. Total cesium loss from the crucible was estimated as 3-5%. Practically all of cesium was trapped in the off-gas purification system.
As seen from Table I, the SYNROC melting process is high productive. SYNROC melt capacity was higher than borosilicate glass capacity by factors of 3 to 5 (10). The melting ratio in both processes is approximately the same (10). So, from technological point of view SYNROC melting process excels glass melting process.
Materials produced were fully crystalline. They were investigated by X-ray diffraction ("DRON-3", Cu K-radiation), optical microscopy ("POLAM L-213"), electron microscopy ("JEM 100c") and electron-probe microanalysis ("Camebax micro-beam", U=20 keV, I=1-3 nA). Leach tests were performed according to IAEA technique (12).
Poured and solidified SYNROC-B material consists of green-gray and grayish-brown sections. The gray-green sections contain microbubbles (0.3-0.5 mm) and tube gas channels (1-2.5 mm). The principal phases are zirconolite (25-30%), perovskite (25-30%), rutile (25-30%) and hollandite (10-15%). Spinel was observed as an insignificant impurity. Zirconolite and rutile crystal dimensions were 0.15-0.7, 0.01-0.05 mm respectively. Compositions of zirconolite, hollandite, rutile and spinel are on the average Ca0.95Al0.14Ti2.22Zr0.70O7.00, Na0.24Ca0.30Ba0.87Al1.86Ti5.92Zr0.04O16.00, Ca0.04Ti1.91Zr0.05O4.00 and Na0.02Ca0.28Ba0.02Al1.94 Ti0.38Zr0.01O4.00 respectively. Sodium presents as impurity.
The grayish-brown sections have microbubble porous texture and fine-grained structure. The large (0.3-0.5 to 1.5 mm) single crystals of zirconolite and microcrystalline assemblage of hollandite and perovskite were observed in the bulk. Hollandite and perovskite crystals measure 0.1-0.5 and 0.05-0.15 mm respectively. These sections contain 40-45% of zirconolite, 30-35% of hollandite, 15-20% of perovskite and 5-10% of rutile. Their formulations are Ca0.93Al0.15Ti2.06Zr0.86O7.00 (zirconolite), Na0.08Ca0.20Ba0.98Al2.00 Ti5.86Zr0.03O16.00 (hollandite), Na0.01Ca0.97Ti1.00Zr0.01O3.00 (perovskite), Ca0.02Ti1.94Zr0.05O4.00 (rutile).
Three samples of SYNROC-C were studied. The sample C-1 was prepared by the melt quenching on metal plate at room temperature. The lower part of sample C-1 is dense and compact. The upper part of the same sample has microporous texture. Zirconolite, hallandite, perovskite and powellite were found in both parts of the sample. The crystal dimensions of zirconolite, hollandite, perovskite and powellite are 0.07-0.2, 0.05-1.5, ~10-2 and 10-3 mm, respectively. Their crystal chemcal formulations are found to be Ca0.83FeII0.03Ni0.02 Al0.19CeIII0.05Nd0.04Ti2.09Zr0.76O7.00 (zirconolite),

$Cs_{0.01}Ca_{0.30}Sr_{0.06}Ba_{0.83}Fe^{II}_{0.19}Ni_{0.18}Al_{1.42}Ce^{III}_{0.01}Ti_{5.93}Zr_{0.15}Si_{0.01}Mo^{VI}_{0.03}O_{16.00}$ (hollandite), $Ca_{0.80}Sr_{0.06}Al_{0.03}Ce^{III}_{0.06}Nd_{0.03}Ti_{0.97}O_{3.00}$ (perovskite), $Cs_{0.01}Ca_{0.66}Sr_{0.18}Ba_{0.26}Fe^{II}_{0.03}Ni_{0.01}Al_{0.16}Ce^{III}_{0.01}Ti_{0.09}Si_{0.01}Mo^{VI}_{0.80}O_{4.00}$ (powel-lite). The debala-nce observed in some cases is obviously due to the presence of the part of iron and cerium in higher valency state. Moreover, the crystal splices of the second generation of hollandite with zirconolite and perovskite (hollandite is predominate) were established. Firstly and secondly generated minerals are differentiated by the crystal dimensions and the intergrowth type and, in some cases, chemical composition as well. For example, hollandite of the first generation contains more Ti, Ca, Sr, Zr and less Al compared to hollandite of the second generation. In total the sample C-1 consists of 45-50% of zirconolite, 35-40% of hollandite, 10-15% of perovskite and <1% of powellite.

The residual melt in the cold crucible was slowly cooled and solidified. The block prepared is inhomogeneous and consists of four zones (Fig. 1). The material in zone 1 is the most dense and fine-grained. The largest crystals are located in zone 3. Zone 2 is intermediate. A lot of gas channels and bubbles are located in zone 4. Two samples from the whole block were cut. The sample C-2 was cut from the upper part of block (zone 1). This sample is not fully uniform too, however, the chemical compositions of its different parts are similar (in wt.%): 0.43 Cs_2O, 17.24 CaO, 2.15 SrO, 2.52 BaO, 1.44 FeO, 1.38 NiO, 12.12 Al_2O_3, 1.83 Ce_2O_3, 2.12 Nd_2O_3, 0.36 SiO_2, 36.25 TiO_2, 19.16 ZrO_2, 3.00 MoO_3. The difference is in crystal dimensions which grow towards the block center. Quantitative minerals ratio in zone 1 is approximately 45-50% of zirconolite, 35-40% of hollandite and 10-15% of perovskite.

The sample C-3 was cut as shown in Fig. 1. The sample is very porous in the near-bottom part. In the central part of the block the sample is dense not containing gas channels although it contains gas bubbles because of gas release was not completed. In this zone 3 the crystal dimensions reach 1 mm. Quantitative mineral ratio is close to one for the sample C-2. Average compositions of minerals as follows: $Ca_{0.84}Fe^{II}_{0.02}Ni_{0.01}Al_{0.19}Ce^{III}_{0.03}Nd_{0.04}Ti_{1.98}Zr_{0.89}O_{7.00}$ (zirconolite), $Cs_{0.01}Ca_{0.06}Sr_{0.03}Ba_{1.02}Fe^{II}_{0.07}Ni_{0.11}Al_{1.94}Ce^{III}_{0.01}Ti_{5.84}Zr_{0.05}O_{16.00}$ (hollandite), $Ca_{0.81}Sr_{0.05}Al_{0.01}Ce^{III}_{0.04}Nd_{0.03}Ti_{1.00}O_{3.00}$ (perovskite), $Ca_{0.01}Fe^{II}_{0.01}Ti_{1.92}Zr_{0.05}Mo^{VI}_{0.01}O_{4.00}$ (rutile) and $Ca_{0.30}Sr_{0.17}Ba_{0.16}Al_{0.02}Ti_{0.02}Mo_{1.10}O_{4.00}$ (powellite). Minor debalance on perovskite and rutile may be connected to transition of the part of Fe(II) and Ce(III) to Fe(III) and Ce(IV) respectively under the air melting condition.

Waste elements partitioning between the co-existing mineral phases from electron-probe micro-analysis data is shown in Table II.

A comparison of the partitioning of waste elements in SYNROC-C produced by hot-pressing (2) and melting in cold crucible is given in Table III.

As seen from Table III, there is some difference in the waste elements partitioning between hot-pressed and melted SYNROC-C probably due to difference in redox conditions. Formation of additional Mo-containing phase of powellite results in the transfer of the significant fraction of strontium and minor cesium to this phase. Unlike hot-pressed SYNROC-C, REE enter both zirconolite and perovskite phases of melted SYNROC-C. Moreover there was no formation of metal alloy at SYNROC melting probably due to mainly oxidizing melting condition. The partitioning of actinides, noble metals and halcogens is now being studied.

Although metal titanium was introduced in the first portion of batch charged into the crucible to produce the initial melt for the start up, its quantity was deficient to ensure the melting reducing condition. Possibly an addition of carbon-based reducing agent must be used to maintain the reducing condition of the melting process.

The results of leach tests are shown on Fig. 2. The leach rate of the most of elements from melted SYNROC-C is at the same level as hot-pressed SYNROC-C except Cs, Sr and Mo. Elevated leach rate of these elements is due to powellite formation. A SYNROC-C doped by Pu has also been produced and the leach rate of Pu has been measured (see Fig. 2). The detailed results of the leach tests will be reported separately.

So, it has been shown from lab-scale experiments that the main problems at SYNROC melting as follows:

dry batch dusting;

low melt viscosity and high melt fluidity and mobility resulting in the sputtering;
formation of gas cavities because of unfinished gas release and cavities at block shrinkage;
formation of large crystals in the central part of the block are being troublesome at alpha-recoil damage and spontaneous fission;
crystal dimension distribution by block height and cross-section;
formation of the undesirable phases because of difficulty of maintenance suitable redox condition.

A work on incorporation of actinide-containing incinerator ash in material similar to SYNROC-A is also being carried out. Incinerator ash oxides contain up to 35 wt.% of SiO2, up to 10 wt.% of mixed alkali oxides (mainly Na2O and K2O) and up to 15 wt.% of P2O5. The rest of oxides are typical for SYNROC (CaO, Al2O3, FeO and other transition metal oxides). The first samples produced have demonstrated a high chemical durability.

INTERMEDIATE-SCALE SYNROC PRODUCTION AND CHARACTERIZATION

First experiments on SYNROC production by melting were performed on simulated intermediate-level waste vitrification pilot plant. This plant was not designed for SYNROC production, however the results reached were quite acceptable. The main results of experiments on intermediate-scale SYNROC production were reported before (9-11). The crucible with melt volume of 10 dm3 and melt area of 0.05 m2 and high frequency generators with output power of 60 or 160 kW were applied for systematical development. The batch preparation and off-gas purification systems were the same type as ones in lab-scale experiments.

Preliminary experiments were conducted at relatively low melt capacity -8-13.5 kg/h (10,11) to try out the batch preparation unit and melters and optimize the process variables. Then it has been shown that melt capacity may be increased to 25-30 kg/h. As before the main problems were the same as in lab-scale experiments.

A demonstration plant is being under development now. Improved batch feeding system is provided. A set of alternatives is being under consideration such as granulation with high carbon binder, low temperature calcination, sol-gel process, wet feeding, direct joining of rotary evaporator to melter. These methods have both advantages and disadvantages. So, melting of precursors prepared by sol-gel method has to increase of melt capacity and produces the high homogeneous material. But, this process is very complex from technical point of view. Wet slurry feeding avoids the dusting, but at the same time increases the sputtering. At the direct joining of rotary evaporator to melter it is difficult to ensure a synchronized operation of these apparata. The development of granulation method is not finished yet. Most probably on the first stage the direct joining of rotary evaporator to melter will be employed. Simultaneously, the development of batch granulation and calcination processes will be conducted.

Current works provide for development and trial of process with existing equipment to eliminate the disadvantages occurring on the melting stage and during the cooling, solidification and annealing (formation of undesirable phases at violation of redox condition, crystal growth, unfinished gas release, formation of cavities at block shrinkage, etc.). To suppress the crystal growth it is necessary to ensure a rapid heat removal from material. It is possible by melt casting as plates or melt granulation.

Moreover a trial of SYNROC compositions is being conducted including uranium-containing compositions such as U-doped SYNROC-C and zirconolite-rich formulation (13). An experiments on production of SYNROC-F is set on 1995.

PROPOSALS ON PILOT PLANT

Proposed process block diagram is shown on Fig. 3. The batch prepared must be fed into the cold crucible energized from generator with output power 160 kW operated at 1.76 MHz. Expected melt capacity is 25-40 kg/h at the operating temperature of 1400-1500oC. Such capacity approximately corresponds to industrial-scale plant. Processing of nitrate solution will require a recovery of nitrogen oxides with nitric acid regeneration, which can be utilized for the interior technical purposes. Off-gas deposit trapped in gas purification system will be recycled. SYNROC melt will be poured directly into containers or charged after preliminary granulation. If the blocks of solidified material will be formed they must be annealed. and then headed for storage.

At the first stage the plant will operate in inactive regime. At the second stage a

simulated SYNROC doped by radionuclides will be produced. The third stage of works an experiments on production of fully active SYNROC is supposed.

CONCLUSION

SYNROC produced by means of the melting and melt solidification is similar to hot-pressed SYNROC. Almost the same mineral assemblage and radionuclides partitioning are observed. The main distinguish of the melted SYNROC from the hot-pressed one is the formation of powellite phase due to the oxidizing melting condition. It is necessary to reproduce the experiments on SYNROC melting under reducing condition to suppress the molybdate formation.

ABSTRACT

At the Nevada Test Site, one potentially disruptive scenario being evaluated for the

Greater Confinement Disposal (GCD) Facility Performance Assessment is deep post-closure erosion that would expose buried radioactive waste to the accessible environment. The GCD Facility located at the Area 5 Radioactive Waste Management Site (RWMS) lies at the juncture of three alluvial fan systems. Geomorphic surface mapping in northern Frenchman Flat indicates that reaches of these fans where the RWMS is now located have been constructional since at least the middle Quaternary. Mapping indicates a regular sequence of prograding fans with entrenchment of the older fan surfaces near the mountain fronts and construction of progressively younger inset fans farther from the mountain fronts. At the facility, the oldest fan surfaces are of late Pleistocene and Holocene age. More recent geomorphic activity has been limited to erosion and deposition along small channels. Trench and pit wall mapping found maximum incision in the vicinity of the RWMS to be less than 1.5 m. Based on collected data, natural geomorphic processes are unlikely to result in erosion to a depth of more than approximately 2 m at the facility within the 10,000-year regulatory period.

INTRODUCTION

At the Nevada Test Site (NTS), one potentially disruptive scenario being evaluated in the Greater Confinement Disposal (GCD) Facility Performance Assessment (PA) is post-closure erosion that would expose buried radioactive waste to the accessible environment (1,2). The GCD Facility is located at the Area 5 Radioactive Waste Management Site (RWMS) in Frenchman Flat, along the eastern boundary of the NTS. This closed basin formed since the middle Miocene (3,4). Alluvium in northern Frenchman Flat is late Miocene to Holocene, with most of the landscape covered with Quaternary alluvium. The RWMS is located at the juncture of three coalescing alluvial fan systems: the Scarp Canyon and Nye Canyon (SC-NC) fan piedmont from the northeast; the southern Halfpint Range and Massachusetts Mountains (SHR-MM) fan piedmont from the north and northwest; and the Barren Wash fan from the west. The Quaternary history of these three prograding fan systems is most relevant to the discussion of erosion and landscape evolution at the RWMS. This paper outlines the surficial geologic history at the RWMS and its implications for future landscape development.

SURFICIAL GEOLOGY

Preliminary geomorphic surface maps have been completed for northern Frenchman Flat. This 1:6000-scale mapping used aerial photographs and field mapping to determine boundaries and composition of map units. Criteria for defining the various geomorphic surfaces include relative geomorphic position, landform morphology, and degree of preservation of surface morphology (5, 6). Seven major geomorphic surfaces are recognized in northern Frenchman Flat. These surfaces range from early Quaternary to historic in age (Table I).

The most dramatic geomorphic features in northern Frenchman Flat are related to evolution of the SC-NC fan piedmont. It is characterized by broad areas of the oldest geomorphic surfaces (S2 and S3). Drainage patterns and clast provenance of the S2 and S3 surfaces indicate that Nye Canyon was the principal source for the alluvium issuing into northern Frenchman Flat in S2 and S3 time. Subsurface investigations indicate these deposition extended to the RWMS (7). Subsequent incision of these old surfaces began in either late S3 or early S4 time. Evidence for this is that S3 surfaces are the youngest fan surfaces entrenched and that terrace remnants with S4 surfaces are the oldest deposits preserved in the canyons. Presumably this incision of Scarp and Nye canyons was climate-driven during late S3 (glacial?) time. The deep fan-head incision means that these canyons continue to distribute water and alluvium to an inset fan (S4-S7 surfaces) downslope of the RWMS (Fig. 1).

Incision of the SC-NC fan piedmont has left the S2 and S3 surfaces as relict fan surfaces. Subsequently, surfaces of S4 and S5 age have formed at the RWMS as a result of: 1) internal drainage on the broad S3 surface; and, 2) drainage along the southeastern flank of the Halfpint Range being directed southwest along the boundary between the SC-NC and SHR-MM fan piedmonts. These surfaces are within the Halfpint Alluvial Fan (Fig.1) of Miller et al. (8). This area of deposition and the erosional landscape upslope is an active drainage subbasin, with most recent geomorphic activity limited to erosion and deposition along small channels (S6 and S7 surfaces).

Geomorphic mapping of the SHR-MM fan piedmont indicates a regular sequence of prograding fans with entrenchment of the older fans near the mountain fronts and

construction of progressively younger inset fans farther from the mountain fronts. At the RWMS, the oldest fan surfaces are of S4 and S5 age. More recent geomorphic activity (S6 and S7 surfaces) has been limited to erosion and deposition along small channels.

Although Barren Wash watershed drains a large part of western Frenchman Flat basin (8), only a small part of this large fan system is within the study area (Fig. 1). The particular fan of interest issues from the west around the southern tip of the Massachusetts Mountains and converges with the other two fan systems at the RWMS. Much of the fan consists of S3 and S4 fan remnants. As with the other two fans, the most extensive surface near the RWMS is of S5 age, with more recent geomorphic activity (S6 and S7 surfaces) being limited to erosion and deposition along small channels.

CHANNEL EROSION

Although geomorphic mapping indicates that the RWMS has been a point of net aggradation since at least S3 time, local incision and local aggradation have been active geomorphic processes even in the depositional portion of these alluvial fans. Detailed mapping of pits and trenches at and near the RWMS provide insight into the type and depth of past channel incision.

At the RWMS, 425 m of pit walls were mapped and sampled to obtain detailed near-surface information about the alluvium to depth of about 8 m (7). This conglomeritic to fine-grained alluvium represents deposition on the lower-middle to distal part of a large fan issuing into Frenchman Flat from the northeast. The alluvium displays characteristics typical of sediments deposited by sheet-floods, in stream channels, and as thin debris flows. Field observations indicate that the landscape at the RWMS has developed by planation by relatively shallow streams rather than by deep stream incision and backfilling. Cross-sectional measurements indicate that paleochannels are less than 1 m deep and typically less than 0.5 m deep.

The four trenches mapped near the RWMS are located at or below the intersection points of the SC-NC and SHR-MM fan piedmonts. Based on measurements of paleochannels and reconstruction of soil profiles at these trenches, the maximum depth of incision was approximately 1.5 m (9, 10). Most of the erosion was less than 0.8 m deep. These depths are similar to data from the pit walls at the RWMS.

CONCLUSIONS

The RWMS Facility lies at the juncture of three alluvial fan systems. Geomorphic surface mapping in northern Frenchman Flat indicates that since at least S3 time, the RWMS has been located in the constructional reaches of these three fan systems. Furthermore, mapping indicates a regular sequence of prograding fans with entrenchment of the older fans near the mountain fronts and construction of progressively younger inset fans farther from the mountain fronts. At the RWMS, the oldest fan surfaces are of S4 and S5 age. More recent geomorphic activity (S6 and S7 surfaces) has been limited to erosion and deposition along small channels. Trench and pit wall mapping found maximum incision in the vicinity of the RWMS to be less than 1.5 m. Based on collected data, natural geomorphic processes are unlikely to result in erosion to a depth of more than approximately 2 m at the RWMS within the 10,000-year regulatory period.

CREDIBLE FUTURE CLIMATE FOR THE NEVADA TEST SITE FOR THE NEXT 10,000 YEARS

Safety and Risk Assessment Department

ABSTRACT

During the mid-1980's, transuranic wastes were disposed of using the Greater Confinement Disposal (GCD) concept, which consists of 3m diameter by 37m deep boreholes located at the Nevada Test Site (NTS). Federal law (40 CFR 191) governing the disposal of transuranic (TRU) wastes requires the assessment of plausible future events and processes that may affect the performance of the disposal system during the next 10,000 years. Performance assessment indicates that changes in the present climate may impact the performance of the disposal system. The screening of processes expected to be affected by changes in climate indicates that roots associated with deep-rooting plants, such as juniper, may have a major impact on facility performance.

Presently, no deep-rooting plants exist in the immediate vicinity of the GCD facility, but may migrate to the area due to increases in precipitation resulting from climate change. The Climate Change Task was initiated for the purpose of defining possible future climate states, and to estimate the affect of possible future climate change on modeling parameters.

The purpose of this paper is to present background information on global paleoclimate records leading to the definition of possible future climate states based on the results of an analysis performed at the Lamont-Doherty Geologic Observatory at Columbia University. This paper does not attempt to link those climate states to a parameter such as precipitation which will in turn indicate conditions conducive to the growth of deep-rooting plants such as juniper. We intend to develop this link through existing literature which evaluates paleobotanical data collected from pack rat middens in the vicinity of the Nevada Test Site. After establishing the link and identifying the climate state that corresponds to the growth of deep-rooting plants, it will be possible to use the results of this paper to estimate the probability of that climate state occurring during the next ten thousand years at the GCD facility.

The results of this study indicate that climate at the NTS will be gradually changing from the interglacial state we are presently experiencing to a cooler interstadial state in the next several thousand years. However, the variability associated with that future interstadial state will increase dramatically during the same time period. This indicates that although the mean climate is not expected to change radically, any climate state from an interglacial to a full glacial is possible.

THE GREATER CONFINEMENT DISPOSAL PROJECT

In 1981, the DOE's Defense Low-Level Waste Management Program asked the Nevada Operations Office of the DOE (DOE/NV) to demonstrate the feasibility of the Greater Confinement Disposal (GCD) concept for disposal of Low-Level Waste (LLW) and certain high specific activity LLW (i.e. tritium) in an arid region. The GCD concept was so named because it provides greater confinement than near-surface burial. This greater confinement is needed for wastes for which near-surface burial is not an appropriate disposal method. Located in the Radioactive Waste Management Site at Area 5 of the Nevada Test Site, this disposal facility consists of boreholes approximately 3m in diameter and 37m deep. Waste is emplaced in the bottom 15m of the borehole and the remaining 22m from the top of the waste to the land surface is backfilled with native alluvium. The bottom of each borehole is approximately 200m above the water table. The average precipitation at the GCD site is approximately 10 cm/yr. Between 1984 and 1989, high specific activity LLW was disposed of in the GCD facility. In addition to this high specific activity LLW, a small quantity of transuranic (TRU) waste was disposed of in four of the GCD boreholes.

GCD PERFORMANCE ASSESSMENT

The regulation governing the disposal of TRU wastes, 40 CFR 191 (1), requires assessing the performance of the disposal system for 10,000 years. To determine the likelihood that the waste placed in the GCD boreholes will comply with the containment requirements of 40 CFR 191, Sandia National Laboratories has applied an iterative Performance Assessment (PA) based on the high-level waste PA methodology developed for U.S. Nuclear Regulatory Commission (2).

The application of this performance assessment methodology to the GCD facility consists of: i) conducting a PA with respect to the containment requirements of 40 CFR 191; ii) determining the processes and parameters that have the greatest influence on the PA results; iii) conducting site characterization activities and additional analysis to reduce the uncertainty associated with the most important processes and parameters; and iv) updating the PA models based on the results from site characterization activities.

In addition to analyzing the facility's performance under current hydrologic conditions, the PA has also analyzed the effect of three disruptive events. These three events (erosion, human intrusion, and climate change) are thought to have the highest likelihood of occurrence relative to all the events and processes evaluated during the screening process.

CLIMATE CHANGE FOR THE PA OF THE GCD SITE

It was beyond the scope of the preliminary PA to consider the evolution of global climate over the 10,000 year period of regulatory concern. Consequently, a simple and conservative approach to simulating the potential impacts of climate change was taken. If this simulation did not result in a modeled violation of performance objectives by itself or when combined with other conditions such as erosion, no additional analysis or gathering of data would be justified. If the simulation did result in modeled violations, additional data would be gathered and included in the modeling efforts, assuming the additional data would justify the relaxation of the original conservative assumptions.

The conservative approach used in the preliminary PA to estimate the potential effects of climate change consisted of modeling the system under a new steady state that began at the present and extended through the next 10,000 years. Climate change was simulated by increasing the current recharge rate by a factor of 20, and raising the level of the water table by 50m. These conditions, when combined with other parameters, resulted in calculated releases exceeding the limits set in the containment requirements of 40 CFR 191. Because of the potential violation of 40 CFR 191, and because the preliminary PA climate change condition was based on what were believed to be very conservative assumptions, it was decided to better define the credible future climate states at the GCD facility, and the effects of these states on the performance of the GCD facility. The Climate Change Studies task was created to define a range of possible future climate states, and to estimate the potential biologic, geomorphologic, and hydrologic changes that might affect the disposal system to these future climate states. This paper addresses only the definition of possible future climate states.

CHOICE OF METHODOLOGY

Three approaches have been considered to define the future climate at the GCD site: i) use of subjective opinions; ii) use of models to simulate future conditions, and

iii) use of paleoclimate data to infer past climate conditions and then project those conditions forward in time.

The first method of defining the future climate at the GCD is to ask the opinion of "experts." The formal process of asking experts their opinion is referred to as the "elicitation and use of expert opinion." The process typically requires a trained facilitator, experts, some preliminary exchange of information, the formal elicitation process and follow up activities. In the case of climate change, the knowledge which is being elicited has its roots in empirical and/or modeled data (the other two methods of predicting the future). Each expert may synthesize these two inputs into an opinion, but as the final opinion must be based on modeled or empirical evidence it was decided to make direct use of the underlying data, and not use this elicitation process.

The second alternative method of defining the future climate at the GCD is through the use of global climate models (GCMs). The development and execution of a GCM computer code requires understanding of a large number of processes and conditions. As a result of the uncertainty associated with each of these processes and conditions, the predictions made by GCMs vary greatly and are often in question. In addition, the uncertainty of applying a GCM to local conditions also argues strongly against the GCM approach. Consequently, it was decided not to use GCMs at this point of the analysis; but it will be necessary to consider their results to evaluate the impact of anthropogenic climate change.

As a third method, paleoclimate data can be used to identify patterns in past climate, and then project those patterns into the future. For example, on the time scale of hundreds of years, we can plot past average daily temperatures from historical records against time (i.e., a time series). On this plot we would observe average daily temperatures increasing and decreasing in a periodic manner reflecting the seasonal cycles of summer and winter. On the time scale of hundreds of thousands of years we could plot average annual temperature against time. As with average daily temperatures we observe patterns, but in this case patterns of warmer and cooler climates. These patterns cannot be created from historical records as with temperature, but must be developed from analysis of ancient records having some relationship to climate such as: fossilized pack rat middens; ancient lake levels; pollens trapped in sediments; and oxygen isotope ratios preserved in ice, cave carbonates and marine sediments.

We have chosen to use paleoclimate records of this type as the basis for defining possible future climate states by identifying the patterns contained in the records and assuming those patterns will continue into the future. A primary assumption required for the use of paleoclimate records is that the range of future climate states will be bounded by those climate conditions that have occurred in the past. Since these records do not include the effects of anthropogenic climate change, attributed to increased amounts of greenhouse gases in the atmosphere, it may be necessary to adjust the results in some manner to incorporate the anticipated effects of anthropogenic climate change. We have not completed the research required to understand what these effects may be, and have not settled on a method of incorporating these effects into our analysis. Therefore, anthropogenic effects will not be considered in this paper.

RECORDS OF PAST CLIMATE

Long-term, direct records of temperature or precipitation at the GCD facility do not exist. However, there are a number of surrogates for past climate contained in paleoclimate records that are useful. For example the width of tree rings serves as a surrogate for temperature, runoff, precipitation, and soil moisture for periods of several hundred years. Fossil pollen types and concentrations are a surrogate for temperature, precipitation, and soil moisture for periods of hundreds or in some cases thousands of years. Oxygen isotope ratios from layered ice cores give a continuous measure of snow accumulation and a surrogate for temperature for periods in excess of several hundred thousand years. Calcium carbonate precipitated from natural spring water results in a continuous record of temperature dependent oxygen isotopes contained in regional groundwater for periods of hundreds of thousands of years. Marine sediments provide a continuous record of planktonic and benthic fossils, including the oxygen isotope composition of fossil remains, which are used to infer sea-surface temperature and global ice volume for periods of hundreds of thousands of years. In a similar manner, lake sediments yield a continuous isotopic record over hundreds of thousands of years that can be used to infer temperature,

precipitation and wind direction (3).
In an earlier paper (4), a number of paleoclimate records were considered while searching for a record that could serve as a surrogate for past climate at the GCD facility. Three of those records are included here to illustrate information contained in the records that will be important later in the paper. Each of the records uses d18O as the surrogate for climate, which by convention is the relative deviation of the ratio (18O/16O) contained in the sample, to the (18O/16O) contained in standard mean ocean water (SMOW). The first record considered is from marine sediments from locations in the Atlantic and Pacific, and consists of d18O plotted against age (5). The second is a record of d18O versus age contained in ice layers from the Greenland ice sheet (6). The third is a record of d18O versus age contained in carbonates from spring deposits in Devils Hole, Nevada (7,8).
The Marine d18O record, shown in Fig. 1, is a composite record from several sediment cores. These cores are from the western and eastern equatorial Pacific, the Caribbean Sea, and the North Atlantic.
The cores were sampled and dated on an interval ranging from 2000 to 6000 years, correlated using nonofficial biostratigraphy and paleomagnetic stratigraphy, and combined to build a composite record representing the last 1.88 million years (5). As the cores were taken from such varied locations throughout the world the composite record is thought to capture the global nature of past climate change.
Figure 2 illustrates the results of the joint European-Greenland Ice-core Project (GRIP) which during 1990-92, drilled an ice core in central Greenland (6). A preliminary chronology for the core was developed with the first 14.5 thousand years before present based on examination of the ice stratigraphy. The remainder of the core was age-dated using ice-flow modeling. This record yields a higher resolution than the Marine record as a result of a finer sampling interval. Assuming the age dating is correct, these results indicate that at least in Greenland, climate can vary at a much faster rate than indicated in the Marine record.
Figure 3 illustrates the results of the analysis of Winograd et al. (7,8) of two cores containing layered calcium carbonate precipitated from spring water. The oxygen bound in the calcium carbonate provides a continuous record of d18O fluctuations for the time period between 60 to 566 thousand years before present. Although the actual source of the water and travel time from the spring are uncertain, the record is expected to ultimately reflect the d18O of precipitation on the Spring Mountains of Nevada (9). As the GCD facility is approximately 110 km northwest of Las Vegas, and Devils Hole is located approximately 115 km west-northwest of Las Vegas, the Devils Hole record is the closest long term paleoclimate record to the GCD facility.

INFORMATION CONTAINED IN THE RECORDS

Prior to beginning the analysis of the records, it is appropriate to consider what information will be needed to define plausible future climate states. First, we need to establish a relationship between the d18O ratio contained in the records, and a characteristic of climate such as temperature. Second, we need to establish what state, or states, climate will take during the regulatory period, their duration if there is more than one, and finally any associated uncertainty.
Concerning the relationship between the ratio of d18O and temperature, the ratio of oxygen isotopes is strongly correlated with mean temperature (10). But, the relationship between d18O and temperature is not constant for different types of paleoclimate records, and also varies with geographic location. A comprehensive description of this behavior can be found in the paper by Rozanski et al. (11). Ignoring the technical details and simply accepting that mean temperature is proportional to d18O, it is apparent that the paleoclimate records contain a history of past climate, with mean temperatures varying between warm periods (interglacials) and cold periods (glacials).
Examination of the Marine record presented in Fig. 1 illustrates this behavior with a pattern that appears to be remarkably consistent for long periods of time. Milankovitch postulated that variations in climate were correlated to cycles in the Earth's orbit around the Sun; with these cycles having periods of 19, 24, 43, and 100 thousand years (12). Spectral and regression analysis performed on marine records indicates that a large portion of the variability seen in these records agrees with the periods defined by this theory (13). Since the primary frequencies attributed to the theory are several times as long as the regulatory period for the site, it is convenient to classify them as low frequency patterns. We consider the

Marine record of Fig. 1 to be a source of low frequency paleoclimate behavior. On the other hand, the Greenland Ice record of Fig. 2 appears to vary much more quickly, oscillating between upper and lower bounds in periods as short as tens of years. Consequently, we consider the Greenland Ice record to be a source of high frequency paleoclimate behavior.

The combination of these two records illustrates the existence of low and high frequency changes in climate that have occurred throughout the 250 thousand year period they share. We believe the low frequency behavior seen in the Marine record is a good approximation of the average global climate state during the last two of million years, while the Greenland Ice record serves to illustrate the extreme variability or high frequency variation that can occur. As the records indicate that past climate has included both high and low frequency patterns, any effort to estimate future climate states must incorporate both types of behavior. Therefore it will be necessary to combine records, as none of the records we have examined, or have presented here appear to be adequate for our purpose.

Examination of the Devils Hole record of Fig. 3 indicates this record contains patterns that are similar to those seen in the Marine record of Fig. 1. Although this is far from a quantitative proof that the patterns seen in global records are representative of local climate conditions, it does indicate that changes in climate which lead to full glacial conditions in the northern hemisphere also impact climate in the vicinity of the NTS, and the GCD facility.

DEFINING FUTURE CLIMATE STATES

In a recently released paper, Kukla and Gavin (14) document the results of an extensive investigation of paleoclimate records from locations throughout the world. Although the paper discusses many facets of paleoclimate records, the portion that is concerned with the development of a mean or average "glacial climate cycle" from paleoclimate records is of the greatest interest. In that section of their report, the authors chose seven different paleoclimate records considered to have high sampling and time resolutions on the order of approximately 500 to 2000 years. Included in this group are records based on marine sediments, ice cores, and pollen. As none of these records share the same relationship to temperature, they were transformed into a dimensionless measure of climate referred to as the Climate Index (CI) (15).

Recognizing the pattern of glacial/interglacial cycles seen in the paleoclimate records, Kukla and Gavin (14) chose to separate each of the records into individual glacial cycles, each illustrating a glacial cycle from its onset, to its termination. After the terminations of each glacial cycle where identified using the times established by Imbrie et al. (10), the records were broken into individual cycles resulting in a total of thirteen cycles from the seven paleoclimate records. By assuming the time associated with the beginning of each cycle was zero, the cycles were stacked creating an overlay of glacial cycles capturing the variability illustrated by the paleoclimate records. This result is presented in Fig. 4.

In addition, the authors established a relationship between the Climate Index and five principal Pleistocene climate states, allowing the division of the Climate Index, and consequently the glacial cycle into five climate states. These states are: i) interglacial, greater that 190 CI ; ii) temperate interstadial, greater than 163 CI and less than 190 CI; iii) interstadial, greater than 137 CI and less than 163 CI; iv) stadial, more than 109 CI and less than 137 CI; and finally v) full glacial, less than 109 CI.

By assuming that each of the thirteen cycles is equally likely to occur, it is possible to calculate an average climate for each the glacial cycles, and in addition, establish an upper and lower bound corresponding to the warmest and coolest climate index as illustrated in Fig. 5. If we assume the most recent glacial cycle terminated some twelve thousand years ago, we are able to locate ourselves within the overall glacial cycle, and from that point estimate the average climate state for the next ten thousand years. Examination of Fig. 5 indicates that the mean climate corresponding to the our present location within the glacial cycle, corresponds to the border between an interglacial and temperate interstadial. Consequently, the mean climate for the next ten thousand years, which will end at the point corresponding to twenty two thousand years from now, indicates a general cooling trend, but with a very large increase in the variability associated with the mean. This variability implies that in the next two thousand years or so, we may experience the continuation of an interglacial similar to what we are experiencing

today, or we may experience episodes of full glacial conditions. We are unable to reduce this level of variability without further investigation of the corresponding paleoclimate records. Therefore, our only recourse is to assume that each of the climate states within the upper and lower bounds are equally likely. As a result of this assumption, a uniform probability density function is the best choice to model the uncertainty associated with the mean climate state.

CONCLUSIONS

Climate change could impact the performance of the GCD facility. The goal of this activity is to define plausible future climate states for the period of regulatory concern, and estimate the effects on model parameters.

Having decided to use the patterns associated with past climate as depicted in paleoclimate records, we began an examination of the available records for use in our analysis. During that study, we recognized that some records (such as the Marine) contained low frequency glacial/interglacial cycles, and others (such as the Greenland Ice) contained high frequency glacial/interglacial cycles. As a result of this behavior, we concluded that no single record was capable of supplying sufficient accurate information to meet our needs, and it would be necessary to somehow combine a number of different records before any conclusions could be drawn. Kukla and Gavin (13) combined seven different paleoclimate records to create a portrayal of a glacial climate cycle. These results allow us to estimate the behavior of the average glacial cycle, albeit without the influence of anthropogenic climate change. In addition the cycle also allows an estimate of the variability associated with that average glacial cycle. By assuming that the last glacial period ended some twelve thousand years ago, we are able to use this information to estimate the mean climate state for the next ten thousand years along with its variance.

ABSTRACT

A stochastic model using a Markov process is proposed in this study with which the need for solving a set of partial differential for nuclide transport can be avoided. Once the single planar fracture in the porous rock is thought of as a series of finite number of compartments and such geologic system is assumed to have Markov property, since the Markov process requires that only the present value of the time dependent random variable (i.e., time dependent number of nuclides or concentration in certain compartment) be known to determine the future value of random variable, nuclide transport in the medium can be modeled as a continuous time Markov process. Through the study we introduce comparative results of the expectation and the variance of nuclide distribution describing the nuclide transport with chain decay of arbitrary members in the single fractured porous rock. To this end some comparisons between available analytical solutions are made.

INTRODUCTION

It is generally conceived that fractures in the bedrock surrounding a radioactive waste repository can play a very important role in the nuclide transport. In such bedrock, usually the permeability of the fracture is greater than that of the porous rock matrix itself offering a pathway for nuclide transport to the biosphere. Since Neretnieks (1) proposed an analytical model for nuclide transport in rock medium showing that the diffusion into the rock matrix from the fracture is very important mechanism to retard the nuclide, the conceptual model considering the fractured porous rock medium as the porous rock matrix having single planar fracture in it has been regarded as a convenient way to describe nuclide transport and has been discussed by many researchers in recent years (2).

Meanwhile, Nassar et al. (3) have applied continuous time Markov process model to stochastic formulation of chemical reaction in a continuous flow system. Knighton and Wagenet et al (4) recently have applied continuous time Markov process model to describing chemical movement through the soil.

Using the similar concept, the fractured rock medium can be considered as a series of discretized compartments of a finite number and the concentration of nuclide or equivalent number of nuclides can be considered as a time-dependent random variable. A random variable X(t) represents the state of the system at a time t, which is defined as a nuclide transition through a series of compartments of the fracture. Then the event X(t) = j denotes the position of a single nuclide to be compartment of the fracture (or state) j at time t. If the nuclide makes a transition from any compartment i to some other compartment j within a small time increment Dt, then there is a finite probability associated with that event.

The transition probabilities Pij(t) of nuclides, by which the nuclide distribution in the medium can be obtained are then formulated by utilizing the Chapman-Kolmogorov equations with the intensities of transition L(t), which are directly related to the processes affecting nuclide transition between and out of compartments.
A nuclide in a given time interval could make a transit to any compartment by groundwater flow or could form and disappear from any present compartment due to radioactive decay or molecular diffusive loss out of the system, i.e., from the fracture into the rock matrix through the fracture wall. All these processes are obviously conditional only on the present location of the radionuclide regardless of its previous history facilitating Markov conceptualization.
MODEL
As mentioned, in each compartment there are processes that influence the state of the nuclides at time t. Also the transition probability from a compartment to another is affected by the transition intensities. In a short time interval, nuclide transition between and out of compartments can be assumed to be governed deterministically. Therefore, once the flow rate of the groundwater between the compartments is known, the transition intensity of a nuclide from compartment i to compartment j at time t due to groundwater flow can be represented, under the assumption that groundwater is mixed well with nuclides instantly, as
Eq. (1)
where lij(t) and Qij(t) are the transition intensity and the volumetric flow rate of groundwater from compartment i to compartment j at time t, respectively, Vi is the volume of compartment i, and fi is the porosity of compartment i.
The transition probability is governed by the Kolmogorov forward differential Eqs. (5).
Eq. (2)
subject to the initial condition
Eq. (3)
which give the relation between the rate change of the transition probability and the transition intensity. A constraint of transition probability of Markov process is
Eq. (4)
Under the assumption of linear isotherm sorption of nuclides in the compartment i, lij(t) should be replaced by l ij(t) / Rfil where Rfil is retardation coefficient in the fracture. When the diffusive loss into the rock matrix in the direction perpendicular to the fracture from the fracture is considered, we should consider corresponding transition intensities for this loss process. The transition intensity for diffusive loss ldiffil(t) into rock matrix can be expressed as (6)
Eq. (5)
where Dbi is pore diffusion coefficient, bi is half-width of the fracture, Rpil is retardation coefficient in the rock matrix, and ll is radioactive decay constant.
Under the assumption that the transport is considered to be made only between adjacent compartments, the transition intensity matrix coefficients can be finally represented as
Eq. (6)
If we let Xil(t) be the random variable representing the number of lth nuclides in compartment i at time t, the distribution of all nuclides in the fracture and within any compartment can be represented as a function of the transition probability of each lth nuclide. For all N compartments,
Eq. (7)
Random vector Xl(t) can be broken again intoYl(t) and Zl(t):Yl(t) represents the number of survived nuclides by the time t, which were originally in the system at time O, and Zl(t) represents the number of nuclides that have entered the system during the time interval [O,t) and have survived in the respective compartment at time t.
If mil(O) denotes the number of nuclides in i at time O, at time t, each of the mil(O) must be either in one of the N compartments or disappear due to diffusion into the rock matrix and radioactive decay. Therefore, for a given mil(O), the distribution of Yjl(t), the remaining survived nuclides, at time t has multinomial distribution according to Eq. (4).
Now at any time t between time interval [O, t), suppose that nuclides flow into each compartment at the rate of z(t) per unit time. Then,

Eq. (8)
where Qi is volumetric flow rate of groundwater into the compartment i and Coil(t) is source concentration in Qi of the lth nuclide at time t, which is given by the solution of Bateman's differential equations as, with l ranging from 1 to the number of decay chain,
Eq. (9)
where is source concentration of the lth nuclide at time 0.
In case of imposing band release boundary condition at the inlet of the system, i.e., for the first compartment, for band release time q Eq. (8) replaced by
Eq. (10)
where U(t) is Heaviside step function.
Similarly, by analogy, at any time t between time interval [0, t), the change rate of nuclides into daughter component from its parent nuclide xil(t) is represented by
Eq. (11)
where Cil(t) is concentration of nuclide l in compartment i at time t.
As soon as a nuclide which fed freshly by supplying at the inlet of the system (Eq. (8)) or by forming due to the radioactive decay of its precursor enters the system (Eq (11)), it may begin to transfer to one of the other compartments at once or may disappear by either diffusion into the rock matrix or decay. Here we can assume that all nuclides in the system behave stochastically and independently with one another. Therefore, vector Zl(t) is the outcome of sequences of events of input, transition between the compartments, and survival from the decay and diffusion.
When both xil(t)dt, the number of new nuclides which entered a compartment during dt and d(t) xil (t) dt, the number of new nuclides that form in the ith compartment from the precursor nuclides in time interval dt have successfully entered compartment j, it must have a respective probability of Pij(t-t) either entering or remaining there. Therefore a binomial distribution can be formed for these new nuclides.
Therefore, finally we can get the expectancy and the variance of Xjl(t) from the distribution of the number of nuclides remaining in each compartment that have survived, as the convolution of the two independent distributions Yjl(t) and Zjl(t):
Eq. (12)
Eq. (13)
Consequently Cjl(t), the expected value and variance of concentration of the lth nuclides in j at time t can be expressed, respectively, as
Eq. (14)
Eq. (15)
Since the model presented here must be sensitive to the number of compartments of the system, in other words, the numerical dispersion phenomena will increase according to decreasing N, some quantitative estimation in the relation between N and the dispersion coefficient must be prerequisite. By comparing the one-dimensional system which is divided in to N compartments of equal size with the only one process of advective transport due to groundwater flow of constant rate and a common advection-dispersion equation for homogeneous porous medium that approximated by the centered difference equations by means of Taylor expansion, following approximate equivalence will be obtained:
Eq. (16)
Where L is the length of the system.
Since no analytical solutions in closed form to the decay chain transport with rock matrix diffusion are yet available, first we introduce a computational result for the case of no diffusion into the rock matrix, which yields one dimensional model for porous medium with decay chain. For simplicity, we further assumed the retardation coefficients of the lth member in the whole medium are equal, i.e., Ril = Rl for all l and for all compartments.
For the purpose of illustration only three members decay chain is considered and the data used are as follows:
DATA
A result by our continuous time Markov process model was compared against those obtained by Lung (7) through his code UCB-NE-40, designed for general solution for a chain of arbitrary length through the semi-infinite homogeneous medium for infinite release boundary condition.
In Fig. 1, the concentration profiles of the first, second, and third member, normalized to initial concentration of the first member at time 0 as a function of

distance at times equal to 100 and 1000 years, respectively, by the present model are plotted showing good comparison of corresponding analytical solution: one is for the retardation of 9352 at the time of 1000 years and the other for the retardation of 100 at the time of 100 years. Even though the retardation coefficients are the same for all members, the profiles at time 1000 years indicate that the third member of the decay chain can travel further along the fracture than the first and second since the half-life of the third member is approximately 15 and 436 times longer than those of the first and second, respectively. Then it is to be expected that the profiles of C1 and C2 at each time will tend to lag behind those of C3.
Breakthrough curves of the three members are also plotted showing relatively good agreement to corresponding analytical solution in Fig. 2 as a function of time at distances of 20 and 50 m, respectively.
As another specific example illustrates the results in case of consideration of the rock matrix diffusion with constant groundwater flow rate throughout in the fracture. The injection of the nuclide, as a source term takes place only in the first compartment, as is previous case, however, decay ingrowth is not considered in this study.
For single-fracture rock matrix system with process of diffusive loss into the rock matrix form the fracture, the parameter values used are as follows:

DATA

Relatively good agreement of concentration profile is obtained when compared with the solution of the deterministic differential equation governing the nuclide transport in the fracture with rock matrix diffusion, available in many literatures (2). As seen in Fig. 3, the results of the present model for values of the retardation coefficient of 5.0 both for the fracture and the rock matrix and decay constant of 0.023 yr-1 and no retardation and for another case of no decay are compared to the equivalent analytical solution adjusted with the equivalent dispersion coefficient in the fracture. For the latter case, the concentration profile in exact case for no dispersion in the fracture is also shown for reference, because it is also of interest to compare the analytical solution for the case of no dispersion in the fracture with the results obtained by present model in order to show the numerical dispersion due to spatial discretization of the medium.
As for the size of discrete time step T, the accuracy of the solution is shown to be improved when smaller size of discrete time is used (the result is not shown here). Figure 4, which is calculated at the distance of 20 m for three cases with respect to the retardation coefficient and the decay constant, exhibits relatively good agreement between continuous time Markov process model developed in this work and the deterministic analytical solution. However, some discrepancy appears in all breakthrough curves in this figure, which may be probably due to still insufficient discretization of space and time.

CONCLUSION

Through this study a stochastic model using continuous time Markov process for nuclide transport in the fractured rock medium has been developed.
Once the single planar fracture in the rock matrix is considered as a finite number of compartments in series, the medium is continuous in view of various processes associated with nuclide transport but discrete in medium space.
By calculating the transition probability for nuclide from the transition intensity between the compartment utilizing Chapman-Kolmogorov equation, the expectation and variance of nuclide distribution for compartment or fractured medium is obtained. Some comparisons between available analytical solutions have been made showing comparatively good agreement for all cases.
Even though the model developed in this study was shown to be sensitive to the number of discretized compartments showing numerical dispersion as the number of compartments increases, with compensating of dispersion coefficient, the present model is considered to agree well to deterministic analytical solutions. However, some discrepancy appears especially in the breakthrough curves for the case of considering the rock matrix diffusion, which may be probably due to insufficient discretization of both space and time.

HUMAN INTRUSION
Some Aspects of Regulation and Assessment of Future Human Actions at Radioactive Waste Disposal Sites

Mikael Jensen
Swedish Radiation Protection Institute
S-171 16 STOCKHOLM

ABSTRACT
A presentation in some detail of the problem of human intrusion is valuable. The issue is related to fundamental reasons why society disposes of the waste. If these questions are not addressed early in the licensing process, they are likely to turn up later as problems for both the waste management and the regulator.
Intrusion scenarios may include individuals who receive high doses, in excess of dose limits. This is a consequence of the strategy of waste isolation which cannot be rejected solely on the basis of the intruder's dose.
A logical presentation of the interdependence of some factors such as environmental consequences versus area restrictions makes it possible to describe this aspect of the licensing as a balanced decision.
An optimization study of the value of an information conservation system may be helpful in bringing into the open some important assumptions made in the human intrusion scenario. Some issues may be worthwhile to discuss: the problems of a large number of minor disturbances, of repeated intrusions and protection of a hypothetical drilling crew versus protection of the general public at risk as a result of the intrusion.
In licensing a repository with a life-time of thousands of years it is impossible to completely separate the responsibility of the waste management and the regulating system. However, it is the responsibility of the regulator to define its role in the process, where this could influence the environmental impact of the repository. This is also important in order to make the process as coherent and transparent as possible.

FUNDAMENTAL CONCEPTS

In the political and technical discussion of high level waste (HLW) disposal, several fundamental concepts must be dealt with, such as the potential danger of plutonium in the hands of future groups of people, even future governments. The same plutonium, however, can also be seen as a value to groups in the future. Thus plutonium may be treated as a detriment in one analysis, and as an asset in a another. Still another and perhaps predominant view is that plutonium as all other radioactive material is toxic and for that reason should be kept separated from the biosphere.
Some of the fundamentals of radioactive waste disposal may not be possible for a regulating agency to define by itself without a dialogue with political decision-makers. If for instance it is considered important to restrict the use of plutonium not only geographically, which is the rationale behind the Non-Proliferation Treaty, but also to restrict access to plutonium for governments in a distant future, then very deep boreholes (VDH) might be the most important alternative of the deep geological disposal options simply because this option could make the waste most difficult to retrieve.
The considerations above are ultimately political in nature, and it must be up the regulator to determine what decisions are necessary so that the prerequisites for a coherent process of waste disposal are at hand.
It follows that it is not possible to avoid the sense of illusiveness felt by many

about the idea of human intrusion, if some of the underlying concepts are not reexamined and given a stringent treatment.
It may therefore be necessary to have a set of fundamental, explicitly given, assumptions which defines society's motives for disposal of the waste. In defining these motives, a strategy should be presented that includes issues like the need for and the value of retrievability of the waste and repairability of the repository, including a description of the waste's potential future value or detriment as assessed by society today. Other concepts, mainly technical but also philosophical in nature can be expected to be decided upon by the regulator, and a few are presented below.
Waste Disposal Strategies and Protection Principles
For protection against toxic wastes, it is in principle possible to have two mutually excluding strategies exemplified by the expressions:
1 dilute and disperse, and
2 isolate and contain.
A complete radiation protection strategy also includes the three principles of Justification, Optimization and Dose Limitation. The first principle must be addressed already in the licensing process of the practice in which the waste is produced. Most often Optimization, the second principle above, leads to a choice of the second of the above mentioned strategies, isolation and containment in the form of a waste storage facility. The third radiation protection principle ensures the protection of single individuals in cases where the collective dose is deemed acceptable, but it is distributed in such a way that high doses are received by single individuals who may not receive all the benefits of the practice. According to ICRP, the principle of dose limitation should be regarded as a boundary condition to the process of optimization.
The principle "dilute and disperse" may seem provocative but releases to the environment may occur for various reasons:
Unavoidable acceptable releases. Almost any practice which produces waste - as well as waste handling itself - includes releases of radioactive material to the environment. If the practice is deemed justified, the regulator defines the acceptable levels of releases. In this framework, however, releases are not always seen as a conscious waste disposal strategy.
In some circumstances, and for some short-lived radionuclides, dispersion can in some cases (such as certain medical practices), be shown to yield the lowest collective and individual doses.
In some cases releases of short-lived nuclides may not be the option which gives the lowest collective dose but may still be acceptable if i) the practice which causes the release has been considered justified and ii) if it can be shown that alternative disposal options would cost more than reasonable (in the eyes of the regulator).
High individual doses would be avoided if the first strategic view were taken and the toxic waste diluted and dispersed, for instance into the sea. This strategy is often rejected by society on grounds that is it unjustified or that it would represent an under-optimized alternative. In most countries, dispersion of radionuclides with half-lives of many years into the sea is not a realistic alternative.
In the environmental impact assessment of a radioactive waste repository design, the special case of intrusion into the repository, may present a possibility for high individual doses to individual, namely the intruder. However safe the repository is designed, intrusion can always be imagined, sometimes by considering simple practices such as drilling for water, sometimes by taking into account extremely improbable events.
The conclusion is therefore that when society, on grounds of justification or optimization, chooses the option of waste containment in the form of a storage, the hypothetical scenario of intrusion followed by doses to the intruder in excess of dose limits cannot be used as a constraint the same way as in normal standards for building X-ray facilities in hospitals or for determining release limitations for nuclear facilities where doses are continuously monitored. On the contrary, the high dose to the potential intruder flows directly from the strategy of waste isolation in a repository.
Intrusion or other human actions that may influence the performance of the waste repository must still be a part of the total safety assessment. But it follows from

the above reasoning, that the threat of intrusion must be balanced against the probability of the intrusion in the regulation, since otherwise dilution would be the only remaining option.

SOME DEFINITIONS RELATED TO THE INTRUSION CONCEPT

In the absence of a definition of the human intrusion concept, almost any scenario leading to some radiation dose to man can be said to constitute a human intrusion or human action scenario which disturbs the repository. It is therefore worth while to establish a common international basis for definitions and judgement of human intrusion scenarios.

The following sections are dedicated to defining some necessary concepts for human actions at radioactive waste disposal sites. It is assumed that an extended analysis covering human intrusion is carried out in two steps:

a first phase consisting of an assessment of the repository performance in the absence of intrusion.

a second phase where human action disturbs or changes the outcome of the initial performance assessment.

It is assumed that performance assessment criteria exist for the first phase. The present task can therefore be described as finding criteria necessary to cover the additional, and separate, second phase. Human actions are seen as a broad concept, not restricted to human intrusion into the primary disposal. It may also include actions far from the disposal site, but close enough to influence the performance assessment. In some cases, like the Swedish repository for low and intermediate level waste, SFR, intrusion may be an important siting factor. This does not prevent that the analysis is made in two steps as mentioned above.

Definition of an Extended Repository Limit

Radioactive disposal concepts imply that the physical and chemical form of the radioactive waste, the repository design and technical barriers, in addition to natural barriers of the site, guarantee a sufficient protection to compensate for the dangers of the waste.

In this formulation, true for most repositories, part of the environment can be considered an integral part of the disposal concept. Sometimes, it may therefore be useful to define a spatial limit outside which human actions would not influence the outcome of a safety analysis. In theory, this limit is defined as a three-dimensional surface around the repository, where doses would be low enough to meet regulatory criteria for the undisturbed repository function. The limit of the extended repository cannot be expected to have the same meaning for all sites. Even for a specific site it may be difficult to define such a limit, but the concept may be useful as a theoretical reference in the discussion.

Restrictions

It should be observed that the range mentioned in the preceding section coincides with the area, or volume, where society may impose restrictions on various forms of activities. Even if the assessment does not rely on such active constitutional restrictions, it can be assumed that some records will be kept in some form for all high level radioactive waste repositories. Keeping such information available can be seen as a passive form of institutional control.

The human intrusion assessment serves to improve the repository concept. When choices are made between different concepts, the total detriment to society should be considered including the detriment of the restrictions described above. Thus, the performance of a repository cannot be improved simply by including a larger part of the environment in the repository concept. Also information conservation through long periods of time implies a cost to society and must have a weight in the assessment of costs and benefits of various solutions of the total problem, involving both radiation protection and use of the land above the repository. Some problems of optimization of the protection is discussed in the next section.

OPTIMIZATION OF RADIATION PROTECTION FOR HUMAN INTRUSION

Optimization as an important, perhaps the most important, concept in radiation protection was suggested in ICRP 26 in 1977 and in ICRP 60 in 1991 (1). It was pointed out that keeping doses as low as reasonably achievable was a powerful tool in radiation protection and that dose limits were to be seen mainly as a limit for the optimization procedure. Governments were advised that, for the activities where uses of ionizing radiation were justified, regulations should ensure not only that dose limit rules were met, but also that efforts were made to reduce individual doses further below those limits.

Both regulator and waste management could benefit from optimization studies, not least because all the underlying concepts will come under scrutiny in the process of determining the inherent factors in the calculation, the numerical result of which may be of limited value compared to the process itself.

Optimization categories for nuclear repositories

It is pointed out in ICRP 46 (2) that optimization of protection is a broad concept in waste management and it can apply at four levels:

A. Comparison of design alternatives for a specific facility such as a waste repository.

B. Comparison of different disposal options for particular waste streams.

C. Comparison of different overall management systems for particular waste streams.

D. Comparison of complete waste management systems, including conditioning, storage, transport and disposal alternatives for a given source or practice.

The global view should never be forgotten, so that for instance doses from waste handling should be added to doses from the repository in a distant future in the optimization.

Optimization may be used to identify the most cost-effective operation and the best (undisturbed) repository. What is balanced in the optimization described here is a special case of A above: the cost of establishing an information conservation system against the potency of such a system to prevent doses to man by deterring inadvertent intrusion. In principle, other costs could enter the calculation, such as choosing a site for which a repository would cost more, but that has not been taken into account in this presentation.

In this case, actions by individuals or groups must be described as an element in the calculation. Such calculations are always problematic, but they are easier for a shallow land burial where analogues may exist (e.g. experiences from waste dumps).

It is worth noting that, for a given repository, the optimization of the benefit from the information system may not have much in common with the protection optimization of the undisturbed repository itself. The difficulties are not necessarily less but they are different.

A NUMERICAL EXAMPLE OF AN OPTIMIZATION CALCULATION

In the following example, an optimization study of intrusion is described for a high-level waste repository. The calculation is meant as an illustrative numerical example of the calculation, and a demonstration of the uncertainties involved. The time span for the optimization may be assumed to be 10,000 years.

Probability of Intrusion Through Loss of Memory

Some estimates of the probability of intrusion has been given in work presently carried out by Sandia National Laboratories for the US Department of Energy's Waste Isolation Pilot Plant (WIPP) in New Mexico (3). Panels of experts have been asked to estimate the probability of inadvertent intrusion by future societies up to 10,000 years into the future. Some panelists have estimated the probability of intrusion to about 0.1 in 10,000 years. This is for a case where nothing denotes the location of the site. Another panel discussed to what extent information at the site (markers) could be a remedy for loss of knowledge. The effectiveness of markers, that is the ability to deter inadvertent intrusion, was believed by some panelists to be near 0.9 for 10,000 years and higher (0.99) for the first 1,000 years. With these estimates, and for the period 1,000 years the probability of intrusion can thus be calculated to be 0.1 * (1-0.99) = 0.001, for 10,000 years: 0.1 * (1-0.9) = 0.01.

In another site-specific study (4) regarding a repository in Boom clay at Mol, Belgium, the authors themselves assigned values to probabilities for loss of information, interest in drilling and a geometrical factor giving the probability of drillers hitting the repository. They combined these probabilities to arrive at a probability for inadvertent intrusion of less than 0.001 for 2,000 years after closure. In that work, probabilities are attributed to intrusion as far as 250,000 years into the future.

It is assumed, in the example below, that direct intrusion, in the absence of an information conservation system, has a probability of 0.1 over 10,000 years.

Individual and collective doses from intrusion scenarios

In a study of doses from inadvertent drilling intrusion into the repository, made for the Swedish Radiation Protection Institute (5), intrusion scenarios with high doses are presented for direct hits of a fuel waste canister followed by routine examination of cuttings in the field, and even higher doses for close inspection of samples in a laboratory (from inhalation as the sample is cut). No probability is

given for either mode of intrusion, except that intrusion into a waste canister or its backfill material is considered "very low". Doses are received by one or a few members of the drilling crew and laboratory personnel.
The collective dose in the example is taken to be such that the probable outcome of each intrusion or disturbance is one case of fatal cancer (20 person-sievert) for the members of the intrusion (drilling) crew and that the damage done by the intrusion in terms of a dose received by a larger number of people does not exceed nine times this value, so that the total collective dose is taken to be 200 person-sievert.
There can be no strong rationale for this value for the collective dose as a consequence of the drilling scenario. But one line of argumentation could be that if the collective dose was higher, it would be very easily detected (from acute radiation effects in the crew) and knowledge about the repository would be reimposed upon society. Such a reimposed knowledge might limit the damage made by the intrusion to the intrusion crew.
The value 0.05 excess cancer deaths per person-sievert is assumed for simplicity. In a detailed calculation, different risk estimates should apply to members in a drilling crew and a whole city population with a different age distribution. The estimate of this value by international expert organizations such as UNSCEAR (United Nation's Scientific Committee on the Effects of Atomic Radiation) and ICRP has changed over the years, but the estimate has always been thought to lie within the interval 0.01 to 0.1 cancer death per person-sievert.
It is assumed, in the field of radiation protection, that efforts are made to lower the dose as long as such efforts are deemed cost-effective. This assumes that the practice has been approved by the proper authorities and that doses are below the relevant dose limits. The limit where dose reduction is regarded barely cost-effective may be given in USD per person-sievert (1 sievert = 100 rem). This limit is often taken to be about USD 100,000 per person-sievert, although both higher and lower values are employed in individual cases.
If the probability of death is 0.05 per person-sievert, a value can be obtained giving the reasonable cost of increased safety in terms of cost to be taken to save one life (on the average). This reference cost may the be used by individuals and society to direct safety measures where these are most cost-effective. A combination of the death risk of 0.05 per person-sievert and the marginal cost of USD 100,000 per sievert yields 100,000/0.05 = USD 2,000,000 per saved life.
The result: The Cost of the Information System
The result of the calculation presented in Table I is that if intrusion can be avoided by information conservation in some form, it would be worth USD 2,000,000 to establish such a system. It can be seen that if the intrusion probability is set to 1 rather than 0.1 in the above calculation the reasonable effort for information retention would rise to USD 20,000,000. The somewhat arbitrary values in the calculation are discussed in section 3.5.
In view of the conceptual problems mentioned in the preceding sections, it must be kept in mind that the calculations are made assuming certain scenarios, and that maximum values of the doses are scenario specific. With such reservations, it is possible to infer some maximum and minimum values for the product of intrusion probability and the collective dose (i.e. the expectation value of the collective dose as a result of intrusion). The maximum value for the first term is 1 and as mentioned earlier 200 sievert constitutes a possible maximum collective dose to the crew and to the public assuming 20 person-sievert to the crew members which is enough to give life-threatening health effects to all members in the crew if the dose is distributed evenly and with some certain deaths if the distribution is uneven.
The lower set of parameters could be 0.001 for intrusion and 10 sievert for the collective dose to the crew plus the exposed public. It is possible to postulate a lower bound for the collective dose by considering natural analogues, such as doses from radon in ground water from a drinking water well. A dose of one millisievert (0.001 sievert or 100 millirem) per person and year is not uncommon for small wells in Sweden, for example (which does not emanate primarily from drinking, but from inhalation of radon daughters brought to indoor air by other uses of water). It seems reasonable that the family's collective dose: 4 persons * 0.001 Sv/year * 50 years = 0.2 person-sievert can give an example of an intrusion with a collective dose which may only deserve moderate concern.

The lower bound given in Table II represents such a low cost that further calculation seems uninteresting, because in no case would the waste management hesitate to pay this amount if safety could be improved.
Perhaps not even the upper bound given in Table III may seem completely prohibitive for such a large scale project as a high-level waste disposal.
For a repository in salt, such as the WIPP, there is no use of ground water by nearby cities. This may limit the collective dose. If 20 person-sievert to the crew members may be taken as a reference as mentioned earlier, perhaps 40 person-sievert can be taken as the collective dose as a result of a drilling intrusion followed by some additional exposure through some less efficient pathways. If the probability of intrusion is 0.1, the acceptable cost for the planned information conservation system (of markers) is given in Table IV.
If only the crew's dose is considered, the result would be USD 200,000.
A calculation as presented here may be useful for a discussion of the parameters and the assumptions used in the exercise. It may also be valuable to discuss some side issues: should the collective dose to the public be the first concern rather than the dose to the intruders? It is possible that history repeats itself so that several intrusions occurs (followed by restoration) during the ten millennia?

REGULATING HUMAN INTRUSION

There is, in principle, two main methods to inform future societies about radioactive waste repositories:

- Marker systems (such as described in reference 6)
- Archives and other information systems

Markers are created to allow individuals in the future to receive information directly, whereas archives and other information in society must be carried from one generation to the next. This is discussed further in Ref. 7.
It is reasonable to assume that the state must have some responsibility for ensuring the continued information content of the National (and other state) Archives, and it is likewise obvious that the waste management must be responsible for constructing the on-site marker system. It may therefore seem reasonable that the state in its regulation, directed towards the waste management, concentrates on the marker system.
However, the waste management must be responsible for collecting the information in the archives. The IAEA has started work recently in this area related to information conservation for LLW. The author has taken part in a consultant's meeting 25 - 29 April 1994 on "Maintenance of Records and Documents for Near Surface Waste Disposal Facilities". Later, the Agency started working on a similar document for HLW.
The state could influence the markers by its regulation in many other fields: the markers themselves could receive protection through both passive (location marked on maps) and active measures (remediation of markers). The state's and waste management's roles are therefore not completely independent.
It is for this reason, that a separate view of regulating human intrusion may be justified. It is sometime remarked that natural science is more suited for prediction or projection than the social sciences, and that, therefore, human intrusion must be treated differently. There is no scientific justification for such a generalization. It is the role and responsibility of the state that provide arguments for a separate, or special, judgement of human intrusion.

ABSTRACT
The Swedish Radiation Protection Institute is one of the nuclear regulatory bodies in Sweden. For its preparation of the licensing procedure for a HLW repository, which is planned to commence within a bit more than one decade, it is necessary with a build-up of both the knowledge in general and by this a public acceptance of the time scales involved for the final disposal of the radioactive waste stemming from the Swedish nuclear power production.
Since the key issue in terms of radiation safety is the longevity of the radiation of the waste, the study discusses the meaning of the expressions "longevity" or "long time". In order to grasp the time scales involved, an overview is given for natural large scale processes (earth-quakes, climatic changes, etc) with frequencies similar to those of the life time of a repository for spent nuclear fuel. These natural processes are chosen since they are judged to have a possible impact on the repository. In addition, in contrast to the frequencies of these large scale processes, a review of the history of man is given. With this backgrund in mind, the predictability of these events in a near and far future are discussed. The study has been carried out as a limited literature survey, mainly intended as a background for discussion among decision makers, and as an educational tool for the non-initiated public opinion.
It is concluded that there seems to be limited risks for geological activities in northern Europe, and that the possibilities to predict future earthquakes are limited. A similar conclusion goes for astronomical events like meteors hitting an area close enough to the repository, a conclusion based on surveys of past meteor hits in northern Europe. The natural climatic changes are, however, reasonably well known. By means of knowledge of past climatic cycles, it is therefore possible to make predictions for the future glaciations, the first one of which in Sweden will take place within a time period of about 10,000 years. These predictions do not include the impact from short-term man induced climatic changes, an issue that appears to be unresolved presently.
Conclusively, large scale processes either can be neglected or be accounted for with a reasonable degree of confidence. Contradictory to this, large uncertainties exist when it comes to factors caused by man. Processes like the green-house effect, the reduction of the ozone-layer, etc were identified as environmental impact matters that could affect the pattern of future societies, which in turn, as a second order consequence, can affect the integrity of the deposit. A complicating factor is the short turn-around time for different types of societies of mankind in the history. When trying to project these short cycles into the future, it appears as if the type of future societies is completely unpredictable. However, since some legal principles regarding releases to the environment can be traced more than thousand years back, to Roman civil right principles, one can assume that some kind of civilized society will exist also for the next millennium, particularly bearing the present well-organized society in mind. This assumption leads to the conclusion that it is possible, and also crucial, that the existence of the repository is well

documented by means of marker systems and archives.

INTRODUCTION

A challenging task from a licensing point of view, is the possibility for the authorities to require a safety analysis covering the time spans involved for the spent nuclear fuel to be disposed. At present in Sweden, there are no detailed regulations with respect to technical criteria, long-term aspects and their implications on radiological protection levels. This implies that there are reasons to discuss the possibilities for predictions of future events that may affect the repository, the actual time span denoted "long-term", and the implications these two issues may have on the present and future legislation in Sweden.

In Sweden, electricity has been produced by the country's 12 nuclear power plants during some 20 years. All of the plants are still in operation. The very short-lived low level waste is presently deposited on ground at the power plant producing the waste. Short-lived low and intermediate level waste is disposed in the SFR-facility, an underground facility situated some 50 m below the Baltic sea-bed. The high level waste (about 8,000 tons of spent fuel) and the long-lived low and intermediate level waste are planned to be disposed of in underground caverns at about 500 m below ground surface, a facility that remains to be located and constructed. Prior to the disposal, the spent fuel is planned to be stored for cooling in pools for 30-40 years in the CLAB-facility. The spent fuel is planned to be encapsulated in copper/steel canisters after the cooling period. A funding system for the disposal of the waste is built up as a result of the Swedish legislation, which implies that the waste generator has to live up to the "polluter-pays-principle".

According to the Nuclear Safety Act and the Radiation Protection Act, any generator of radioactive waste in Sweden is obliged to provide all necessary means for the disposal of the waste. As a regulatory body, the Swedish Radiation Protection Institute (SSI) is facing the task of formulating the technical criteria for the licensing of the repository. These criteria have to fulfill the mission of convincing not only scientists and researchers, but also the public opinion, that the strategy chosen is sensible.

Based on scientific considerations, mathematical models are made which in principle can be used to predict a release of radionuclides from a repository for eternity, although substantial uncertainties will exist. This approach is, however, judged to be less meaningful since the confidence that can be expected from such calculations is limited, at least when times scales of millions of years are studied. A more realistic approach is to seek for a suitable Itime span for which a) the radiological impact from the repository is acceptable when damaged for one reason or another, and b) build confidence in the manners by which this is proved. From this we can draw the conclusion that there is a need for a cut-off in time, a limit beyond which it is not worthwhile striving for. This cut-off must, however, not be regarded as an indulgence to safety in a far future. Rather, it must be looked upon as sensible considerations in terms of what can be achieved with an acceptable degree of confidence.

The Swedish disposal strategy complies with the international understanding that those who are consumers of nuclear power generated electricity also should be responsible for the development of a safe disposal handling system, and that the protective limits for man and environment shall be in compliance with those agreed by international organizations in the field on waste management (OECD/NEA, IAEA). One of the issues put forward by the IAEA, states that the waste must be isolated in a manner so that no health risks or environmental risks that are not accepted today can be foreseen in the future. However, this puts us in the situation when we have to face questions like "How can we today state what future generations claim is harmful? What do we know about societal patterns of future generations and their sensitivity to radiation? When does 'future' take place?" Obviously, we have to define what we mean with endurance, persistence, far future, etc, etc.

ENDURANCE - PERSISTENCE - TIME PERSPECTIVES

General

The expected lifetime of constructions like bridges, roads, houses, for example, are based on statistical considerations - accounting for destructive processes with reasonably well known frequencies and magnitudes (rain, wind, erosion, etc). In other words, the sustainability of the construction can be estimated once the destructive processes are accounted for. The time-scales involved, i.e. the planned lifetime, are in the range 50-100 years. Similarly, the environmental impact and the

need for protection, of man-made constructions like, e.g. chemical plants, can be assessed. The plant owner invests in security systems to prevent damages to the environment and his plant. The environmental risk from e.g. an accidental release is, however, put to an end once the plant is shut down.
These two principles of endurance assessment and environmental risk management, respectively, are coupled when designing a repository for radioactive waste, although a repository is a much more complex construction: The repository has to be persistent to destructive processes for enormous time perspectives, and furthermore, the potential release from it has to be considered for thousands of years. The release does not cease due to the termination of the operation of the "plant".
How Long is a Long Time?
A time span of 24,000 years is often mentioned when waste disposal is discussed. This time corresponds to the half-life of plutonium-239. Scientists in climatology seldom dispute that the northern part of Europe, including Sweden, will be subjected to several glaciations, the first major of which will occur in about 10,000-20,000 years. Although a tundra-like climate with endurable conditions could prevail during the interglacials, this part of Europe will probably not be inhabitable to a very large extent for the next 75,000-125,000 years. An upper limit for long time, from a licensing point of view, could according to this discussion be about 20,000 years.
A lower limit for long time can be harder to define. For the low and intermediate level waste the first 500 years is considered the most crucial ones, a time span after which the radiotoxicity has declined to harmless levels. For the high level waste, on the other hand, a direct contact during the first 1,000 years is regarded as dangerous. Although the radioactivity has decreased to 0.1% after that time, the waste is still considered injurious for thousands of years, mainly by uptake in the body by inhalation or food intake.
According to the discussion above, a minimum time span, from a climatic/scientific point of view, for the endurance of the repository is in the range 1 000 - 20 000 years. The question is how this complies with the legislation. Are there means for the authorities to put safety requirements covering these time spans? Are the time spans long enough?
Legal Aspects
The present legislation in the area of environmental protection in Sweden is rather vaguely formulated in terms of acceptable release rates, time limits, etc, and can be characterized as a legal framework. More detailed regulations needed to fulfill the purpose of a specific act can be laid down by the government or an authority appointed by the government. Such an authority could be the Radiation Protection Institute. An act on protection is also characterized in that it contains a certain amount of public influence, e.g. by a concession system implying that certain activities cannot be practiced without being licensed. A license shall contain all the prerequisites to maintain the desired protection, and an official authority is conducting the supervision of the activity. If the conditions change after the license has been granted, the license can be withdrawn or modified. A license can also be restricted in time.
The present legislation in Sweden offers good possibilities for the licensing authority to successively increase the protective demands on the license-holder. Thus, at present there are no incitements for the licensing authorities to carry through a close study of the posed protective demands in a longer time perspective. Deposits for municipal and industrial wastes have thus been regarded as material being temporarily stored awaiting technical solutions for a proper management of the wastes, recirculation or re-use. No time limits or release rates on a national basis have been stated. However, during recent years, the authorities have started discussing the "glaciation perspective" when the endurance of disposal sites for municipal wastes is considered. The implementation of this notion in juridical terms still remains.
However, the nordic countries have suggested in common that an acceptable limit for a highest yearly radiation dose from deposited radioactive waste, should be considered for "a time span reasonably possible to predict over". Accordingly, it is stated that dose rate as a measure of protection limit is very uncertain for time periods exceeding 10,000 years.
The same time span is discussed in the US, although a period of 1,000 years to begin with was regarded as a time during which a repository should provide protection for man and groundwater. This was postulated by the EPA. In court, however, it was found

that the protective measures for radioactive waste, in principle had the same purpose as those for drinking water, long term effects from unsorted hazardous waste, etc. The time span considered for the latter ones is 10,000 years, and therefore the court argued and abolished EPA's statement on 1,000 years. EPA had the time perspective reinvestigated and laid down new regulations implying that the 1,000 years had been changed to 10,000 years [EPA]. EPA claimed that the main reasons for this change were:

A prolongation to 10,000 years would stimulate a better technical design of the repository.

A higher level of confidence can be put into calculations covering long time spans by means of the rapid development in computer hardware.

The marginal cost for investigations on the 10,000 years perspective were considered reasonable.

A harmonization of time limits with corresponding regulations in near-by areas is desirable.

In the US regulations, it is clarified that there are no requirements for an undisputable proof of complete radiation protection, but rather that future predictable courses of events have to be thoroughly investigated.

PAST AND FUTURE EVENTS - PREDICTIONS POSSIBLE BY LEARNING THE LESSON?

In order to grasp the time scales discussed for the longevity of a repository for spent nuclear fuel, it may be worth considering a backward glance on the history of Earth and mankind - what can we learn from history and how much of it is possible to project into future? Apart from geological and climatological events, that seem relevant to discuss here, we also have to look at the implications that life of the modern and future man can have on a repository for nuclear waste. Is the modern man affecting his environment in such a degree and so rapidly that nothing can be taken for granted? Can we by any means predict events taking place in the near future of only a 100 years? As an illustration to these thought-provoking questions, Table I (derived from [NRPB, 1991]) indicates approximate time scales for major events in the history of man, potential future events, and possible different phases of a repository for spent fuel designed for Swedish conditions.

Geological Activity

The oldest type of bedrock in Sweden is found in the northern part, and is about 1.5-2.0 billion years, whereas the more recent (50 million years) types of bedrock are found in the southern part. Volcanic formations younger than about 250 million years have not been found in Scandinavia, although younger formations (about 55 million years) have been found outside the Norwegian coast.

Regional land uplift prior to the last glaciation have amounted to about 1200 m in a series of 13 occasions for about 5-50 million years ago. More large-scale land uplifts of the bedrock amounted to about the same magnitude, but these movements are considered to have ended about 1.6 billion years ago.

Scandinavia has not been subjected to any major earthquakes in historical time. Occurrences of minor earthquakes are on the other hand rather frequent. During the period between 1951 and 1976, some 200 quakes were registered with regional magnitudes lower than 3.8. The quakes took place mostly at depths of about 15 km with minor vertical movements in the bedrock. These movements preferentially takes place at depths far deeper than 500 m where the repository is planned to be located. Furthermore, it is believed that the movements measured in modern time originates from the land uplift caused by the last glaciation, and that the movements thereby will decrease with time.

Science has, during the last decades, found ample evidence for the plate tectonic (or "Pangea") hypothesis. The hypothesis leans on the theory that all continents once were connected, but now drifting apart on the uppermost part of the crust of the earth; movements that have been reconstructed from today's positions of the continents (plates) back to 200 million years ago. The boarders between the plates usually represent areas with a certain degree of geological activity, exemplified by for instance the mid-atlantic ridge and the zone following the west coasts of North and South America (the well-known San Andrea fault forming part of the North American zone). None of the boarders between the drifting continents crosses the northern part of Europe, which in turn would imply that Sweden rests on relatively stable geological formations.

It is of interest to discuss the possibility to predict major events that possibly can affect the integrity of a repository, and to pose the question if there are

means to forecast the next geological activity (earthquake, volcanism) within the Swedish territory for the next, let's say 100,000 years. The answer to this question, taken literally, is of course "no". However, based on earthquakes in historic times (or rather the absence of them), and the present monitoring of quakes of low order magnitudes combined with the understanding of the origin of geological activities due to the plate tectonics, one could possibly state that the probabilities of earthquakes or volcanism of magnitudes large enough to affect the repository, appear to be extremely low in northern Europe.

Climatic changes

During the past two million years (the Quaternary era) the average temperature has fluctuated with about 1-2 degrees (Celsius) at the equator and as much as about 10 degrees in Scandinavia. These temperature variations have given rise to glaciations with large ice-sheets covering parts of the earth. Glaciations means that enormous amounts of water is withdrawn from the hydrological cycle, forming ice instead of flowing water.

It is assumed that ice-sheets with a thickness of 1-3 km covered parts of the northern hemisphere during the last glaciation, while the sea-level was lowered some 100 m. Stagnant groundwater conditions have prevailed down to depths of about 500 m due to permafrost. From these hydraulically stagnant periods, the melting away of the ice-sheet during the deglaciation implies that the water, including the groundwater, is let loose. These both extreme conditions are of course interesting in the context of waste disposal.

The glacial and interglacial periods have been going on for the last two million years. The last glaciation in northern Europe had its largest extent for about 18,000-20,000 years ago with an extent southward to Germany, and its withdrawal took place for about 10,000 years ago. It has been well-known that the glaciations occur with some sort of frequency, but until a few decades ago the origin and frequency of glaciations were disputed.

The possibilities to predict future major climatic changes have improved since 20-30 years. The reason for this is that there seems to be evidence for that variations of the solar radiation causes climatic changes on the earth, and that these variations appear with a certain frequency. The variations occur mainly due to a) changes of the orbit of the earth around the sun (supported by Milankovich's orbital theory), b) periodical changes of the inclination of the axis of the earth, and c) gravitational interaction between the earth and other planets. From today's knowledge of these interacting factors, it is possible to count backwards in time in order to determine temperature variations in the past.

The history of previous temperature variations based on the factors mentioned above, is supported by e.g. sediment samples from deep-sea graves in the Indian Ocean. From the ratio between two isotopes of oxygen (oxygen-18 and oxygen-16) in the samples, it is possible to study the accretion of the sediment (i.e. dead vegetation). The isotope oxygen-18 occurs somewhat more than the oxygen-16 during colder periods, and vice versa for warmer periods. Once the age of the samples has been determined, the history of temperature variations can be studied. It has been found that these measurements support the frequencies of climatic fluctuations in the past determined with the method based on differences in solar radiation mentioned above.

Now that some degree of confidence obviously can be put into the fact that variations in the solar radiation causes climatic changes on earth, it could be possible to predict future major climatic changes based on well-known facts about orbits of planets, etc.

In a report issued by the Swedish Nuclear and Fuel Waste Management Co. (SKB), two studies are referred to, both having investigated the possibility to predict the time of future glaciations in northern Europe [Ahlbom, et al, 1991]. Both aforementioned methods (solar radiation variation and sediment samples) were applied with rather unanimous results. SKB formulates its so called ice-age scenario accordingly: A first minor glaciation occurs within about 5,000 years, covering only the northmost part of the scandinavian mountains. The second glaciation takes place within about 20,000 years from now with a duration of about 5,000 years, the ice-sheet will be about 1.5 km thick, the sea-level will have dropped about 25 m and permafrost conditions are prevailing in the southern Sweden. In about 60,000 years full glacial conditions will prevail, with an ice-sheet of 3 km thickness covering entire Scandinavia, the crustal movement is thought to be about 600 m in the Stockholm region.

Notably though, their predictions do not account for anthropogenic effects on the environment. This means that the lives and beings of present and future mankind societies that may affect the conditions on earth, have to be studied separately.

Societal and legislative perspective

The oldest remains of man or man-like apes are about 1.5-3.5 million years old, and have been found in East Africa. The European continent have been inhabited for about 100,000-500,000 years. The oldest remains of human beings in the northern part of Europe are not older than roughly 30,000 years; although relics of settlements have been found, the majority of them was swept away by the ice-sheet during the last glaciation. Still, we discuss time scales of tens and hundreds of thousands of years.

The first steps of the evolution of man towards modern life, were taken when man started organizing his living in more or less permanent agricultural settlements for about 8,000 years ago. The start of this evolution took place in the middle-east, a point in time approximately coinciding with the withdrawal of the ice-sheet of the last glaciation when the climate went warmer. The agricultural living was spread over Europe within about 4,000 years. At about this time, town-like settlements were formed at places in for example Egypt, India and China. The time scale for this evolution is thousands of years.

Subsequent to the town-like formations, historic "super powers" started to evolve in the Mediterranean and Oriental areas. The Roman empire, and other empires like China, India, Persia, etc, had survival times of less than a thousand years, sometimes far shorter time periods than so.

We see from these figures that the time scales involved are extremely short compared to those of climatic cycles and geological activities earlier discussed. Bearing this in mind, the question arises as to whether or not it's possible to predict forthcoming societies of mankind, their way of living, their potential impact on the environment, their sustainability, etc. The key issue is not to predict the future type of society in detail, but rather to design a repository in such a way that it is persistent to any type of influence - induced by man or by natural causes.

It is possible to identify some actions by future societies which may impair the integrity of the repository:

- planned or unplanned penetration of the repository due to e.g. mining or exploration activities
- political unstableness, sabotage, nuclear war, etc

Although future development cannot be predicted in detail, it is possible to take some actions today which are in the interest of future societies. In a Nordic study [Nordic Council of Ministers, 1993] different mechanisms for informing future societies about the repository, such as markers and archives, are discussed and recommended. This study suggests that a strategy could be built on both markers and archives, and that the relative importance of both strategies should be evaluated for a specific repository. The strategy chosen must involve an assessment of both the durability of a marker system and the retrievability of its information, and the survival of information in a national archive.

CONCLUSIONS

The present study has focused on the predictability of future events that may affect the integrity of a potential repository for spent nuclear fuel. The key issues are the long time periods to account for, the presumed relative lack of sustainability of future societal structures, the present and future legislation, and the necessity of a transfer of the knowledge of the existence of the repository.

Thus, based on the limited literature survey that formed the basis for this study, it is possible to divide the main conclusions into three main categories accordingly:

Geological and Climatic Effects

Apart from anthropogenic effects, the conditions for climatic changes are deemed to be predictable up to the next glaciation. It is therefore reasonable to formulate relatively detailed acceptance criteria for the repository relating to the environmental impact during this period.

Large scale processes like meteors or large earthquakes cannot be ruled out in a longer time perspective. However, these phenomena are associated with so low probabilities that the corresponding risks are deemed acceptable in the shorter perspective. Some processes can be foreseen and described quantitatively (continental movements).

Legal Considerations

The "polluter-pays-principle" implies - because of the extremely long time periods involved - that society must predict environmental impacts from a certain practice in advance in the licensing procedure. This constitutes a new approach in the environmental legislation, which presently allows for a successive increase of the protective demands from the authorities.

Information Transfer

It may be assumed, by considering the climatic development, that societal structures may exist in Sweden in at least a 1,000 year perspective. This implies that there is a basis for an information conservation and transfer strategy to future societies.

The authorities must define criteria for judging the reasonable cost, covering the creation and future maintenance of an archive for a nuclear waste repository, and the measures taken by the waste generators such as constructing passive markers on the site.

ABSTRACT

Accuracy in construction cost estimating is a science that is dependent on specifics such as project definition, accurate construction schedule, accurate material take-offs (MTOs), a reasonable estimating schedule, and experienced staff. Specific information may come from the planning or engineering of the project itself; or it may come from historical information about other similar projects.

Primary costs should be based only on "knowns", for example, soil types, cut and fill quantities, and materials and equipment required to perform the work being scoped based on accurate MTOs. The most accurate estimating method is called the "bottoms-up technique." This method utilizes a Statement of Work and a set of drawings and/or specifications to "take-off" material quantities required to execute each discrete task performed in accomplishing a given operation. From these quantities, direct labor, equipment, and overhead costs can be derived. Other peripheral activities that can be costed with reasonable accuracy include project engineering and oversight costs, with the former being based on workhours to perform, and the latter based on engineering and construction scheduled durations (resulting in workhours).

Waste stream cost is the most difficult cost to estimate. The engineers developing waste stream volumes must work diligently in the preparation of these quantities and must readily provide information relative to the technology used for treatment of materials, storage requirements and durations, and final disposition because the costs for these scenarios remain volatile.

Contingency should be dependent on the status of design, procurement, and construction, as well as the complexity of each project, and should be assigned to incremental components of the cost estimate based on definition, material and equipment, pricing and confidence. Contingency should never be used as a substitute for risk and uncertainty. This analysis should only be performed after completion of the base cost estimate.

INTRODUCTION

Reliable cost estimating is one of the most important elements of remediation or decommissioning planning. As various technologies are evaluated and compared based on their efficiency and effectiveness, so their costs must also be considered throughout the planning process. When the planning process is complete, a thorough cost estimating procedure ensures that a project is economically sound.

Accuracy in construction cost estimating is a science that is dependent on specifics such as project definition, accurate construction schedule, accurate material takeoffs (MTOs), an understanding of the political environment and an experienced staff. Specific information may come from the planning or engineering staffs of the project itself, or from historical information about other similar projects.

The results of an estimate can vary because of changes in assumptions, labor force mixes, assigned escalation values, oversight costs, specific contaminated materials involved, waste stream generated, characterization, and the applicable environmental compliance requirements. Although working within these parameters can be difficult, an experienced staff can prepare a reliable working tool (construction cost estimate) for the majority of projects.

METHODOLOGY

The initial step in preparing a remediation or decommissioning cost estimate should be to gather all available data that may help define what is existing. This may include original design drawings, as-built drawings, construction records, and purchase and installation records for equipment and materials. Some sites have accumulated much of the information pertinent to the remediation or decommissioning task into a single source document such as a System Turnover Package or a Technical Data Summary document. This information provides a preliminary framework for developing an inventory of the materials to be handled in the project. This inventory is necessary to develop the comprehensive cost estimate; that is, the total project cost (TPC). The TPC includes primary cost that are both activity-dependent and period-dependent associated with the intended task and includes direct and indirect construction costs, waste stream costs consisting of both on and off site waste disposition costs, and peripheral costs such as design, engineering, regulatory interfaces, and oversight costs.

The accuracy of TPC estimates depends on the availability of specific information about the activities to be performed. Again, specific information may come from the planning or engineering of the project itself, or it may come from historical information about other similar projects. The cost estimating process may be requested at any stage in the planning, engineering, or design of the project.

It is best to include as few unknowns (contingencies) as possible in a construction cost estimate because as criteria, methods, or peripheral parameters change during the evolution of the project, adjustments can be made more easily and accurately if the original cost figures are based upon known data.

PRIMARY COSTS

The basic elements of primary cost for any task or subtask in a remediation or decommissioning project work sequence include labor, materials consumed, equipment, subcontracts, and other factors such as energy, overhead, and fee.

This primary cost can be estimated in a number of ways. Among other sources, recorded experience from other similar projects, estimating handbooks, and equipment catalog performance data, may be used to develop cost data. The techniques used for preparing cost estimates will necessarily vary with the project's degree of definition; the state of the art of the project; the availability of databases, cost estimating techniques, time, and cost estimators expertise; and the level of engineering detail available. Primary costs should be based only on "knowns". For example, soil types, cut and fill quantities, materials and equipment required to perform the work being scoped are known factors based on accurate MTOs. Direct labor, equipment, and overhead costs can be derived from these quantities.

There are two types of primary cost factors: activity-dependent and period-dependent. Activity-dependent cost factors are further divided into two types: unit cost and fixed cost. Unit costs are expressed in cost per unit output (e.g., $/in. of cut, $/ton, $/yd, $/pump, $/valve). The unit costs may be developed by calculation or from actual field experience. Those derived through calculation are based on a performance parameter such as speed of cut. Fixed cost items reflect those costs fixed by lease, or outright purchase of equipment and materials. As an example, the purchase or lease price of special rigging and handling equipment used

during the removal of a vessel and its internal component parts is a fixed cost. The cost of each activity is calculated by multiplying the appropriate activity parameter (e.g., the volume of heavily reinforced concrete to be removed) by the corresponding unit cost figure. The duration of the activity performance is calculated by selecting the degree of parallel activity considered reasonable for the work; for example, determining how many crews can be effectively utilized for pipe removal during a defined period of work.

Period-dependent cost factors represent costs related to specific phases of a remediation or decommissioning project and are expressed in cost per unit time. Period-dependent costs include such items as administration, insurance, site security, health physics support, and Quality Assurance. It may include certain equipment rentals when their use is common to many activities.

The costs of all period-dependent items are calculated by multiplying each cost factor by its corresponding assigned period. However, some costs that should be captured in the details of an estimate may be insignificant to the cost of a projecttypically less than 1%and should have a dollar amount assigned to that activity based on prior experience. These assigned or "plugged" numbers are typically given to the costs for utilities and consumables required during the performance period of the project.

When both time and project definition are available, TPC is usually best defined by using the "bottoms up technique". To best utilize this technique, a work statement and set of drawings or specifications are used to "take-off" material quantities required to execute each discrete task performed in accomplishing a given operation. From these quantities, direct labor, equipment, and overhead costs can be derived. Using this approach, a project is divided into discrete and measurable work activities. Where possible, the division should provide a sufficient level of detail so that the estimate for a discrete activity can apply to all occurrences of the activity.

Some factors that may affect primary cost calculations include setup time, operating time, required crew size, consumables usage, support services, and energy consumption.

PERIPHERAL COST FACTORS

Peripheral costs include all planning and engineering tasks such as performing radiation surveys; calculating activation and contamination inventories; performing engineering studies; preparing a work plan; preparing major activities specifications and descriptions, designing special tools; characterizations or preparing detailed procedures. Other peripheral activities that can be costed with reasonable accuracy include detailed project engineering and oversight costs with the former being based on workhours to perform and the latter based on engineering and construction scheduled durations (resultant in workhours). All oversight tasks, such as ensuring regulatory compliance, including preparation of permit applications; assisting in negotiations, reviewing the project process to ensure compliance with federal and state regulations; ensuring that the selected technologies comply with administrative and regulatory requirements and attending project status meetings are also considered as peripheral cost factors that are included.

WASTE STREAM COST

Waste stream cost is the most difficult cost to estimate. The engineers developing waste stream volumes must work diligently in the preparation of these quantities and readily provide information relative to the technology used for treatment of materials, storage requirements and durations, levels of contamination, and final disposition, as the relative costs for these scenarios remains volatile.

Because remediation or decommissioning involves the handling of some contaminated materials or equipment, some waste streams will be contaminated. However, these projects generate different wastes which affect the costs differently for each project. Because of changing regulatory requirements, waste facility requirements, and DOT regulations, waste stream costs include both on-site costs for laydown areas, interim storage, processing costs to reach waste minimization, volume reduction, packaging, and transportation, and off-site disposal costs that include special and specific packaging, labeling, transportation, loading and unloading, final burial fee, and surcharges, all of which are principally dependent on the characteristics of that waste. Therefore, identification of the character of waste streams is imperative to reliable cost estimating.

The areas of waste stream generation for a remediation or decommissioning project include the material being dismantled, waste containers, the medium used and its by-products to decontaminate the source material, and the personal protective equipment used by the workers.
Waste stream disposition can be on-site or off-site specific in the cost estimate. The major decommissioning waste stream costs to consider are handling, decontamination processing for waste minimization, volume reduction, packaging and containment, characterization of the waste, shipping and transportation regulations, burial, and any additional fees or surcharges.

CONTINGENCY

Contingency is applied to the cost estimate based on uncertainties associated with the available design information. Contingency is usually applied to discrete elements of a project as a percentage and the contingency for the total project cost is the weighted average of these percentages. The estimate must include all known costs and the identified cost factors for unknowns, and contingency based on the level of design information available, overhead, and fee, thus providing a cost in current-day dollars for each incremental task. Each of these tasks is then merged with the proposed schedule information so that cost can be escalated over the proposed schedule duration (cost increase over time).
Contingency should be dependent on the status of design, procurement, and construction, as well as on the complexity of each project. It should be assigned to incremental components of the cost estimate based on definition, material and equipment, pricing, and confidence. Contingency should never be used as a substitute for risk and uncertainty and this analysis should only be performed after completion of the base cost estimate.

COST ESTIMATING PROCESS

The scope of work can provide a basic foundation for the cost estimate because it specifies the work to be performed (primary cost), ancillary activities required and time constraints (peripheral cost), and known contaminants involved (waste stream cost).
Preparation of remediation or decommissioning construction cost estimates must place emphasis on the basic framework of any reliable costing process including: making a thorough review of the work scope; placing specific emphasis on projected waste stream characteristics (contaminated material); documenting regulatory references and applicability, as well as site-specific or company-specific procedures pertaining to the project; developing a building block approach to establish the total project breakdown by identifying the upper-level requirements and/or specifics for client funding of the project.
From this building block framework, a detailed description of the project in a logical, time-related sequence of series and parallel work activities, broken down into primary cost, peripheral cost, and waste stream cost can be prepared. Once the cost estimate is prepared, a draft project schedule is developed based on the calculated activity durations and the sequential relationship between activities, which can be used to calculate period dependent costs (i.e., project security, or management staff) cost elements.
The three following steps are then needed: estimating each work activity's primary cost and period of performance; generating peripheral costs based on activity-dependent cost data specifics, regulatory requirements, and additional procedural requirements; and estimating waste stream costs.
The TPC is calculated by adding the primary (activity-dependent and period-dependent) cost, peripheral cost, and waste stream cost; the appropriate contingency, overhead, and fee is applied and escalation costs for the scheduled duration of the project are then added.

RISK AND UNCERTAINTY ANALYSIS

A credible cost estimate must take into consideration all the key points described in this paper; however, a Risk and Uncertainty Analysis (RUA) is a task that is rarely requested of the cost estimating group. Many managers feel that contingency included in an estimate has already stretched funding levels to a point that jeopardizes project funding limits; thus they may not want to add confusion by adding the cost associated with possible or probable project overruns. These overruns are usually associated with quantity overruns previously based on engineering judgement rather than on information readily available, and always carry the additional costs associated with lost schedule. These are not, however, the only

risks to a project. The most volatile risks are those associated with omissions and errors, followed by expanded scope, lost schedule, Acts of God, and, to a lesser extent, escalation costs and equipment and materials pricing uncertainties.

DISCUSSION

Should project funding plans fail in this volatile marketplace, blame may be initially cast on the construction cost estimate originally put in place to support project funding. Eventually, though, most projects find that blame for funding shortfalls can be attributed to the lack of a project specific RUA, or discounting the results of a RUA that was performed to support project planning. A RUA is a valuable tool used to support the costs associated with the "what ifs" of a project. Projects can be reliably costed in a quantitative manner, such as costing the removal of contaminated soil/cu. yd. as defined in the project plans. However, when site activities require removal of twice the assumed quantities of contaminated soil as previously costed and the overhead cost associated with a schedule loss, it must be understood that the construction cost estimate is not necessarily flawed; rather, the increased cost is due to a risk associated with the work performed and was (or should have been) identified in a project RUA.

THE BACK-END OF FUEL CYCLE IN ROMANIA

M. Radu
A. Panait
G. Popescu
Center of Technologies and Engineering for Nuclear Projects - CITON
Bucuresti - Magurele, Romania

ABSTRACT

We shall present in this paper the appropriate variants for the nuclear spent fuel intermediate storage, both for the dry and wet solutions. Also, we shall present the Spent Fuel Transport System from the NPP Cernavoda to the Interim Storage (IS) and to the Nuclear Research Institute Pitesti. Our opinions presented here are based on studies and analysis performed in our Institute, especially in the last 3 years.

INTRODUCTION

In 1992 RENEL initiated a research and development program for the management of nuclear waste produced by nuclear energetics in Romania. CITON, as a subsidiary of RENEL, is the manager of this program.

CITON is involved now in developing the following subprograms:

- a subprogram having the goal to choose and to build an Interim Storage Facility, and
- a subprogram having the goal to select the site and to build a Final Repository.

This year (1995) the first nuclear unit will be put in operation in Romania. NPP Cernavoda is of the CANDU type, and is planned to have in final 5 units of 600MW each.

The spent CANDU fuel will be stored in the NPP Spent Fuel Storage Bay for 7 to 10 years, and after that it has to be removed. The studies performed in our Institute showed that the intermediate storage of the spent fuel cooled for maximum 10 years will be the best solution for the next step of the back-end cycle in our country.

FUEL BACK-END CYCLE

The spent fuel quantity resulting from NPP Cernavoda's 5 units in 30 years of operation is estimated to be 1440OUt. The quantity is large, but the burn-up is relatively low, about 7600 MW day/Ut.

In NPP Cernavoda the spent fuel is manipulated and stored underwater. There are four pools for each nuclear unit, having different destinations: Discharge Bay, Reception Spent Fuel Bay (RSFB), Defective Spent Fuel Storage Bay, and Spent Fuel Storage Bay (SFSB), which is the only having the possibility to be extended with another similar pool. The spent fuel is stored here in trays (24 bundles in a tray).

NPP Cernavoda project doesn't include yet the documentation related to the spent fuel evacuation. However, in the project, areas equipped with some of the facilities are provided for spent fuel manipulation and for cask expedition.

The spent fuel is stored in the NPP for 10 years. The evacuation of the spent fuel from the NPP will be made in one of multiple variants, depending on the Interim Storage type. In the initial project, the spent fuel is transferred in the RSFB, where it will be loaded in a container. We have also studied another variant, in which the spent fuel will be loaded in a basket in the SFSB and lifted in a Loading

Station to prepare the basket for transport and storage.
The next step in the fuel back-end cycle will be the Intermediate Storage. This solution allows to delay the choosing between reprocessing and final repository, and to have enough time to find the optimum solution and the appropriate site.
Also, some defective spent fuel bundles will be sent to Nuclear Research Institute in Pitesti, for research reasons.

SPENT FUEL INTERIM STORAGE

In the studies performed in our Institute, we used the following definition for the Interim Storage main function:

storage of the spent fuel resulted from the NPP's operation after a cooling period in NPP bays, ensuring nuclear shielding, cooling and maintaining the spent fuel bundle integrity for 50 years, so that the impact against the operators, public and environment is within accepted limits.

The Interim Storage is considered to be built in 4 stages, each stage having the capacity for storing 3600 Ut.
The optimum variant for intermediate storage of the spent fuel was not chosen yet. We have already studied two type of IS: wet storage in rectangular pools and dry storage in modules. This year, we will continue the studies started last year with the dual purpose casks and we will start to study the feasibility for using CASCAD solution.

Wet Interim Storage

The first stage of the Interim Storage in this variant represents a complex comprising two main buildings:

the Storage Building, including the storage bays (SB);
the Auxiliary Building, including the reception bay and the auxiliary systems for this unit.

The Interim Storage is planned to be built in 4 stages, corresponding in time with the NPP units commissioning. The facility for the whole quantity of spent fuel will comprise 2 parallel Storage Buildings and one Auxiliary Building, each of them having the length double than the buildings for the first stage (see Fig. 3).
For a wet interim storage variant we think that it is necessary to take into consideration the experience achieved in NPP Cernavoda SFSB design and construction. For this reason, we started to study this solution having in mind the following premise: the Interim Storage SB has the same dimensions as the SFSB from NPP Cernavoda (12m x 20m, with 7.8m in depth). Therefore, for the first stage, 2 bays are necessary. The increasing of spent fuel density compared with the NPP SFSB is done by using modules instead of storage trays and by decreasing the water layer above the fuel, because of the decreased radiation level.
The loading of the spent fuel into the transport cask is done in the NPP SFRB The IS is provided with a RSFB. for unloading the spent fuel from the cask. The bay is connected with the SFSB by means of a transfer channel. The IS RSFB and the main systems serving the facility are located in the Auxiliary Building.
The advantages of using a wet IS in Romania are:

there will be operating experience at IS commissioning time;
it is based on known technologies;
doesn't need modifications in the NPP Cernavoda project for loading the spent fuel into the cask;
allows to keep a lower temperature on the spent fuel bundle;
allows easier access to the spent fuel bundle for inspection and manipulation;
allows a dense storage.

The disadvantages of using this solution are:

needs continuous operation and maintenance;
generates nuclear waste;
can give undesirable effects because of the corrosion;
needs, generally, higher expenses;
it is vulnerable to heavy objects falling or missiles.

Dry Interim Storage - Storage Module Type

The Interim Storage module called MMB is a parallelipipedical construction made of reinforced concrete. The upper part is designed to sustain 20 cylinders filled each with 10 baskets containing 60 spent fuel bundles. There are necessary 16 storage modules for storing the spent fuel for the first stage. In Fig. 4 you can see the layout for the whole IS.
The basket is filled with the spent fuel in the NPP Cernavoda SFSB and lifted in a

Loading Station. In this shielded area placed on the SFSB edge, the baskets are washed, dried, sealed by welding and lifted in the transport flask. Also, we have analyzed a Loading Station comprising two separated and shielded areas (a "dirty" one made of metal and a "clean" one, made of concrete) connected by a shielded channel, with a gate. An auxiliary building is necessary, for both solutions, to prepare the cask for transport.
The loading of the spent fuel into the Interim Storage will be done periodically, according to the meteorological conditions.
The IS module type solution studied in our Institute is based on the AECL's CANSTOR model.
The advantages for using IS modules type in Romania are:
- the construction will be done in stages, according to the IS loading necessities, with minimum capital blocked;
- doesn't need continuous operation, needs only a minimum of maintenance and supervision;
- doesn't generate nuclear waste
- it is adequate for simple decommissioning;
- it is less vulnerable to heavy objects falling or missiles;
- needs smaller expenses than the other variants analyzed by us until now.

The disadvantages of using this solution are:
- changes in NPP Cernavoda SFSB area for building the Loading Station;
- decreasing of the spent fuel storage area by placing a loading table in the bay;
- difficult access to the spent fuel bundle;
- higher temperature on the spent fuel bundle;
- reduced operating experience.

Dry Interim Storage - Dual Purpose Cask Type
We have studied the feasibility of the interim storage in dual purpose casks (DSC type from Ontaryo - Hydro), but a detailed analysis will be done this year, taking into consideration other solutions, too. In this case, the loading of the S.F. into the cask will be done in the NPP RSFB.
The advantages for using dual purpose cask IS in Romania are:
- manufacturing can be done in stages, according to the IS storing necessities, and allows at every moment to change the back-end strategy or the site;
- doesn't affect the storage area;
- the container can be used for transporting the spent fuel to a conditioning facility for the final repository or to a reprocessing facility, too;
- eliminates the spent fuel bundle manipulation between NPP and the conditioning or reprocessing facility; minimum of operation, minimum number of operators, smaller operating expenses;
- doesn't generate nuclear waste;
- simplifies the IS utilities;
- it is less vulnerable to heavy objects falling or missiles;
- may reduce the cost of the back-end cycle, because the cask is both for transport and for storage;

The disadvantages of using this solution are:
- the IS cost is higher than for other solutions;
- higher temperature on the spent fuel bundle;
- reduced operating experience.

THE SPENT FUEL TRANSPORT FROM THE NPP CERNAVODA TO THE IS
We have analyzed the spent fuel transport considering it to be a system. This system represents the ensemble of equipments, devices and tools necessary to do the spent fuel transport according to approved procedures, in good technical and economical conditions and according to the existing laws and standards.
The system composition and its operation are determined, at first, by the IS type and its site (inside or outside of the NPP site), and second, by the NPP spent fuel area design.
In the case of choosing the wet IS or double purpose casks variants, the spent fuel will be stored 10 years in NPP Cernavoda bay. The spent fuel transport and storage will be done probably in modules (2 to 4 modules in a cask), and the loading will be done in NPP RSFB.
In the case of choosing the dry IS in modules, the spent fuel will be stored only 7 years in the SFSB The transport and storage will be done in baskets, and the transport cask will accommodate 1 basket. The basket will be tightened by automatic

welding, and, as we have already mentioned, this operation will be done in a Loading Station. The loading and unloading of the basket into/from the cask will be done with a hoist placed inside the upper part of the cask. Another spent fuel transport type will be done from NPP Cernavoda to the Nuclear Research Institute Pitesti. The transport will be done with defective spent fuel bundles, for research reasons. Therefore, CITON with the Nuclear Research Institute Pitesti are designing a cask for this purpose.

FINAL

In this paper the Romanian variants for the fuel back-end cycle studied until now are presented based on the following:

- the characteristic of Romanian Industry, which has experience in designing and manufacturing utilities for the spent fuel storage bays;
- the NPP Cernavoda site characteristics, which affect the Interim Storage maximum area (if the IS will be inside NPP);
- the NPP Cernavoda SFSB arrangement, which influences the spent fuel evacuation;
- the CANDU spent fuel quantities and characteristics.

All the facilities and equipments involved in the fuel back-end cycle are analyzed as parts of a single system, because the decisions and changes done for one component in one step of the program will influence the other components of the system as well. For this reason, our studies take always into considerations the interfaces between each component of the system and the system.

A sustained activity of information updating about the international practices in the fuel back-end cycle is necessary in this stage of the Waste Management Program. Also, it is necessary to be in touch with designers, manufactures and operators of similar facilities.

The back-end of the fuel cycle is currently under study. The Waste Management Program has the deadline for the Spent Fuel Interim Storage in 2006 if it will be adopted the wet variant, or 2003 if it will be adopted the dry variant. This requires also to bring up to date the legal frame for nuclear materials transport and storage, according to the IAEA standards.

ABSTRACT
To satisfy the requirements imposed by the German regulations, a system for the documentation of radioactive NPP wastes with negligible heat generation has been developed. This system, called AVK, consists of several database PC-programs and has a tight organizational structure including a quality control office and an active user support, which ensure an appropriate quality level of the database. AVK keeps track of the waste packages from the moment of their creation to the deposition in a final repository. It registers the characteristics, activity inventory, predecessors, relocations etc. of each package and generates the documentation required by the authorities. In addition, AVK includes a module for the computation of the nuclide-specific activities based on the default nuclide assessment procedures. This module can compute the activity inventory of a waste package from a wide variety of input data, such as the experimentally known activities of the representative radionuclides (Co-60 and Cs-137), the total b/g activity of the g emitting radionuclides, the total a activity, the dose rate, the experimentally determined mixing ratios of radionuclides (e.g. in the primary coolant) and the humidity of the waste package (relevant for H-3). AVK is currently in full operation at all NPPs, waste conditioners and interim storage facilities in Germany.
INTRODUCTION
To improve the documentation about radioactive wastes, the Federal Ministry for the Environment, Nature Conservation and Nuclear Safety published the "Guideline on the Control of Radioactive Wastes with Negligible Heat Generation" in 1989, which is colloquially known as the "Waste Control Guideline". The objective of the Waste Control Guideline is to regulate the documentation and control procedures for these radioactive wastes.
The Waste Control Guideline prescribes the information which has to be documented of the radioactive wastes and makes the producer of the wastes responsible for the book-keeping. Furthermore, it requires that the waste producer keeps track of his wastes, which means that he must always know their exact location and the current state of treatment. In view of these requirements, a book-keeping system had to be developed, which could keep track of the origin, type, quantity, radioactive inventory, state of treatment and location of the radioactive wastes. Such a book-keeping system helps the waste producer to provide the responsible authority promptly upon request with the latest information about his wastes.
However, even before the Waste Control Guideline was enforced, all operators of the German nuclear power plants initiated with consent of the Federal Ministry of Environment the development of a documentation and book-keeping system called AVK. AVK is an acronym for "Abfallflu-Verfolgungs- und Produkt-Kontrollsystem" which means "waste flow tracking and quality assurance system". AVK has been designed as a decentralized database system consisting of several PC-programs and a tight organizational structure. It keeps track of the radioactive wastes from their origin to their disposal in a final repository and ensures that the exact location and the state of treatment of any nuclear waste can be accurately determined at any time required.
Overview
A particular radioactive waste is registered in AVK as soon as it exists as a closed unit, which is not subject to any further operational changes. The data which have to be registered are
- the general data (mass, volume, package label, package characteristics, type of treatment, location, etc.);
- the radioactive inventory and radiological data;
- data needed for the quality assurance as specified by 1) the "Waste Control Guideline", 2) the "Preliminary Requirements for the Final Disposal in the Repository KONRAD" and 3) the "Acceptance Requirements for the MORSLEBEN Repository".

The data in AVK have to be updated following every relocation or modification of the

waste. Provided that the treatment of the waste results in the production of a new waste package, the latter has to be registered with reference to its predecessors. In this way, AVK provides a complete track of each radioactive waste package.
The participants in AVK are
- the producers of the radioactive wastes;
- the waste treatment plants;
- the external interim storage facilities;
- the central office.

The waste producers are the nuclear power plants and, to a minor extent, the waste treatment plants and the external interim storage facilities. All waste treatment plants, irrespective of their actual location and ownership are the legal responsibility of GNS, the service company of the nuclear power plants seated in Essen (North Rhine-Westphalia). The external interim storage facilities are located in Gorleben (Lower Saxony), Mitterteich (Bavaria) and at the nuclear power plant Unterweser in Rodenkirchen (Lower Saxony). The central office in Essen is also the responsiblity of GNS, but is organizationally independent of the waste treatment plants.
All AVK-participants, except for the central office, use the PC-program AVK and a subsequently developed independent module AVK-ELA. However, some nuclear power plants do not operate AVK-ELA directly, but prefer to use a service offered by GNS to operate this program . In addition, the module AVK-ELA is operated by instituitions which are involved in the final disposal of radioactive waste, but which are not direct AVK-participants. The central office uses a different PC-program described below. The data are exchanged via off-line data carriers.
The main features of the AVK-program are
- a database system with encoded data files and a hierarchical access system;
- data acquisition is possible only after inspection by a second person;
- input support via reference files and list boxes;
- four distinct modules for input of the data about 1) raw waste, 2) storage characteristics, 3) conditioned waste and 4) transportation;
- a report generator to create free lists, standard lists and other documents;
- a module for the computation of the activity inventory (cf. below).

The program AVK-ELA has been developed after the Morsleben repository (Saxony-Anhalt) was reopened for the final disposal of radioactive wastes (It was closed between 1990 and 1994 for legal reasons in connection with the German reunification). The purpose of AVK-ELA is
- the determination of the activity inventory of the radioactive wastes;
- the check for compliance with the "Acceptance Requirements for the MORSLEBEN Repository";
- the recording of the administrative procedures in connection with the final disposal;
- the generation of data sheets, i.e. documentation;

The central office runs its own PC-program for the autonomous control of the AVK-system. The objective of this program is to
- archive all AVK-data:
- inspect the data for mistakes and changes;
- balance the AVK-data between the individual AVK-participants;
- evaluate the complete AVK database of all participants.

The quality assurance measures carried out during the input of data (data input by two persons, data input support, plausibility checks), and completed by the inspection of the data of all the AVK-participants by the central office, ensure an appropriate quality level of the database. Thus, the requirements for a documentation system for radioactive waste tracking are fully met by AVK.
FIG. 1
The exchange of data between the programs and participants of the AVK-system and between the AVK-system and other programs and institutions takes place via several interfaces, cf. Fig. 1. Between two AVK-programs the data are transfered via checksum protected export and import interfaces. The module AVK-ELA and the program used by the central office can import data from the AVK-program but the reverse flow of data is not allowed. Furthermore, the AVK-system possesses interfaces to external institutions and data processing systems, e.g. to ISAR, a PC-program installed at the authorities to support their surveillance activities. In addition, the AVK-program can exchange data with other data processing and documentation systems

and devices, e.g. the dose rate detector, via standard import and export interfaces. Finally, an ex- and import interface between two AVK-ELA modules enables data transfer to external institutions involved in the final waste deposition.

Organizational Structure

The cooperation between all institutions participating in the AVK-system, their organizational integration and responsibilities are regulated in the AVK Organization Handbook. This handbook lists all AVK-participants, describes their tasks, regulates the data exchange and specifies additional requirements where necessary. The tasks of the waste producers, waste treatment plants and the interim storage facilities are for example

- the creation of the waste package and successor records by the waste producers and waste treatment plants;
- the import of externally created waste package records by the waste producers, waste treatment plants and interim storage facilities;
- the updating of the waste package records;
- the input of nuclide-specific activity measurements by the waste producers, waste treatment plants and interim storage facilities;
- the maintenance of the accompanying documentation;
- the export of the AVK-data to the central office;
- the data security measures.

The Organization Handbook demands that all AVK-participants send a back-up of their data, including the program and auxiliary files, to the central office every three months. These are then checked for virus and topicality and compared with the last back-up archived at the central office. Any changes to the data sets are recorded and the AVK-participants are informed in a so-called control message about the result of the comparison and whether any inconsistencies or incorrect files were detected. If there are no complaints, the data is added to a master file containing the waste package records of all AVK-participants, which is then checked for consistency. If inconsistencies are detected, e.g. in the location of a waste package, the corresponding AVK-participants are informed and required to correct their data.

The Organization Handbook also regulates the data exchange between the AVK-participants 1) in connection with the transport of the radioactive waste packages, 2) in the case of updating procedures and 3) for organizational reasons. The data are exchanged via disks or paper. The form and content of the data, the accompanying documentation, the deadlines and other organizational requirements are precisely defined.

The Waste Control Guideline (cf. above) regulates the scope of the reports which the waste producers, waste treatment plants and interim storage facilities have to supply to their authorities. In order to standardize these, the organizational regulations about the form and content of the AVK-reports are specified in the Organization Handbook and are implemented in the AVK-code.

The AVK-Code

The AVK-program is a database system which runs under the operating system DOS. It consists of modules for the input of waste, transport and storage data, for the system maintenance and for the activity calculation.

AVK recognizes three levels of user authorization

- the authorization for the output of data;
- the authorization for the input and output of data;
- the authorization to act as a supervisor for the system maintenance;

The user's identification and password enable the program to recognize the appropriate level of authorization. If the database is not in a correct state, only the supervisor is authorized to log in.

The AVK-program is menu-driven and comprises

1. MADA (Module for the input of raw waste data);
2. MOTRA (Module for the input of transport data);
3. MOZILA (Module for the input of interim storage data);
4. MOKON (Module for the input of treated waste data);
5. MOPRO (Module for the activity determination and quality assurance);
6. MOBERI (Module for the reports);
7. MOSERV (Service module for the system maintenance).

The waste package data are registered using the modules MADA and MOKON. The input is standardized by extensive use of reference files. The AVK-program automatically

supplies each new waste package record with a unique identification number, the AVK-ID. This ensures that a specific AVK-ID occurs only once within the entire AVK-system.
The input fields are either obligatory or optional. The obligatory fields must be filled during the registration of a waste package, whereas the optional fields can be completed later. A waste package record cannot be saved before all obligatory fields are filled. To track the treatment of a waste package, a new data record must be created. In this case, the old data record is automatically saved, so that the complete history of the waste-flow is always consistently documented.
The registered waste package data are saved in a buffer. These data must be inspected by a second user before they can be transferred to the master database . The AVK-program does not allow a single user to register the waste package data and transfer them to the master database.
The module MOTRA makes it possible to register the transport data. A transport data record contains essential transport data together with the AVK-IDs of the waste packages which are transported. The AVK-program automatically assigns unique labels to each transport in a manner similar to the AVK-ID assignment described previously. Following dispatch, the AVK-program registers the waste packages as being underway. The recipient of a transport must inform the dispatcher about the receipt. The dispatcher then registers the date of the receipt and the new location of his waste packages in his AVK-database. Thus, the transport history of each waste package is always documented transparently.
The module MOZILA serves exclusively to supplement the location data.
The module MOPRO computes the radioactive inventory for radionuclides which have to be declared according to the "Waste Control Guideline", but for which no experimental data are available. The experimentally known activities always have higher priority than calculated values and are never overwritten by the computed data. The data which MOPRO uses to compute an activity include
the experimentally known activities of the representative radionuclides (Co-60 and Cs-137);
  the total b/g activity of the g emitting radionuclides;
  the total a activity;
  the dose rate;
  the experimentally determined mixing ratios of radionuclides (e.g. in the primary coolant);
  the humidity of the waste package (relevant for the computation of the H-3 activity).
Based on the available information, MOPRO automatically selects the best calculation method to be used for each radionuclide and documents it together with the result. The module MOPRO computes activities for any arbitrary date and presents the results in any of the several available output formats. In addition, MOPRO determines whether the declaration limits of the "Waste Control Guideline" have been exceeded and whether the preliminary KONRAD waste acceptance requirements are met. Finally, it assignes the waste package to the corresponding waste product category.
The module MOBERI selects the waste package data records and generates the standard lists and documents, displays, prints or saves them in a file. The standard lists are predefined output formats, in which the AVK-user can list the selected waste package records. The standard documents are reports to the regional authorities (cf. above).
The module MOSERV is used for the system maintenance, i.e.
  the import and export of data;
  the transfer of waste package records from the buffer to the master database;
  the defining of the free lists via a list generator (the arrangement of the fields in the list can be predefined, group sums can be formed, etc.);
  the editing of the reference databases ;
  the editing of the master database .
At the end of each session, the user is prompted to save his database on an external data carrier.
Activity Determination
Table I lists the AVK-relevant nuclides.
The radioactive inventory of a waste package can be either based on experimental data or computed ones using default nuclide assessment procedures, representative nuclide distributions and/or surface dose rates. The default nuclide assessment

procedures are based on
  statistical analyses of activity measurements on representative radioactive wastes;
  burn up calculations;
  activating calculations;
  secular equilibrium;
  transient equilibrium;
  other procedures.
Statistical analyses are the preferred approach, provided that a sufficient number of representative experimental data sets is available. The default nuclide assessment procedures require the knowledge of the key nuclides Co-60 and Cs-137, the activities of which can be determined from the total activity or the dose rate. The parameters required for the computation of the activities from the dose rates, e.g. the geometries, the densities, and the shielding characteristics, are determined from the corresponding package characteristics. Thus, the activities can be calculated knowing the waste mass, the dose rate, and the Cs-137/Co-60-ratio or the nuclide distribution.
Figure 2 shows a commonly used procedure for the determination of activities. In this procedure, a sample is drawn from the raw waste before it is processed to waste packages, e.g. drums. The nuclide specific analysis of this sample yields activities, which can be registered in AVK either directly or in form of a representative nuclide distribution or the Cs-137/Co-60-ratio. Independently, the dose rate of the waste packages is measured and registered in AVK together with the general package characteristics, such as the drum type, the waste mass etc. Using these data and the implemented results of the nuclide assessment procedures, the AVK-program computes the radionuclide inventory and generates a data-sheet.
In addition to the common procedure shown in Fig. 2, there are 19 other possibilities for the determination of the radionuclide inventory, which can be combined nuclide-specifically in a multitude of ways.
User Support
In order to optimize the operation of the AVK-system, an extensive user support is arranged
  hotline
The AVK-hotline supports the AVK-participants with respect to organizational, radiological (activity determination) and data processing aspects. Each hotline message is documented on a formsheet and recorded in a database . If any program errors are reported, they are immediately corrected and an upgrade is sent to the users. The frequency and the content of the hotline messages reflect the educational level of the users, the stability of the AVK-program and the consistency of the AVK-system. The analysis of the messages gives hints for the future development.
  user support at the site
Periodically all AVK-users are visited by the members of the AVK-developer staff in order to evaluate their practical experiences. During these visits their problems are discussed and the data processing equipment is checked and optimized when necessary. All results are recorded in questionaires and collected in a database. The collected information is analyzed and used together with that of the AVK-hotline for the optimization of the AVK-program and the AVK-system.
  training
Training is offered to the users twice a year .
  user meetings
The development of the AVK-system, including the programs, is discussed and harmonized during the periodic user meetings.
  newsletter
The current developments, changes, information and hints about AVK are periodically published in an AVK- newsletter.
AVK Project Development and Status
The development of AVK was initiated in autumn 1988. Several weeks later an input module was installed with the users and AVK began with its test operation. The first full version, AVK-V1.0, was introduced for test purposes in May 1989. The experience with AVK-V1.0 was continuously analyzed and used for the development of AVK-V2.0, which was then installed in summer 1992. The latter was upgraded several times. The current upgrade which was installed with the users in August 1994 is AVK-V2.12.

In the opinion of the users AVK-V2.12 is sufficiently comfortable and stable to fulfill their requirements. The module for activity determination is now under expertise by TV-Bayern/Sachsen e.V. Thereafter it will be recognized as a standard. The central office began with the test operation of its first module in March 1992. The second module was installed a year later and since 1994 it is in full operation. The module AVK-ELA-V1.0, which generates the documentation required for the final disposal of radioactive wastes and for the control of the waste packages for the MORSLEBEN Repository, was programmed in 1994. Currently it is in its test phase. With AVK-V2.12, AVK-ELA-V1.0 and the programs for the central office the development of the AVK-system is temporarily completed. Future development is intended only if the corresponding prerequisites, such as the administrative regulations and the requirements for final disposal, change.

MODELING PRECIPITATION FROM CONCENTRATED SOLUTIONS WITH THE EQ3/6 CHEMICAL SPECIATION CODES
Lee F. Brown
Michael H. Ebinger
Los Alamos National Laboratory
ABSTRACT
We designed four hypothetical problems in which portlandite (Ca(OH)2), gypsum (CaSO4.2 H2O), or both precipitated from concentrated solutions. The problems are used to compare predictions of precipitate formation from the hypothetical solutions. Precipitates are predicted assuming ideal solution theory as well as various methods of accounting for nonideal behavior. The Davies modification of the Debye and Hckel approximation, the B-dot approach, and two approaches employing virial equations are used to accommodate nonideality. All nonideal modeling is conducted with the EQ3/6 codes, whereas ideal solution predictions are made algebraically.
Three problems involved precipitation of portlandite or portlandite and gypsum. The results of the three problems showed reasonable replication of the amounts of precipitates that formed. Activity coefficients and final solution concentrations differed according to the methods used to model the problem, but comparable Ksp values are calculated for each prediction. The fourth problem modeled precipitation during evaporation. The results showed that the expected amounts of precipitates varied according to the modeling approach that is used. There is also significant variation in activity coefficients and concentrations of different solution constituents after precipitation.
The results of all the tests indicate that the ideal and nonideal approaches to precipitate prediction can be similar when the amount of precipitates is considered. The modeling suggests that ideal solution approaches can be used on occasion to predict precipitation from concentrated solutions. The benefits of ideal solution modeling are that solubility data exist for most species and precipitates of interest. The important drawback to using ideal solution modeling in concentrated solutions is that predictions may not be valid for the system under consideration. Our results show that ideal solution modeling agreed with nonideal solution modeling for the hypothetical problems we designed.
INTRODUCTION
The main purpose of the work presented in this paper is to compare predictions of precipitate formation from concentrated solutions using different chemical modeling databases and different equations that characterize nonideality of solutions. We are interested in precipitation from concentrated solutions and how consistently numerical speciation codes model this phenomenon. Available chemical speciation data are limited for modeling concentrated, nonideal solutions, whereas there are more extensive databases that can be used to model the solution and precipitation if ideality or only weak nonideality of the solution is assumed. Our goal is to use ideal and nonideal approaches and model the solutions, then compare the results of the different approaches. The hypotheses tested in this paper are: 1) ideal and nonideal calculations provide similar predictions of the precipitation processes; 2) variation in activity coefficients depends on how the coefficients are calculated but make only small differences in Ksp and saturation index values; 3) variations in activity coefficients resulting from using different databases or nonideality equations result in significant variations in predicted precipitation during

evaporation campaigns.
We designed four hypothetical problems for the paper, and they are discussed in detail below. Three problems concern precipitation of Ca(OH)2 (portlandite) alone or portlandite and CaSO4.2 H2O (gypsum), and one concerns precipitation during evaporation. The results from modeling the four problems are compared and are used to examine the above hypotheses. We chose the EQ3/6 chemical speciation codes (1, 2) to model the four problems.
Uncertainty in the data from databases or references causes significant uncertainty in the predictions. In general, uncertainty in data and equations used for calculation of activity coefficients, redox states, and ionic relations leads to variation in predictions of the chemical behavior of solutions (3). Users of speciation codes must also be aware of the data used in modeling calculations and the limitations of the databases used for the calculations. Daveler and Wolery (4) discuss specifically the limitations of the EQ3/6 databases, and the results of our calculations illustrate some of these variations and limitations. A note of caution by Wolery (1) is also worth repeating: "Geochemical modeling codes are not black boxes. Much of the usefulness (or lack of) that comes from their use is determined by the level of knowledge brought to bear by the user...Any results obtained by modeling calculations should be weighed against descriptive knowledge of the system being modeled."
METHODS
Overview of Problems
We designed four problems to test the EQ3/6 codes in modeling precipitation of Ca(OH)2 (portlandite) and CaSO4.2 H2O (gypsum) in concentrated solutions. Problem #1 concerns the precipitation of a single substance, portlandite. One liter of a water solution containing 500 g dissolved CaCl2 was mixed at 25C with one liter of a water solution containing 100 g dissolved NaOH. We predict how much portlandite precipitates and the composition of the remaining solution. Problem #1 serves to validate the EQ3/6 codes on an elementary level. In this problem, the solutions are concentrated and calcium is in excess, so most of the hydroxyl ion precipitateds as portlandite.
Problem #2 examines precipitation from a high ionic strength solution that is dilute in precipitating species. One liter of a solution containing 8 g dissolved CaCl2, one liter of a water solution containing 3 g dissolved NaOH, and one liter of a water solution containing 500 g dissolved NaCl are mixed at 25C. We consider if calcium hydroxide precipitates, and if so, how much. We also predict the concentration of different constitutents in the remaining solution.
Problem #3 investigates simultaneous precipitation of portlandite and gypsum. The purpose of Problem #3 is to compare relative amounts of two precipitates, both of which should form because of the concentrated solution. Three solutions are mixed at 25C, and one liter of the mixed solution is modeled. The initial solution concentrations are 167 g CaCl2, 33 g NaOH, 167 g Na2SO4 in one liter of water. We predict how much portlandite and how much gypsum precipitate as well as the composition of different constitutents in the remaining solution.
The fourth problem examines the evaporation of the supernatant of Problem #3. We predict the precipitates after the supernatant evaporated from 1000 g of H2O to 45 g. Problem #4 illustrates possible differences in the predicted results of evaporation campaigns when different thermodynamic databases or different nonideality relationships are used to calculate the solution compositions.
Calculation of Activity Coefficients and the Saturation Index
The "tendency of a species to react (5) is the activity of a substance. Activities are used to calculate thermodynamic equilibrium constants and solubility products (Ksp). The solubility products predict precipitation of solids from solutions and dissolution of solids into solutions. Thermodynamic activity (ai) of a component is calculated from its concentration (Ci) and activity coefficient (gi) by

$$a_i = g_i C_i \qquad (1)$$

Activity coefficients approach one in highly dilute solutions and are defined as unity in ideal solutions. Equation 1 is also called the activity product, Q, of the constituent i.
The first successful approach to estimating activity coefficients for species in ionic solutions was proposed by Debye and Hckel (6). Their approach has been widely used and extended since its introduction. Glasstone (7) and Lewis and Randall (8) give good descriptions of the theory and its applications, and Mazo and Mou (9) give

a sophisticated treatment of Debye-Hckel theory.
Unmodified Debye-Hckel theory may be suitable for modeling solutions only at concentrations less than 0.003 M (10). Thus, unmodified Debye-Hckel equations are not used in the EQ3/6 codes. An extended Debye-Hckel equation proposed by Davies (11) is incorporated in EQ3/6 as is the "B-dot" equation (12, 13). Activity coefficients calculated from high concentration solutions, however, are inaccurate even when these modifications to Debye-Hckel theory are employed. Recent modeling efforts have incorporated virial equations developed by Pitzer for activity coefficients (14, 15, 16). Use of these virial equations allows more exact calculation of activity coefficients for solutions at high concentrations.
The saturation index, SI, is defined as the log of the ratio of the activity product to the solubility product (2). We calculate activity products, Q, from the output values of the EQ3/6 calculations and Equation 1. When Q is greater than Ksp or, alternatively, when SI is greater than 1, we expect a precipitate for the solid of interest. The activity product is particularly useful in explaining some of the results of our predictions.
Chemical Speciation: EQ3/6 Codes
Several chemical speciation codes have been developed since about 1965. The characteristics of some of the codes are compared by Mangold and Tsang (17). We use the EQ3/6 codes (1, 2, 18) because these codes model more aqueous species and more possible precipitated mineral types than most other codes. The EQ3/6 codes also model the evolution of a solution from its starting point toward final equilibrium. The final solution and any intermediate solutions and precipitates can be examined during the course of reaction path modeling. Few other chemical speciation codes have reaction path modeling capability.
The EQ3/6 codes have undergone continuous improvement with expansion of their capabilities and databases. The number of elements included in the most frequently used database now numbers 78, the number of aqueous species 851, the minerals 885, and gases 75 (4). The EQ3/6 codes have their databases in separate files that can be individually addressed and modified if desired. The COM file is the largest of the five databases and draws on many sources of data (1). It encompasses the broadest range of elements and species of any of the five files, taking some of its data from the other four files. Other files have greater internal consistency or apply to specific situations but possess data on fewer species.
The Pitzer equations require specific parameters, and databases developed particularly for using these equations are necessary (14, 15, 19). The PIT and HMW data files were created for using the Pitzer equations with the EQ3/6 codes. The PIT file includes more species, but the HMW file has better internal consistency. The HMW file includes mutual consistency of activity coefficient data and standard-state thermodynamic data. However, the HMW file is limited to the set of components present in the "sea-salt" system, and is restricted to 25C. Wolery (2) and Daveler and Wolery (4) give additional information about these databases and their uses.
The Databases and Activity-Coefficient Relationships Used in this Study.
Employing the Pitzer equations for the concentrated solutions in Problems #1-4 is the first choice of prediction methods. The numbers of solution species and solids available in the PIT and HMW databases, however, are not as extensive as the databases for the Debye-Hckel approach. Therefore, while the Pitzer approach is preferable from a theory standpoint, the data necessary for adequate description of the problems sometimes dictate the use of the Debye-Hckel approach. Because of the uncertainty of the Debye-Hckel approach in modeling activity coefficients at high concentrations, an indication of the errors involved in using the Debye-Hckel approach is desirable.
The Davies and B-dot equations are used to compare the results of the two approaches with the COM database. The Pitzer equations are used with the PIT and HMW databases to compare this approach with different databases. The results of each problem allowed comparison of the Debye-Hckel and Pitzer equations in examining the four problems.
RESULTS AND DISCUSSION
Precipitation Problem #1
The amounts of portlandite that precipitate in the different solutions to Problem #1 range from 44.9 g/l to 46.3 g/l (Table I). The higher value is calculated assuming ideal solutions, the lower value with EQ3/6 and adjusted for nonideality. The amounts precipitates predicted from the ideal solution are expected to be greater

than the amounts predicted from the nonideal solutions because the product of the activity coefficients tends to be less than 1 in nonideal solutions. Thus, the activity product, Q, should be smaller for nonideal solutions than ideal solutions. Most of the Ca++ precipitates because of the small Ksp of portlandite, and there is minimal effect of the product of the activity coefficients on the calculations. The low Ksp gives reasonable predictions of the amounts of Ca(OH)2 precipitation for Problem #1 regardless of ideality or nonideality of the activity coefficients.
The activity coefficients for both the Ca++ and OH- ions show wide variation. The coefficients for the calcium ion range from 0.35 to 2.65, for the hydroxyl ion from 0.035 to 0.57. There seems to be little consistency in the activity coefficients, either within the same database using different relationships for the coefficients, or within the same relationship but using different databases. The listed concentrations are dilute, so they do not differ much in absolute terms. They nevertheless exhibit significant relative differences. The existence of these differences illustrates the uncertainties in using computer codes for chemical speciation as mentioned above.

Precipitation Problem #2

Table II shows the results of Precipitation Problem #2. Ideal solution approaches predict small amounts of portlandite, whereas three of the four nonideal calculations predict no portlandite. Since the solubilities of solids are higher in nonideal solutions than ideal, there is a possibility that precipitates will be predicted in some of the calculations but not in others. The Q for the Davies and B-dot predictions is significantly less than the pKsp for portlandite and no precipitation is expected. The Q for the HMW prediction is also less than pKsp, but the difference between the Q and pKsp is much less than for the COM database. While no precipitate is predicted using the HMW database, a small variation in one of the activity coefficients could result in Q greater than pKsp and portlandite precipitation. The Q calculated in the PIT prediction is equal to the pKsp and portlandite precipitates. Slight variation in either activity coefficient for the PIT calculations could also mean that Q becomes less than pKsp and no precipitation would occur. Alternatively, variation in the pKsp could result in similar changes in predictions.

Since the solubilities are generally higher for solids in nonideal solutions, there should be a possibility that no precipitation is predicted when nonideal solutions are modeled. The Pitzer calculations using the HMW database predicted no precipitation even though a precipitate is predicted when the PIT database is used. The reason for the discrepancy is that the Ksp value for portlandite in the HMW database is significantly less than in the PIT database. Precipitates are considered more likely in the simulations using the Pitzer equations than in the Debye-Hckel simulations. The Debye-Hckel relationships tend to predict activity coefficients that are lower than the coefficients from the Pitzer equations when solutions are concentrated. The expected outcome is reflected in Table II when the low value of the Ksp in the HMW database is factored into the comparison.

The difference in the precipitates predicted from the two ideal solution calculations shows the significance of a small variation in solubility products. There is a 12% difference in the masses of the precipitates from the two predictions, resulting from a variation of about 16% in the listed solubility products. A larger difference in the listed solubility products, such those of gypsum (Table III), could be significant in predicting precipitation or no precipitation from different solutions.

Results of Problem #2 show that there is a significant difference in ideal and non-ideal predictions when the precipitating species are in low concentration and the solution is of high ionic strength (high concentration). Debye-Hckel relationships tend to predict lower activity coefficients in concentrated solutions than do Pitzer relationships. Results from B-dot calculations reflect the tendency to predict lower activity coefficients, but the Davies results show larger activity coefficients than calculated with the Pitzer equations. The reason for larger activity coefficients from the Davies equation is not clear. Results of Problem #2 show the importance of including non-ideality in calculating precipitation from solutions dilute in the precipitating species.

The results of Problem #2 also show the effects of different Ksp values in different databases. The PIT and HMW databases show different values for the Ksp of portlandite. The result is that calculations using the PIT database predicted

precipitation of portlandite and those using the HMW database did not. The results of Problem #2 reinforce the principle that uncertainties for predicting chemical speciation behavior are important and should always be considered when using computer codes.

Precipitation Problem #3

Gypsum and portlandite are precipitated simultaneously in Problem #3. The amounts of portlandite range from 28.6-29.8 g/l, and the amounts of gypsum range 181 to 192 g/l (Table III). The exception is 26.3 g/l portlandite and 197.6 g/l gypsum that result from the unusually low Ksp for gypsum in one of the data sources used for evaluating ideal solutions.

The nonideal and ideal approaches predict similar amounts of portlandite and gypsum. The consistency in the precipitates is illustrated by the following. Let x be the amount of Ca++ that precipitates as Ca(OH)2 and y the amount of Ca++ that precipitates as CaSO4.2 H2O. The ratio y/x ranges from 2.66 to 2.77 for the nonideal calculations and is 2.89 for the ideal calculation, showing the preference for gypsum precipitation. A second ratio is also defined. Let xreal be the amount of portlandite from any of the nonideal solutions and let xideal be the amount of portlandite that is expected from an ideal solution. The ratio of xreal/xideal ranges only from 1.01 to 1.02 and suggests that the nonideal and ideal predictions are similar. The same ratio is calculated for gypsum with similar values of xreal/xideal. Thus, ideal or nonideal approaches predict essentially the same amounts of gypsum and portlandite, and either approach can be used. The nonideality of the solution changes only slightly the amounts of the precipitating species. The results of Problem #3 show the effects of higher solubility in nonideal solutions. In each case the predicted gypsum is less when nonideality is considered than when the solutions are assumed ideal.

Results of Problems #1 and #3 show that predicted amounts of precipitates from ideal solutions can be similar to predictions from non-ideal solutions. The reason for the apparent agreement lies in the calculation of the Ksp and Q values. As calculated with Eq. 1, Q is the product of ion concentrations and activity coefficients derived from the EQ3/6 output. Nonideal activity coefficients tend to be either greater than or less than 1 as shown in Table III. The value of Q is thus a product of large and small numbers, and apparent differences in Q's are minimal when calculated from ideal and nonideal solutions. The activity products, however, do not necessarily cancel in every case, leaving open the possibility of significant divergence of nonideal and ideal predictions. Brown and Ebinger (20) consider the phenomenon of ideal-solution-predicted precipitation agreeing with nonideal-solution-predicted precipitation in more detail.

Precipitation Problem #4

Problem #4 begins with the final solutions from Problem #3. The final concentrations of the different ions of Problem #3 vary in each prediction, so the starting concentrations for each prediction of Problem #4 are not equal. It is expected that the amounts of precipitates predicted from different approaches will not be very similar (Table IV). Water is evaporated to 45 g from 1000 g in each prediction . Four minerals are predicted from the ideal and nonideal calculations: portlandite, halite (NaCl), thenardite (Na2SO4), and glauberite (Na2Ca(SO4)2). Precipitation of no other minerals is predicted.

All starting solutions are concentrated with regard to Na+ and Cl-, and agreement in the amount of Na-containing precipitates is expected when ideal and nonideal predictions are compared. The results show that Ca-containing solids do not agree when the ideal and non-ideal predictions are compared. The discrepancy in the Ca-containing compounds is due to low concentration of Ca++ in the starting solution for Problem #3 and, thus, for Problem #4. Non-ideality is important when the precipitating species are in low concentration. In Problem #3 Ca++ precipitates from the ideal solutions and the Pitzer prediction. In Problem #4 the Pitzer and ideal approaches predict the smallest masses of Ca-containing solids because there is less Ca++ available to precipitate. There is still significant difference between the ideal and the four non-ideal predictions due to the effects of non-ideality on the solubility of Ca-containing solids.

Halite comprises 91-94% of the mass of the precipitate. Halite precipitates because the starting solutions contain large amounts of soluble sodium and chloride ions from the original solution for Problem #3. Calcium, hydroxyl, and sulfate ions have largely been removed in the precipitates predicted in Problem #3. The two

calculations using the Pitzer activity coefficient relationships predict about 10% more halite than the two calculations using Debye-Hckel activity-coefficient relationships.

The reason for the Pitzer calculations predicting more halite than the Debye-Hckel calculations is not clear. In spite of the different activity coefficient relationships and different databases, the ionic concentrations in the water are not greatly different, nor are the calculated activity coefficients. The principal differences in the predictions seem to be the larger number of aqueous species considered in the Debye-Hckel calculations and the solution concentrations of the species considered. This result illustrates the importance of knowing the contents of the databases used for predictions and the limitations of the databases.

The predicted amounts of portlandite, thenardite, and glauberite differ significantly among the calculations. The high value of portlandite is 46% above the low value, the high value of thenardite is 44% above the low value, the high value of glauberite is over twice the low value. There seems to be little correlation of the high and low values with the methods of calculation. The cause for the range of values in the results could lie in the number and kind of species considered, the databases utilized, or the equations used to calculate the activity coefficients. There is also large variation in ion concentrations and activity coefficients. Variations in the results of the Pitzer activity-coefficient relationships are less than the variations in the results derived from the Debye-Hckel relationships. The Pitzer relationships are supposed to be more appropriate for concentrated solutions, and they show that quality here.

Mass Balances

Calcium mass balances in each prediction of Problem #1 are excellent, showing much less than 0.1% error in each case. Calcium mass balance in each prediction of Problem #2 show less than 0.2% difference and are insignificant. We expected more error in the predictions of Problem #3 since the calculations were more complex. The mass balances are satisfactory for calcium and sulfur, the important ions in precipitate formation and in solution after precipitation.

Some of the mass balances for Problem #4 are not as good as in Problems #1-3. Calcium mass balances for each prediction of Problem #4 agree within 1% which is satisfactory for modeling an evaporation campaign. Mass balances for sodium differ by up to 17%, chloride mass balances differ up to 16%, and sulfur mass balances differ up to 7%. The large discrepancies in sodium, chloride, and sulfur raise questions about how well the EQ3/6 codes model evaporation when the volume of the solution decreases by more than a factor of 20. These discrepancies also illustrate the magnitude of the uncertainties in predictions that depend on databases considered very comprehensive in scope.

Solubility Products

We discuss above that variation of solubility products from different databases can be significant and occasionally drastic. For example, the solubility product of gypsum differs by a factor of 7.8 in the two sources used for the ideal solution predictions, and the solubility product of portlandite differs by 17% in the same databases. One test of the consistency of different thermodynamic databases is to calculate activity products from the concentration and activity coefficient information, then compare the calculated Q to the database Ksp values. The EQ3/6 calculations show excellent agreement between calculated and reference (database) values of the different precipitates. The Q values predicted for portlandite from the COM database agree well with the Ksp in the database in Problems #1 - #3, and the same is true for gypsum in Problem #3. The Q calculated from the PIT and HMW databases agree with their respective reference Ksp values. The PIT Ksp values are essentially equivalent to the Ksp values calculated from the COM database. The HMW Ksp values in the databases are 78% greater than the PIT values for portlandite and 26% greater for gypsum. Although large, the differences in Ksp between the PIT and HMW databases is within a factor of 2 which is a relatively small difference for Ksp values.

The free energies of formation for the above constituents are identical in the COM and PIT databases, and it is not surprising that the solubility products calculated using these databases are also identical. However, the activity products calculated from concentrations and activity coefficients in Tables I-IV are slightly different than the solubility products listed in the databases. The solubility products listed in the databases agree with solubility products hand calculated from free energy

data in the databases. The differences between the activity products calculated from the concentrations and activity coefficients and the Ksp listed in the databases are small. The difference is probably caused in part by the convergence criteria used in the calculations.

CONCLUSIONS

The EQ3/6 chemical speciation codes satisfy simple qualitative consistency tests posed by the four elementary equilibrium problems. Usually precipitates show higher solubilities when the solutions are regarded as nonideal than when they are considered ideal. The codes predict almost complete precipitation when solids are of low solubility. Both of these qualitative aspects agree with expectations and chemical theory. The speciation codes also satisfy the simple quantitative consistency tests posed by the four problems. Solubility products are identical when derived from the same database, and numerically close when calculated with values from different databases. Mass balances in the first three problems are consistent regardless of the approach used on a particular problem. The calculations converge to values of concentrations and activity coefficients that give activity products close to Ksp values listed in the databases and those calculated from listed Gibbs free energy data.

The results from solving the four problems using different databases suggest that the amounts of precipitates predicted from ideal solutions are similar to those predicted from nonideal solutions when the initial concentration of the precipitating species is high. The similarity in results between the ideal and nonideal approaches decreases when the initial concentration of the precipitating species is low. While our results show apparent agreement in predictions from ideal and nonideal approaches, extrapolation of our results to other concentrated solutions is not warranted. The predictions of the four problems illustrate well the warnings in the chemical modeling literature about the use of numerical speciation codes. There were large and unpredictable differences in the concentrations and activities of the various ions in the solutions that resulted in significant differences in amounts precipitated in Problem #4.

There are circumstances where a combination of concentrations and activity coefficients allow ideal solution theory to predict precipitation from nonideal solutions with reasonable accuracy. These circumstances can exist even when activity coefficients do not cancel in calculating activity products and/or solubility products.

Argonne, Illinois

ABSTRACT

The level of treatment and the treatment and interim storage site configurations (decentralized, regional, or centralized) impact transuranic (TRU) waste loads at and en route to sites in the U.S. Department of Energy (DOE) complex. Other elements that impact waste loads are the volume and characteristics of the waste and the unit operation parameters of the technologies used to treat it. Projected annual complexwide TRU waste loads under various TRU waste management alternatives were calculated using the WASTE_MGMT computational model. WASTE_MGMT accepts as input three types of data: (1) the waste stream inventory volume, mass, and contaminant characteristics by generating site and waste stream category; (2) unit operation parameters of treatment technologies; and (3) waste management alternative definitions. Results indicate that the designed capacity of the Waste Isolation Pilot Plant, identified under all waste management alternatives as the permanent disposal facility for DOE-generated TRU waste, is sufficient for the projected complexwide TRU waste load under any of the alternatives.

INTRODUCTION

Projected waste loads are important considerations in evaluating management alternatives for transuranic (TRU) waste generated at sites in the U.S. Department of Energy (DOE) complex. Projected TRU waste loads can be used to (1) determine whether the capacities of existing treatment, storage, and disposal (TSD) facilities are sufficient, (2) estimate the required sizes and expected costs of new TSD facilities, and (3) assess the potential health risks from transportation of the waste and operation of the facilities.

This paper describes the parameters used to calculate TRU waste loads and compares waste loads calculated for the TSD of TRU waste under various management alternatives considered for sites in the DOE complex.

TRU WASTE MANAGEMENT ALTERNATIVES

The 10 TRU waste management alternatives evaluated for DOE sites consist of various combinations of treatment levels, treatment processes, and treatment and storage locations, including no action. The three levels of treatment considered are described below.

The minimum level of treatment reduces TRU components in the waste to levels acceptable for disposal under the current waste acceptance criteria of the Waste Isolation Pilot Plant (WIPP) in New Mexico, currently identified as the permanent disposal facility for DOE-generated TRU waste. Only waste streams that do not already meet these disposal criteria will be treated, usually by solidification and appropriate packaging.

The intermediate level of treatment meets the waste acceptance criteria of WIPP and further treats the waste to reduce gas generation during degradation of organic materials and corrodible metals. Shredding and grouting debris waste and using non-iron-based containers reduces gas generation in the treated waste after disposal.

The highest level of treatment considered would destroy or stabilize all hazardous constituents in the waste to comply with the Land Disposal Restrictions (LDRs) of the Resource Conservation and Recovery Act. For the purposes of this study, incineration is considered a representative process for treating TRU waste to meet LDRs.

Treatment and interim storage sites also vary among the TRU waste management alternatives. TRU waste from individual DOE sites may be treated on the site where it was generated (decentralized configuration), it may be sent to regional centers for treatment (regional configuration), or it may be sent from all sites to WIPP for treatment (centralized configuration). All treated TRU waste would be stored at the treatment site until being shipped to WIPP for disposal.

TRU WASTE LOAD CALCULATION PARAMETERS

The level of treatment and the site of treatment and interim storage impact TRU waste loads at and en route to a given DOE site. Other elements that impact these waste loads are the volume and characteristics of the waste and the unit operation parameters of the technologies used to treat it.

Waste Volumes

The treatment sites identified in a given alternative determine the volume of waste treated at a site. For example, the volume of TRU waste to be treated at Site 1 under Alternative A is derived by combining the TRU waste contributed by all sites whose TRU waste is being sent to Site 1 for treatment under Alternative A.

The annual waste loads contributed include TRU waste inventories plus 20 years of projected TRU waste generation, divided by 10 (assuming treatment will begin 10 years from now). TRU waste inventory and projected generation volumes for each DOE site can be found in the Interim Mixed Waste Inventory Report (DOE 1993) and the Integrated Data Base for 1992 (DOE 1992). At the end of 1991, there were approximately 65,000 m3 of retrievably stored contact-handled (CH) TRU waste and about 4,300 m3 of retrievably stored remote-handled (RH) TRU waste at DOE sites (DOE 1993). (Packaged TRU waste with a surface dose rate less than or equal to 200 mrem/h is categorized as CH-TRU waste, and that with a surface dose rate of greater than 200 mrem/h is categorized as RH-TRU waste.)

An estimated 54,000 m3 of the waste (PNL 1994) could result from environmental restoration (ER) activities under a mixed-land-use scenario (assuming semi-restricted access to sites after remediation).

Waste Characteristics

Information about the characteristics of TRU waste has been obtained through process

knowledge supplemented by x-ray examination, radioassay, analysis of the gas in storage drum headspace, and sampling of the contents of a limited number of waste containers. Most TRU waste exists in solid form (e.g., contaminated protective clothing, rags, glassware, and machine parts), but some is in liquid sludge form. On the basis of its physical and chemical characteristics, TRU waste is grouped into waste stream categories, each of which has its own treatment train to facilitate efficient processing. The waste stream categories include aqueous liquids, organic liquids, solid process residues, soils, debris, special waste, inherently hazardous waste, and unknown.

Figure 1 illustrates treatment trains for five TRU waste streams being treated at a high level in order to meet LDRs. All treatment trains include a pretreatment step to segregate the waste into waste streams by separating liquids from solids or sorting out solids that have different physical properties. Currently, waste load calculations do not include three of the waste streams. The three, special waste, inherently hazardous waste, and unknown, constitute less than 10% of total TRU waste volume and are assumed to be set aside to await special processing.

Technology-Specific Unit Operation Parameters

The unit operation parameters of the technologies used to treat the waste influence waste load as well. These parameters include (1) volume factor, which is the ratio of product output stream volume to incoming stream volume, (2) mass fraction of product stream relative to input mass, and (3) mass fractions of secondary output streams relative to input mass. Unit operation parameters are specific to treatment technologies. For example, the volume factor for incineration is 0.1, for wet oxidation is 0.9, and for solidification is 1.2.

The ratios of specific contaminant quantities in TRU waste after treatment to their quantities in the waste before treatment are also calculated using unit operation parameters. The ratio of mercury in the treated product to mercury in the incoming waste stream, for example, is 0.01 for incineration, 0.1 for wet oxidation, and 1 for solidification. (In this case, solidification does not reduce contamination levels, but reduces a waste's ability to release the contaminant.)

Calculation of waste loads requires identifying the portions or combination of portions of incoming and secondary output waste streams assigned for each of the unit operations in a treatment train. For the incoming waste streams the assignments selected are generally averages of values conservatively estimated from analysis of data in the Interim Mixed Waste Inventory Report (DOE 1993). The assignments of secondary output streams are based on the expected makeups of the incoming streams and, in some instances, on engineering judgements about the expected waste stream behavior in a given process operation.

CALCULATED TRU WASTE LOADS

Total projected CH-TRU waste loads were calculated for the various TRU waste management alternatives using the WASTE_MGMT computational model (AVCI 1995). WASTE_MGMT accepts as input three types of data: (1) the waste stream inventory volume, mass, and contaminant characteristics by generating site and waste stream category; (2) TSD unit operation parameters; and (3) waste management alternative definitions. Some TSD processes generate secondary output streams that are also followed through the treatment process. For example, the primary output stream of incineration is ash, but a secondary stream of high-chloride salt waste is generated in the off-gas treatment of combustion gases (see Fig. 1).

Table I shows the projected annual complexwide waste loads of CH-TRU waste for four representative treatment technologies under three of the alternatives evaluated. As expected, the decentralization/treat-to-meet-minimum-disposal-criteria alternative, which does not use shredding or incineration, has the highest waste load for packaging among the three alternatives. The high waste load for shredding and low waste load for packaging in the regionalization/intermediate-level-of-treatment alternative indicates the effectiveness of the shredding process for reducing the volume of TRU waste, as well as for reducing gas generation to improve performance at WIPP.

Table II shows the projected total complexwide CH-TRU waste loads for storage and disposal, including waste loads from ER activities. The ER waste loads, which constitute approximately 30% of the total, were calculated from ER waste volumes projected to be generated under the mixed-land-use scenario assuming semi-restricted access to the site after remediation.

The maximum total projected CH-TRU waste load for disposal at WIPP under any of the

waste management alternatives is approximately 130,000 m3, which is less than the designed capacity of 170,000 m3 for CH-TRU waste at WIPP.

SUMMARY

CH-TRU waste loads were projected for treatment and storage facilities at each DOE site for all management alternatives considered. Results indicate that the designed capacity of WIPP is sufficient for CH-TRU waste loads currently projected for the DOE complex under any of the alternatives, as well as for projected TRU waste loads from ER activities assuming semi-restricted access to sites after remediation. The projected waste loads can be used to calculate size requirements and estimated costs of new treatment or storage facilities and to assess potential health risks from transportation of waste and operation of facilities. TRU waste management decision making can be facilitated by comparing calculated waste loads, costs, and risk among TRU waste management alternatives.

ABSTRACT

Mapping the gamma activity of irradiating zones is often an important prerequisite in dismantling nuclear facilities. This operation is necessary to define a suitable decommissioning strategy before any work begins; it is also required during the procedure to measure the residual activity wherever dose rates are too high to allow human intervention. This paper summarizes the work carried out to develop a prototype imaging system designed to display radioactive sources superimposed in real time over a visible light image on a video monitor. This project was developed from an earlier off-line system.

The gamma photons are collimated by a double cone system. The imaging system comprises a transparent scintillator bonded to the fiber-optic window of an ultrasensitive camera. The camera was miniaturized to meet specification requirements: with its radiological shielding, the gamma camera weighs 40 kg and is 120 mm in diameter. The processing system is compatible with a real-time camera, and small enough for use at any nuclear site. The point-source angular resolution is 1.4 for 60Co and 0.8 for 137Cs. The dose rate sensitivity limit is approximately 0.01 mGy.h-1. Process reliability was confirmed by tests in a high-level radiometallurgy cell at an actual decommissioning site.

INTRODUCTION

Existing detectors for absorbed dose rate measurements are based on the ionization chamber principle. When the objective is to localize radioactive emission zones, this equipment is usable only in simple situations. These detectors generally require human intervention, and are inefficient in the presence of multiple sources. They are unable to determine the true location of numerous radioactive sources, in

which case other methods are required.
Gamma mapping is a valuable technique for a variety of operations during decommissioning of nuclear facilities with highly irradiating zones:
prior to dismantling, in order to define the overall decommissioning strategy;
during the dismantling procedure to monitor the residual activity wherever the equivalent dose rates are too high to permit human intervention;
to organize decommissioning tasks in highly irradiating environments, and to define decommissioning procedures.
A photographic technique for localizing radioactive sources was developed by the Commissariat l'Energie Atomique (CEA) during the 1980s. The system uses a pinhole camera, in which the objective consists of a gamma radiation collimator and the visible light image is formed by a simple pinhole in a light-tight body opaque to radiation. An ordinary photographic emulsion is used for the visible light image, and a radiation-sensitive film reveals radioactive sources by differences in contrast. A gamma-transparent shutter is opened only for the visible light photo. After developing the films, the two images (exposed under identical geometric conditions) are superimposed to form a composite image on which radioactive emission sources in the field of view are immediately identifiable.
Numerous experimental measurements in a variety of nuclear facilities have demonstrated the advantages of this technique, notably to optimize radiation protection and dose limitation. Nevertheless, a number of major drawbacks in the initial procedure (uncertain interest of the observed zone, excessively long exposure times, complex processing required before obtaining a result) prompted us to develop a real-time technique (1). Work began in 1988 by the CEA, and a research contract was signed in October 1991 with the Commission of the European Communities to design and build a prototype imaging device meeting the following requirements:
dimensions compatible with telemanipulator penetrations 170 mm in diameter in the target cell;
weight not exceeding 50 kg to allow handling and remote manipulation;
allowance for subsequent installation on a carrier system to allow remote orientation;
maximum sensitivity to radiation emitted by 137Cs and 60Co;
rapid source localization (in no more than a few minutes) without diminishing the angular resolution of the off-line system (1 to 1.5).
ALADIN REAL-TIME GAMMA MAPPING SYSTEM (2)
The double-cone collimator design was maintained. In order to allow real-time operation, the photographic and radiation-sensitive emulsions were replaced by a scintillation screen. The scintillator converts the incident g radiation to visible wavelengths that can be registered by the camera. A transparent screen does not interfere with the visible light exposure of the scene. The camera thus observes the scene through the transparent screen when the shutter is open, and the radiation sources when the shutter is closed. An ultrasensitive camera is used to collect the weak light emitted by the scintillator. The camera supplies a standard CCIR video output (50 Hz, 625 lines). The very principle of this technique ensures perfect superimposition of the gamma sources on the visible light image of the scene.
Figure 1 shows the main components of the system: the objective or collimator, the image converter, the ultrasensitive camera and the computer processing unit. Each subsystem comprises a complete step in processing the initial signal, and the overall system performance depends as much on the inherent performance of each element as on their coherent integration.
Objective
The front part of the device serves as a collimator for g photons, and as a lens for visible light photons. A shutter that is virtually transparent to the observed gamma energy range allows switching between the two operating modes.
In visible light, the pinhole objective forms an image of the scene observed with a definition that depends on the diameter of the opening and the focal length separating it from the image plane. In the gamma range, the collimator limits the gamma photon flux from the radioactive source to a thin beam in order to determine its direction. The collimator determines the spatial resolution, and thus has a controlling effect on the final quality of the "gamma image". The double-cone collimator is a simple device covering a relatively large and fixed solid angle with a suitable collimating power. The spatial resolution depends on the observed energy level; the cone angle represents a tradeoff between the collimation power and the

observed solid angle. The collimator material has a significant effect on the collimating power; the prototype gamma camera allows for interchangeable tungsten alloy collimators with different aperture angles.

Image Conversion

The g-ray converter is a scintillation crystal meeting specification requirements for both visible light and g ray operation. In visible light it must offer maximum transparency and must not deform the image. At the same time, it converts g radiation into visible light, to which the photocathode is sensitive. The major parameters include the light efficiency, the crystal scintillation spectrum (which must be adjusted with the acceptance band of the input photocathode) and the high-energy g radiation stopping power (referenced to 60Co). Other criteria must also be taken into consideration, including the optical refraction index, which affects both the resolution and sensitivity, and the hygroscopic properties of the crystal, which must be low for ease of use.

Signal Amplification

Interactions with g radiation generate very little visible light in the scintillator, and strong amplification is required to detect the signal. The imaging device is a CCD camera coupled with two image intensifiers in series: a "first-generation" unit with a 50 mm input window, followed by a "second-generation" microchannel plate unit. Coupling the two image intensifiers in series provides an overall photon gain on the order of 106.

The input photocathode of each image intensifier tube converts the photon image into an electronic image. It is characterized by its spectrum response and sensitivity. In order to maximize the detection signal/noise ratio, particular attention was given to tuning the crystal scintillation spectrum and the photocathode spectrum response. The second important point is the dimension of the input window, which affects the spatial resolution.

Image Processing

Digitizing the video signal from the camera does not provide a usable image directly. As the gamma image is a statistical phenomenon, the signal must be integrated by summing a large number of corrected images to determine the radioactive emission centers. Dedicated circuitry is required to separate the image acquisition and processing functions.

Acquisition. The images are integrated at the video scanning rate (25 images/sec) by means of a dedicated circuit, which also subtracts the background from each frame to offset the poor black image from the CCD. The image is then sent to the processing circuit.

Display. The system is designed to provide a real-time on-screen display of the visual image from the camera together with the gamma source image as it is acquired: to ensure fully interactive operation, the radioactive source image is displayed in real time as it forms.

Processing. The correlation of a visible light image and a gamma image requires multiple processing: isocontours, filtering, false color enhancement, etc. This is done by a dedicated workstation, using custom application software developed specifically for the station to archive the images, quantize the relative dose rates, provide various superimposition modes and display a color map directly usable at the decommissioning site.

PROTOTYPE COMPONENT OPTIMIZATION

Detection Circuit

Theoretical optimization studies were conducted for the collimator and for the screen and fiber-optic system. Laboratory tests were then carried out to characterize the prototype in various detection circuit configurations.

Double Cone Collimator

The double-cone collimator is defined by three geometric parameters: the aperture half-angle, the pinhole radius and the extension or focal length between the gamma pinhole and the image plane. The collimator material determines the linear activation coefficient mb(E) for the observed gamma radiation of energy E (Fig. 2). The flat portion of the profile is formed by the direct g photon flux passing freely through the aperture. This is the "primary spot", i.e. the zone of highest density, corresponding to the projection of the pinhole onto the image plane P in the direction of the observation. The surrounding region of diminishing density is due to the incidence of the flux attenuated by the shielding, the thickness of which increases with the off-axis distance. The step S in the distribution profile

corresponds to the shielding thickness encountered by the photons outside the aperture radius r0. The collimator material, 97% tungsten alloyed with nickel and iron (s.g. 18.5), was selected to obtain the maximum gamma ray stopping power for the smallest possible dimensions.

The collimator is characterized by two fundamental criteria: its sensitivity (which depends on the sum of the direct and attenuated flux transmitted by the collimator) and its angular resolution (i.e. the ability to discriminate between adjacent point sources). The gamma image obtained with this type of collimator represents a tradeoff between the sensitivity, the resolution and the field of view.

The primary requirement was to ensure optimum resolution for 60Co and 137Cs. A theoretical study revealed the advantages of a modular configuration with interchangeable collimators and a mechanical system for adjusting the extension over a 50 mm travel range between the collimator and the image plane. The two collimators are compared in Table I.

Scintillation Screen and Fiber-Optic Window

The detection system comprises a scintillation crystal bonded to the camera input window. The window must be a fiber-optic design to ensure transparency for the visible light image used to situate the gamma sources.

For a given collimator, the sensitivity and resolution of the unit depend in the opposite manner on the dimensions of the converter screen. A thick scintillator ensures high radiation stopping power, but also diminishes the angular resolution; conversely, a thin screen ensures better spatial resolution, but with poor sensitivity. The optimum tradeoff must also take a number of other factors into account:

- the inherent stopping power of the crystal, depending on its composition;
- the luminous efficiency and optical properties of the crystal;
- optical coupling between the scintillator and the first image intensifier;
- the observed dose rate level and the nature of the incident radiation.

The physical properties of the principal inorganic crystals considered for the scintillation screens are indicated in Table II. The two crystals selected for testing were bismuth germanate (BGO) and thallium-activated cesium iodide (CsI(Tl)). During experimental testing, CsI(Tl) exhibited substantially greater sensitivity for practically the same resolution.

Fiber optics must be used for the camera input window to allow localization of nuclear events. When a gamma photon interacts with the crystal, it loses part or all of its energy to atoms in the screen which in turn emit de-excitation photons in the visible spectrum, isotopically from the point of interaction. A fraction of these photons enters the optical fibers, depending on their numerical aperture and on the crystal refraction index. The optical fibers available on the market were tested at numerical apertures of 0.33, 0.66 and 1.00). The results clearly showed that reducing the numerical aperture from 1.00 to 0.66 enhances the angular resolution; at the present state of development, however, this requires an additional fiber wafer on the camera input window that results in a significant drop in sensitivity. We therefore chose to use fibers with a numerical aperture of 1.00.

EXPERIMENTAL RESULTS

For the collimators considered for our image acquisition system in the observed energy range (0.66 to 1.25 MeV), a scintillator thickness of 2 and 4 mm provides an acceptable balance between sensitivity and resolution. The mean experimental results obtained for observation of 60Co sources are indicated in Table III for various possible configurations.

The results obtained with two 60Co point sources confirmed and quantified the following characteristics: higher resolution is obtained with the 19 collimator; increasing the extension significantly enhances the resolution; the resolution is inversely proportional to the thickness of the scintillator. The point-source angular resolution is approximately 1.4 for 60Co and 0.8 for 137Cs.

Response linearity tests were conducted to evaluate the possibility of using 60Co and 137Cs point source images to quantify the irradiation dose rates. The results observed with different detection configurations showed satisfactory linearity of the response over at least two orders of magnitude of absorbed dose rates. The linearity range may be extended to higher absorbed dose rates simply by modifying the amplification gain. Typical experimental results for a 60Co source observed through a 26 half-angle collimator are shown in Fig. 3.

Amplifier Circuit

The amplifier circuit configuration was determined to meet the compact design requirements and to ensure compatibility with the gamma camera operating principle, i.e. the use of a single digital imaging system to ensure perfect superimposition of both the visible light and gamma images. The system (Fig. 4) comprises a "first generation" (electrostatic lens focusing) intensifier tube coupled to a CCD camera that is in turn intensified by a "second-generation" (proximity focusing) tube. In order to adapt the amplifier spectrum response to the CsI(Tl) scintillation crystal response, the first amplifier stage includes a photocathode with peak response in the blue wavelengths. The maximum diameter of the configuration adopted is 70 mm, and the overall length is less than 170 mm.

Computerized Image Processing System

Generally very few nuclear events occur in the scintillator during an individual video frame, so that simply displaying the incident image on a video monitor is not sufficient to localize the sources in the field of view. When the number of irradiation events in a given direction is too low, they cannot be distinguished from the camera's inherent pulse noise. Moreover, multiple sources are not sufficiently discriminated regardless of the noise level.

Instead, the statistical nature of the events is used to reconstitute "nuclear spots" on the image plane. The camera noise and the ambient background radioactivity are uniformly distributed over the image plane, while interactions due to irradiation sources are statistically localized. The system then simply integrates a suitable number of video frames to generate the source images. The device specifications called for a standard frame rate of 25 images per second. The system comprises a Hamamatsu DVS 3000 real-time acquisition unit and a DEC 5000 UNIX workstation for image processing, display and archival (Fig. 5).

Modular software design was preferred, and three modules were developed: an image acquisition module with provision for real-time control by the operator; the actual image processing module; and a module controlling the final superimposition of the visible light and gamma images.

Radiation Protection of the Detection Unit

The shielding is designed to provide effective collimation of the high-energy gamma photons, while protecting the electronic and optoelectronic components from radiological damage; it also provides mechanical protection, allows handling of the camera assembly and basic photographic functions (shutter, focusing extension, etc.). The specification requirements called for a compact unit. The result is a compact, cylindrical unit 120 mm in diameter and 445 mm long.

TESTING AT AN ACTUAL DECOMMISSIONING SITE

The prototype unit (Fig. 6) was tested in the radioactive cells of the RM2 radiometallurgy facility at the CEA's Fontenay-aux-Roses center, currently being decommissioned by UDIN.

The gamma camera was mounted on a specially designed carrier unit and inserted vertically into irradiating cells through overhead ports. Because of the relatively high ambient dose rates (5 to 30 mGy.h-1) the configuration with the lowest sensitivity and the highest resolution was selected, i.e. the small-aperture (2 19) collimator with a 2 mm CsI(Tl) scintillator.

Figure 7 is a typical image obtained in less than 2 minutes in Cell 2. The photo shows a strong irradiating source (about 2 mGy.h-1 at 1 meter) due to accumulated contamination around the edge of an intercell conveyor access hatch.

CONCLUSION

Since the completion of this work program at the end of 1993, a prototype gamma camera is now operational for mapping of irradiating zones. The unit provides an angular resolution of about 1.4 for 60Co and 0.8 for 137Cs, with a sensitivity of about 0.01 mGy.h-1 at the camera position for 60Co and 137Cs point sources.

Tests under actual decommissioning conditions demonstrated the satisfactory operation of the unit and its advantages, notably for obtaining a radioactive inventory prior to dismantling. The device design and performance allow gamma mapping to be performed in any irradiating room or cell provided with direct access openings, even of small dimensions. The system is compatible with multiple sources and large aperture angles (38 or 52), and is capable of achieving high measurement rates because of its detection sensitivity (for example, a 60Co or 137Cs source delivering 0.1 mGy.h-1 at the camera position can be detected in 60 seconds. Moreover, the system may be remote controlled.

Although the device was initially developed for decommissioning purposes, it may be

applied to other nuclear activities including maintenance, surveillance of high risk zones, process control and waste or fissile material management applications. The primary interest of the gamma camera is in the field of radiation protection. The results obtained are extremely helpful in applying the dose limitation principle.

A HISTORY OF SOLID WASTE PACKAGING AT THE HANFORD SITE

ABSTRACT

Since the initiation of the defense materials product mission, a total of more than 600,000 m3 of radioactive solid waste has been stored or disposed at the U.S. Department of Energy's (DOE) Hanford Site, located in southeastern Washington State. As the DOE complex prepares for its increasing role in environmental restoration and waste remediation, the characterization of buried and retrievably stored waste will become increasingly important. Key to this characterization is an understanding of the standards and specifications to which waste was packaged; the regulations that mandated these standards and specifications; the practices used for handling and packaging different waste types; and the changes in these practices with time.

INTRODUCTION

The generation of radioactive solid waste began coincident with the defense materials production mission begun at the Hanford Site in 1944. Since then, the Hanford Site has been managed and operated by several onsite Government contractors. Throughout the years, these contractors developed standards and specifications in the form of waste acceptance criteria for the handling and packaging of solid wastes. As local, state, and federal regulations and requirements evolved, so did the waste acceptance criteria. Knowledge of the changes that occurred in waste handling and packaging will help to assure the safety and health of personnel involved in the restoration and remediation of historical waste and waste facilities, while providing adequate environmental protection.

BACKGROUND

The Hanford Reservation, a 1450 km2 tract of land located in semiarid southeastern Washington State, began operations in 1944 as a major site for production of plutonium and other nuclear materials for World War II. Between 1944 and 1970, approximately 388,000 m3 of unsegregated solid wastes were buried at the Hanford Site, as both transuranic (TRU) and low-level waste (LLW) were disposed in shallow land trenches. In 1970, the Atomic Energy Commission (AEC) issued Immediate Action Directive 0511-21 directing AEC sites to segregate TRU wastes from other waste types (1). The AEC further directed that TRU wastes be packaged and stored as contamination-free packages for at least 20 years. To date, a total of over 600,000 m3 of solid radioactive wastes have been buried or stored at Hanford, including 595,000 m3 of LLW and 15,500 m3 of TRU waste (2). Table I inventories the waste

stored or disposed onsite at the end of calendar year 1992.

EARLY WASTE MANAGEMENT AT HANFORD

Prior to the first waste acceptance criteria, which were released in the late 1960's, early waste management procedures were simple and primarily based on operator safety. Early Hanford procedures define solid radioactive waste as "radioactive waste which is essentially dry, or whose fluids are of small volume and are contained or absorbed to the extent that they are essentially immobile during storage" (3). Since documentation that refers to solid waste is scanty during the early years of Hanford operation, it is assumed that this definition, or one similar, was observed in the 1940's and 1950's. In the mid-1950's, radioactive wastes were classified as either "dry" or "industrial" waste. Dry wastes were described as wastes containing little contamination, including absorbent tissues, rubber gloves, wood, metal parts, broken glassware, small tools, and other small miscellaneous items. Industrial wastes consisted of large items or failed equipment. Radioactive solid waste has been disposed by shallow land burial or stored in underground vaults and caissons since 1943. The Hanford Site is divided into several distinct "areas". The three primary areas of interest in this study include the 100 Area, where the nuclear reactors are situated; the 200 Areas (200 East and 200 West), where the fuel reprocessing, plutonium recovery, and waste management facilities are located; and the 300 Area, where fuel fabrication took place, but which now houses mostly research and development facilities and administrative offices. Prior to 1968, all waste buried in the 200 Areas was generated as a result of the fuel reprocessing operations. After 1968, the waste generated by the 300 Area operations was sent to the 200 Areas for burial. Wastes from the reactor operations in the 100 Area have been sent to the 200 area for burial since 1973.

HANFORD WASTE ACCEPTANCE CRITERIA

In the late 1960's, the first waste acceptance criteria documents were written for the 200 and 300 Areas (4,5). These documents provided specifications and standards for industrial wastes, as well as for chemical hazards control with respect to the burial grounds. Waste generators were required to segregate their waste with respect to compatibility and content. During this time, small materials were packaged in fiber drums, liquid wastes were acceptable only if absorbed by an inert absorbent material, and organic matter had to be sealed in plastic and packaged in wooden or metal containers.

In 1970, a new specifications and standards document, Specifications and Standards for the Burial of ARHCO Solid Wastes, ARH-1842, was released shortly after the AEC directed the segregation of TRU wastes (6). This document stated that generators and operators must segregate and package waste materials containing or suspected of containing, plutonium or other TRU radionuclides for containment and retrievability.

The Specifications and Standards for the Packaging, Storage, and Disposal of Richland Operations Solid Waste, ARH-3032, which was released in 1974, superseded the two documents for the 200 and 300 Areas (7). This document classified wastes into four different segregation groups: nonradioactive, non-hazardous, combustible wastes; low-level, non-TRU wastes; TRU wastes; and high-level wastes (HLW). Packages that contained less than 200 counts per minute beta/gama and less than 500 disintegrations per minute alpha contamination were classified as non-radioactive and disposed in the Central Landfill Facility. Solid wastes containing less than 10 nCi/g of plutonium and/or other TRU radionuclides were considered LLW and were further divided into combustible and noncombustible wastes, which were packaged separately. Solid wastes containing or suspected of containing greater than 10 nCi/g plutonium and/or other TRU radionuclides were considered to be TRU waste. Failed equipment and large items contaminated with TRU radionuclides were also included in this category.

The five revisions of RHO-MA-222, Hanford Radioactive Solid Waste Packaging, Storage, and Disposal Requirements, spanned from 1980 to 1988, and established new definitions for waste classes, placed restrictions on waste contents, provided new specifications for container designs, and included other key elements that directly impacted the waste classification system and segregation requirements. This was the first document that referred specifically to waste classifications, including radioactive solid wastes and TRU solid wastes. Additional requirements mandated segregation of combustible and noncombustible TRU waste. Combustible material was defined as "any material which can be ignited to produce fire through friction,

absorption of moisture, spontaneous chemical changes, or application of an external flame." This manual also included the requirement that waste containers be designed to provide the option of a vent or test connection capable of being fitted with or adapted to accept an air or vacuum hose, or gaseous diffusion vent.

One important change during the early 1980's was the revised AEC definition of TRU waste released in 1982 (8). TRU waste was redefined as waste, without regard to source or form, that was contaminated with alpha-emitting radionuclides of atomic number greater than 92 and half-lives greater than 20 years in concentrations greater than 100 nCi/g at the end of institutional control periods.

The Hanford Radioactive Solid Waste Packaging, Storage, and Disposal Requirements, WHC-EP-0063, was released in 1988 and superseded RHO-MA-222 (9). This document required generators to:

segregate, to the maximum extent feasible, TRU waste, LLW, radioactive mixed waste (RMW), chemically incompatible waste, and uncontaminated waste to facilitate cost effective treatment, storage, and disposal;

segregate radioactive solid waste recognizing waste minimization practices;

segregate TRU, LLW, RMW, hazardous, and non-contaminated waste into separate containers;

treat mixed TRU waste to destroy or remove and segregate any hazardous waste components, where permitted, feasible, and practical;

segregate certified TRU from non-certified TRU waste; and

segregate low-level RMW from TRU RMW.

Since 1970, retrievable storage requirements for TRU waste have mandated interim and long-term storage facilities. Beginning in the mid to late 1980's, changes in the management of dangerous or hazardous waste have mandated storage facilities for these wastes as well. Since 1985, non-radioactive hazardous waste was not accepted for burial in the central landfill. This waste was temporarily stored awaiting shipment offsite for treatment and final disposal. Starting in 1987, LLW containing hazardous constituents was segregated and temporarily stored awaiting future treatment before final onsite disposal.

Subsequent revisions of WHC-EP-0063 further developed low-level waste classifications; expanded the storage and disposal requirements for RMW; and added new sections for handling, storing, and disposing non-radioactive hazardous waste and a waste minimization section. They have also provided updated container design specifications, and included other key elements that directly impacted the waste classification system and segregation requirements. The latest revision of WHC-EP-0063, released in 1993, defines the current waste acceptance criteria for the Hanford Site. This version contains requirements similar to the previous revisions, as well as a new section defining the waste acceptance criteria for disposal of solid sanitary waste at the central landfill.

GENERAL WASTE PACKAGING PRACTICES

Waste packaging practices during the 1940's, 1950's, and early 1960's depended primarily on the size and type of waste being packaged, with special consideration given to dangerous or hazardous wastes. There were several different kinds of waste containers used in the packaging of solid waste. Small materials consisting mainly of dry waste were placed in quart-size cardboard containers, which were than placed in larger cardboard cartons for burial. Equipment was buried in wooden boxes when available and, if a wooden box could not be provided, the equipment was buried without a protective covering. If it was determined that the equipment was too hazardous to bury without confinement, the equipment was wrapped in plastic prior to disposal. Prior to the late sixties, there were no state or federal regulations on segregation requirements for packaging waste for burial at Hanford. There were attempts to package waste to minimize personnel exposure and prevent the spread of uncontained radioactivity to the environment; however, these were not set guidelines and were done at the discretion of the generator.

In the 1960's, low level wastes that were small in size were placed in plastic-lined cardboard boxes and large waste items were wrapped in plastic shrouds; whereas, grossly contaminated mixed fission products were packaged in high integrity containers. The most common method of depositing wastes in trenches during the 1960's was to dump boxes of solid waste directly into the burial trenches. Wood or concrete boxes that contained bulky or highly contaminated materials were dragged from railroad cars into the trench by bulldozers using long cables. Before 1970, the primary concerns during burial operations were to assure confinement of contaminated

materials during transport, minimize exposure to operating personnel, confine radioactive or chemical materials to prevent releases to the environment, and protect public health.

The packaging of waste materials was designed to maintain safety until the material was securely buried; once buried, the containers were considered permanently disposed. Because of the favorable hydrological conditions, concern was not given to whether the containers remained intact after burial. Until the mid-1970's, there were no requirements for venting burial containers to allow for the release of built up pressure. If waste materials were known to generate gases, they were placed within containers constructed of a material known to collapse under the weight of backfilling. Once the integrity of the container was no longer intact, it was considered vented.

Beginning in 1970, in addition to fiber drums and metal containers that were used to bury failed equipment, iron or galvanized steel drums and boxes constructed of fiber reinforced polyester plywood or concrete were used for packaging small materials. The Design Criteria for Transuranic Dry Waste Steel and Reinforced Concrete Burial Containers, ARH-CD-353, released in 1976, stated that burial containers were provided with vents if there was a requirement that they be protected against variations in internal pressure. With the release of RHO-MA-222 in 1980, each container was required to be capable of being fitted with an air or vacuum hose or a gaseous diffusion vent. As of 1980, wood, steel, and/or concrete boxes were used for the burial of process equipment. It was also around 1980, that the DOT 17C 55-gallon galvanized drums were declared to be the required packaging for TRU waste. The 17-C and 17-H non-galvanized drums were used for non-TRU waste shipments (10).

To indicate the segregation of TRU waste from LLW, some facilities used painted drums; for a period, yellow drums were used to package low-level wastes and black drums contained TRU waste. At the 200 Areas, color-coding of drum lids was done to indicate the segregation of hood waste from room waste. Hood wastes were wastes generated inside processing hoods and were considered highly contaminated with plutonium (11). Room wastes were wastes generated from operations outside the processing hoods and were considered potentially contaminated with plutonium. Solid wastes were segregated into combustible hood waste, combustible room waste, and non-combustible room and hood waste. Combustible hood waste was comprised of material such as plastic, rubber, rags, and cardboard. Combustible hood waste was placed in drums with yellow lids, combustible room waste was stored in drums topped with silver domes, and non-combustible hood and room waste was collected in drums topped with red domes.

For safe storage, TRU wastes were segregated into combustible and noncombustible. Small TRU items were also segregated from larger TRU items or equipment pieces. Separate storage facilities and burial trenches were designed for TRU waste storage. Solid TRU waste was packaged, stacked, and stored in trenches with an earth, gravel, plywood, or asphalt pad foundation. Small items were stored on asphalt pads, in underground trenches, or in caissons, whereas larger items were stored primarily in burial trenches. The TRU wastes that were unsuitable for asphalt pad or caisson storage because of size, chemical composition, security requirements, or surface radiation were packaged in reinforced wood, concrete, or metal boxes. High-level (high activity) solid wastes were defined as wastes that emitted high levels of beta and gamma radiation. This waste did not contain TRU radionuclides and typically included failed equipment from B Plant, tank farm operations, etc. The operation of high level (high activity) waste during this time period is different from the current definition of HLW, which refers to waste resulting from nuclear fuel processing. Small HLW items were transported to the caissons or burial trenches, while large items or failed equipment were buried in the industrial waste trenches. In the late 1970's, more specific packaging procedures requirements were introduced. Multiple containment barriers were required in the packaging of waste. In addition, more concern was given to void spaces left in waste packages and the increased used of filler materials. As time passed, the regulations became more focused and the disposal of waste began to follow a set standard of guidelines.

Containment Barriers

In the early years, waste at Hanford was disposed of in the burial grounds using only a single containment barrier. This barrier was the package in which the waste was placed. Typical packages were concrete boxes, cardboard boxes, plywood boxes, or drums. As time passed it was observed that some waste was escaping the single

containment barrier; for example, liquid leaking from a drum. This posed harmful effects for the environment and decreased personnel safety. Therefore, requirements for the number of containment barriers increased as listed below:

In 1968, wastes containing contamination that was easily airborne were contained by an inner container (e.g., sheet plastic) (5).

In 1978, a second polyethylene drum liner was placed inside the first polyethylene drum liner (12).

In 1979, 55-gallon barrels used at Z Plant to store radioactive wastes were lined with a polyethylene drum liner, 99 x 137 cm and 4 mil thick (13).

In 1980, solid radioactive waste containing asbestos had to be packaged within at least one layer of 6 mil polyethylene film. Transuranic solid waste was packaged inside at least two containment barriers, the storage container and an inner sealed liner (10).

In 1981, it was stated that polyethylene liners were to be "horsetailed" and then taped shut before the drum lid was installed (14).

In 1985, all LLW determined to be radioactive mixed waste was packaged with at least three containment barriers (15).

In 1993, PNL determined a 90-mil high density polyethylene inner liner was required for liquid RH waste. A 10-mil nylon reinforced plastic liner was required for solid RH waste. For liquid radioactive mixed waste, inner containers were almost always glass, with a capacity of 18.9 L or less (16).

Filler Materials

Filler materials became important around the early 1980's. At this point a focus was made on the void space left inside some packages and the benefits obtained by reducing this volume. The addition of non-radioactive materials to radioactive waste resulted in improved heat transfer, radionuclide immobilization, and increased physical support. The following list gives an overview of the void space limitations:

From 1978 to 1984, waste package contents were not to exceed 80% of the active volume of the waste container (17).

In 1984, it was stated that to prevent subsidence in Hanford burial grounds interior void spaces within non-TRU packages were to be minimized. However void spaces did not need to be filled in containers which were to collapse during the initial backfilling process (e.g., fiberboard boxes, plastic wrapped equipment) (18).

From 1985 to 1986, interior void spaces for LLW were not to exceed 20% of the active volume of the waste container (15).

In 1987, the list of items which were exempt from being filled was expanded. Items which were not to be filled were high efficiency particulate air filters, which posed hazards to personnel during filling, waste packages with a total internal void space less than 0.042 m3 (1.5 ft3), and any specially designed reinforced-concrete burial boxes with a design life in excess of 300 years under burial conditions expected in the Hanford Site burial grounds. All RMW packages accepted for storage were exempt from requirements for filling void spaces (15).

Prior to 1990, no specific list was provided for approved filler materials. The following list contains materials that were approved for use as void space filler in 1990:

- Diatomaceous earth
- Soil, sand, lava rock
- Tightly packed cellulose matter
- Clay
- Concrete, cement, grout
- Gravel

SPECIFIC WASTE PACKAGING PRACTICES

With an increased knowledge about certain types of waste, new, more specific packaging practices were developed for these waste types.

Process Equipment

Process equipment consisted of equipment used by several of the large plants at Hanford. The equipment caused several problems when it came time for disposal. Due to the large size and odd shape of the majority of process equipment, special measures had to be taken for burial. In the early years the equipment was buried in wooden boxes. Sometimes a wooden box could not be provided and the equipment was buried with no protective covering. When it was determined that the equipment was

too hazardous to bury without confinement, the equipment was wrapped in plastic prior to burial. In addition, large pieces of process equipment were cut into smaller sections and packaged prior to burial. A chronological list of different burial procedures for process equipment follows:

Beginning in 1964, failed process equipment was packaged in concrete boxes. Process equipment from Plutonium Uranium Extraction (PUREX) Facility that was too large to bury was stored in special railroad tunnels adjoining the PUREX Plant (19).

Beginning in 1970, metal containers were used to bury failed equipment from the PUREX Plant and the Plutonium Finishing Plant (6). Some items of failed equipment, such as 12 to 15 meter long pumps used in the transfer of wastes from underground storage tanks, were flushed and packaged in plastic prior to burial (20).

As of 1980, wood, steel, and/or concrete boxes were used for the burial of process equipment.

Beginning in 1981, large radioactive waste items from the PUREX canyon were packaged in burial boxes of precast, reinforced, concrete slabs with a concrete slab lid held in place by its own weight. A steel liner box was sometimes inserted, depending on the waste being packaged. Box configurations varied depending on the waste being packaged, but the most commonly used size had a void volume of 50 m3.

Around 1987, old gloveboxes were packaged in intact burial boxes. For a brief period of time they were sent to the 231-Z Facility to be cut up into smaller pieces. The pieces were then packaged in steel culverts, steel boxes, plywood boxes, and some of the smaller pieces were placed in 55-gallon drums.

In 1993, large process equipment, including leaded glass, fluorescent lamps, and PCB ballasts, were stored in burial boxes of mixed waste.

Class B Poisons

Class B poisons were a main focus of disposal due to the effects the poisons had on the environment and personnel safety. Solid waste containing Class B poisons was packaged in double containment. Small quantities were placed in small containers, which were then placed in storage or disposal containers and the small containers were fixed or surrounded by concrete on all sides. In 1980, it was determined that packaging for larger quantities was to be approved on a case-by-case basis (10). In the mid-1980's mercury, a specific Class B poison, was confined in a concrete culvert and the culvert was then placed in a drum. It was common to fill the space around the culverts with bagged poly bottles and other items. In 1992, PNL packaged liquid metallic mercury in a polyethylene or glass container with a screw-type lid.

Sodium and Alkali Metals

Prior to 1977 there were no documented packaging requirements for sodium and alkali metals. Beginning in 1977, special approval of any waste package containing sodium or other alkali metal was required. Unreacted alkali metals in solid waste was not accepted for disposal. The shipper had to specify quantities, concentrations, and contamination levels of each alkali metal to assure that the appropriate methods of handling, storage, and/or disposal were used (21). The requirements established in 1977 are being observed today.

Oxidizing and Corrosive Materials

Oxidizing and corrosive materials are of special interest because they break down the integrity of the container in which they are packaged. In addition, during the break down of the containers, gases are generated. It was not until the late 1960's that oxidizing material were prohibited from being packaged with combustible wastes or in combustible containers. Rags used to cleanup oxidizing materials had to be well-rinsed to remove all oxidizing materials before they were discarded. Beginning in 1984, wastes containing corrosives were to be treated to eliminated their corrosive properties and to form a chemically stable compound or they were packaged such that the storage container was not exposed to the corrosive agent during its 25 year design life. To enhance the corrosive protection, the interior and exterior of the waste containers were galvanized or painted with a two-component epoxy-polyamide paint system or functionally equivalent paint (18).

Tritiated Waste

Beginning in the early 1980's procedures were introduced for packaging tritium wastes. Tritiated waste, including tritium oxide, in liquid form was to be packaged in steel or concrete containers. Waste containing tritium or tritium oxide was absorbed on silica gel, packaged in a leak-tight 1-gallon metal cans, surrounded by asphalt, and packaged in 55-gallon drums. Waste packages with heat output greater than 3.53 watt/m3 required a special thermal analysis to determine whether special

separation distances for the waste within the burial trench were required. In 1993, the tritium waste was defined as waste containing greater than 20 mCi of tritium/m3 of waste and its disposal requirements changed:

Tritiated waste with less than 100 Ci tritium/m3 in either absorbed liquids or solids was to be sealed in one layers, of 4-mil (nominal) or thicker polyethylene and disposed of in a steel or concrete package.

Containment systems for tritiated waste with greater than or equal to 100 Ci tritium/m3 were to be documented in the storage/disposal approval record.

Liquid and Animal Wastes

Due to the increased knowledge about the waste and the better packaging techniques, the guidelines of liquid and animal wastes have changed throughout time. Table II summarizes the changes in packaging since 1967.

ABSTRACT

In a deep geological repository, the internal transport of waste packages with vitrified HLW and spent nuclear fuel will include several steps of horizontal and vertical movements from the waste reception station on the surface to the final disposal position underground. During such transport, situations may arise leading to undue mechanical and/of thermal loads acting on the package that could eventually jeopardize its containment. Under very unfavorable circumstances, these loads can even exceed significantly the very tough requirements for type B(U) transport packages. Appropriate measures and/or safety devices must therefore prevent these situations from occur and/or limit their consequences to values within the design limits of waste packages. Using an integral approach, such systems, devices and/or measures have been developed, key issues important to safety being tested under realistic conditions in special purpose installations in 1:1 scale. This paper gives an overview on the design and R&D effort carried out and of the safety relevant results obtained.

INTRODUCTION

In the framework of a project aimed at demonstrating the feasibility of spent fuel final disposal, all transport steps of the final disposal procedure were carefully evaluated from the point of view of safety. Every waste package movement from delivery of the spent fuel to the site until final emplacement underground were considered. The aim was finding out weak point requiring special attention, and developing the measures and/or devices necessary to guarantee the radioactivity containment under all circumstances. The basic assumptions were:

- delivery of the spent fuel and the HLW to the site by road or rail transport in a container complying with Type B(U) requirements;
- conditioning into a Pollux cask for final disposal;
- transport to the underground repository mine via a shaft;
- final disposal in drifts of the repository mine with subsequent backfilling of the emplacement galleries.

As initiating events for potential lost of radioactivity containment during the waste package handling in the surface facilities the following events were identified:

- accidental cask drop from a height in excess of the package design value during crane handling;
- accidental drop during crane handling of a heavy hart object onto the cask;
- fire in the reception or in the shaft dispatching area;
- fall of a loaded cask carrier into the shaft.

As initiating events for potential lost of radioactivity containment during shaft cage charging and during hoisting to the underground the following events were identified:

- fall of a heavy hart object into the shaft and onto the cask during hoisting; hoisting machine overwinding after failure of the machine control system;
- fire in the shaft cage;
- failure of all shaft cage ropes.

As initiating event for potential lost of radioactivity containment during shaft cage discharging or in the underground facilities the following events were identified:

- accidental cask drop from a height in excess of the package design value during handling or disposal;
- accidental drop of a heavy hart object onto the cask;
- fire during underground transport;
- fall of a cask into the shaft sump.

TRANSPORT SYSTEM DESIGN AND TESTING

Taking the listed initiating events into account, a waste package transport and handling system was developed. It consists of a special waste package design, rail-guided transport vehicles, a specially conceived shaft cage, and the corresponding shaft cage charging/discharging equipment. An overview of the initiating events and of the measures and/or devices and/or pieces of equipment designed to prevent them from occurring and to cope with their consequences is given in Table Ia,b,c.
Since in the Federal Republic of Germany only proven technologies and pieces of equipment may be used in a repository, a test programme aimed at demonstrating the safety of the transport system as a whole was carried out. Simultaneously, studies dedicated to single questions, as e.g. a test programme for shaft cage ropes and a Probabilistic Safety Assessment of the complete shaft hoisting system, were carried out. The most important test, the simulation of the shaft transport of payloads of up to 65 metric tons, has already been finished, conclusive results are available. Other ones are in due course, final results will be available by the end of 1995.
CONCLUSIONS
To comply with requirements of the licensing authorities, the transport pathway of waste packages with spent fuel and HLW in a repository has been scrutinized. The objective was to find out situations eventually leading to loss of radioactivity containment. All locations, operations, and movements of waste packages were considered. From the analysis of hazardous situations likely to arise requirements were derived for the design of systems, components and operational procedures. In addition, preventive measures were planned.
Some of the systems and/or components designed were novel. To satisfy regulatory requirements these systems were tested under realistic conditions in 1:1 scale. The complete handling and transport procedures and equipment have been subjected to a final evaluation considering the test results and the results of specific studies, as e.g. a Probabilistic Safety Analysis of the shaft transport. The results of already finished tests, as well as results obtained until now of still running tests, confirm the reliability and safety of the handling and transport systems to the level required by the authorities.

RISK CONSIDERATIONS FOR THE PACKAGING AND TRANSPORTATION OF PLUTONIUM-CONTAMINATED WASTE FORMS AT DEPARTMENT OF ENERGY NUCLEAR FACILITIES
R.L. Cropper
S.W. Woolfolk
T.A. Kuykendall
Parsons Engineering Science, Inc.
ABSTRACT
Plutonium waste streams of various compositions exist in inactive process systems that will be removed during deactivation activities at the various Department of Energy (DOE) nuclear facilities. Also, a number of differing plutonium-bearing waste streams will be generated during the conduct of decontamination and decommissioning (D&D) efforts associated with the site mission of waste management and environmental restoration. The waste streams will include contaminated concrete, metals, soils, ceramics, sludges and liquids that may require processing and must be packaged for transportation and storage/disposal. In many instances, the mixture of waste components may meet the definition of a hazardous/radioactive mixed waste, or a hazardous/transuranic mixed waste.
The packaging requirements for each of these different waste streams is dependent upon the volume of waste material, waste form (i.e., solid, gas, liquid, etc.), waste constituents (i.e., plutonium, acids, uranium, etc.), radiological (Curie) content, dose rate, planned disposition (e.g., storage, disposal, processing, etc.), and preferred method of transportation (e.g., highway, air, rail, etc.). In each instance, the packaging requirements designated in both the DOE and site procedures must be met. In many instances, the DOT transportation regulations (49 CFR) and the waste acceptance criteria (WAC) of the targeted disposal facility will also be factors.
Based upon the considerations of efficiency, cost, disposal space, and risk, support to the program has been structured not only to comply with the applicable regulations, but to minimize the quantity of waste that must be disposed/stored through processing and innovative D&D technologies that generate minimal or no

additional waste streams. Additionally, the DOE nuclear facilities intend to package and transport the remaining hazardous/radioactive/mixed wastes in as an efficient and expedient manner as possible, correlated to the characteristics of the waste stream to be managed.

Risks to the site workers, general population, and the environment associated with the transportation and storage/disposal of the waste materials will be an important factor in the choice of packaging containers and methods of transportation. The use of risk-based analyses and analytical tools which consider the final D&D waste form and volume prior to the choice of the actual D&D technologies is a new and innovative measure which aids in the protection of both human health and the environment. Risk evaluation, management, and mitigation are all elements of the comprehensive planning for handling, transportation, and disposal of plutonium-bearing wastes.

This topic should be of interest to any individual or company that is in the process of, or plans to, remediate or perform D&D activities. As the particular slant of this paper concerns plutonium, it should be of particular interest to those facilities that deal with fissile materials. The anticipated end result of this presentation is to provide an awareness of the risks associated with the packaging and transportation of hazardous/radioactive materials and potential manners in which these risks can be mitigated.

INTRODUCTION

As many of the Department of Energy (DOE) facilities are commencing decontamination and demolition (D&D) activities, the disposition of the plutonium-contaminated wastes is becoming a major concern. In particular, the risks associated with the packaging and transportation of these waste materials must be acknowledged. The volume, waste form, and treatment/decontamination methodologies for the plutonium-contaminated waste must be chosen with the final disposition in mind. For material that is to be disposed of, the waste must meet the Waste Acceptance Criteria of the facility. The purpose of this presentation is to provide evidence that risk must be addressed at the time the decisions affecting the disposition, in particular packaging and transportation, of the plutonium-contaminated materials are made.

PLUTONIUM-BEARING WASTES

Production of Plutonium-Bearing Wastes

The DOE nuclear facilities have been involved in the production of nuclear weapons for the federal government. Some of the key production activities were associated with the fabrication of parts from plutonium, uranium, beryllium, stainless steel, and aluminum. Additionally, some DOE nuclear facilities disassembled and processed components from obsolete nuclear weapons in order to recover the plutonium and americium. DOE nuclear facilities have also operated facilities for the storage, treatment and transport of waste; chemical laboratories; research and development laboratories; and special support operations for the other DOE facilities. Due to both regulatory and environmental concerns, as well as end of the Cold War, the current stockpile of nuclear devices exceeds the requirements of the United States government. To this end, the production of the nuclear devices has been curtailed. Both radioactive and hazardous materials were utilized in association with the activities and processes that took place at the DOE nuclear facilities. Both hazardous and radioactive materials were stored, processed, and transferred throughout the various tank farms and pipe runs. Additionally, over the years, spills, fires, ventilation and leaching problems have also occurred at the site. Because of this, various media, or waste streams, at the DOE nuclear facilities have became contaminated. Plutonium is not the only contaminate of concern at the DOE nuclear facilities. Additional contaminants include americium, uranium, thorium, as well as organics, metals, and pesticides.

Waste Streams

Much of the plutonium-contaminated waste at the DOE nuclear facilities will be generated as a result of the decontamination and decommissioning (D&D) activities. Plutonium-contaminated materials currently reside in many of the tanks (sludges, liquids, and solids); on raschig rings; in ventilation ducts and pipe runs (utilities); within building walls, flooring, and support/bracing; within soils; and as loose contamination within the facility.

During the D&D activities, it is anticipated that the different types of plutonium-contaminated media will generate a variety of different waste streams. The

waste streams will include:
1 Contaminated concrete;
2 Metals;
3 Soils;
4 Ceramics;
5 Sludges;
6 Liquids;
7 Decontamination solutions;
8 Plastics; and
9 Wood.
Each individual waste stream will need to be evaluated to determine its optimum disposition option. Factors that will need to be evaluated include waste form, efficiency, cost, disposal space and risk. Some of the different disposition options that exist include decontamination, material treatment options, unrestricted release, disposal as low-level radioactive/TRU/mixed waste, and storage.
Waste Forms
In some instances, the waste stream may compose the final waste form of the plutonium-contaminated materials, i.e., concrete. In many other instances, some form of treatment or decontamination may be required in order to achieve a waste form that meets the final disposition option requirements. Typical waste forms that would be expected to be composed at least partially from the plutonium-contaminated waste materials include solids, sludges, and liquids.
As an example, generally speaking, one cannot dispose of liquid radioactive waste. Liquids and sludges will need to be treated in some manner such that the waste form meets the criteria stipulated in the disposal facility's waste acceptance criteria (WAC). Additionally, one must be able to transport the waste form to the disposal facility. 49 Code of Federal Regulations (CFR) stipulates shipment criteria for packages, i.e., gas emissions, dose rates, criticality.
Waste Stream Characterization
Waste stream characterization plays an extremely important part in determining the packaging and transportation requirements. Waste that can meet either the criteria for low-level radioactive waste or transuranic waste can be disposed at more facilities than listed (hazardous) or mixed waste. One of the few facilities to accept mixed waste is Envirocare of Utah. Different packaging and transportation requirements may, and often do, exist for each of these types of waste materials.
PACKAGING AND TRANSPORTATION PROGRAMS
Handling Requirements
The handling requirements for the different waste streams will vary based upon the waste stream characteristics. In many instances a worker that is handling plutonium contaminated materials is isolated from the material itself. This is accomplished by the use of glove boxes and/or remote control devices. In addition, the chemical characteristics (i.e., pH, gas production, total dissolved solids) of a particular waste form may require special handling techniques. In some instances, the plutonium-contaminated waste materials will be treated to eliminate chemical constituents. Also, the material may be decontaminated or treated in an attempt to segregate a constituent from the waste such that the material may be disposed as low-level radioactive waste rather than TRU or mixed waste. Waste materials may also be size reduced or compacted to reduce the volume or provide a shape/size/weight that can be more easily handled/treated/packaged. Compaction may also be required to meet the disposal requirements regarding the minimization of void spaces (10 CFR 61).
Packaging Considerations
Packaging considerations include the waste form, volume, dose rate, quantity of the waste constituents, cost, packaging efficiency, disposal space available, the WAC (as appropriate) and the packaging risks. Based upon these criteria, the plutonium-contaminated materials could be shipped in bulk, boxes, drums, casks, etc.

The packaging considerations include not only the onsite packaging concerns, such as personnel exposures and industrial accidents, but the off-site risks to human health and the environment. To address the off-site risks, it must be determined that for the material of concern, what type of package would best protect the contents in an accident situation while minimizing the number of shipments that are required. It should be noted that routine, non-radiological accidents typically are responsible

for the majority of the risk associated with any shipment. This is an example of why efforts should be made to minimize the number of shipments that are required. Packaging concerns, risks, and mitigators are displayed on Table I a, b.

Transportation Considerations

Transportation and packaging considerations are in many respects similar. In both situations the major considerations are the waste form, volume, dose rate, quantity of the waste constituents, cost, packaging efficiency, disposal space available, the WAC (as appropriate) and the packaging risks. Since different modes of transportation (i.e., truck, rail, air, ship, private vehicle, etc.) could be utilized, the different regulations stipulated in 49 CFR for the various modes of transportation must be considered.

As with the packaging considerations, both on-site and off-site transportation concerns must be addressed. Accident scenarios as well as routing considerations (i.e., population density, accident rates, types of roads, etc.), number of shipments, dose rates, etc., must be reviewed when determining the appropriate type of transportation to utilize. The mode of transportation that is chosen should protect the packages in case of an accident situation as well as minimize the number of shipments required. Transportation concerns, risks, and mitigators are discussed in Table II.

Other Factors

Additional factors include the existence and types of contractual agreements with the transportation firms and waste disposal facilities; the availability of both disposal/storage space and of shipping containers; as well as routing and time frame requirements. In almost any specific situation, additional considerations, other than those already noted, will be required. They can range from contractual considerations, to weather, to individual state requirements for transportation to client specific requirements.

RISK CONSIDERATIONS AND FACTORS

Risk-Based Analyses and Analytical Tools

A variety of risk-based analyses may be performed and/or analytical tools may be utilized to determine the risk associated with the packaging and/or transportation of plutonium contaminated waste. Some of the commercially/DOE available codes which look at transportation risk and routing include RADTRAN, HIGHWAY, INTERLINE and INTERSTAT. HIGHWAY, INTERLINE and INTERSTAT aid in the routing of any given shipment. The concerns of these models include population density, accident rates, type of road, etc. The output from these codes is then utilized in the RADTRAN program. The RADTRAN program calculates the risk associated with a particular shipment, or number of shipment, utilizing a particular mode of transportation and designated route.

Parsons developed a computer-based qualitative risk-based analysis program concerning the choice of D&D methodologies for particular facilities or types of materials. This program took both packaging and transportation into consideration. This analysis was comprised of a set of questions to which a designated number of points are assigned to each particular response. The questions concerned the waste volume that would be generated, the types of wastes that would be generated, waste disposal feasibility, the dose rates and the use of Type B packaging. An example form utilized for this screening mechanism is provided as Table III.

Application of Risk Mitigation Programs and Analyses

Risk mitigation analyses and programs should be applied prior to the generation of the waste to be packaged and shipped. If this is not possible, the analyses should be performed prior to the packaging of the waste. If the risks associated with prematurely packaging and transporting waste were considered prior to their generation, much of the exposure, handling, and accident risk - not to mention cost, ALARA, and efficiency considerations - associated with the duplication and "forced-fitting" of these activities could be alleviated.

Risk Evaluation, Management, and Mitigation

Sections 4.1 and 4.2 discuss risk-based analyses and analytical tools and their application. The risk evaluation should include the situation specific information, as much as possible. The evaluation must take into account the form, treatment, packaging, transport and final disposition of the plutonium-contaminated waste. This can be accomplished by utilizing both qualitative, as well as quantitative, methodologies. Once the risks have been evaluated for each step in the process, an intelligent decision concerning the optimum course of action can be made. At this

point, it is possible to begin to manage the risks. Risks in particular that must be managed include limiting the number of shipments, minimizing the volume of material to be transported, criticality, and treatment/decontamination methodologies and their secondary waste products.

The use of mitigative measurement to minimize the risk to human health and the environment is an important concept to accept and understand. While lowering the overall risk of the process, in many instances, mitigative measures may increase the total cost. In cases where the cost versus the benefit is extreme, a cost-benefit analysis should be performed. Simple ways to mitigate the risk include personnel training, the utilization of decontamination/treatment techniques, the segregation of waste types, choosing the optimum package and mode of transportation for each particular situation, and minimizing the volume of waste that must be dispositioned, and thereby limiting the number of shipments required.

CONCLUSIONS

Packaging and transportation risks cannot be adequately or efficiently addressed after the processing, treatment and packaging of the waste materials has been completed. These are considerations that must be addressed at the beginning of the process, not the end or the middle. As previously stated, in order to best utilize the information provided in a packaging and transportation risk analysis, the evaluation should be performed prior to the generation of the waste. In almost any situation, the sooner these considerations are addressed, the more cost efficient and ALARA the final resolution can be. For D&D, as well as other types of waste generating activities, it is extremely important to consider the entire process by using an integrated system engineering approach which considers all of the facets of the task, from the initial action through the material transport and disposal.

ABOUT THE AUTHORS

Rebecca L. Cropper holds a B.A. degree in Physics and a M.S. in Health Physics. With over 15 years of experience, Ms. Cropper has managed health physics, computer services, and health and safety groups as well as managed projects for state, DOE, Department of Defense (DOD), and commercial clients. Ms. Cropper is currently the Rocky Flats Environmental Technology Site Program Health and Safety Manager for Parsons Engineering Science, Inc.

Stephen W. Woolfolk, C.H.P. holds a B.S. in both physics and mathematics from Oregon State University. Mr. Woolfolk possesses over 20 years of experience in radioactive waste management, environmental protection, operational health physics, radioactive waste transportation, and risk management. He is currently a Senior Health Physicist for Parsons Engineering Science, Inc.

Terry A. Kuykendall holds a B.S. in Chemistry/Biochemistry and an M.S. in both Environmental and Chemical Engineering. He has over 17 years of experience in the areas of program/project management and in the development of environmental, safety and health protection programs. Mr. Kuykendall is currently the Deputy Program Manager for the Parsons Engineering Science, Inc. Denver Major Projects office.

ABSTRACT
An environmentally-safe, regulatory-compliant method of macroencapsulating filters, sources, irradiated and contaminated hardware and demolition debris is needed by the commercial nuclear industry and DOE/DOD installations.
Traditional methods of high-activity source disposal have been encapsulating a single source or filter element in grout inside a 55-gallon drum (liner), or cement encapsulation of a larger number of filters in a liner. Debris is typically disposed of in metal boxes or liners without assurance of future integrity of the container. If the activity of the debris requires waste stability, the use of a HIC has been the only disposal option.
In the past, none of the encapsulation technologies employed have undergone testing to demonstrate waste form integrity in compliance with 10 CFR Part 61. Recently, a new encapsulation process has been submitted to the N.R.C. for review and approval. This ENCAPTM process has been used successfully for filter encapsulation at the Diablo Canyon Power Plant.
The ENCAPTM process is the subject of an Addendum to Topical Report DT-VERI-100-NP/P-A, VERITM (Vinyl Ester Resin In Situ) Solidification Process for Low-Level Radioactive Waste (Docket Number WM-105R1)(1). This process utilizes an N.R.C.-approved binder to encapsulate or entomb waste in a free-standing monolith. The incorporation of non-uniform waste products in the monolith generates a heterogenous waste form. This process is applicable in liners as large as 200 ft3. This paper describes the process for encapsulating heterogenous wastes in an entombing monolithic polymer matrix, including steps taken to protect the integrity of the monolith, the design basis to preclude environmental exposure of the entombed waste, and limitations on the applicability of the process. The economic impact of this technology is discussed, as well as typical applications at commercial nuclear and DOE/DOD sites.
INTRODUCTION
The ENCAPTM Process, subject of a Topical Report(1) submittal to the N.R.C., has the potential to minimize the environmental impacts and costs of shallow land burial of waste filter cartridges from nuclear power plants at low-level waste disposal facilities. The reduction in environmental impact and in waste disposal costs would be achieved by reducing waste packages to be handled at the reactor site, shipped on public highways and buried at the disposal facility. The cost of a vinyl ester styrene (VES)-solidified liner is lower than N.R.C. metal HICs and lower than poly HICs in an overpack. Poly HICs designed to accept heterogenous waste are often foamed to prevent damage to the HIC, further reducing the volumetric and cost efficiency of HICs.
The ENCAPTM Process encapsulates numerous filter cartridges and other solid debris in a matrix of VES and spent ion exchange bead resins. The spent bead resins may or may not be contaminated with radionuclides. An ENCAPTM monolith as large as 200 ft3 could encapsulate from 100 to 200 filter cartridges. The number of cartridges or amount of debris to be loaded in a given ENCAPTM liner would depend on a number of variables, including the size of the filter cage in the liner, size and shape of the cartridges, and the concentration of radionuclides on the filters and in the resin matrix.
PROCESS DESCRIPTION
The ENCAPTM process uses Vinyl Ester Resin In Situ (VERITM) solidification to create an enveloping monolith around a caged region of heterogenous wastes (i.e., spent filter cartridges). The ENCAPTM process involves loading waste into an encapsulation liner and solidifying the liner with the VERITM polymer.
An encapsulation liner has dewatering internals identical to a VES bead resin solidification liner. A cage is installed in the encapsulation liner to prevent the waste from coming in contact with any portion of the liner internal surfaces.
A protective layer of ion exchange resin (or other inert granular material) is

introduced to the liner first. This resin layer must be at least 4" deep, and may consist of either contaminated or non-contaminated resins. The resin, sluiced with water or manually poured into the liner, serves a dual function of physically protecting the dewatering internals from damage during introduction of filter cartridges and establishing the lower exclusion zone which consists entirely of VERITM-solidified resins.

When the cage has been loaded with filter cartridges or other wastes to be entombed, the cage lid is closed and the liner is filled with ion exchange resin to a level covering the caged waste by a minimum of 4". The fill resin may be contaminated or non-contaminated, as long as it is of the type identified in the parent TR as being accepted for VERITM solidification.

When the ENCAPTM liner has been filled with resin, VERITM solidification equipment is positioned and VES binder is added to the liner entombing the waste from top to bottom. Upon completion of introduction of the catalyzed and promoted binder to the encapsulation liner, the exotherm is monitored, compliance with acceptance criteria is verified, and the ENCAPTM liner is capped and prepared for shipment.

ENCAPSULATION LINER

The encapsulation liner is a right cylinder of carbon steel or polyethylene plastic with maximum bounding dimensions of 78" in diameter and 72" in height, yielding a maximum volume of approximately 200 ft3.

No credit is taken for the structural strength of the disposal liner in the encapsulation process for waste form qualification.

The key feature of the encapsulating liner is a cage positioned inside the liner to receive the material to be encapsulated. This cage is designed to create an exclusionary zone between the entombed waste and the side wall of the encapsulation liner. Several generic features must be incorporated in the cage to ensure maintenance of the exclusionary zone and prevent buoyant surfacing of the filter elements. A general configuration drawing of the ENCAPTM liner is shown in Fig. 1 at the end of this report.

WASTE FORM

The encapsulating media is spent ion exchange resin solidified in a VES polymer matrix. The waste to be encapsulated does not affect the structural integrity of solidified monolith when the potential void spaces are limited. Such waste form characteristics as compressive strength, resistance to degradation (water immersion), biodegradation, irradiation tolerance and leachability are not influenced by the entombed waste. As a minimum, the requirements 10 CFR 61.56(a) apply to all waste, waste products and waste forms.

Structural Stability

The ENCAPTM entombing of waste within the VERITM-solidified monolith does not physically impair dimensional stability under the expected disposal conditions such as weight of overburden and compaction equipment. Previous testing has shown that the presence of liquid, microbial activity, and radiation (when limited to <1 x 108 Rad) has no negative effect on the structural integrity of the binder matrix and, hence, on the integrity of the monolith.

It has been shown (in the parent TR), that the compressive strength (typically >2000 psi) of the VERITM waste form is several factors greater than the minimum required for stability. Qualitatively, the plasticity of the VERITM waste form is well suited for encapsulation.

Unlike cementious waste samples (which tend to experience acute failure by sheering or spalling during testing), the VERITM waste form tends to bulge circumferentially without failure when subjected to maximum yield compressive forces. It is postulated that this plasticity may tend to protect the integrity of the monolith when subject to compressive forces in the burial environment. It should be noted that no credit is taken for the favorable plasticity of the waste form.

Likewise, no credit for stability is taken for the liner in which the VERITM process is used. In those instances when the entombed waste may be stored on an interim basis before final disposal, consideration should be given to performing the ENCAPTM process in corrosion-resistant containers such as poly containers or lined carbon steel liners. Such corrosion resistance, while not an issue from a waste form perspective, may be important to ensure viability of the waste package a number of years from now, when the waste is moved from its storage site to the transport cask for disposal. No aspect of the ENCAPTM process is affected by, or prohibits use in, such liners.

The waste forms produced by the ENCAPTM process meet the structural stability requirements of land burial without the need for an overpack (per N.R.C.). The minimum separation of the waste-containing cage from the side wall of the liner is intended to ensure sufficient strength to prevent environmental intrusion into the caged waste area, or escape of waste from the area. The filling of interstitial space within the caged waste provides additional strength and stability to the monolith. Some states may require all Class B and C waste to be placed in concrete overpacks. An ENCAPTM liner can readily be overpacked, though there is no technical reason for doing so.

FULL-SCALE EXPERIENCE

In addition to the full-scale testing performed by DTS in support of the parent TR, commercial solidifications have been performed using this process. In 1992, a nuclear power plant successfully solidified spent resin generated from cleanup of a LOMI-CANDEREM decontamination process. The solidified liner was buried at the Barnwell, South Carolina disposal site. Also in 1992, approximately 450 drums of VES-solidified decontamination solution were processed and buried in Beatty, Nevada prior to its closing.

In 1993, a liner of spent mixed bed resin, primarily RCS (Reactor Cleanup System), was solidified using the VERITM process. This liner was also buried at Barnwell. Also in 1993, three liners of spent filter cartridges were encapsulated utilizing the ENCAPTM process. These cartridges were generated from the primary, spent fuel pool and radwaste cleanup systems in a PWR plant. The encapsulations proceeded in the manner typical of a VERITM solidification, though three enhancements were incorporated in the ENCAPTM process as a result of this experience.

First, the vacuum pump drawing a suction on the liner was turned on before introduction of the binder. This initiated a suction on the liner immediately when the binder cap was established on the resin bed, and provided a downward pathway for air displaced by the binder.

Second, a closure was placed on the internal cage to preclude buoyant objects from breaching the surface prior to gelation of the binder. Upon gelation, all objects were effectively locked in place throughout the balance of the cure process.

Third, a low-volume sweep of the air from the freeboard of the liner was procedurally implemented, using ports already available on the fillhead. This air was exhausted to a HEPA-protected exhaust point as a protective measure, though no airborne contamination was expected or found. This air sweep was designed to minimize the condensation that occurs on the cold steel liner during the exothermic cure. A small amount of moisture was present on top of the first ENCAPTM-solidified monolith. Though an on-site assessment of moisture deemed the volume to be insignificant, "0" moisture was desirable, and the described action was implemented. This procedural action was successful in preventing the formation of condensation in subsequent ENCAPTM solidifications.

ENCAPTM solidifications performed after implementation of each of these process enhancements were performed successfully and without incident.

WASTE LOADINGS

Waste loadings (or packaging efficiencies), for ENCAPTM entombing of spent filter cartridges were ascertained from full-scale encapsulations. Filter media loading values for the 80 ft3 ENCAPTM liners referenced in the table below are based on the volume of entombed filters calculated by two different methods.

Loading values for filter media were determined by subtracting the internal void volume of the cartridge from the outside envelope volume, divided by the disposal volume of the liner. Filter envelope volumes are based on the exterior volume of entombed filters divided by the volume of the solidified monolith. Based on this data, typical filter loadings for the ENCAPTM process can be expected to be a minimum of 15% by filter media volume and 30% by filter envelope volume. Table I shows the actual data from three 80 ft3 ENCAPTM liners.

Low activity filters at Diablo Canyon (generally less than 500 mR/hr) are compacted using a drum compactor prior to placement in a liner. The packaging efficiency (on average) of compacted and non-compacted filters has been 1.6 filters per cubic foot. Recently, Diablo Canyon has procured a unit to cut/crush high-activity filter elements, which has increased average loading capacity from 1.6 to 2.3 filters per cubic foot.

VOIDS

A number of qualitative postulations provide grounds for belief that the fraction of

void space in the waste cage is minimal. Void spaces or pockets inside irregularly-shaped objects introduced randomly to the solidified liner cage are minimized by the inherent characteristics of the encapsulation binder and process. The vacuum drawn on the liner during the introduction of binder to the liner in the VERITM solidification process tends to expend the air present in void spaces in and around the waste objects, resulting in a net reduction of air volume in the voids. Upon cessation of the vacuum, the pressure of the downward flowing binder will collapse any remaining air pockets. This collapse tends to pull additional binder into these pockets, thus reducing the net volume of the void space present.

The low viscosity of the VERITM binder (100-200 cps) and its natural wetting properties enable migration of the binder throughout the monolith, while displacing both air and water. The water and air are swept downward toward the dewatering internals by the driving forces of the vacuum being applied and the gravitational push of downward flowing binder. The water and air are preferentially pulled into the dewatering internals, due to their much lower viscosity. The more viscous binder meets resistance in passing into the internals through the restrictive openings.

PROSCRIBED WASTES

Certain wastes and waste forms are not physically compatible with the polymer encapsulation process, or are prohibited for regulatory reasons.

Physical Incompatibility

Included in incompatible waste forms are those materials which interfere with the proper migration of the encapsulating binder throughout the monolith, or which may react chemically with the solidified monolith, negatively impacting its strength and durability.

The variety of physical sizes and characteristics of waste to be encapsulated cannot be precisely defined or quantified. Nonetheless, prudent judgment can be exercised regarding introduction of many objects to ensure maximum monolith integrity.

An example of an inappropriate physical waste form is plastic bags of dry active waste (DAW). Plastic bags, or other objects with a large horizontal cross-section, may result in excessive void space, as well as create a shadow directly below the object which may have deficit binder impregnation. In the case of large flat objects, the shadowing problem can be mitigated or eliminated by positioning the object in a vertical orientation to minimize the cross-section of the object when viewed from above. Likewise, a large sheet of plastic draped in the cage may unnecessarily obstruct the normal binder pathway. The same plastic, when formed into a tight roll, would permit adequate polymer impregnation past and under the roll.

Objects with a potential to expand in size due to chemical or biological reactions which may impugn the integrity of the monolith are prohibited. No objects with this potential have been identified. Likewise, no solid wastes subject to encapsulation are chemically incompatible with the solidified polymer monolith.

Regulatory Incompatibility

10 CFR Part 61 and certain other regulations prohibit solidification or encapsulation of wastes which may physically impair the integrity of the final waste form, or result in a waste form which is not allowed under present regulations. Neither the VERITM-polymerized binder material nor the waste that is acceptable to be entombed contains materials identified or defined as hazardous, biological, pathogenic, or infectious. Numerous TCLP tests of the binder, catalyst, promoter and additives have consistently shown the polymerized waste form to be non-hazardous both with and without the presence of wastes that were initially non-hazardous.

ACCEPTANCE FOR BURIAL

The VERITM process is qualified for stabilization of Class B and C wastes when spent ion exchange resin is solidified in liners no larger than 200 ft3. VERITM solidification of spent ion exchange resin is utilized as the base process for the ENCAPTM process for encapsulation of heterogenous wastes.

Since the mechanical and chemical nature of the in situ solidification process (and the resulting waste forms) are unaffected by the presence of heterogenous wastes, it is presumed that the solidified homogenous spent resin remains an accepted stabilized waste form.

The State of South Carolina Department of Heath and Environmental Control (DHEC) granted approval on June 28, 1993 for burial of resins solidified using the VERITM process. The ENCAPTM filter encapsulation process was reviewed, and approval by DHEC was granted on July 8, 1993. A clarifying letter was issued by CNSI on August 3, 1993 which confirmed that encapsulated filters were acceptable for burial at

Barnwell, with the provision that they would be subject to the same burial restrictions and requirements as all other Class B and C wastes.
The solidified polymer material passes TCLP testing for absence of toxic or hazardous materials, including volatiles. The Department of Energy's Hanford, Washington facility has approved the VERITM solidification agent as meeting its Waste Acceptance Criteria (WAC) for disposal in its land burial facility.

CURIE CONCENTRATION AVERAGING

Present industry practice varies among licensees, but the standard method is to average curie content over the filter envelope. In some instances, when filters are shredded, or when a more conservative approach is desired, curie concentration is averaged over the filter media volume, which yields a higher concentration.
The proposed BTP(2) on encapsulation permits the radionuclides of an encapsulated source to be averaged over the volume of a 55-gallon drum (0.2 m3) container. The practice of encapsulating a single filter element (e.g., 1 ft3) per drum equates to a waste loading of 13% (1 ft3 filter volume 7.5 ft3 container volume).
The waste loading of ENCAPTM liner will be greater than the 13% cited for cement encapsulation of a filter in a 55-gallon drum. As a result, the averaging of radioisotopic activity over the volume of the ENCAPTM solidification liner is less dilutive (more conservative) than that of a filter or source encapsulated in a 55-gallon drum.
A key aspect affecting the utility of the ENCAPTM process is the ability to average the curie content of the encapsulated waste over the volume of monolith. Based on the September 16, 1993 Proposed BTP(2) on Concentration Averaging and Encapsulation, a specific rationale was offered in the TR(1) submittal before taking credit for volumes or masses larger than 0.2 m3 when determining waste concentrations. Such a rationale has been reviewed by the N.R.C., and accepted in principle.
The Ward Valley license issued by the State of California permits curie averaging over the entire package when an NRC approved stabilization media (such as VES) is used for encapsulation. The practical effect of curie averaging is (in some instances) derating or lowering of waste classification from Class B and C to Class A for burial purposes.

CONCLUSION

The ENCAPTM process uses VERITM solidification to encapsulate a caged region of waste cartridge filters in a 200 ft3 monolith. The monolith is composed of a waste form (i.e., spent ion exchange resin beads stabilized in VES) which has been demonstrated to comply with the structural stability requirements of 10 CFR 61 for Class B and C waste forms.
A 200 ft3 ENCAPTM monolith could encapsulate a large quantity (up to 200) waste filter cartridges or other solid waste debris with the capacity being limited by physical volume and radionuclide content of the waste, as well as the radionuclide content (if any) of the spent ion exchange resin beads in the ENCAPTM monolith. The caged region is positioned within the liner so that it is at least 4" from any surface of the monolith. Thus, the cage which contains the filters or debris entombed in VERITM waste form is itself entombed in a 4" thick cylinder of VERITM waste form. Generally, no credible mechanism has been identified for an acceptable entombed waste to impugn the integrity of the monolith, when encapsulated with the ENCAPTM process.
Encapsulation of cartridge filters or debris in VES to provide stability offers a less expensive alternative than packaging such wastes in HICs. Where ergonomically desirable, disposal of sources and activated metals, which qualify as low-level waste, in an ENCAPTM liner would greatly improves upon present packaging techniques for these wastes.

LOW LEVEL WASTE SHIPMENT ACCIDENT LESSONS LEARNED

David M. Rast

DOE-FN
Jeffrey G. Rowe
FERMCO

ABSTRACT
On October 1, 1994 a shipment of low-level waste from the Fernald Environmental Management Project, Fernald, Ohio, was involved in an accident near Rolla, Missouri. The accident did not result in the release of any radioactive material. The accident did generate important lessons learned primarily in the areas of driver and emergency response communications.
The shipment was comprised of an International Standards Organization (ISO) container on a standard flatbed trailer. The accident caused the low-level waste package to separate from the trailer and come to rest on its top in the median. The impact of the container with the pavement and median inflicted relatively minor damage to the container. The damage was not substantial enough to cause failure of container integrity. The success of the package is attributable to the container design and the packaging procedures used at the Fernald Environmental Management Project for low-level waste shipments. Although the container survived the initial wreck, is was nearly breached when the first responders attempted to open the ISO container. Even though the container was clearly marked and the shipment documentation was technically correct, this information did not identify that the ISO container was the primary containment for the waste.
The lessons learned from this accident have DOE complex wide applicability. This paper is intended to describe the accident, subsequent emergency response operations, and the lessons learned from this incident.

BACKGROUND
The Fernald Environmental Management Project, formerly known as the Feed Materials Production Center, is located about 20 miles northwest of Cincinnati, Ohio. Uranium metal products for the nation's defense programs were produced at the facility between 1953 and 1989. During those years the facility produced slightly enriched or depleted products for use in production reactors to make plutonium and tritium at other DOE sites. Uranium production was suspended in July 1989 to focus on environmental restoration. The Fernald workforce has been dedicated entirely to environmental restoration since 1989. Also in 1989, the site was added to the Environmental Protection Agency's National Priority List of federal facilities in need of remediation. In 1991, the DOE officially announced that production at the facility was ended and the program management responsibility within the DOE was transferred to the Office of Environmental Restoration and Waste management. In February 1992, an Ohio Field Office was established to oversee all aspects of a full-scale environmental restoration and waste management effort which is expected to last several years.
On October 1, 1995 at about 1550 (all times in Central Standard Time), an accident occurred involving a shipment of low-level waste from the Fernald Environmental Management Project, in Fernald, Ohio. The shipment was in route to Mercury, Nevada for disposal. The vehicle transporting the waste for the Fernald Environmental Management Project lost control and rolled over in the westbound lane of Interstate 44, approximately one mile southwest of Rolla, Missouri.
The shipment was comprised of a single cargo container designed in accordance with International Standards Organization (ISO) specifications. The Fernald Environmental Management Project uses ISO containers for packaging contaminated debris for disposal at the Nevada Test Site. Loose bulk radioactive waste is not accepted for disposal at the Nevada Test Site. All bulk waste must be packaged to prevent the spread of contamination at the disposal facility. The use of large scale bulk packaging is more economical and a more efficient disposal practice compared to the use of smaller individual packages.
The container involved in this accident contained radioactive contaminated debris generated as a result of the ongoing remediation activities at the Fernald Environmental Management Project. The material in this package, crushed drums and wood pallets, was loaded directly into the container.
The ISO containers are transported from the Fernald Environmental Management Project to the Nevada Test Site on standard flatbed tractor trailers. A loaded ISO container can weigh between 20,000 and 42,000 pounds gross weight. The container involved in this accident weighed 29,160 pounds gross weight. Containers are fastened to the trailer using chains, binders, and straps.

When the transport vehicle involved in this accident rolled onto its side, the force of the impact, combined with the abrasion of the tie-downs between the trailer and the road surface caused the container to separate from the trailer. The container slid about 40 feet before coming to rest in the median. The transport vehicle continued to slide on its side more than 100 feet further down the pavement. There were no injuries as a result of the accident and the container maintained its integrity thus preventing the release of material.

INITIAL RESPONSE

The Rolla Missouri local emergency organizations provided first response to the accident scene. The container placarding and shipping papers correctly identified the hazards associated with the container and resulted in additional notifications. The State of Missouri Department of Natural Resources and Department of Health were called to assist the local responders. A hazardous materials response team from Fort Leonard Wood Missouri was also contacted for support.

Initially, the Missouri Department of Natural Resources attempted to contact the Fernald Environmental Management Project. Failing to contact the consignor of the bill of lading, they contacted the consignee, the Nevada Test Site. The Nevada Test Site emergency operations personnel contacted DOE-HQ who then notified the Oak Ridge office. The Oak Ridge office was contacted because it was the nearest DOE facility with an established Radioactivity Assistance Program team.

Once the Fernald Environmental Management Project was notified, the Fernald Environmental Management Project Assistant Emergency Duty Officer requested a 100 foot exclusion zone around the container until all the facts concerning the waste were established. The Assistant Emergency Duty Officer then contacted the Fernald Environmental Management Project Emergency Duty Officer to report the event.

The Missouri Department of Health, Department of Natural Resources, and the HazMat team from Ft. Leonard Wood had previously determined that there was no contamination as a result of the accident. After determining that there was no breach of containment, the local response organizations announced their intention to initiate recovery operations.

For unknown reasons, the local fire department attempted to open the ISO container. Had the fire department been successful in this attempt to open the ISO container, the containment would have been breached resulting in a high probability of a material release.

The Fernald Environmental Management Project personnel in contact with the on scene commander requested that recovery operations involving the waste container be postponed until a recovery team from the Fernald Environmental Management Project was on the scene. This decision was based on indeterminate level of confidence in the radioactive material experience and instrumentation available at the scene to truly evaluate the situation. The equipment on the scene was assumed to be civil defense 7000 series portable radiation detection instrument. This instrumentation is not sensitive enough to accurately assess the potential contamination released from this container. Given this situation, the Fernald Environmental Management Project determined that it was best to have representatives from the facility at the scene. Recovery operations would be safer with the assistance of a team of personnel familiar with the waste and supported with the proper instrumentation.

Since initial surveys indicated that no contamination was detected and the container was out of traffic, the recovery operations were postponed until the Fernald Environmental Management Project team arrived. Security of the accident scene was maintained by the Phelps County Sheriff Department. One deputy was at the scene when the Fernald Environmental Management Project team arrived at the scene at 0200, October 2, 1994.

RECOVERY OPERATION

The Fernald Environmental Management Project sent a team of personnel knowledgeable of the waste and equipped with the proper equipment to Rolla Missouri to assist with the recovery operation.

A chartered jet flew the team to St. Louis, Missouri where they rented a car for the last leg of the trip. The accident scene was 80 miles southwest of St. Louis, Missouri. The Fernald Environmental Management Project team arrived at the scene at 0200 CST, eleven hours after the accident occurred. This response time was entirely dictated by the conditions. Because the Fernald Environmental Management Project knew there was no release of contamination, additional time could be used to assemble the necessary equipment for the response team.

Once on the scene, the Fernald Environmental Management Project team immediately started air monitoring and surveyed the site to establish a clean command point. The area between where the container contacted the road and where it came to rest in the median was surveyed first. After confirming that this area was not contaminated, the team began to survey the container. The container survey confirmed that there was no release of contamination. Further surveys of the ground beneath the container had to wait until recovery operations were initiated.

The Missouri State Highway Patrol requested that recovery operation be delayed until daylight. During this time, the Fernald Environmental Management Project recovery team evaluated the accident scene to assist with anticipated internal investigations. The team also used this time to coordinate recovery operation activities with the local wrecker operator. A trip to the wrecker yard was made to inspect the original trailer. This inspection identified minor repairs which were completed while waiting for sunrise. The wrecker operator also located a power unit to pull the repaired trailer to and from the accident scene.

The wrecker operator had contracted two cranes with operators to remove the container from the median. Both eastbound lanes of Interstate 44 were stopped by the Missouri state police for approximately ten minutes while the cranes were positioned in the left lane. Once the cranes were in position, the right lane was reopened for east bound traffic. The west bound lanes remained open for the entire recovery operations.

The Fernald Environmental Management Project recovery team remained at the scene ready to provide radiological support during the recovery. Because the container was lying on its top, the team could not certify the integrity of the entire container. As planned, the wrecker crew attached cables to the container. Using the cranes, the container was rolled 90 degrees exposing the top of the container. The Fernald Environmental Management Project radiological support personnel then completed the survey of the container and the ground beneath it to complete the container integrity examination. The Missouri Department of Health, Department of Natural Resources representatives were then invited to perform their own surveys to confirm the Fernald Environmental Management Project results.

After determining that the container was strong tight, the wrecker operator was directed to attach cables and roll the container into an upright position. After a final survey of the container to confirm the container did not breach during recovery operations, the container was lifted onto the highway. The Missouri State Highway Patrol stopped east bound traffic one final time to allow the container to be loaded onto the trailer. Once the container was on the trailer, the loaded trailer and the cranes were moved out of the left lane on to the right shoulder. Traffic was released to use the entire eastbound interstate.

The entire recovery operation was complete by 1150 CST, October 2, 1994, less than 20 hours after the accident first occurred. The actual recovery operations only required 45 minutes from the time the cranes were in position until the time the container was on the shoulder of the road. Eastbound traffic was restricted only during the actual recovery operation and totally stopped for a total of 20 minutes. The entire recovery operation was completed without further incident.

The trailer with the ISO secured to it was hauled to the wrecker yard to await a properly trained and licensed driver to arrive in Rolla and haul the load back to the Fernald Environmental Management Project. The local power unit was used only to get the container off the highway. An authorized driver with the proper training and permits was required to return the container back to Ohio. The container arrived back at the Fernald Environmental Management Project on October 4, 1994.

ACCIDENT EVALUATION

The root cause of the accident was driver inattention. The driver indicated that he was looking in his right side rear view mirror to determine if he had cleared a vehicle that he was passing. While checking the mirror, he failed to realize that his truck was drifting toward the median. The left front wheel dropped into the median which was six to eight inches below the pavement. The driver immediately attempted to recover from this path but the center of gravity of the load had already shifted causing him to loose control of the vehicle.

The driver fought to regain control over a distance of more than 700 feet before the truck rolled over. The speed limit in the accident area is 65 mph. The police report did not identify the truck speed, mechanical condition, or the physical condition of the driver as possible contributing causes of the accident.

LESSONS LEARNED

The Fernald Environmental Management Project conducts regular emergency response exercises at the facility. These exercises have intentionally focused on more likely potential on-site emergencies or natural disasters. The transportation accident in Rolla, Missouri made it perfectly clear that the facility was not completely prepared for an off-site transportation emergency. During the event, each person involved maintained personal field notes of actions taken or observed. After the event was declared to be secure, the parties involved convened a meeting to critique the response. The following observations were noted during this review.

The Fernald Environmental Management Project Emergency Communication Center was not notified of the accident until nearly two hours after it occurred. The primary cause of this delayed notification was the location of the emergency phone number on the bill of lading. This number was in very small type and not conspicuously displayed. The number that was more prominently displayed and called first by the local responders is a dispatcher office which is not manned 24 hours. The corrective action for this issue is to revise the bill of lading and drivers instructions to clearly identify the emergency phone number.

After the Fernald Environmental Management Project was notified of the incident, initial response efforts were dedicated to working with the on scene commander to determine the magnitude of the situation, and assemble the appropriate personnel. Once the situation was clearly communicated to the Fernald Environmental Management Project Emergency Operations Center, the task of classifying the event was initiated.

The Emergency Duty Officer could not find an appropriate reference in DOE Order 5000.3b that addressed transportation accidents with no release of material. This order primarily addresses transportation accidents where there is a release. The Emergency Duty Officer then referred to the "Fernald Environmental Management Project Emergency Plan". In the chapter entitled "Emergency Action Levels", he identified the classification for transportation accidents involving non-release of material. This plan and event classification is applicable to all site transportation accidents involving shipment of hazardous or radiological material coming from the Fernald Environmental Management Project in which the integrity of the shipment is in doubt or can not readily be determined. This plan determined the incident classification as Emergency/Alert. This classification required additional notifications of DOE-HQ and USEPA Region 5. The delay in classifying the event and subsequent notification of DOE-HQ resulted in a temporary confusion as to ownership of the response actions. The Fernald Environmental Management Project Emergency Operations Center was working independently of the DOE-HQ. Until the Fernald Environmental Management Project contacted DOE-HQ to notify them of the incident, neither had any indication that the other was involved. Once DOE-HQ was apprised of the situation and knew the Fernald Environmental Management Project Emergency Operations Center was involved, the response was turned over to Fernald.

The corrective action for this issue will be addressed by the revised shipping papers. Clearly identified emergency phone numbers will prevent the delayed notification of incidents to the Fernald Environmental Management Project. This issue will also be addressed by issuing the completed Fernald Environmental Management Project Transportation Emergency Response Plan. The plan was in rough draft and out for review at the time of the accident. The plan will address the lessons learned from this incident, and provide a ready resource to assist in classifying incidents and identifying the notification requirements.

The delay in contacting the Fernald Environmental Management Project was complicated when specific information concerning the waste in the container was not readily available. The Fernald Environmental Management Project shipment certification files are stored in locked files as required by DOE orders. To protect the integrity of the files, only authorized personnel can open them. No authorized personnel were available to retrieve them at the time of the accident. The on scene commander had the bill of lading but the description on this document is based on DOT proper shipping name. The DOT shipping name does not specify that the container was full of contaminated metal and wood. As a result, the on scene response team, unaware that the ISO contained loose bulk waste, attempted to open the container. There was no indication in the shipping documentation that this was a bulk waste container.

The corrective action for this issue is to revise the drivers instructions provided with every load to better identify the contents of the container. Additionally, a

daily shipping record is provided to the Fernald Environmental Management Project Assistant Emergency Duty Officer and available if needed.
After the Fernald Environmental Management Project Emergency Operations Center committed to send a response team to the accident scene, additional time was required to assemble the people and equipment. There was no established response team for off-site transportation emergency responses. The team that was assembled for this response was well informed but there was no guarantee that these individuals would have been contacted in different circumstances. Once on the scene, the team realized that the emergency communications equipment on hand was limited. The cellular phones provided to support the team were not fully charged and there was no adapter to charge the batteries or operate the phones using the rental car electrical system. Use of these phones was limited to short calls and resulted in some calls being disconnected in mid-conversation. The phones could not be left on due to the weak batteries and the "sky-pager" provided for the trip did not function as expected. The team was basically out of direct contact with the Emergency Operations Center which stood down soon after the team departed for the airport. The corrective action for this issue is to staff an emergency response team with knowledgeable personnel and provide them with the proper equipment and training. This issue will be included in the Fernald Environmental Management Project Transportation Emergency Response Plan.
The wrecker operator involved in the accident recovery operation was extremely cooperative and well organized. The operator assembled the necessary equipment and personnel to quickly and safely recover the container. This situation is more likely the exception than the rule and therefore, better planning will be required in the event such a wrecker operator is not available. In the Rolla incident, the wrecker operator was very instrumental in the success of the operation. As a corrective action for this issue, the Fernald Environmental Management Project secured funding from DOE-HQ for an outreach program for communities along the route. This funding is intended for training first responders along the transportation route but this stakeholder interaction will enable the Fernald Environmental Management Project to identify potential resources for future reference.
The recovery operation was delayed while the wrecker operator repaired the original transport trailer. This was necessary because the transporter of record could not provide another trained driver with truck and trailer in the time frame required. The container could not be placed on a trailer that was not permitted to haul the waste back to Ohio. An alternative plan would have been required had the original trailer been damaged beyond repair.
The corrective action for this issue is to identify transportation services along the route that can provide emergency support and include them in the Fernald Environmental Management Project Transportation Emergency Plan.
CONCLUSION
The Fernald Environmental Management Project has been shipping low-level waste to the Nevada Test Site for disposal since 1985. During this time, more than three-thousand truck loads have been successfully shipped without a serious transportation accident. This performance has resulted in more than 6.4 million loaded miles traveled before the first serious accident was encountered. This performance exceeds national highway transportation safety statistics and the Fernald Environmental Management Project risk assessment projections.
Never-the-less, a thorough review of the occurrence was conducted to enable the Fernald Environmental Management Project to improve future transportation emergency response.
During the critique of this incident, several commendable aspects of the response was documented. One of the more notable highlights of this review is the recognition of the professionalism exhibited by the people involved in this response. The local response organizations performed well and were augmented by competent Fernald Environmental Management Project individuals. The successful integration of the multiple response organizations at the scene resulted in a completed response in a relatively short period of time.
The actual circumstances surrounding this accident dictated the response actions and time frames. The Missouri Department of Health, Department of Natural Resources, and the HazMat team from Ft. Leonard Wood had previously determined that there was no contamination as a result of the accident. Because the container did not fail and was not in the traffic lanes, the actual response permitted some degree of

deliberation. Had the container failed or if it was lying on the highway, the two hour delay in notification to the Fernald Environmental Management Project would have had greater consequences.
Recognizing that the primary cause of the delayed notification was due to the format of the shipment documentation, the Fernald Environmental Management Project has revised these documents to better delineate the emergency response information. This communication will be duplicated on a pocket emergency response instruction card to be provided to the drivers. These corrective actions are intended to prevent recurrence of the destination facility receiving first notification of the transportation accident and to prevent emergency response actions from proceeding without Fernald Environmental Management Project involvement. It is imperative that the facility generating the shipment be involved with the response actions because that facility has the most personal knowledge of the shipment contents. This involvement is most important in the event that the driver's paperwork could not be retrieved from the power unit. The originating facility has the only other copy of the shipment documentation for deciding response actions.
An accidental breach of the container, which nearly happened in this incident, must be addressed. Even though the shipping papers clearly identified the hazards associated with the shipment and the container was properly marked, local first responders attempted to open the container. While it is not known why they tried to open the container, it is clear that the communication to local emergency response organizations must be better. The Fernald Environmental Management Project recognizes that the many local communities along the transportation route must be provided better information concerning the waste. The Fernald Environmental Management Project is pursuing an outreach program to promote awareness for communities along the transportation route, but the effectiveness of this program will be too limited in scope. The primary communication must be provided in the shipment documentation and driver training. The Fernald Environmental Management Project is in the process of implementing these changes.
Instrumental to the success of this recovery operation was the local wrecker operator. This individual secured the required equipment to hoist the container back onto the truck. The wrecker operator also made repairs to the original trailer making it road worthy and able to be used to reload the container. This support was crucial to the recovery operation and cannot be taken for granted. Had the original trailer been rendered unfit for reuse, a local transporter would have been required to support the recovery operation. Finding a driver permitted to haul radioactive material for the return trip to Fernald, Ohio, would have resulted in a longer delay before the operation would have been completed. As it occurred, the original transporter was used to return the container to the Fernald Environmental Management Project. The corrective action for this issue will be for the Fernald Environmental Management Project to contact the transporter to initiate transportation support earlier in the response action.
The final improvement developing as a result of this incident is an improvement of the Fernald Environmental Management Project off-site emergency response capability. Once on the scene, the Fernald Environmental Management Project team performed well but it took too long to assemble the equipment and the communications equipment did not function as required when the team arrived at the scene. The Fernald Environmental Management Project is in the process of organizing a trained and knowledgeable staff of personnel to participate on a facility response team. The lessons learned from this incident will improve the readiness of this team in the future. The team will be assigned Emergency Operations Center pagers to directly contact the team members on duty. This corrective action is intended to prevent recurrence of the obstacles encountered by the team involved with this response.
The Fernald Environmental Management Project is the first DOE facility to be declared a total remediation project. As the remediation of the Fernald Environmental Management Project continues, the volume of off-site transportation will increase. Because the root cause of the accident was driver inattention and no mechanical or driver physical conditions were identified as contributing factors, it is safe to assume that the incident was not the result of a system failure. In actuality, the proper preparation of the shipment contributed to the success of the response. However, despite the best efforts of the generating facility to properly package the waste, an accident will occur involving the release of material. A review of the current notification communication process by the generating facility

prior to an accident could minimize the impact of the incident. The primary revisions required for improved response notifications at the Fernald Environmental Management Project have been identified and implemented. This paper is intended to share the Fernald Environmental Management Project lessons learned from this low-level waste transportation accident to provide other radioactive waste generators an opportunity to be better prepared for a transportation accident.

ABSTRACT
The Transportation Management Division (TMD) of the U.S. Department of Energy has supported the development of an expert system for enhancing compliance with hazardous materials packaging and transportation regulations at the Oak Ridge National Laboratory. This system, the Hazardous Material Expert System (HaMTES), was developed with the objective of providing a computerized expert system which a) is easy to use, b) will provide straightforward and consistent application of the hazardous material transportation regulations, and c) will reduce the potential for human error in applying the regulations to both packaging and transportation of hazardous material activities.
HaMTES is based on an analysis of what an expert in hazardous materials shipping regulations could and should do when preparing a shipment of such materials. The system's proof-of-concept was demonstrated using the radioactive material regulations, and it was then expanded to include regulations for all hazardous materials. It has incorporated, as much as possible, multi-media capabilities so that the user can access audio/visual demonstrations of explanations and applications of regulations, the descriptions of package designs, and the actual loading and preparation for shipment of specific package designs. It can be used to determine for a given set of contents, the proper shipping name, hazard class, packing group, whether the material is a hazardous substance as defined by the U.S. Environmental Protection Agency, and whether it is a marine pollutant as defined by the International Maritime Organization. Specific modal requirements, packaging requirements, marking, labeling, and placarding requirements are also identified for the specified hazardous materials contents. It takes a user beyond simply "browsing" through the regulations to using embedded logic that allows the computer to make decisions and ensure all requirements have been scrutinized. The system consists of the program, a few full-motion video files, and a special search engine that allows access to a regulation scanning data base. The system has been developed based upon U.S. regulations, has been tested by experts, and is being upgraded based upon the results of these tests.
Coupling of HaMTES to other transportation operations management software is underway, and methods for maintaining and upgrading the program have been developed. The details of the capabilities of HaMTES, its computer hardware requirements, and the plans for implementing HaMTES within the DOE shipping community will be presented in this paper.
INTRODUCTION
The ability of the computer to simulate and make decisions as a subject matter expert (expert system) has greatly expanded potential computer applications in complex decision-making situations. With this type of computing power available in an increasingly user-friendly format (using object-oriented programming and Hypermedia capabilities), the development of a transportation packaging expert system that is based on the hazardous material regulations was possible. Under the sponsorship of the U.S. Department of Energy's

(DOE's) Transportation Management Division (EM-261), the Transportation Technologies Group at Oak Ridge National Laboratory (ORNL) has designed and developed an expert system application of the U.S. hazardous materials transportation regulations.
The strategy to develop the expert system prototype was to, first, develop modules to capture the knowledge of different areas of the transportation regulations; and, second, append these different modules into one final package. The individual module development focused on one prototype for transporting and packaging radioactive material and another for transporting and packaging hazardous chemical materials.
It was found that the capability to scan the pertinent regulations in an interactive mode is invaluable. The regulations are always at hand for further consultation using a regular menu or a hypertext search mechanism. Graphic files with package information (such as dimensions, authorized contents, etc.) can also be accessed. Additional assistance is provided by means of graphic files and/or video images.
From the analysis of the different features required for the expert system prototype, it was concluded that the developmental efforts should be directed to a WindowsTM 3.1 Multimedia environment. Multimedia technology usually works as an interactive software system that gives personal computer users the ability to organize, manage, and present information in a number of formatstext, graphics, sound, and full-motion video.
The two prototype modules have been developed and have incorporated within them the expertise for the transportation and packaging of radioactive and hazardous materials. The two modules are integrated into a single system being implemented to support DOE-wide transportation operations.
Work is in progress to include HaMTES as the major portion of the hazardous materials module of the automated transportation management system being implemented to support DOE-wide transportation operations.
The verification and validation of HaMTES has been performed by comparing the operation of the HaMTES system with known shipments and packages. Model validation was performed by trained and experienced traffic specialists at ORNL using 49 CFR. HaMTES was also sent as a beta-test version to transportation experts in several DOE and contractor locations who then tested whether the computer model accurately represents the real system. In addition, experts from the U.S. Department of Transportation (DOT) and the Nuclear Regulatory Commission (NRC) reviewed and commented on the logic diagram.

DEVELOPMENT

The strategy to develop the expert system was to, first, demonstrate the feasibility of developing an expert system prototype by developing modules to capture the knowledge of different areas of hazardous materials transportation based on the shipper's perspective; second, select an appropriate environment in which to deploy the expert system; third, analyze the feasibility of appending these different modules in one final full package; and fourth, develop the full-scale expert system.

Knowledge Acquisition

The DOT and the U.S. Environmental Protection Agency (EPA) have stringent regulations regarding the shipment of hazardous materials which must be complied with before these materials are shipped. These regulations are extremely complicated. To achieve compliance, the shipper must sift through hundreds of regulations, search large tables, and perform calculations, depending on the applicable regulations. Only when all the applicable information has been determined, depending on the regulations and the tables, can the shipper properly prepare a package for shipment. Transportation specialists and packaging engineers must have the expertise to know which regulations to apply to a given shipment. It is this knowledgethat of the correct and complete path through the regulationsthat this expert system contains.
The initial requirement for proper knowledge acquisition was to identify the regulations pertinent to hazardous and radioactive material transportation. From those identified, it was decided to implement in the HaMTES the 49 CFR 100-173, the transportation sections of 10 CFR, and the transportation sections of 40 CFR. When this project began, HM-169A and a corresponding NRC rule making proposed changes to the radioactive materials portions of the regulations; these were expected to be finalized by 1994. The decision was made to develop the prototype to these proposed regulations to minimize obsolescence. HM-169A has not yet been finalized. In order to complete and release version 1.0, the radioactive module was modified recently to

reflect the current DOT and NRC regulations.
These regulations state the mechanism by which the transportation of hazardous and radioactive materials must be done. There is also room for interpretation of the regulations. It is also agreed that understanding the mechanism of how these regulations should be applied may signify a large task and representing them computationally undoubtedly poses a formidable endeavor. Consequently, the first obstacle faced by this project was to choose an appropriate way of representing the regulations and how to navigate through them. The solution was found in the use of logic diagrams. Logic diagrams allow the representation of a knowledge base by means of a graphic tree where a decision point is found at the beginning of each branch. Figure 1 illustrates a simplified number of decision points found in the logic for determining packages for the transportation of radioactive materials.
An IF-THEN rule mechanism applied to the decision points in the logic diagram made it possible to convert the logic tree into a computer program.
Environment to Deploy the Program
To determine the appropriate deployment environment, some developmental stages were necessary. The first stage was to produce a proof-of-concept version of the program. The preliminary program to support the proof-of-concept process was developed using Prolog (Programming in Logic). This preliminary program helped determine that it was possible to develop such an expert system. At the same time, this preliminary prototype was an aid in recognizing the basic requirements for development and the required features of the program. The goal of the proof-of-concept stage was to determine if it was feasible to develop a more comprehensive expert system.
The basic requirements of the prototype development were that the expert system would run on the personal computer (PC) platform. It was clear that one requirement of the expert system was that it should provide the ability to access the regulations from the commercial programs that update the regulations on regular basis. The friendliness of the user interface along with the ability to navigate throughout the regulations and display graphics and full-motion video information on the screen were other important requirements. The first concern of the knowledge engineer was to develop an interface between the user and all the specific program(s) that were transparent regarding the manipulations that are required to go from a) one set of input data, to b) calculation programs, to c) decision-maker programs, etc. Thus, a straightforward system of a question-answer relationship between the computer and the user was highly desirable. The environment selected had to be able to implement a rule-based system that represents the regulations.
Other requirements, including access to several types of information sources, were suggested by the logic diagram. Behind every question asked of the user there is a set of regulatory requirement(s) which may influence the answer given by the user. Thus in some cases, it was obvious that the user had to access the regulations before an answer could be given to the question. This feature provides the less knowledgeable user with enough information to give an appropriate response. It is well-known that regulations normally refer to other regulations or parts of regulations, which in turn may refer to other regulations and so on. In such complex cases, the expert system not only needs to access regulations, but also it must be able to browse through them. Additional explanations about regulations, interpretation of regulations, or any other aspect of the decision mechanism to determine types of packages were required to be available in a form of video images or audio. Consequently, multimedia elements, such as Hypertext navigation, visual aids (whether as graphic or full-motion form), and mouse-driven interface elements, were considered to be essential parts of the expert system.
To decide what software tool would be used to create the expert system prototype, five possible tools using six criteria were rated. These criteria were 1) multimedia capabilities, 2) rule-making capabilities, 3) flexibility of the environment, 4) user interface provided by each tool, 5) data-handling capabilities of each tool, and 6) ease of use of each tool. The following tools were rated: OWLTM Industries GuideTM (a multimedia document presenter), the C/C++ programming language (a general programming language), the Prolog programming language [a logic-based disk operating system (DOS) programming language], general expert system shells (tools used to create expert systems), and the Visual BasicTM programming language (a general Windows programming language).
Ratings on these criteria suggested that Visual Basic was the best environment in which to create the expert system. Although a Prolog-based code had already been

created during the proof-of-concept stage, it was clear that putting the Prolog version together with multimedia features would be difficult. Consequently, this option was abandoned. The solution found for the prototype stage was to translate the Prolog code into the Visual Basic code, which is a Windows application. Figure 2 illustrates the general architecture of HaMTES and the various interactions of the system with sources of information.

The prototype expert system that covers radioactive materials shipment preparation has been subjected to a review and validation process by experts in the field. Minor changes have been suggested, the program has been revised, and implementation of this module within the complete system has been undertaken. The development of the expert system prototype has demonstrated that it is possible to represent knowledge about radioactive material transportation using a logic diagram that has been translated into a rule-based system. The mechanism to access updated regulatory information from RegScanTM, a commercial program, has also proven to be technically feasible.

Appending Modules

The radioactive and hazardous chemicals modules have been finalized and integrated. Consequently, the final version has incorporated both modules with the appropriate links so the user can prepare shipments involving radioactive, hazardous, and most importantly, mixtures of both types of materials. The system developed here promises to help transportation management not only with routine daily shipping duties but also, and more importantly, with those unusual cases requiring more regulatory analysis to ensure compliance.

Implement the Full Program

The full program development has occurred in several stages and will continue to develop depending on the funding resources allocated to the project. Version 1.0 of HaMTES will help the user to prepare the shipment and the shipping papers. The HaMTES output includes information on the proper shipping name, markings, labeling, and placarding as well as package type. Version 1.0 does not include accessing a data base of Type A packages, UN packages or Type B packages since such a data base has not been built. However, it will indicate the specific paragraph(s) of the regulations where the type of package is referenced and the special provisions indicated. HaMTES Version 1.0 has been prepared for the shippers' most pressing needs.

It is anticipated that later versions of HaMTES will include hazardous wastes and/or a completed package data base. Further releases will include better audio and video features that have not been included inversion 1.0. These Multimedia features were demonstrated in the beta test release with positive comments from the reviewers.

VALIDATION AND VERIFICATION

The following subsections describe the validation and verification of HaMTES which has been complete.

First Phase of Verification and Validation of HaMTES

During the first phase of verification and validation, experts from ORNL reviewed the program and submitted their written and oral comments. Their comments varied from changes to the screens to changes in the logic diagram. All these comments have been incorporated into the computer program.

Second Phase of Verification and Validation

During the second phase of verification and validation, the HaMTES program and a review package were sent to experts at several DOE and contractor sites. The review package consisted of an installation manual, an operating manual, and a set of eight disks containing the program, full-motion video files, and the special search engine that allows access to regulation scanning (RegScan) for those who have this commercial program. For those who did not own a copy of RegScan, the beta test release version of HaMTES simply provided an error message if access to the non-existent regulations data base was attempted.

Presentation of HaMTES to a JAD Session

The DOE Transportation Management Division has different software applications under development. Joint Application Development (JAD) sessions are being held to analyze, improve, and discuss the integration of these software packages for transportation purpose. The presentation and discussion of HaMTES during a JAD session resulted in suggestions on user interface as well as changes in logic. As DOE funding allows, it is anticipated that HaMTES will be the front end for the hazardous module of the Automated Transportation Management System (ATMS) being

developed under the sponsorship of DOE's Transportation Management Division.

Logic Diagram Analysis with NRC and DOT

A meeting was held with regulatory experts from the NRC and the DOT. At these meetings, the HaMTES logic diagram for transporting materials according to the current regulations was thoroughly reviewed. During the NRC review of the logic diagram, the work was concentrated in the radioactive module of HaMTES. The review with the DOT experts was essentially focused on the hazardous materials portion of HaMTES. The findings of these two meetings were incorporated into HaMTES Version 1.0.

FUTURE OF HaMTES

As previously mentioned, DOT regulations determine the shipping requirements for the transportation of hazardous materials, including radioactive materials. The logic involved in determining these requirements for a shipment has been successfully implemented as a decision tree, using the Revised Radioactive Materials Transportation Regulations as proposed in HM-169A and the collateral proposed changes in NRC's 10 CFR Part 71. Since HM-169A has not yet been published, HaMTES Version 1.0 has been built on a modified logic diagram which reflects the current regulations. The version of HaMTES based on the proposed regulations has been filed for use when the regulations are finalized.

Version 1.0 of HaMTES, which is a stand-alone version, will be distributed to DOE facilities during early 1995. Concurrently, methods for making HaMTES available to users outside of DOE are being investigated. Future versions of HaMTES are expected to include more detailed data bases of package designs (Type A, Type B, UN packages, etc), waste material shipment capabilities, and audio and video help to users. Eventually, when resources are available, HaMTES will be integrated into ATMS. Modifications to fit the ATMS systems requirements will be necessary. Mechanisms of integration have already been analyzed and tested.

ABSTRACT

In this paper we present a new 20' box container, designed by the firm CORROBESCH for the transport of radioactive and other dangerous wastes, and having a carrying capacity of 22 tons. The container itself weighs only 4 tons, and it incorporates a proprietary corrosion finish that is highly resistant to mechanical wear, deformation, and radioactive contamination. Recently, the container was subjected in Germany to a series of collision and drop tests, as specified by the International Atomic Energy Agency (IAEA) , and it passed these tests to complete satisfaction. As a result, the container received certification by agencies such as the Germanischer Lloyd (GL), the Deutsche Bahn A.G. (DB), and the Bundesanstalt fr Materialprfung (BAM). At the same time, the writers have also developed a mathematical model of the container to predict its dynamic behavior during service loads, and have been able to make motion predictions that are in good agreement with signatures recorded during tests.

BOX CONTAINER

The German firm CORROBESCH, with corporate offices in Hamburg, has recently developed a 20 foot ISO box-container of type M-CB 49, intended for the transport of highly radioactive wastes and other dangerous products stored in liquid and granular form within steel drums. While the container weighs only four tons, it can carry up to 22 tons of cargo in various configurations. The container is made of stiffened steel plates, and is closed at one end by two doors with latches and bolts. All interior and exterior surfaces are covered with a highly resilient paint developed

and patented by CORROBESCH, which is resistant to chemical corrosion, to mechanical deformation and wear, to scratches and tear, and to radioactive contamination. Indeed, the anti-corrosion finish can sustain radiation levels as high a 30 MGy without damage or permanent contamination, and painted steel plates can be bent by up to 140 degrees without obvious fissures in the corrosion finish. As a result of these characteristics, the container can easily be cleaned, decontaminated and reused.

SUPPORT TRAYS AND MOTION-RESTRAINING DEVICES

One of the aims in the development of this container was to achieve a system that could transport cargoes with variable numbers of drums stacked in changeable configurations -including an only partially filled container- while ensuring the safety of the container for accidental dynamic forces and vibrations that could conceivably arise during transport. This goal led CORROBESCH to the design of an interchangeable tray system for the drums that can easily be handled and loaded into the container, together with passive restraining devices that prevent this assembly from moving inside the container when solicited by dynamic forces. Another important consideration was the fact that after loading and sealing of the container, it is not possible to inspect or adjust the contents until after it has arrived at its destination. Since the transport can last days, weeks or even months, it was deemed necessary to avoid the use of restraining devices on the drums that rely on initial set forces, such as tension straps, because with time such devices can loose their tension, and thus their effectiveness. Hence, CORROBESCH developed passive restraining devices that adjust themselves as the drums vibrate back and forth, see Fig. 1.

The drums are stacked in two layers, and rest on light flexible trays within grooves that have been carved out in the shape of the drum heads. There are three layers of trays: one on the bottom surface, one between the two drum layers, and one on the top covering the drums. These trays are not continuous at a given elevation, but consist of individual trays having the width of the container, with space for up to three drums; these are placed, one at a time, into the container. Between each individual tray lies a removable restraining bar that is anchored elastically to the side walls of the container. A remaining clearance space above the top tray layer of about 50 cm, which is needed to load or unload the drums using forklifts, is then secured with passive restraining devices consisting of masses and springs that lock the trays into place, and which adjust themselves as the container is shaken by vibrations during transport.

DYNAMIC TESTS

On June 29, 1994 the fully loaded container with a total weight of 26 ton was subjected to a series of controlled collisions tests (1) at the experimental facilities of the German Railroads (Deutsche Bundesbahn, DB) in Minden, FRG. The container was loaded and anchored onto a 20 ton flat car, which was subsequently rammed by an 80 ton car at varying speeds. The speed was adjusted in steps so as to achieve prescribed levels of acceleration of up to four times the acceleration of gravity at the anchoring points of the container. Acceleration signatures were recorded at various points in the container, and extensive measurements were made of the motions experienced by the drums. The container withstood these tests without external damage, no drums were broken, and no fill material was spilled. Following these test, the container received certification by the Deutsche Bahn, the Germanischer Lloyd, and the Bundesanstalt fr Materialprfung as being fit for the transport of dangerous goods.

Six months later, on December 6, 1994, a fully loaded container was subjected to a drop test at the port facilities of Blohm+Voss in Hamburg (2). The container was hung by one edge 30 cm above the ground and dropped with some inclination onto a concrete mat overlain by a thick steel plate. The container crashed first onto a corner, then pivoted about this point and slammed onto the surface with great violence. The motion signatures were recorded at various points with triaxial devices; additionally, the test was captured on video. While the container suffered some external damage, no fill material was spilled to the exterior.

MATHEMATICAL MODELS

Clearly, full scale dynamic tests are very expensive and time consuming. Even though a number of essential tests are prescribed by the licensing agencies and must unavoidably be carried out, it is also true that these test may often not be exhaustive enough. One can easily imagine-or postulate-scenarios not covered by the

tests. Thus, it is desirable to supplement the physical tests with mathematical models that can be used to make predictions about hypothesized accidental conditions. Such tools can be invaluable for the prediction of the behavior of the container during such conditions, and can also be used to interpret any measurements made during actual tests. These considerations moved the writers to develop a discrete numerical model for the analysis of the container when subjected to dynamic conditions (3). In essence, the authors implemented a finite element model with discrete elements that allow for large motions of the components. The technical details will not be presented in this paper, however, not only because of the limited space available, but also because the theoretical details of such discrete models are generally well understood. Thus, we shall describe only in very general terms some of the characteristics of the model used to predict the behavior during collisions.

Consider a container loaded onto a flat car, which is in turn impacted from the rear end by another heavy car (Fig. 2a). The container is loaded with two layers of drums on trays, and there are eight rows with three drums in each (Fig. 2b). Thus, the container contains a total of 2x3x8=48 drums. To a first approximation, such a collision elicits mostly longitudinal horizontal forces within the container, so it suffices to represent this system in terms of a plane (two-dimensional) geometry. In such model, we have made the following assumptions:

Both the ramming and flat cars as well as the container itself ---but not its contents-are infinitely rigid separate bodies of known masses.

The shock absorbers between the cars are modeled as a linear spring-damper system, which may neither exceed a maximum elongation, nor be subjected to tension. Upon reaching its maximum elongation, the ensuing collision is assumed to be of negligible duration (the time required for a shock wave to travel through the flat car is between one and two orders of magnitude smaller than the response time of the container with the drums inside).

The drums in the container are rigid bodies connected by elastic springs (the trays and the restraining devices); each drum can both translate as well as rotate about a transversal axis.

The longitudinal motion of the bottom edge of the inferior row of drums is impeded by friction against the bottom of the container. Upon exceeding its maximum frictional value, each drum may slide independently.

Inelastic damping forces are neglected.

Using these assumptions, we have then made motion predictions for tested configurations considering three mechanical models of increasing sophistication:

First, the two colliding cars were assumed to be perfectly rigid and obeying the physical laws governing an elastic-plastic collision (conservation of momentum and energy balance). This is the very simplest model that we used to make predictions about the abrupt change in velocity that takes place when the shock absorbers between the cars have reached their maximum deformation (21 cm).

Secondly, we considered the collision of two rigid bodies separated by a spring. This model can be evaluated in closed form, it supplements the previous model, and allows one to make simple predictions about the orders of magnitude of the response (accelerations, forces, etc.).

Finally, we developed a complex numerical model in which the contents of the container are discrete masses separated by springs that can move, rotate, or slide relative to each other. The resulting system of non-linear equations were then solved numerically by means of a special computer code written in the FORTRAN language. Motion signatures were then evaluated at various points and compared to those recorded at the Minden facilities.

After the two cars make contact, momentum begins being transferred through the shock absorber to the flat car with the container, which in turn transfers some of its kinetic energy to the drums in the form of a wave propagating through them in both a horizontal as well as vertical direction. If and when the maximum elongation of the shock absorbers is reached, an elastic plastic collision ensues, which changes abruptly the momentum, and thus the velocity of the flat car. This collision is associated with very large accelerations, which do not immediately affect the drums, since the compliance of the trays and the sliding capability of the drums on the bottom of the container limit the forces that can be transferred to them. A shock wave then develops which again propagates through the system eliciting translations, rotations, and sliding. Each drum experiences then different motions, and must be

analyzed in turn.
Figure 4 depicts the maximum acceleration of one of anchor points of the container as computed with the aid of the second elementary model (the spring-mass system), and shows also values recorded during the actual tests at the DB Minden facilities (where the actual mass ratio was 0.625). As can be seen, the simple model provides excellent estimates of the maximum acceleration, even though the actual system exhibits a more complex (non-linear) behavior due to the changing participation of the contents of the container with the impact velocity.
Figures 5 and 6 show a comparison of the motions in the front left row of barrels in the container, as computed with the discrete model and as recorded at the Minden test facilities, for a collision velocity of 10 km/hr. Figure 5 gives the motion at the bottom of the lower layer of barrels (similar to the container's motion), while Fig. 6 provides the acceleration at the top of the upper layer of barrels. In both cases, the synthetic signatures have been low-pass filtered to match the filtering used during the tests (although this made little difference in the computed motions). While the computed and recorded motions are clearly not the same, they exhibit similar overall trends, the orders of magnitude of the acceleration are similar, and there is general concordance in the duration of the process and in the frequencies of oscillation. Indeed, the differences in these figures is no worse than the variations that were observed in actual motions recorded at the left, center, and right barrel columns (not shown), which on account of symmetry could have been expected to be very similar, or even the same. This experimental observation indicates that the trays supporting the barrels may not have had symmetric stiffness/geometric properties, and/or that non-linear processes (e.g. local yielding of materials etc.) played an important role. Nonetheless, the numerical model provided useful results concerning overall physical behavior.
CONCLUSION
Discrete numerical models for the dynamic analysis of box containers intended for the transport of drums filled with radioactive products, such as that briefly described herein, can provide valuable insight in the behavior of such systems during hypothesized accidental conditions. More importantly, they can be used to supplement and expand the results obtained in actual testing, to help in their interpretation, and above all, to test for design changes in the computer without the need for expensive experiments. The model considered in the context of the new 20' box container designed by CORROBESCH has yielded prediction numbers that were in reasonable agreement with the signatures recorded during actual tests.

ADVANCED TRANSPORT SYSTEM FOR DANGEROUS MATERIALS BASED ON A NEW 20' ISO CONTAINER WITH COMPUTABLE LOAD BEHAVIOR
Friedhelm H. Timpert
Vertriebsgesellschaft mbH, Hamburg, Germany
Stephan R. Halaszovich
Forschungszentrum Jlich GmbH, Jlich, Germany
ABSTRACT
Transports of dangerous materials have to meet increasing safety requirements. An essential prerequisite in the licensing procedure for a new transport system is the demonstration of its integrity even under accident conditions.
The transport unit presented here is based on the 20' ISO steel container. It has been provided with a new system for reliably fixing the loaded material, which is self-locking and does not have to be retightened and whose behavior under load can be mathematically precalculated due to its well-defined geometry and known material properties.
The new container for dangerous materials has been designed for an optimum payload capacity of 22 tons with a low dead weight of 4 tons. A positive self-retaining cargo securing system was developed so that no tightening belts are necessary.

Vibrations during transportation (whether by road, rail or ship) are largely neutralized by the self-securing system. Moreover, this cargo securing system can be computationally and technically adapted to all load cases. The precalculated load capacity of the transport unit was practically confirmed by a crash test with an impact velocity causing fourfold gravitational acceleration at the loaded material. Loading and transport times are uncoupled by the application of this new safety system because no retightening of the securing elements is required after loading, unlike the case of tightening belts, even after an extended service life.
The container is internally and externally provided with a coating which is easy to decontaminate. The radiation resistance of this coating has been demonstrated in practice up to 30 MGy. The coating is extremely corrosion-resistant and considerably prolongs the container life.
The necessary certifications by the competent institutions Germanischer Lloyd, Deutsche Bahn AG and Bundesanstalt fr Materialforschung are available.

INTRODUCTION

The newly developed FHT freight securing system is a reusable, elastic system consisting of support trays serving to secure drums with dangerous goods in a 20'I SO box container during road and rail transport. The geometry and material of the support trays can be varied within broad limits so that the system can be adapted to the various levels of demand in the transport regulations for dangerous goods corresponding to the classification of the dangerous goods. In the following, this is shown in detail on the basis of restraining devices for steel drums used for the transport of low level radioactive wastes.
To date, steel drums with dangerous freight have often been anchored by tension straps to secure the load in the container. The tension straps were applied around several steel drums and attached at the bottom to the anchoring points in the container. Securing the load in this way often proved to be disadvantageous in practice since steel drums do not have any special anchoring facilities, such as eyelet attachments, shackles or clips, for reliable restraining with tension straps. Due to the inevitable vibrations and movements of the steel drums in the container during transport, the tension straps may slip and thus fail to fulfill their task of securing the load.
The FHT freight securing system avoids this disadvantage since an interchangeable tray system takes up the forces emanating from the drums and transfers them to the container walls or container roof and floor. Wedges between the individual trays ensure that the system automatically adjusts itself.
The system can be described mathematically. It can thus be precalculated and designed for different load cases, e.g. collisions at various speeds or drops from different heights. Expensive and time-consuming tests to demonstrate the safety of different load variants can be dispensed with.
The container, interchangeable tray system and drums form one package, which fulfills the requirements for the transport and storage of radioactive substances. Not only is the tray system of significance, but also the jointless interior design of the container and is paint finish. this paint finish is radiation- and corrosion-resistant, provides good protection against mechanical damage and can be easily decontaminated.

CONTAINER

The container is a 20' I SO piece goods container according to DIN ISO 668:1 CC, closed on all sites and of an all-steel design. The manufacturer's model code is M-CB 49. It has a double-wing door at one end. The door wings each have a rubber seal all the way around and in the closed state they are secured by latches and bolts. the container floor is shaped like a trough. The inner surfaces of the walls and their transition of the floor are jointless. The container is coated on the inside and outside with a paint finish whose surface is easily decontaminated pursuant to DIN 25415 Part I. Inside, the container is equipped with anchoring points to secure the load. The permissible total weight is 26,000 kg, and the payload 22,000 kg.

FREIGHT SECURING SYSTEM, PAYLOAD

The FHT freight securing system is a dynamic system whose main elements are the support trays shown in Fig. 1. These shaped pieces serve as elastic top and bottom shock absorbers, which in this example comprise the top and bottom sections of the drums. They are contiguous to each other and the container walls, to which they transfer the forces.

Figure 2 shows a layer of 24 x 200-l drums in a 20'container. The support trays of the second and third level have grooves at the side (Figs. 1 and 2), to accommodate the restraining and tensioning devices. The restraining elements are bars anchored to the side walls of the container to effect load transfer. The tensioning elements are wedges which slide into the wedge-shaped grooves due to their own weight and thus continuously ensure passive tightening of the entire formation.
The drums are attached to the container roof by passive restraining devices consisting of masses and springs that lock the trays into place and which adjust themselves as the container is shaken by vibrations (Fig. 3).
Figure 4 shows a view inside a container with secured drums.
The geometry, mass and physical properties, such as spring and damping behavior, of the materials are known. The formation consisting of the drums and restraining devices represents a system of coupled oscillators, whose essential properties can be described mathematically and may thus be precalculated. The mathematical modeling of such a system for the collision was undertaken by H. Flessner and E. Kausel (1).
The advantage of this freight securing system is its calculability. Different configurations can be designed computationally, thus enabling their reliability to be predicted. Expensive and time-consuming collision and drop tests, which have to be performed for systems not determinable mathematically in order to demonstrate transport safety, could be dispensed with.
Standard configurations with the FHT freight securing system are:
  48 200-l drums in two layers with a maximum drum weight of 437.5 kg;
  42 200-l drums in two layers with a maximum drum weight of 500 kg;
  24 200-l drums in one layer with a maximum drum weight of 875 kg;
  42 280-l drums in two layers with a maximum drum weight of 500 kg;
  21 280-l drums in one layer with a maximum drum weight of 1,000 kg.
The maximum drum weight depends on the weight of the freight securing system, in which connection the permissible payload of 22,000 kg per container may not be exceeded.
Figure 5 shows the container before loading.
LOAD TESTS
The load tests necessary for granting the qualification certificate for the design as a package pattern type IP-2, IP-3 and type A for the transport of radioactive substances by the Federal Institute for Material Research and Testing (BAM) were successfully performed on a container fully loaded with 48 200-l drums.
For these tests, the support trays and restraining devices were made of pasteboard.
The following tests were performed:
  tests Pursuant to DIN-ISO 1496 Part I
with the following supplementary tests:
  front and door wall load: 51,000 kg
  side wall load: 33,000 kg
  anchoring point tensile test with 1.5-fold rated load.
  Collision tests with delayed impacts at the advancing lower corner fittings of the container with low pass filtering of 16 Hz
- up to 40 m/s towards the rear door and
- up to 32 m/s towards the front wall
  Free-fall tests, primarily from 0.3 m approx. along the principal diagonal onto the roof edge of the container door side and secondarily on the roof surface.
On the basis of the positive test results, BAM certified that the package type
  fulfilled the requirements specified in Exception 49 of the Exception Regulation for Dangerous Goods for the scope of the German Ordinance on the Transport of Dangerous Goods on the Rhine (ADNR), the Dangerous Goods Ordinance for Inland Waterways (GGV BinSch), the Dangerous Goods Ordinance for Rail Transport (GGVE) and the Dangerous Goods Ordinance for Roads (GGVS) for the transportation of Substances with low specific activity and of surface-contaminated objects and
  corresponds to the requirements made on Type A packages for the transportation of solid radioactive substances laid down in the Regulations for the Safe Transport of Radioactive Material, 1985 Edition (as amended in 1990) of the International Atomic Energy Agency in Article 524.
The following data were recorded for the collision tests:
  collision velocity v km/h
  longitudinal acceleration velocity m/s at the advancing restraining fittings of the container to evaluate container strength

longitudinal acceleration velocity m/s of the bottom, central and top layers of drums in rows 1, 3, 6 and 8 to evaluate the vibration behavior of the drums inside the container.
The loaded container was placed on a flat car with a net weight of 20,500 kg. A ramcar with a weight of 80,000 kg ran down a shunting slope against the free, breakless flat car standing on the track. Changes in the direction of load (rear door or end wall in the direction of collision) were effected by rotating the flat car. Before beginning the tests and after changing the direction of load, a setting blow was first executed in order to exhaust the axial play between the holding pins and the restraining fittings in the direction of collision.
Table I shows the results of the collision tests with the rear door in the direction of collision.
After test no. 5, damage to the support trays was found upon opening the rear door. No obvious damage to the drums and container was established. No permanent deformations occurred at the container door and in the roof region. Tightness of the rear door was maintained. On the basis of the container stability, which was sufficient for the evaluation criteria, a further test with an acceleration of 4 g (test no. 10) was carried out at the client's initiative (CORROBESCH Vertriebsgesellschaft mbH), after the variants with the end wall in the direction of collision.
The interior of the container was not inspected after test no. 10. However, no external damage was apparent.
Three tests were performed with the end wall in the direction of collision and the results are shown in Table II.
After test no. 9, the interior of the container was not examined. No external damage to the container was detected.
Figure 6 shows the interior view of the container before unloading after the collision tests. The support trays and passive restraining devices display damage, whereas the drums and container remain undamaged.
The free-fall test was performed on a crash plate consisting of a concrete mat of 18.0 m x 15.4 m with a thickness of 1.5 m (approx. 800 t total weight), which was overlain by a steel plate 35 mm in thickness. The container was hung in such a way that it was dropped from 0.3 m on to its upper corner on the doorside and then pivoted about this point and slammed onto its roof.
The container was equipped with a total of 14 acceleration sensors. The acceleration signatures display values of up to approx. 140 g.
Inspection of the container after the drop revealed the following:
No damage occurred which would permit any escape of the radioactive contents or would result in reduced shielding.
Control measurements of the upper door was corner fittings at the corner pillar, the longitudinal roof bar and at the side wall in the direction of the was diagonals did not indicate any measurable linear deformations.
The front corner pillar directly above the corner fittings displayed a compression, which may in part be attributable to the fact that the other corner fitting did not crash onto the steel plate during the drop test.
ANTI-CORROSION FINISH
The containers are coated with the special anti-corrosion finish CORROBESCH-DF-Nuklear. This paint coating is smooth, glossy and tight to water vapor diffusion. Its base component consists of tar epoxide polyurethane and inert additives as well as color components. The second component is a cycloaliphatic amine.
Its good radiation and corrosion resistance and ease of decontamination was experimentally demonstrated according to the relevant DIN and ISO regulations (2). Anti-corrosion finishes were tested in the colors black, yellow, blue, red and white.
After exposing the test pieces to radiation of 107 Gy discolorations of various intensities resulted (greatest discoloration of the white finish, least of the black finish), as well as very slight decreases in gloss. Other changes were not detected. In order to evaluate possible changes after the action of chemicals and decontamination solutions, ethanol, 20% phosphoric acid as well as sodium hydroxide solution, materials testing mixture A 20/NP II and additionally two decontamination detergents frequently used in practice were applied to the test pieces which had been irradiated with various energy doses.

After an exposure time of five minutes, both unexposed surfaces and also those exposed to a radiation dose of up to 107 Gy displayed only insignificant changes, irrespective of coloring agent.

After an exposure time of 24 hours, all surfaces displayed very slight changes after the action of the materials testing mixture A 20/NP II and the two water-diluted decontamination detergent solutions.

After an exposure time of 24 hours to ethanol, phosphoric acid and sodium hydroxide solution the color change increased with rising radiation exposure of the surface and the hardness of the finish temporarily decreased (the white finish had the poorest values).

Other changes such as blisters, fissures or swelling due to the action of the above-mentioned solutions were not detected on any of the specimens irradiated with up to 107 Gy.

All anti-corrosion finishes, whether black, yellow, blue, red or white, are easy to decontaminate before irradiation.

The following results were obtained after irradiation:

with 3 x 105 Gy = very easy to decontaminated,
with 3 x 106 Gy = easy to very easy to decontaminate,
with 6.8 x 106 Gy = easy to decontaminate,
with 107 Gy = moderately easy to easy to decontaminate.

CERTIFICATION

To date, the following certification has been granted for the container or for the package:

By Germanischer Lloyd

CSC license,
certification of the successful free-fall test in accordance with the requirements of the Regulations for Safe Transport of Radioactive Material, 1985 Edition (as amended in 1990) of the IAEA in Article 524 (622).

By BAM

license as a IP-2, IP-3 and type A package

Deutsche Bahn AG

certification pursuant to UIC 592-1

Main Customs Office Bremerhaven

license for the transportation of goods in bond.

CONCLUSIONS

The ISO piece goods container MCB 49 coated with CORROBESCH-DF-Nuklear with the FHT freight securing system represents an advanced system particularly suitable for the storage and transport of radioactive substances.

It offers economic benefits due to the fact that

the computational demonstration of the safety of the box-container system can replace expensive tests,
the container shows a very favorable ratio between payload and net weight, and
the anti-corrosion finish of organic base material displays, contrary to expectation, a high radiation resistance, so that it can be used instead of electrodeposited coatings.

ABSTRACT
Accident source terms, source term probabilities, consequences, and risks are developed for ship collisions that might occur in U.S. ports during the shipment of spent fuel from foreign research reactors to the United States.
INTRODUCTION
In support of U.S. nuclear weapons nonproliferation policies, Foreign Research Reactor spent nuclear fuel may be shipped to the U.S. in break-bulk freighters. The risks associated with such shipments were examined qualitatively by an Environmental Assessment (EA) that was published in 1994 (1). Accidents that occur in ports and thus near population centers were the principal contributors to accident risks. Because EA results were obtained using source term probabilities that did not decrease as the severity of the postulated accidents increased, the EA may have significantly overestimated the risks posed by severe accidents that occur in ports. Therefore, to support the preparation of the Foreign Research Reactor Spent Fuel Environmental Impact Statement (EIS), event trees were constructed that allowed the decreasing probability of increasingly severe ship accidents to be estimated. Next, source terms were developed for those very improbable long-duration, high-temperature, fire scenarios that might lead to melting of research reactor aluminum-uranium alloy fuels, or the burning, if exposed to air, of TRIGA research reactor fuel. Finally, the radiological consequences that might result from these improbable accidents were estimated using the MACCS site-specific accident consequence code.
EVENT TREES
Figure 1 presents an event tree that depicts the course and probability of a severe ship collision that leads to the release of radioactivity from a radioactive material (RAM) cask. Because ship collisions are not high-speed events, impact forces are not large enough to damage the cask or its contents. Therefore, release occurs only if the cask is subjected to crush forces. Crush forces are most likely to cause seal failure. If only seal failure occurs, release must occur by diffusion and consequently will be small. However, if the collision leads to an engulfing fire, expansion of cask gases will transport radioactive aerosols and vapors from the cask. Finally, if an unusual configuration of collapsing ship structures occurs that leads not only to seal failure, but also to a second failure due to shearing or puncture, then differential heating by the fire could induce convective flow through the cask and thus transport to the environment of all materials released from the fuel to the cask interior.
Consistent with past EAs (1,2), accidents that lead only to seal failure are placed in Severity Category 4, accidents that lead to seal failure and a long-duration engulfing fire are placed in Severity Category 5, and accidents that add shear or puncture failures to Severity Category 5 conditions are placed in Severity Category 6.
In Fig.1, the ship collision probability per port call was developed from accident data (3-6). The probability that the hold that is struck contains the cask is 1/7 as the prototypic break-bulk freighter (3) used in this analysis has seven holds. The probability that the cask is subjected to crush forces was estimated using the Minorsky method (7) and distributions of ship displacements, speeds, and collision angles developed by ORI, Inc. (3). The probability that a ship collision leads to a long-duration fire that engulfs the failed RAM cask was estimated from ship fire data (4-6,8,9) and from the number of locations (holds and decks within holds) where a fire might occur. The probability that an engulfing fire would heat the cask to temperatures above 900 K where aluminum-uranium alloy fuels melt and, if exposed to air, TRIGA fuels burn, was developed by constructing an oxygen availability event tree. The probability that the collision leads not only to seal failure but also to a second failure due to shearing or puncture was estimated to be no larger than 0.1.
Oxygen Availability Event Tree
Figure 2 presents the oxygen availability event tree. The probability that the hold is open to the air when the fire occurs was estimated from the fraction of port-call

time spent loading or unloading the ship, and from the fraction of time that a hold is open while the ship is loading or unloading. Ship data (10) suggest that the chance that the break-bulk freighter will be equipped with CO2 fire suppression systems is about 0.6. The chance that these systems fail on demand was conservatively estimated at 1 time in 5. Thus, the probability that an engulfing fire will heat a cask and its contents to 900 K was estimated to be 0.087, which was rounded up to 0.1 in Fig. 1.

Impact Forces

Modeling of RAM cask drop tests (11) indicates that 100 g accelerations may sometimes damage fuel rods contained in the cask. For ship collisions, the acceleration experienced by cask contents is the time derivative of the transverse speed of the struck ship. The acceleration varies with the distance of penetration of the striking ship prow into the hull of the struck ship. Average acceleration is obtained by integrating the instantaneous acceleration over the penetration distance and dividing by that distance. Average accelerations were calculated for a range of striking ship displacements (5 - 75 kilotonnes) and speeds (4 - 10 m/s), and four cargo loading cases: no additional cargo, light cargo shipped in cartons (packing fraction = 0.6, crush strength = 6.9 MPa); medium cargo shipped in wooden crates (packing fraction = 0.2, crush strength = 34.5 MPa); and heavy cargo, for example machinery (packing fraction = 0.5, crush strength = 1500 MPa). The calculations showed that cask contents would be subjected to average accelerations no larger than 0.2 g, which suggests that damage to cask contents or cask failure will not be caused by ship collision impact forces.

Crush Forces

By applying conservation of momentum and energy to ship collisions, Minorsky derived a set of equations that express the distance that the prow of the striking ship penetrates the hull of the struck ship in terms of the displacements of the two ships, the mass of water that moves with the ships during the collision, the speed of the striking ship, and the collision angle (7). Using collision data for nine severe accidents, Minorsky showed that the energy expended penetrating the struck ship to a given distance was a linear function of the sum of the volumes of the deformations in important deformed structures (hulls, decks, bulkheads).

Compaction of cargo around the RAM cask due to collapse of ship structures will subject a cask to crush forces only after all of the empty space in the hold has been used up by the penetration of the striking ship prow into the hold in which the cask is stowed. Although collision speeds are not high (typically less than 25 knots, much less in ports), because collision masses are very large, ship collisions are always high kinetic energy events. Therefore, if a collision subjects a cask to crush forces, it is certain that the cask will be damaged.

The probability that a ship collision will subject a cask to crush forces due to compression of cargo around the RAM cask was examined using the three cargo cases described above. If the RAM cask is assumed to be stowed on the ship centerline, cargo compression always causes the hold to go material solid before the prow of the striking ship penetrates to the centerline of the struck ship. Material solid conditions were predicted to occur most often for the medium cargo case. Figure 3 presents a histogram of the penetration distances calculated for this case. The figure shows that the hull of the struck ship is not penetrated about half the time. By comparing penetration distance to the critical penetration distance needed to cause the hold to go material solid due to cargo compression about the RAM cask, the probability that the collision will subject the cask to crush forces was estimated to be about 0.25 for the light cargo case, 0.4 for the medium cargo case, and 0.25 for the heavy cargo case. Thus, 0.4 is a reasonable estimate for the probability that a ship collision involving the RAM hold will subject the RAM cask to crush forces.

Thus, the impact and crush calculations suggest 1) that impact forces are too small to be of concern, 2) that crush forces are applied to the spent fuel cask when the collision uses up all of the empty space in the hold by collapsing and compressing the other cargo stowed in the hold with the cask, 3) that the very large kinetic energies that typify ship collisions ensure that the cask will be damaged if it is subjected to crush forces, and 4) that the likelihood of crush can be substantially decreased by restricting the amounts of cargo stowed with the cask.

CASK INVENTORIES AND RELEASE FRACTIONS

This study examined four spent fuels: the fuels used in the BR-2, RHF, OSIRIS, and

TRIGA research reactors. ORIGEN calculations provided inventories at three years after reactor shutdown. Screening calculations showed that 34 of the ORIGEN nuclides accounted for at least 99 percent of the dose that would result from the full set of ORIGEN nuclides. Cask inventories for these 34 nuclides were developed assuming that each spent fuel would be shipped in a Pegase cask (12). Table I presents the four inventories used in the study.

Three of the fuels examined, BR-2, RHF, and OSIRIS, are aluminum-uranium (Al-U) alloy fuels that melt at temperatures above 900 K (13). The fourth fuel, the TRIGA fuel, contains zirconium hydride which burns spontaneously and exothermically if exposed to air while at temperatures above 900 K (14). Because melting or combustion will greatly increase radioactive release, two sets of release fractions had to be developed for Severity Category 5 and 6 accidents, one for fires that do not heat the RAM cask and its contents to 900 K (Severity Categories 5A and 6A), and one for accidents that do (Severity Categories 5B and 6B). Table II presents the release fractions used in this study, summarizes in footnotes the basis for the fractions, and compares the fractions to those used in the Foreign Research Reactor EA (1).

CONSEQUENCES AND RISKS

Accident consequences were estimated using the site-specific consequence code, MACCS (16,17). The MACCS code was used because port accidents are most likely to occur at specific locations, either dockside or at some unfavorable location in the port channel. Use of MACCS also allowed the effects of nonuniform population distributions and of variable rather than constant weather conditions to be examined.

Footnotes to Table II

a. EA Category 4 release fractions are those developed by Wilmot (15) for release from power reactor UO2 pellets clad in zircaloy when the cask that contains the fuel is subjected to a severe impact. Wilmot assumes that the impact fails 10% of the fuel rods, that release fractions from the rod to the cask cavity are 0.2 for Kr and 2E-6 for fuel mass released as fuel fines, and that release fractions from the cask cavity to the environment are 0.6 for gases and 0.05 for fuel fines (particulate). Thus, release fractions from the fuel to the environment for commercial pelletized UO2 fuel are 1E-2 for Kr and 1E-8 = 0.1 x 2E-6 x 0.05 for all radioactivity contained in fuel fines (i.e., Cs, Ru, and Particulate).

b. Because TRIGA fuel is fabricated from several large U-Zr-H pellets that are clad in stainless steel, as long as the fuel is not exposed to air while at temperatures above its ignition temperature, release fractions should be quite similar to those used in the EA that were developed by Wilmot for power reactor UO2 fuels. Even if exposed to air while above its ignition temperature, release to the environment will be significantly increased only if there is an efficient mechanism for transport from the cask to the environment of fission products released to the cask by fuel oxidation. Thus, release fractions for TRIGA fuel for Category 5B conditions should be similar to those assumed for Category 5A conditions.

c. Because Al-U metallic fuels are stacks of plates or sets of nested cylinders, most fuel bundles are likely to fail during a ship collision that causes 5% of the cask volume to be lost by cask compression due to crush. Therefore, all of the bundles here are assumed to fail. However, because Al-U fuel is constructed from metal plates, the fraction of fuel present as fines should be substantially less than the fraction of UO2 pelletized fuel that is in fines. If the fraction of Al-U fuel that is present as fines is 10% of the fraction of UO2 pelletized fuel that is in fuel fines, the release fraction for fuel fines for Al-U metallic fuels should be quite similar to the value developed by Wilmot for UO2 fuel fines. Accordingly, the release fraction for fuel mass from plates to the cask cavity for Al-U fuel is conservatively taken to be 2E-7 = 1.0 x (0.1 x 2E-6).

d. Because diffusion in metal plates is negligible, until the metal fuel plates melt, only Kr trapped in fuel fines that become suspended in the cask interior volume will be available for release to the environment. Thus, the release fraction for Kr is the same as that for Cs, Ru, and Particulate, which are all released only as components of fuel fines.

e. Release fractions (FR) for Al-U fuel released as particles for Severity Categories 5A and 5B are calculated using the following equation:

$$FR = FBFFC[1.0(FCE) + (1.0 - FCE)(1 - RT)]$$

where

FB = fraction of fuel bundles that fail

FFC = fraction Al-U plate mass released to cask cavity as fuel fines
FCE = fraction of fuel fines released from cask cavity to environment
RT = TA/TP
TA = temperature of cask gases before the fire (ambient temperature)
TP = peak temperature reached by cask gases due to fire.
Because TA/TP = VA/VP = fraction of gas left in the cask after expansion due to heating from TA to TP, 1 - RT = the fraction of the cask gases that are expelled from the cask due to heating from TA to TP. For Al-U fuel, the release fractions given in the table for Categories 5A and 5B were calculated using the following parameter values: FB = 1.0, FFC = 2E-7, FCE = 0.05, TA = 300 K, TP = 600 K for Category 5A where 600 K is the midpoint of the softening range for carbon steels, and TP = 1023 K for Category 5B where 1023 K is 100 K above the melting point of Al-U alloy fuel.
f. Once fuel plates have melted, release fractions for Kr and Cs from Al-U alloy fuels are calculated as follows:

$$FR = FMC(1 - RT)$$

where
FMC = release fraction for Kr or Cs from melt to cavity
RT = TM/TP
TM = melting point of Al-U alloy fuel
TP = peak temperature reached by cask gases due to fire.
For Category 5B releases for Kr and Cs for Al-U alloy fuels, the following values were used: TM = 923 K, TP = 1023 K, FMC = 1.0 for Kr, and FMC = 0.1 for Cs.
g. For Category 6, all materials released to the cask cavity are released to the environment because convective flow through the cask is assumed to be considerable. Therefore, for Category 6, FR = FFC where FFC = the release fraction from fuel to the cavity for Category 6 conditions. The following values for FFC were assumed: For Al-U alloy fuels, 2E-7 for Kr, Cs, Ru, and Particulate for Category 6A; and for Category 6B, 1.0 for Kr, 0.1 for Cs, and 2E-6 for Ru and Particulate since melting of Al-U alloy fuel is not expected to be violent. For U-Zr-H TRIGA fuel, because it burns at temperatures significantly above 900 K, for Category 6B, 1.0 for Kr, 0.3 for Cs and also for Ru due to oxidation to volatile RuO_4, and 0.01 for particulate on the assumption that burning of the fuel will aerosolize 1 % of the fuel mass.
Given an inventory, release fractions for the accident severity category being examined, a population distribution constructed on a compass sector polar-coordinate grid out to some specific radial distance (here 50 miles), one year of meteorological data (hourly readings of wind speed, atmospheric stability, and accumulated precipitation) recorded in the site region, and a site wind rose, MACCS calculates plume dispersion and deposition; individual and population radiation exposures for the cloudshine, inhalation, groundshine, resuspension, and ingestion exposure pathways; acute injuries (e.g., prodromal vomiting) and fatalities; cancer fatalities due to radiation induced cancers; and accident costs caused by emergency response actions, and by the decontamination, temporary interdiction, or condemnation of contaminated property.
Each MACCS calculation performed develops consequence estimates for about 150 weather sequences selected by an importance sampling routine. Each sequence is examined using each of the sixteen compass sectors in the population distribution (plumes wider than a compass sector spill over into the two neighboring sectors). Thus, about 2400 trials are performed during each MACCS calculation. The product of the accident severity category probability, the weather sequence probability, and the population sector probability (the inverse of the wind rose) gives the probability of the predicted consequences for a given trial. By cumulating the trials, a Complementary Cumulative Distribution Function (CCDF) is constructed that depicts the probability that a consequence of a given magnitude will be equaled or exceeded.
Figure 4 presents CCDFs for cancer fatalities for the channel accident location at each of the 12 representative ports of entry examined. Each of these calculations used the BR-2 inventory, the largest of the four inventories studied, and Severity Category 5A release fractions. Category 5A results are presented because this is the more likely large accident, as fires that reach 900 K and accidents that lead to shear or puncture failures are problematic.
The probabilities displayed in Fig. 4 are conditional on the occurrence of a Severity Category 5A accident, that is they reflect the wind direction probability

and the weather sequence probability, but not the accident severity category probability which is 4.6 x 10-9 per port call for this severity category. The leftmost CCDF in Fig. 4 was obtained for the port with the smallest surrounding population (265,000) out to a distance of 50 miles. The rightmost CCDF in the figure was obtained for the port with the largest surrounding population (1,672,000) out to a distance of 50 miles.

Table III presents a full set of results at the dock of the hypothetical port of entry having the largest surrounding population. The calculation for this port used the BR-2 inventory and Severity Category 5A release fractions. These results are typical of all of the calculations performed. Table IV presents expected (mean) cancer fatality results for the 0 to 50-mile distance range for the BR-2 and TRIGA inventories for all five accident severity categories (Categories 4, 5A, 5B, 6A, and 6B). The expected cancer fatality results are conditional on the occurrence of an accident representative of the indicated severity category. The table also presents the probability of occurrence per port call of each severity category and the absolute cancer fatality risks that are obtained by multiplying the conditional expected result for each severity category by that category's probability of occurrence.

In summary, the MACCS calculations showed that:

Similar consequence predictions are obtained using two quite different types of weather data (a) constant weather conditions measured at the port, and (b) variable weather data measured at the National Weather Service station nearest to the port.

No acute health effects (e.g., prodromal vomiting) are predicted for the few quite improbable accidents that release the larger source terms studied, even when the accident takes place in a port located in a highly populated metropolitan area.

Total population dose is almost entirely due to long-term groundshine exposures.

The expected (mean) number of cancer deaths that might occur several decades after the accident due to the radiation exposures are small compared to the number of cancer deaths (200 per 100,000) normally expected to occur in the exposed population (18).

Finally, for the 12 hypothetical ports studied, the cancer death risk per port call ranged from 1.0 x 10-10 for the hypothetical low-population port to 1.7 x 10-8 for the hypothetical high-population port. If the high-population port is the destination for all shipments and each shipment makes two intermediate stops at high-population ports, then the cancer death risk for the entire shipping campaign would be about

2.9 x 10-5.

STUDY OF EVACUATION TIMES BASED ON RECENT ACCIDENT HISTORY

G. S. Mills
K. S. Neuhauser
Sandia National Laboratories
Albuquerque, NM*

ABSTRACT

A key parameter in the calculation of accident dose-risks by the RADTRAN 4 code is the time assigned for evacuation of the affected area surrounding the accident. Currently, in the interest of assured conservatism, this time is set at 24 hrs. Casual anecdotal evidence has indicated that this value is overly conservative and results in assignment of overly conservative estimates of accident dose-risk. Therefore, a survey of recent truck accidents involving various hazardous materials which required evacuation of surrounding populations reported in various news media was undertaken. Accounts of pertinent scenarios were gleaned from databases citing newspapers and other periodicals, and the local authorities involved in each were contacted to get details of the evacuation including time required.
This paper presents the data obtained in the study and the resultant mean evacuation time plus limits and factors influencing specific results together with conclusions regarding the appropriate value to be used in the RADTRAN 4 code.

INTRODUCTION

The RADTRAN 4 computer code, which calculates estimates of accident dose-risk corresponding to specified transportation scenarios, ascribes doses to potentially exposed members of the public. These persons are modeled as not being evacuated from the affected area for 24 hours following a release of radioactive material. Anecdotal evidence has suggested that this value may be unnecessarily conservative; consequently risk estimates are unnecessarily high. A survey of recent trucking accidents, reported in newspapers and other periodicals (1988 through 1994), that involved evacuation of the general population in the affected areas was undertaken to establish the actual time required for such evacuations. Accidents involving hazardous materials other than those which are radioactive (e.g., gasoline, insecticides, other chemicals) but also requiring evacuations of nearby residents were included in the survey in order to obtain a statistically significant sample size. A total of 25 references (including some duplications) to incidents in the United States was found; approximately half of them could be sufficiently documented for inclusion in the analysis of evacuation time reported here.

DATA COLLECTION

An initial collection of abstracts was obtained from searches of a computer database, available through CompuServe, which included abstracts of newspapers and periodicals published in the U.S. and internationally. From this group, a subset of 25 abstracts was identified which met the criteria of the study: evacuation of the general public from areas surrounding truck accidents involving hazardous materials. Using the information included with the abstracts, local authorities were contacted

to obtain details of each incident including the amount of time required, the number of people, the size of the area, and other details as they were volunteered. In some cases, no record of the evacuation time was available, but verbal accounts were obtained from involved agency personnel to corroborate or correct the press accounts. Generally, it was found to be essential to verify or correct press accounts of incidents by contacting local authorities, e.g., the number of people evacuated was often a factor of 2 greater in press reports than the number given by authorities. Also, the data included in official accident reports do not consistently include details of the evacuation, e.g., highway accident reports primarily provide information on traffic/roadway details, injuries/fatalities, and responding personnel. The final list of incidents analyzed qualitatively and statistically in this study consisted of 13 accidents for which data judged reliable were obtained. Table I lists these incidents, pertinent data obtained, and derived parameters.

Population divided by the area defined by Evacuation Radius.

In the course of discussions with local authorities, information relating to non-truck accident emergencies requiring evacuations was obtained. All except one occurred at a fixed location such as a chemical plant; the exception was a train accident in Mississauga, Ontario, Canada. These additional cases are tabulated in Table II.

ANALYSIS

Inspection of the data revealed that the time required for an evacuation was influenced by population density, location of the population (e.g., residential, business, industrial, school) and perception of the urgency by the affected public. This can be seen from a comparison of Case A1 (suburban setting) with Case Q (rural setting) listed in Table I or comparison of Case A1 with Case --, in which 3200 of the 5200 evacuees were students at four schools. In addition, some evacuations occurred in stages spaced over times which were longer than the actual time required to evacuate groups once the decision to clear an additional area was made. For this initial evaluation of evacuation data, total number of people and total time were tabulated; differences in details of the evacuations were ignored.

Averaging the evacuation times in Table I yielded a value of 2.0 hours with a standard deviation of 2.6 hours; including the values in Table II changes these values to 3.9 6.8 hours. If the exceptionally large evacuation of Mississauga, Ontario, Canada (250000 people) is excluded, the average is 2.8 hours with a standard deviation of 5.0 hours.

A histogram of the evacuation times listed in Table I is plotted in Fig. 1. Adding the times from Table II yielded a histogram which is not significantly different in shape over the region where they overlap. The general shape of these plots suggests a lognormal distribution, as may be seen from Fig. 2 which displays normalized (at 10 hours) graphs of the two histograms and an approximate fit of a lognormal distribution. The roughness of the fit is attributed to the sparse data in the two histograms; more precise definition of the actual distribution of evacuation times using a larger sample of data would make a more precise fit feasible.

CONCLUSIONS

Three conclusions were drawn from this preliminary study:

1. Adding data describing evacuations resulting from incidents at fixed sites to trucking accidents does not significantly alter the distribution of evacuation times.
2. Average evacuation times derived from the data obtained to date are substantially shorter than the value of 24 hours currently used in RADTRAN 4 analysis.
3. The longest evacuation time (23 hours) obtained indicates that the 24-hour value is in fact a properly selected conservative value.

In addition, since the histograms in Fig. 1 do not suggest normally distributed evacuation times, a better definition of the distribution, allowing more precise statistical inferences to be drawn, is needed. Calculation of risk estimates based on values of evacuation time randomly sampled from such a distribution would provide an improved representation of accident-related risks. Since fixed-site and rail-accident data appear to have the same type of distribution, a broader search of news abstracts, including evacuations for incidents other than truck accidents, will be undertaken to increase the statistical significance of the derived distribution of evacuation times.

RADTRAN 4 TRUCK ACCIDENT-RISK SENSITIVITY ANALYSIS

G. S. Mills
K. S. Neuhauser
F. L. Kanipe
Sandia National Laboratories
Albuquerque, NM*

ABSTRACT

The sensitivity of calculated dose estimates to various RADTRAN 4 inputs is an available output for incident-free analysis because the defining equations are linear and sensitivity to each variable can be calculated in closed mathematical form. However, the necessary linearity is not characteristic of the equations used in calculation of accident dose risk, making a similar tabulation of sensitivity for RADTRAN 4 accident analysis impossible. Therefore, a study of sensitivity of accident risk results to variation of input parameters was performed using representative routes, isotopic inventories, and packagings. It was determined that, of the approximately two dozen RADTRAN 4 input parameters pertinent to accident analysis, only a subset of five or six has significant influence on typical analyses or is subject to random uncertainties. These five or six variables were selected as candidates for Latin Hypercube Sampling applications.

To make the effect of input uncertainties on calculated accident risk more explicit, distributions and limits were determined for two variables which had approximately proportional effects on calculated doses: Pasquill Category probability (PSPROB) and link population density (LPOPD). These distributions and limits were used as input parameters to Sandia's Latin Hypercube Sampling code to generate 50 sets of RADTRAN 4 input parameters used together with point estimates of other necessary inputs to calculate 50 observations of estimated accident dose risk.

Tabulations of the RADTRAN 4 accident risk input variables and their influence on output plus illustrative examples of the LHS calculations, for truck transport situations that are typical of past experience, will be presented.

INTRODUCTION

The transportation risk analysis code, RADTRAN 4 [Neuhauser, 1992], computes estimates of incident-free dose consequence and accident dose risk. The output of the code can include a tabulation of sensitivity of the result to variation of the input parameters for the incident-free analysis. The values are calculated using closed mathematical expressions derived from the constitutive equations, which are linear. However, the equations for accident risk are not linear, in general, and a similar tabulation has not been available. It is, nevertheless, important to know how the accident risk is affected by uncertainties in the input parameters. A direct investigation of the variation in calculated accident dose-risk with changes of individual parameters was undertaken. Initially, a limited, representative group of transportation scenarios was used to determine which of 23 accident-risk input parameters or arrays affect the calculated accident dose risk significantly. Many of the parameters were observed to have minimal effect on the output while others were judged as "fixed" either by regulation, convention or standards. The remaining 5 input arrays were selected for further study through Latin Hypercube Sampling (LHS) (1). LHS yields statistical information from observations (risk calculations) resulting from multiple input parameter sets compiled from "random" sampling of cumulative probability distributions. The LHS method requires fewer observations than classical Monte Carlo methods to yield statistically significant results. This paper presents the preliminary input parameter studies and their results together with some initial LHS investigations.

ANALYSIS

A list of the RADTRAN 4 input parameters and arrays employed in accident-risk calculations was compiled and is presented in Table I. RADTRAN calculations of accident risk were performed for transportation scenarios drawn from actual experience or special cases designed to emphasize a parameter of interest (e.g., non-dispersal accidents). The baseline values used in this study were adapted from archived input files supporting published Sandia analyses, e.g., shipment of spent nuclear fuel by highway from Norfolk, VA to the Savannah River Site, SC. Actual input files used in the examples presented here are listed in the Appendix. Either eight-category or six-category accident-severity schemes are typically employed in RADTRAN analyses depending on the specific isotopes being shipped and the type of

packaging used. Thus, the SEVFRC (all parameter names are defined in Table I) arrays in the test files have six or eight baseline values for each population density category (rural, suburban, urban). The RFRAC, AERSOL, and RESP arrays have six- or eight-element arrays defined for each physical-chemical group (only 1 in the examples listed in the Appendix) required to describe the materials being shipped. Relationships between various possible severity schemes are discussed in Whitlow and Neuhauser (4,2).

The results of discrete calculations, in which values other than the RADTRAN-supplied value for a particular input parameter were tried are listed in Table II. The "Results" are values of the "Total" accident dose-risk calculated by RADTRAN 4. Although some of the input variables listed had a larger effect on component risks such as the "Urban", "Inhaled" and "Resuspended" dose-risks, the "Total" risk is the value most often quoted in applications of RADTRAN 4 analyses. Therefore, it is the basis for sensitivity evaluations reported here. Current practice in reporting results has been to tabulate values to two significant digits, in keeping with the uncertainties of the analysis.

Discussion of each of the five input variables and the test calculation results listed in Table II follows:

BRATE (breathing rate) -- The suggested point estimate is based on the maximum rate for humans and a reduction to half of that value did not change the risk estimate.

BDF (fraction of respirable aerosol inside buildings) -- Changes of a factor of 10 up and down yielded the same results as the point estimate.

RPD (ratio of pedestrian to resident population density) -- An increase by a factor of two resulted in the slightest reportable change in the result: 2.7E-08 to 2.8E-08.

RU (Urban building shielding factor) -- As noted in Table I, it only affects accident risk results in cases of non-dispersal accidents. The calculated change in risk (3.0E-11 to 3.1E-11) occurred for an increase of RU by a factor of 10.

CULVL (cleanup level) -- This has a significant effect on calculated risk upon being lowered by a factor of 10, but such a change in regulations is not presently known or expected.

In summary, none of these five input parameters was included in subsequent LHS analysis since, for reasonable distributions of their values, their effects on risk calculations would be hidden by the effects of other input parameters or arrays. Some of the variables listed in Table I were not subjected to these tests because they were viewed as not being subject to random uncertainties, or clearly would affect output significantly (proportionally). The list of input parameters and arrays from Table I and the sensitivities of total risk to them, are presented in Table III together with an indication of which (five input arrays) should be studied further with LHS.

To date, two of the input arrays identified in Table III as suitable for LHS analysis have been investigated through use of LHS in conjunction with RADTRAN calculations: Pasquill Category Weights (PSPROB) and Link Population Densities (LPOPD). These inputs were selected for initial study because justifiable distributions of their values could be estimated easily and because LPOPD and PSPROB array sizes are not affected by the choice of accident-severity scheme. Accident-severity and related variables are to be addressed in the future.

Use of LHS requires definition of probability distributions for each variable of interest. In the case of the six Pasquill Stability Class variables (PSPROB array), a uniform distribution between 0.0 and 1.0 for each of the six classes was sampled independently and the sum of each set of six samples was normalized to 1.0, as required by RADTRAN 4. For the link population densities (LPOPD values) normal distributions centered on the point estimates for each of the links describing a

particular route were used. The widths of the normal distributions were chosen such that s (standard deviation parameter of the normal distribution function), was 10% of the mean for one set of calculations and 25% of the mean for a second set of calculations.
Table IV summarizes the results from 50 observations (RADTRAN accident-risk calculations) employing 50 samples from either the PSPROB or one of the LPOPD distributions in the input files. Also, Table IV includes results from calculations employing 50 samples from the PSPROB and one of the LPOPD distributions, together, in the input files. The risk value calculated for the same transportation scenario without LHS, 5.32E-05 person-rem, is higher than values for the three cases in which PSPROB values were varied. This is because the default set of PSPROB values in RADTRAN leads to a more severe dispersion situation than the "random" mix of all six conditions. When each Pasquill category was applied individually, the results varied by more than a factor of 10.
CONCLUSIONS
The rather long list of input parameters and arrays required to calculate accident dose-risk estimates with RADTRAN 4 has been pared down to five arrays that have proportional effects on the estimate of total risk. A few additional input variables have proportional effects on component risks such as risk in urban areas or the respirable component, but negligible effect on the total risk. Use of Latin Hypercube Sampling on two of the input arrays, PSPROB (6 array elements) and LPOPD, revealed that quite reasonable selections of distribution type and limits yield risk estimates and uncertainties which are in accord with expectation based on the input array means and the randomness of the input values. In the case of Pasquill atmospheric stability classes, random mixes of the 6 class weights result in lower risk estimates than those calculated with the RADTRAN 4 default set. Treating link population densities (LPOPD's) derived from the HIGHWAY (3), 1992] routing code as normally distributed variables with 25% standard deviation led to risk estimates having an average value equal to the risk estimate calculated without LHS; the standard deviation of the 50 risk estimates was 11%.
Further studies of the rest of the input variables to which accident risk estimates were found to have proportional sensitivity must be investigated further, individually and in combinations, to determine the range of uncertainty to be expected in typical RADTRAN 4 accident dose risk calculations.

ASSESSMENT OF RISKS TO INDIVIDUALS FROM THE TRANSPORTATION OF RADIOACTIVE MATERIALS*

B.M. Biwer
F.A. Monette
D.J. LePoire
S.Y. Chen
Argonne National Laboratory
Argonne, Illinois

ABSTRACT

The radiological impacts to individuals from the transportation of radioactive materials must be assessed when evaluating alternatives for major federal actions as required by the National Environmental Policy Act. Public comments on past environmental impact statements indicate that the public is concerned about the risks of radiation exposure to individuals along a transport route from radioactive materials shipments. Individuals may be exposed during routine, incident-free, transport of radioactive materials or, potentially, as a result of transportation accidents. This paper discusses the computer model RISKIND, which was developed at Argonne National Laboratory to estimate the potential radiological risks to individuals and population subgroups from the transportation of radioactive materials. The code was designed to use site-specific data to provide a detailed analysis for each receptor location. This type of analysis complements the traditional collective-population transportation risk analyses conducted for radiological transportation risk assessments.

The RISKIND program features an easy to use WindowsTM interface with on-line help for all input parameters. The majority of these parameters are user-accessible to provide the flexibility needed to model a variety of distinct individual circumstances. In addition, a complete set of input data for spent nuclear fuel transportation risk assessments is included with provisions for assessing other radioactive material shipments. A detailed analysis of incident-free and accident risks is performed on the basis of site-specific input such as receptor location, weather, and agricultural data. RISKIND incorporates a number of advanced features, including cask size correction for external exposures, buoyant plume rise, terrain height adjustments, wet and dry deposition, plume depletion for atmospheric dispersion estimates, and acute and long-term models for estimating health risks. RISKIND can be used to estimate consequences to individuals under a given set of

accident and weather conditions, or the program can be used to perform a probabilistic risk assessment encompassing the entire spectrum of potential accident and weather conditions.

INTRODUCTION

As required by the National Environmental Policy Act (NEPA), the radiological consequences to individuals, in addition to the risks to the collective population, from transportation activities must be considered when evaluating major federal actions that could adversely impact the environment.

Individuals may be exposed during routine, incident-free, transport of radioactive materials or, potentially, as a result of transportation accidents. During routine transport, individuals in the vicinity of a radioactive materials transport vehicle receive an external exposure dose from the low-levels of radiation emanating from the shipping package. Should a transportation accident occur, individuals could be exposed, via a number of exposure pathways, to radiation from the material that might be released to the surrounding environment following an accident. Predicting exposure risks from accidents requires a complex model and detailed information on accident parameters. Such information should include data on accident severity, radioactive releases, probabilities of occurrence, weather conditions, and the relative proximity of the individual receptors to the release point.

Early NEPA documents used different approaches to assessing individual risk that were sometimes too simplistic, incomplete, or inconsistent with previous analyses. This paper discusses the computer model RISKIND (1,2) that was developed at Argonne National Laboratory (ANL) to provide a complete individual risk analysis that complements the traditional collective population risk analysis performed with RADTRAN (3).

A comprehensive transportation risk assessment can be performed using RISKIND's emphasis on site-specific individual scenarios and RADTRAN's more generic route-specific collective population characteristics. Several major environmental impact statements (EISs) (4,5) are presently using this approach.

RISKIND is a self-contained, highly flexible program that is able to model most location-specific scenarios. Features of the program that are discussed in subsequent sections are as follows:

- Scenario-specific ("what if") conditions involving individual risks;
- Easy to use graphical interface with on-line help;
- User-accessible input for most routine and accident model parameters;
- Waste package shape adjustment and shielding options;
- Standard datasets for spent nuclear fuel (SNF) analysis;
- Gaussian puff atmospheric dispersion model with waste package geometry considerations, thermal conditions (fire with buoyant plume rise), terrain height considerations, plume depletion, and wet and dry deposition;
- Site-specific population, weather, and agricultural productivity input; and
- Acute and long-term health risk models.

BACKGROUND

The RISKIND computer code was developed by ANL for the Office of Civilian and Radioactive Waste Management within the U.S. Department of Energy (DOE) to assess the radiological consequences and risks to individuals associated with the transportation of SNF (1). This development was in response to public comments on the NEPA documents concerning the repository environmental assessments (6,7,8,9). These comments expressed the public's concern over specific risks to individuals near the transportation route. The RISKIND program was designed to implement site-specific data to provide a detailed analysis for a wide variety of local situations.

The original release of RISKIND contained radionuclide inventories of SNF for commercial boiling-water reactors (BWRs) and pressurized-water reactors (PWRs) (10) and release fractions for 20 accident response regions. The response regions (severity categories) were developed specifically for spent fuel casks in a Lawrence Livermore National Laboratory (LLNL)/U.S. Nuclear Regulatory Commission (NRC) study (11) referred to as the modal study. In response to user requests, the RISKIND code is being updated (RISKIND 1.00, forthcoming). The older DOS-based menu system has been replaced with a WindowsTM-based application that provides a user-friendly interface. Also, the spent fuel inventories have been updated (12), and users have the option of inputting their own radionuclide inventories and release fractions to assess the transportation risk associated with other radioactive materials.

USER INTERFACE

The new RISKIND user interface was designed for ease of use and relies on the point-and-click familiarity and graphics capabilities of the Windows™ 3.1 environment. The main user screen is shown in Fig. 1. The main screen provides for selecting the major input options, provides quick access to more detailed input and output options, and serves as a brief overview of the analysis to be performed. Once the problem to be analyzed is defined, the selections can be saved to an input file for later use, if desired, and the analysis can be performed. On-line help is also available to assist the user with input parameter descriptions.

If a large number of similar analyses are required, RISKIND can be run in batch mode under the DOS operating system. This mode of operation foregoes the Windows™ interface and uses previously generated input files.

INCIDENT-FREE RISKS

Individuals would be exposed to external radiation from the radioactive materials shipment under various incident-free (normal) conditions (Fig. 2). Pedestrians along the transport route would receive a dose from the passing shipment, whereas others may be exposed for longer periods of time, such as the truck crew and motorists beside the shipment in stop-and-go traffic, or service attendants at refueling stops and persons at rest stops. These examples are typical of the situations for which RISKIND can be used to assess the incident-free risks to individuals.

Routine analysis with RISKIND entails the assessment of specific gamma and neutron dose rates at various receptor distances. External exposures and health risks are determined by scaling dose rate curves, as a function of distance, on the basis of the user input values for the external dose rates of the shipping package at a given reference distance. Waste package geometry and shielding effects are taken into consideration.

The reference gamma and neutron dose rate curves in RISKIND are based on a three-dimensional Monte Carlo dose model. The model incorporates an energy spectrum representative of commercial spent fuel and considers air and ground scattering. An option may be selected to employ a user-supplied dose rate curve if the appropriate data are available for a nonstandard type of SNF or other radioactive material of interest.

Conventional numerical methods are used to estimate gamma and neutron doses to individuals, both from a passing shipment and for a fixed period of time and distance from the shipment. Up to 20 individual locations relative to the shipment route may be specified for a single analysis. Shielding options are also available. For subpopulations, doses from a passing shipment to groups along the route and sharing the route are estimated. Doses from a stationary shipment to subgroups at up to 10 locations may also be calculated in a single run.

ACCIDENT RISKS

The RISKIND code assesses the doses to individuals via a number of pathways from potential accidental releases of radioactive material during transportation (Fig. 3). Individual dose and health risks can be calculated with RISKIND for the median (50% probability) and highly unlikely (less than 5% probability of being exceeded) accident cases through consideration of the entire spectrum of potential accidents, the entire range of weather conditions, or both. These results provide a comprehensive probabilistic transportation risk assessment.

Radionuclide inventories may be selected from PWR or BWR SNF options, or they may be user-specified on a radionuclide-by-radionuclide basis if nonstandard SNF or other types of radioactive materials are shipped. The SNF inventories are extracted from the latest spent fuel database (12) and characterized by the amount of uranium present, the fuel burnup, and the fuel cooling time.

For risk analysis, default accident rates are available for population zones (rural, suburban, and urban) by state. The default accident model from the modal study contains 20 accident response regions (accident severity categories) categorized by the level of strain on the shipping cask (impact force) and thermal stress (fire considerations). Each region is assigned a conditional probability of occurrence for truck and rail transport in conjunction with release fractions of the radioactive inventory. The regions cover accidents with high probability and no release to accidents with very low probability and some release. Users may specify their own accident rates, conditional probabilities, and release fractions if the data are available for a custom analysis.

An accidental release of radioactive material would generally result in a plume of

radionuclides being discharged to the air; the material would be dispersed by atmospheric transport to various locations. RISKIND uses a Gaussian puff model to estimate dispersion of the plume and calculates the time-integrated ground-level air concentrations at each receptor location. Pasquill-Gifford dispersion coefficients (13) are used for releases near ground level, while Briggs dispersion coefficients (14) can be used for elevated releases involving fire and subsequent plume rise. The dispersion model in RISKIND accounts for buoyant plume rise should the accident scenario under consideration involve fire, for differences in elevation between the release point and receptor, for plume depletion, and for dry and wet deposition of radionuclides as the plume travels.

Dispersion of the plume is dependent on the prevailing weather conditions. For a consequence assessment where conditions are known, a given wind speed for a specific weather stability category is used to determine the plume dispersion and subsequent receptor exposure. For a risk assessment where conditions are unknown at the time of an accident, all possible combinations of stability categories, wind speeds, and joint frequency data are used. RISKIND now has the capability to read STability ARray (STAR) files containing the joint frequency data. Over 200 STAR files from the U.S. National Oceanic and Atmospheric Administration covering the 48 contiguous states are included in RISKIND. These files are a superset of the STAR data provided with the U.S Environmental Protection Agency CAP88-PC code (15). CAP88-PC is the code that DOE facilities are required to use to demonstrate compliance with radionuclide emission standards (16).

Exposure pathways considered are external exposure from the shipping package, inhalation from the passing plume, external exposure from the passing plume, external exposure from radionuclides deposited on the ground, inhalation of resuspended radioactivity, and ingestion of contaminated foodstuffs (Fig. 3). As was also the case for the incident-free analysis, shielding options are available with RISKIND, and up to 20 individual locations relative to a potential accident scene are possible in a single analysis. Location-specific weather and agricultural productivity data are used for the most relevant assessment. Results for population consequence assessments are provided on an isopleth-by-isopleth basis to better define the outcome.

An example of RISKIND's graphic output capabilities is a concentration isopleth contour plot (Fig. 4) that is available when performing a population consequence assessment. Such a plot gives the analyst a better perspective on the problem. Other plot options include cumulative dose distribution function curves, depending on the input options selected.

HEALTH RISKS

RISKIND estimates health risks in terms of chances of fatalities and genetic effects for both acute (short-term) and latent (long-term) exposures. Acute risks are estimated on the basis of the NRC health effects model (17). Latent risks are estimated on the basis of the Biological Effects of Ionizing Radiation (BEIR) V Report (18) and International Commission on Radiological Protection Publication (ICRP) 60 (19).

CONCLUSIONS

With an easy to use graphical interface, the RISKIND code provides a comprehensive transportation risk assessment for individual receptors near a radioactive shipment route. A complete set of input data for SNF transportation risk assessment is included with provisions for assessing other radioactive material shipments. A detailed analysis of incident-free and accident risks is performed on the basis of site-specific input data. This type of analysis complements the traditional collective population transportation risk assessment conducted for radioactive material shipments.

ABSTRACT
On the direct disposal of spent fuel elements development work has been done since 1979 based on a governmental resolution. In the period 1981 - 1984 the R&D program "Alternative disposal technologies", sponsored by the Ministry of Research and

Technology (BMFT), was established to study the technical feasibility and safety and to demonstrate, that direct disposal can be an alternative to reprocessing.
From 1985, the German nuclear industry continued to develop a final disposal cask and planned a pilot conditioning plant (PKA).
As a result of this work two containers have been developed:
the final disposal cask POLLUX (for final storage in drifts),
the final disposal canister (for final storage in bore holes).
These containers and the status of their development are described in more detail in the following report.

DESIGN REQUIREMENTS FOR THE FINAL DISPOSAL CASK POLLUX

The following requirements have to be met by a final disposal cask:
Safe enclosure of the radioactive substances
- after treatment in the pilot conditioning plant, during handling, transport and intermediate storage
- during the operating phase of the final repository
- after close down and sealing the final repository

Appropriate shielding
- during handling above ground
- during handling in the final repository

Transport and handling ability
Suitability for final disposal
- in drifts (reference procedure)
- in bore holes.

These requirements, the properties of the handled fuel and the specific data of the final repository led to the following planning conditions:
barrier resistance in accordance with the requirements for a final repository 500a

temperature in the final repository 200C
maximum rock salt pressure 300 bar
maximum mass of cask 65 Mg
type B(U) requirements in accordance with IAEA transport regulations
approval for storage of radioactive sub-stances in an intermediate storage facility.

DESIGN CONDITIONS--FINAL STORAGE CASK

A standard PWR fuel element was used as the design fuel element.
10 PWR fuel elements with a fuel equivalent of approx. 5.5 tHM were taken as maximum load for the final disposal cask.
PWR and BWR fuel elements are conservatively covered by this type of fuel element with respect to the radioactive inventory and the geometric fuel dimensions.
It was considered that the PWR fuel element could contain uranium or two types of MOX fuel, respectively.
The two selected Pu vectors were taken to be representative for MOX fuel elements to be expected in the future.
In accordance with the practiced mixed loading of nuclear reactors with approx. 2/3 uranium fuel elements and 1/3 MOX fuel elements, the same load variants were considered for the final disposal cask as envelope.

DESIGN CONDITIONS--FINAL DISPOSAL CANISTER

The final disposal canister is designed to be loaded with uncut fuel rods of 4 PWR or alternatively 12 BWR fuel assemblies.
The outer diameter of the final disposal canister is the same as for the glass canister for vitrified high-level wastes from fuel reprocessing. Thus, a joint handling and final disposal of both canister types in bore-holes are possible.

CONSTRUCTION OF THE FINAL DISPOSAL CASK

Fig. 1 shows the basic construction of the final disposal cask design. The cask consists of a shielding cask with a screwed on lid and an inner cask with a screw-fitted primary lid and a welded secondary lid.
The radioactive material is enclosed in canisters, the canisters itself are loaded into the final disposal cask.
Fig. 2 shows the design of the final disposal cask in more detail.

INNER CASK

The cylindrical shell and the bottom of the inner cask Fig. 3 are made from fine-grained construction steel 15 MnNi 6.3 pressed from a single piece without seams. The wall thickness of the cylindrical shell is designed to comply with the

mechanical and shielding requirements and has a thickness of approx. 160 mm. The weight of the complete inner cask is approx. 21 metric tonnes.
Primary lid The primary lid of the inner cask is made from the same materials as the inner cask. It provides for leak tightness and shielding before and during welding of the secondary lid.
Below the lid a plate is attached that is made of materials which moderate and absorb neutrons.
Secondary Lid
The secondary lid of the inner cask is also made from the same material as the inner cask (see Fig. 4). It is welded with the body. The welded seam joint, which is approx. 50 mm thick, is made using a special technique - the narrow-gap welding. It ensures leakproof and durable barriers against radioactivity releases during transport, storage and final disposal of the fuel elements.
Inner Structures
The inner cask has a basket structure. It consists of an inner square box connected by sheets at each corner with the cask and thus forming four cavities for canisters with consolidated fuel rods. The sheets center the basket structure and ensure good heat transfer from the center to the outer cask wall.
The central square position can be filled with the fuel rods of two PWR fuel elements or with compressed structural parts of fuel assemblies.
Fuel rod canisters with consolidated fuel can contain rods from two PWR fuel elements.
To guarantee subcriticality even in case of a rather hypothetical flooding of the final disposal cask, boronated steel plates are screwed at the outer side of the canisters. This measure assures neutron decoupling between the canisters.
After remote-controlled loading, the canisters and the central basket position are sealed dust tight with lids.
CORROSION PROTECTION
The complete inner cask can be coated to avoid corrosion, if the final storage conditions should require it.
SHIELDING CASK
Body
The body of the shielding cask is cast in a single piece from nodular cast iron GGG 40. It is designed to comply with the mechanical and shielding requirements and has a wall thickness of 265 mm. The weight of the body is approx. 34 metric tonnes.
There are two circles of drilled holes with moderating material in the wall of the shielding cask. Each one has 36 holes with a diameter of 75 mm each.
This arrangement of the moderating material inside the shielding wall corresponds to the previously tested concept used for the CASTOR casks-family.
The primary function of the shielding cask is to reduce the gamma and neutron dose rate at the surface, so as to comply with the envisaged limit for intermediate storage of 0.5 mSv/h.
Furthermore, in the final repository, the shielding cask has to withstand the isostatic salt pressure of approx. 300 bar.
The shielding cask lid is screwed down using multiple-threaded trapezoidal threads.
CONSTRUCTION OF THE FINAL DISPOSAL CANISTER
The final disposal canister is a cylindrical cask. Its design and components are shown in Fig. 5.
It consists of:
- a cylindrical canister piece made of fine grained construction steel;
- a welded lid plate with a grapple device and
- two holes for the loading and ventilation.

The holes are shut by a primary plug and ventilation valve after loading.
By welding the disposal canister after loading, the gas-tight containment of the radioactive material during transport, storage and final disposal is ensured.
An anti-corrosion coating of the canister offers further protection against corrosion inside the repository.
The loading of the final storage canister with fuel pins from spent LWR-assemblies will be done in the PKA using hot cell technology. After completion, the canisters are inserted into a transport/storage cask.
RESULTS OF THE DESIGN CALCULATIONS--CALCULATED DOSE RATES
Based on the shielding geometry and burnup calculations using the computer code OREST, shielding calculations were performed for the three types of fuel under

consideration with a mean burnup of 55 GWd/tHM. The calculated dose rates at the cask surface are in compliance with the envisaged value for intermediate storage of 0.5 mSv/h.

CRITICALITY CALCULATIONS

The final disposal cask is designed in such a way that even during unfavorable operating events and assumed accidents, the neutron multiplication factor keff maintained below 0.95.

The criticality calculations show that the subcriticality of the loading arrangements is guaranteed by design, also in the case of

- assumed fresh fuel and
- assumed penetration of moderating water without salt content.

THERMAL CALCULATIONS

The maximum permissible thermal output in the final repository under normal conditions is derived from the following requirements:

- the integrity of the cask and the enclosure of the radioactive materials, must be guaranteed for the long-term storage
- the integrity of the fuel cladding must be preserved.

In order to fulfill safely the demand for the integrity of the fuel cladding and of the leakproof enclosure, it is necessary to determine - as precisely as possible - the maximum quantity of heat transmission by the cask.

Using the burnup calculations made with OREST, the fuel rod temperatures were determined as a function of the decay time for the three types of fuels. The calculations proved the design to be in accordance with the requirements.

In addition it could be shown, that the surface temperature of the cask was below 85C as demanded by transport regulation for a type B(U) package.

MECHANICAL DESIGN

Stress Analysis for 9-meter Drop Test

The verification that the final disposal cask withstands the load conditions to be taken into account in its design is provided by FEM calculations and drop tests with a 1:1 prototype cask.

The final disposal cask is initially designed to withstand the rock salt pressure under final storage conditions. The resulting cask structure is than used to show its compliance with IAEA-transport-related design requirements.

The calculation of temperatures proceeds from stationary temperature profiles with a maximum decay heat of the fuel rods and 38C ambient temperature. Characteristic values of the material and admitted tensions are used in each case for the most unfavorable temperature. The following calculated temperatures for transport and intermediate storage are used as the basis of the calculations of tensile strength to provide a conservative safety margin.

- Shielding cask 135C
- Inner cask 250C

Taking into account the maximum possible effects on the inner and shielding casks, the impact positions described below have been selected as representative for the analysis and drop test.

Impact on the Shell Line, Drop Test No. 1

The final storage cask falls onto the shell line of the shock absorber with its longitudinal axis parallel to the impact plate.

To examine this drop test, shielding and inner casks are analyzed by means of a three dimensional FEM calculation and taking into account non-linear material characteristics. The shock absorbers are also calculated with a non-linear characteristic.

The structure has, as starting condition, the drop speed of 13.3 m/s, which results by being dropped from a height of 9 meters.

The positions of the strain gauges and the accelerometers were selected for areas of the cask with the greatest impact and expected strains.

Impact on the Lid, Drop Test No. 2

The final disposal cask falls on the shock absorber with its longitudinal axis rectangular to the impact plate.

Impact on the Edge of the Lid, Drop Test No. 3

The final storage cask is dropped onto the corner of the shock absorber with the diagonals of its center of gravity rectangular to the impact plate.

Stress analysis for 5-meter drop tests without shock absorbers

Impact on the Trunnions, Drop Test No. 4

The final storage cask falls onto both trunnions simultaneously with its longitudinal axis parallel to the impact plate (concrete foundation), without shock absorbers.
The method of calculation corresponds to that of drop test no. 1, but with the difference that the trunnions are modelled as "shock absorber" with non-linear material characteristics.
Impact on Cask Bottom, Drop Test No. 5
The final storage cask falls with its bottom to the impact plate (concrete foundation), without shock absorbers.
THE PRESENT STATUS OF DEVELOPMENT
The safety analysis report and the approval documents FOR THE FINAL DISPOSAL CASK were submitted to the authorities (BAM and BfS) to obtain a type B(U) license and the approval for the storage of radioactive materials in an intermediate storage facility.
For demonstration purposes, the final storage cask was built in the model dimensions 1:10, in order to demonstrate the functional interaction of essential cask components.
Then a prototype cask on the scale 1:1 was built. To achieve leak tightness of the inner cask in accordance with final storage conditions, 1:1 welding tests were performed for the secondary lid. The narrow-gap welding technique proved on nuclear power plant components was selected as the suitable welding technique.
The tests for the welding technique including ultra sonic tests were performed under the supervision of the German Technical Inspectorate (TV) and the authority (BAM), and received a positive evaluation.
To prove the theoretically determined heat transfer of the final storage cask, heat load tests are planned with the prototype casks. These tests are to determine the temperature fields of the cask in a horizontal and vertical position.
To prove the analytically performed verifications and to provide verification of the ANSIS FEM program used for calculation of the mechanical tensile strength in accidents (e.g. drop from a height of 9 meters onto an inflexible base), 1:1 drop tests were performed by BAM. On the basis of these tests we expect no difficulties in obtaining approval for the final storage cask.
We expect to receive the type B(U) license for the final disposal cask at the end of 1995 and the approval for storage for the intermediate storage plant in 1996.

DOE SPENT NUCLEAR FUEL DRY STORAGE DESIGN REQUIREMENT: A COMPARATIVE ANALYSIS OF NRC REQUIREMENTS WITH DOE ORDERS FOR DESIGN OF A DOE SPENT NUCLEAR FUEL DRY STORAGE FACILITY
Howard Goldin
Marshall Anderson
Joy Burdick
Joanne Steingard
BDM Federal, Inc.
ABSTRACT
The Department of Energy (DOE) Office of Spent Fuel Management, EM-37, is currently proceeding with actions to implement safe and cost effective long-term interim storage for DOE-owned spent nuclear fuel (SNF) prior to its final disposal. These actions include evaluation of alternatives for design, construction, and operation of new storage facilities in accordance with either Nuclear Regulatory Commission (NRC) requirements, DOE Orders, or both. This paper presents the results of an evaluation of DOE Orders pertaining to the design of a dry storage SNF facility to analogous NRC requirements. This evaluation included identification of differences between DOE and NRC requirements, as well as identification of DOE requirements for which no analogous NRC requirements exist. Requirements that govern all safety related aspects for design of these facilities including quality assurance, safety analysis and review, technical safety requirements, and radiation protection were considered.
INTRODUCTION
DOE's responsibility for establishing requirements for safe and efficient operation of its SNF facilities and ensuring compliance with those requirements is derived from the Atomic Energy Act of 1954 (as amended), the Energy Reorganization Act of 1974 and the DOE Organization Act of 1977. The primary means of discharging this

responsibility and for specifying the associated nuclear policy and requirements with respect to health, safety, and the environment are the DOE Orders issued by DOE Headquarters in Washington, D.C.

The increasing concern of the Nation, in both government and private quarters, in regard to the disposition of SNF has resulted in a growing constituency favoring subjecting DOE SNF storage facilities to the same management standards imposed upon commercial spent fuel. Furthermore, these facilities have been designed, constructed and operated under DOE self-regulation, which has created the public perception of a credibility problem. The House of Representatives of the U.S. Congress has considered legislation that would require DOE to submit to external regulation of its defense nuclear facilities. In an effort to be proactive, EM-37 has undertaken an evaluation of approaches associated with NRC external oversight of future DOE SNF dry storage facilities.

A key aspect of future NRC external oversight is compliance with the body of NRC regulations and guidance. This study provides the technical validation for this proposition that compliance with NRC minimum requirements will ensure compliance with all DOE technical requirements for design of a SNF dry storage facility.

Objectives

The goal of this evaluation was to review the DOE Orders pertaining to the design of a DOE-operated SNF dry storage facility, and to compare them with similar requirements developed and imposed by NRC upon licensees of SNF storage facilities. The specific objectives of the analysis comprised:

- identifying and evaluating areas of differences between DOE and NRC requirements, and;
- identifying DOE requirements for which no analogous NRC requirements exist.

Scope

This evaluation focused upon the DOE's design requirements for a SNF dry storage facility. These requirements govern not only the structural design criteria but also quality assurance, safety analysis and review (i.e., Safety Analysis Reports and Unreviewed Safety Questions), Technical Safety Requirements, radiation protection and fire protection concerns. Therefore, this study includes related DOE orders (e.g., DOE Order 5480.28, "Natural Phenomena Hazards Mitigation" and related DOE Standards for its implementation), as well as the primary DOE Order for design criteria 6430.1A "General Design Criteria".

In many cases, the requirements and guidance contained within the DOE documents were of a general nature and applied to design of all facilities (e.g., Plutonium processing, fuel fabrication). Furthermore, requirements contained within DOE Order 6430.1A specific to SNF storage (i.e., Section 1320, Irradiated Fissile Material Storage Facilities) required evaluation for applicability to dry storage. For example, requirements pertaining to water pool design were not considered.

The evaluation reviewed only those DOE requirements that pertained to safety class equipment or impacted facility safety. For a dry storage SNF facility only the physical confinement systems, such as storage cask and cement pad, would meet the DOE's definition of safety class equipment. Hence, ancillary support systems, (i.e., instrumentation and control systems, constant air monitors, etc.) would not be subject to the additional constraints of a safety class system. Whereas, 10 Code of Federal Regulations (CFR) 72 states that these types of ancillary support systems are important to safety and thus, subject to a more stringent set of requirements. Therefore, in all of these cases, the NRC requires more attention to the design of these types of systems, that is, the NRC requirements and guidance are more restrictive than the corresponding DOE requirements. Additionally, DOE and NRC definitions of safety-related equipment as it pertains to natural phenomena hazards (NPH) differ in several aspects; this difference was considered in the analysis. Requirements associated with the Environmental Protection Agency (EPA) and other government agencies' documents prepared by licensees for review and approval by NRC, and requirements pertaining to the design and handling of SNF storage casks were not considered in this review because they generally did not provide requirements applicable to existing DOE SNF storage facilities.

EVALUATION

The methodology identified and considered all safety related aspects for design of SNF dry storage facilities including quality assurance, safety analysis and review, technical safety requirements, and radiation protection design-limiting criteria. The analysis identified all requirements and guidance contained in DOE Orders that

pertained to the design of SNF facilities. It then identified all analogous NRC requirements and evaluated the differences as they would impact the technical safety basis.
The resulting 50-page report was subjected to a peer-review by the SNF Dry Storage Demonstration Working Group. This group included representatives from sites storing DOE-owned SNF, as well as an independent national laboratory. Although the final report was modified to provide a more detailed discussion on the differences in seismic design constraints, no substantive comments on the technical validity of the report were received.
The evaluation recognized that implementation of the DOE Order system results in the development of individual site specific criteria for DOE facilities. This development requires application of engineering judgment to ensure that the site criteria will result in meeting the DOE requirements. Thus individual site criteria and corresponding conservative margins vary from site to site. Due to this variation, the evaluation considered only those DOE requirements established at the Headquarters level.
DOE Orders
The requirements from the following DOE Orders were evaluated:
DOE Order 5480.7A Fire Protection
DOE Order 5480.11 Radiation Protection
DOE Order 5480.21 Unreviewed Safety Questions
DOE Order 5480.22 Technical Safety Requirements
DOE Order 5480.23 Nuclear Safety Analysis Reports
DOE Order 5480.24 Nuclear Criticality Safety
DOE Order 5480.28 Natural Phenomena Hazards Mitigation
DOE Order 5700.6C Quality Assurance
DOE Order 6430.1A General Design Criteria
NRC Requirements and Guidance
Requirements and guidance from the following NRC Regulations, Regulatory Guides (RGs), and NRC Nuclear Regulations (NUREGs) were evaluated:
10 CFR 20 Standards for Protection Against Radiation
10 CFR 50 Domestic Licensing of Production and Utilization Facilities
10 CFR 72 Licensing Requirements for the Storage of Spent Fuel in an Independent Spent Fuel Storage Installation (ISFSI)
RG 1.13 Spent Fuel Storage Design Basis
RG 3.43 Nuclear Criticality Safety in the Storage of Fissile Materials
RG 3.48 Format and Content for License Application for an ISFSI (dry type)
RG 3.49 Design of an ISFSI (Water Pool Type)
RG 3.50 Format and Content for Application
RG 3.53 Applicability of Existing Regulatory Guides to the Design and Operation of an ISFSI
RG 3.60 Design of an ISFSI (dry type)
NUREG 0800 Standard Review Plan
CONCLUSION
The results of this evaluation verified that DOE requirements for the design of a SNF dry storage facility are analogous to NRC requirements with few exceptions. Notably, NRC generally provide greater specificity than corresponding requirements contained within the DOE Orders. However, meeting NRC requirements would not be a significant obstacle since the DOE Orders are similar in intent to their NRC counterparts.

ISOLATION PERFORMANCE OF NORTH-EAST GRANITES IN TURKEY

Ahmet E. Osmanlioglu
ekmece Nuclear Research and Training Center
NAEM
P.K. 1 Havaalani 34831
Istanbul Turkey

ABSTRACT

In this study, locations of granite formations and main fault system of Turkey are mentioned and shown in maps. Simple isolation performance tests are applied on granite samples. These samples are taken from north-east region of Turkey. For this reason, most of these samples include fractures and filling minerals. Dimensions of the tested samples are; diameter:50 mm. and width: 3 mm.. Plastic columns (diameter:50 mm.) are used for isolation tests. Both ends of the plastic columns are opened. Each granite sample is emplaced into the plastic column tightly. Each column is filled by Cs-137 solution (Initial specific gamma activity:260 bq/ml). Transported solution that passed through the fractured sample is taken periodically from the bottom part of the column. The amount of this solution is determined and analyzed by a gamma spectrometry during the test period (test period:100 days). Results are shown in regression graphs.

INTRODUCTION

High-level nuclear wastes should be permanently isolated from the environment and remain safe for very long periods. Migrations of radionuclides from the waste form, is prevented by surrounding rock. For this reason, host rock has been considered as a final barrier in multibarrier designs (1). Radionuclide migration in geologic media is occurred by groundwater. If radionuclide transferred directly by the flowing groundwater, this is called advection. Furthermore, dispersion in the pores of host rock is occurred with the interactions of minerals, this is sorption effect. In this study, isolation performance of cylindrical granite samples are analyzed. The dimension of these granite samples are; diameter = 50 mm., width = 3 mm. These samples are prepared from the granite blocks that are taken from the north-east region of Turkey. These granites naturally includes fractures and fissures. Therefore permeability of these granites is greater than massive types.

NORTH-EAST GRANITES

General tectonic conditions of our country can be described according to the basic fault zones and previous earthquakes. Our country can be separated into five earthquake levels. Especially North Anatolian Fault is more effective in this separation (2). Several candidate host rocks are available in Turkey. General locations of main formations of these host rock types are; rock salt and tuff formations are in the middle region of Turkey, Granite formations are in the north-east region of Turkey (Fig. 1). In fact, north-east granites has not any priority to take into consideration among from the other candidate host rocks. Tectonically, locations of rock salt and tuff formations are more convenient than granites. Since this is not a site selection study, north-east granites have been chosen as a fractured media for this type of study. The aim of this study is: taking information about the isolation performance of these granites. Main fault system of Turkey is shown in Fig. 2.

Fig. 1. Locations of main granite formations in Turkey (2).

Fig. 2. Main fault system of Turkey and lateral stress directions (3).

RADIONUCLIDE TRANSPORT

Radionuclide transport can be described for the two geological media; porous media and fractured media. In this study, radionuclide transport for fractured media is taken into consideration.

Fractures are natural pathways for groundwater flow and also radionuclide migration. During the groundwater flow through the fractures, radionuclides diffuse into pores from the fracture surface to the interior of rock sample. At the same time, diffusion into infilling minerals is expected. This is called matrix diffusion and it cause retardation of radionuclide transport in rock sample.

Radionuclide transport in fractures (advection and dispersion) is expressed by the

following Eq. (4).
Eq. (1)
Eq. (2)
Radionuclide transport in the matrix (matrix diffusion) is expressed as follows;
Eq. (3)
Eq. (4)
In these equations, the subscript i denotes the i th radionuclide in a decay chain, the subscript f denotes a variable within fractures and the superscript m denotes a variable in the rock matrix. Variables in the equations are as follows;

Rdif :Retardation coefficient through adsorption onto fractured surfaces (-)
Rdim: Retardation coefficient through adsorption into rock matrix (-)
Cif: Radionuclide concentration within fracture (LT-1)
t: Time (T)
V: Groundwater velocity within fracture (L)
z: Distance in the direction of fracture (L)
DL: Dispersion coefficient (L2T-1)
Dpm: Diffusion coefficient in pores of rock matrix (L2T-1)
Cim: Radionuclide concentration within pores of rock matrix (ML-3)
x: Distance in a direction perpendicular to the fracture (within rock matrix) (L)
ll: Decay constant (T-1)
Kai: Distribution coefficient related to adsorption onto fracture surface (L)
Kdi: Distribution coefficient for rock matrix (L3M-1)
2b: Fracture aperture (L)
em: Porosity of rock matrix (-)
rm: Theoretical density of rock matrix (ML-3)

ISOLATION PERFORMANCE TESTS

Recent results have demonstrated that direct measurements of unsaturated transport parameters on subsurface materials and engineered systems, e.g., hydraulic conductivity, vapor diffusivity, retardation factors, thermal and electrical conductivities, and fluid potential, are essential for defensible site characterization needs of performance assessment and restoration or disposal strategies. Predictive models require the transport properties of real systems which can be difficult to obtain (5).

This study illustrates the results of a simple method. Isolation performance tests are applied on granite samples in a plastic column. Granite sample (diameter=50 mm., width=3 mm.) is fixed back end of this column. Between the column circumference and side surface of the granite sample, seepage is prevented by using PVC glue. After this isolation operation, column is filled by Cs-137 solution, which has approximately 260 Bq/ml. specific activity. Test time is considered as 100 days. During this time period, solution that passed through the granite sample is taken under the column periodically. Passed solution amounts determined and their final specific activities measured by a gamma spectrometry. Final specific activities and volumes of passed solutions are recorded and plotted during the test period. Power regression is applied on these graphs. According to the test results, isolation performance of these granites are determined (Fig. 3 and Fig. 4). Therefore, regarding to the mass transport and radionuclide transport, isolation performance of these fractured granites is not convenient for long term isolation.

EVALUATION OF STORAGE TECHNOLOGY ALTERNATIVES FOR FOREIGN RESEARCH REACTOR SPENT NUCLEAR FUEL

Alex Murray
Steven Mirsky
Aris Papadopoulos
Abe Zeitoun
Science Applications International Corporation
Charles R. Head
Darren Piccirillo
United States Department of Energy

ABSTRACT

The U.S. Department of Energy (DOE) has been evaluating alternatives for managing spent nuclear fuel (SNF) from DOE and research facilities. Two environmental impact statements (EIS) are in progress: the first covers all of this fuel programmatically (i.e., generally), while the second one specifically addresses foreign research reactor (FRR) SNF. Safe storage technologies are an integral part of each EIS, and these technologies are briefly summarized and evaluated in this paper.

FRR SNF consists primarily of metallic fuels with aluminum cladding, which are more susceptible to degradation than the zircaloy-clad oxide fuels used in power reactors. FRR SNF also utilizes higher Uranium-235 (235U) fuel enrichments, in some cases up to 93 percent assay. Consequently, both wet and dry storage technologies were evaluated for potential use, with emphasis on the following criteria: chemical compatibility, subcriticality assurance, shielding effectiveness, structural integrity, thermal performance, ease of application, economics, accident risks/consequences, and regulatory bases. The evaluations concluded that current wet and dry storage technologies were appropriate for FRR SNF, with a preference for approaches that allow monitoring and SNF retrieval and examination. FRR SNF storage is approximately equivalent in size to a large commercial SNF storage site. Utilization of existing facilities (i.e., for staging) favored wet and individual unit (e.g., cask) dry storage, whereas "greenfield" approaches favor integral dry storage (e.g., vault designs). For FRR SNF, either route would require approximately 2 hectares (5 acres) of land for the storage areas and fencing.

INTRODUCTION

In the 1950's, the United States began providing assistance for the peaceful application of nuclear technologies to countries that agreed with its policy on the nonproliferation of nuclear weapons. The assistance included the supply of highly-enriched uranium (HEU) fuels for FRRs. HEU consists of uranium enriched to 20 percent or more in the fissile isotope 235U. After irradiation in the research reactor, the SNF was returned to the United States for recovery of the HEU by reprocessing and, subsequently, manufactured into new fuel. This provided a closed cycle for the HEU fuels, minimized SNF storage requirements, and maintained U.S. control of the HEU.

Research reactors represent the principal civilian use of HEU fuels. Thus, in 1978, the United States refined its nonproliferation policies to minimize HEU civilian use by instituting the Reduced Enrichment for Research and Test Reactors program. This program had the objective of replacing HEU fuels with low enriched uranium (LEU) (up to 20 percent 235U assay) fuels in research reactors, with the ultimate goal of eliminating HEU use. The United States continued accepting FRR SNF until the policy expired, in 1988 for HEU SNF and in 1992 for LEU SNF.

FRR SNF has accumulated at the overseas sites, forcing many operators to expand storage facilities or seek offsite alternatives. DOE has decided to pursue an EIS addressing options for management of the FRR SNF and alleviating FRR storage concerns(1)(2). This paper discusses the storage component and technologies of the proposed action.

A BRIEF DESCRIPTION OF FRR SNF

Figure 1 compares power and research reactor fuels. Unlike power reactors, most research reactors use metallic fuels, usually based upon uranium-aluminum alloys, with a thin metal cladding. The cladding is usually aluminum. A small fraction of

the FRR SNF consists of Test, Research, Isotope, General Atomic (TRIGA) elements, which differ from the all-metal element. TRIGA SNF contains HEU as a uranium zirconium hydride, clad in incoloy, stainless steel, or aluminum. The element typically contains around 1 kilogram (kg) of uranium (LEU or HEU) and has a total weight a little over 5 kg. High density, LEU FRR fuels contain slightly more uranium. Many variations of fuel exist, but the elements usually are within 1 meter (m) in height and 10 centimeters in overall diameter. Thus, at least five FRR elements can fit within the dimensional envelope of a commercial reactor assembly. The FRR SNF has very high burnups, typically exceeding several hundred thousand MegaWatt Days per Metric Tons of Heavy Metal (MTHM); but, isotopically, the fission product inventory is at least an order of magnitude below a commercial SNF assembly. Relatively small quantities of transuranics are produced due to the enrichment level in the research fuels.

The potential exists for up to approximately 23,000 FRR SNF elements, containing a little over 19 MTHM. The storage period might be as long as 40 years, and followed by ultimate disposition, either by processing or disposal in a repository. The storage of FRR SNF is approximately equal in scope to a large dry storage area at a multi-unit, commercial plant.

EXISTING STORAGE METHODS FOR COMMERCIAL SNF

The commercial utility industry has addressed the storage of SNF using both wet and dry technologies(2). Figure 2 provides an overview of storage approaches and a partial list of commercial designs. Wet storage of SNF in a stainless-steel lined concrete pool is the historical choice. Assemblies are stored vertically on racks mounted on the floor of the pool and can be visually inspected at any time. Cranes and long-handled tools are used to handle and move SNF within the pool. Water provides the shielding and heat transfer medium. Ion exchange columns, filters, and heat exchangers maintain water quality within specifications. The entire pool is housed within a seismically-qualified facility that includes Heating, Ventilating, and Air Conditioning and High-Efficiency Particulate Air filters. A wet storage facility for SNF contains active mechanical components and requires staffing and maintenance.

In the past decade, the accumulated quantities of commercial SNF in wet pools at nuclear power plants have provided the incentives for the development and implementation of dry storage technologies. Dry storage methods are inherently passive in nature and, once loaded, require very little attention and operating costs. Dry storage involves the placement of SNF in a metal canister. The canister is subsequently dried, inerted (usually with helium), and sealed. Subsequently, two different approaches can be followed. In a vault design, a bridge crane transfers the canister in a shielded container to a charging face, which is inserted into steel tubes within a concrete vault. Natural convection of outside air through the vault, around the tubes, and up a stack provides for the cooling of the fuel. The vault is also a self-contained facility that includes an inspection cell and a shipping cask loading/unloading area. Currently, there is one vault licensed and operating with commercial SNF in the United States.

The second approach utilizes either metal or concrete casks, and multiple licensed designs have evolved. With metal casks, the loaded SNF canister is usually designed as the storage cask itself and, thus, provides the necessary shielding. Heat transfer is accomplished by conduction through the thick metal walls of the cask. Alternatively, the loaded SNF canister is placed within the cavity of a concrete cask for shielding and storage. The canister can be either horizontal or vertical. Natural convection of the air inside this cavity provides heat transfer; and, thus, shielded labyrinth air inlets and outlets exist in the concrete design. Cask approaches are inherently modular in design and rely upon the use of existing facilities (e.g., a wet storage pool) for loading, unloading, and inspection (i.e., "staging").

Most commercial utilities have analyzed the SNF storage alternatives, and concluded that cask approaches represent a logical, operational extension of their existing wet pools for rapidly providing safe and cost-effective SNF storage. Many of these same utilities have also concluded that concrete casks offer the best combination of parameters. Several installations already exist at commercial reactor sites. Programs within DOE are also developing a multi-purpose canister (MPC), with the intention of reducing the handling and operating costs from reactor storage, transportation, and ultimate disposal in the proposed SNF repository. The MPC is

essentially a standardized SNF transfer canister for dry storage. The MPC concept is still evolving and will not be available for several years.

EVALUATION CRITERIA FOR FRR SNF STORAGE METHODS

SNF storage approaches and designs have been compared and evaluated, with an emphasis upon the use of designs already in use for commercial SNF. The evaluation criteria and the results are briefly discussed in the sections that follow. Overall, wet and dry designs were found to be comparable from a program perspective, although significant differences exist in some areas.

Chemical Compatibility

The storage environment must be compatible with the cladding material and mitigate, or preferably prevent, its degradation. Aluminum cladding can deteriorate under both acidic and alkaline conditions in water, and this effect has been observed in older fuel pools with poor water chemistry and lacking a concrete coating or liner. However, continuously filtered and demineralized high-purity water has been observed not to result in any degradation of FRR elements. Thus, a modern fuel pool design is expected to provide satisfactory long-term storage. In contrast, dry storage uses an inert gas (usually helium) within the canister, and this is not expected to react at all with the cladding. HEU FRR SNF has been dry-stored for up to 30 years without any cladding degradation in Australia, Japan, Denmark, and Canada(2).

Subcriticality Assurance

Both HEU and LEU FRR fuels have higher enrichments than fresh commercial fuel, even after discharge from the reactor. Both wet and dry storage methods maintain subcriticality principally by geometry. Water pools use racks to maintain spacing and sometimes include neutron absorbing materials in the spacers and racks (e.g., borated steel). Dry storage methods would probably utilize an additional geometric barrier by individual containerization of each element, thus avoiding reconfiguration concerns from slumping. The total fissile material in a dry storage canister of FRR SNF is expected to be comparable to or below that of a canister loaded with commercial SNF.

Shielding Effectiveness

FRR SNF shipped to the United States will contain fission product inventories at least an order of magnitude lower than commercial SNF. Thus, since the radiation energy spectrum is approximately the same, shielding designed for commercial SNF can easily accommodate the FRR SNF. This translates into approximately 8 feet of water cover in pool storage and 30 inches of concrete in dry designs.

Structural Integrity and Confinement

The two principal structural effects of FRR SNF relate to its weight and strength in dry storage methods. FRR SNF weighs considerably less than commercial fuel. On an equivalent volume basis, 5 FRR SNF elements have a total mass of approximately 25 kg, compared to around 800 kg for a typical commercial assembly. For a typical storage transfer canister, this corresponds to weight savings exceeding 30 tonnes, thus increasing the design margins.

The lower strength of the FRR SNF will require additional analyses to demonstrate that operational and postulated accident events do not impact the integrity of the cladding. However, the principal confinement remains the canister surrounding the fuel, and this has already been qualified for the heavier loads due to commercial fuel. Thus, commercial design margins are expected to be more than adequate and meet DOE requirements(3).

Thermal Performance

Wet storage of SNF utilizes water as the heat transfer mechanism, which provides for effective cooling and low cladding temperatures. Dry storage utilizes convection cooling from the fuel to the metal canister, conduction through the canister, followed by natural convective heat transfer to the atmosphere. Thus, when compared to wet storage, it is less effective and results in higher cladding temperatures for a given heat load. For commercial fuels, the cladding temperature must be maintained below 350oC during routine operations, and concrete temperatures must be kept lower (around 150oC maximum, depending on the design). Most of the FRR SNF elements have aluminum cladding. Aluminum undergoes a phase transition just above 200oC which greatly reduces its strength and results in highly undesirable slumping of the fuel(4)(5)(6). Consequently, a conservative 175oC temperature limit has been defined for FRR SNF. This effectively derates existing commercial designs by approximately 60 percent [e.g., 24 kilowatts (kw) down to 10 kw]. Analyses further indicate that this only impacts FRR SNF with a heat load above 40 Watts per element, a situation

that only exists within the first 3 years or so after discharge from the reactor. Therefore, dry storage would entail the use of a small wet pool facility for up to 3 years prior to dry storage.

Ease of Use

FRR SNF storage would utilize existing designs which are modified to accommodate the FRR SNF(2)(7). Wet storage allows for easy periodic fuel inspection, but requires the greatest amount of maintenance and operation of all the storage designs and generates the largest amount of waste. The dry vault and dry metal or concrete casks generate less waste and inherently demand less maintenance and operation, but do not offer convenient periodic visual inspection of the SNF. The vault's design includes many operational functions (i.e., loading and fuel inspection) that require a separate pool and transport cask for the metal or concrete cask designs. Casks allow for incremental increases in capacity without large outlays. The passive nature of the vault and cask heat removal and confinement systems results in minimal operation expenses; whereas, the wet storage design demands monitoring and maintenance of active safety systems for heat removal, water purification, and maintaining water inventory.

Accident Risks/Consequences

Analyses were performed of postulated accidents at wet storage and both vault and cask dry storage facilities containing FRR SNF at five DOE sites (Savannah River Site, Idaho National Engineering Laboratory, Oak Ridge Reservation, Hanford Site, and Nevada Test Site). Five different conservative accident scenarios were developed: fuel element breach, criticality, dropped fuel cask, and airplane crash with or without a resulting fire. Source terms specific to FRR SNF were calculated using the ORIGEN2 computer code(8), and the GENII code(9) was used to calculate atmospheric releases and doses. Using site-specific population distribution and both 50 percentile and 95 percentile site-specific meteorology, doses to the workers, maximally exposed off-site individual, nearest public access individual, and the 50-mile-radius general population were calculated. Calculated individual doses due to these accidents at the 5 sites varied from 0.00034 millirem (mrem) to 2,300 mrem, which are all within regulatory limits. The comparable population dose range was 0.11 to 2,900 person-rem. The highest risk for any accident, accounting for the probability of each accident, was 0.0044 latent cancer fatalities. The accident risk and consequence analysis results did not show that any one storage technology was safer than any other, but did substantiate the very small radiological risks associated with FRR SNF storage.

Economics and Costs

Typically, wet designs tend to be more capital and labor intensive and generate more waste than dry storage designs for the same quantity of SNF. This is principally due to the use of active systems in wet storage. Also, dry concrete cask systems have lower capital costs than dry metal cask systems(7).

Regulatory Basis and Licensing

Wet and dry storage facilities for commercial SNF have been built and licensed domestically. FRR SNF would occupy the same physical space as approximately 4,500 commercial assemblies, which is comparable in size to large SNF facilities at multi-unit commercial sites. DOE sites are required to meet specific requirements for SNF storage facilities(3), which are generally the same as 10 CFR 72.

Table I summarizes the FRR SNF storage parameters for several approaches.

SUITABLE APPROACHES FOR FRR SNF STORAGE

The analyses identified three generic designs that could be utilized for the construction of new facilities for FRR SNF storage. These are:

- The Modular Vault Dry Store (MVDS),
- Dry Cask (Metal, Vertical Concrete, or Horizontal Concrete) Storage, AND
- Wet Pool Storage.

The MVDS would occupy an area approximately 213 m by 61 m (700 ft by 200 ft), and include its own receiving and staging area for transferring SNF. The storage vault itself would contain up to 29 modules with up to 44 tubes per module. The Dry Cask Storage would utilize up to 94 casks with up to 260 elements per cask. Cask storage would occupy an area approximately 91 m2 (300 ft2). The generic wet storage approach would use 2 pools, each 16.5 m by 10.4 m by 9.5 m (54 ft by 34 ft by 31 ft) deep. Four smaller pools would provide for unloading, cutting/canning, and leak checking operations(10).

The analyses also identified existing facilities that fit within these categories

and which could rapidly implement FRR SNF storage. MVDS analogs include the Engine Maintenance and Disassembly (E-MAD) facility in Nevada, the Test Area North (TAN) facilities at Idaho, and the Fuel Materials Examination Facility (FMEF) in Hanford. The E-MAD has sufficient capacity for all of the currently identified FRR SNF, while TAN and FMEF would require some supplemental storage capacity (e.g., by an adjacent small vault or casks). Dry cask technology could be implemented incrementally at any of the DOE sites with SNF handling capabilities, including Savannah River, Idaho, Hanford, Oak Ridge, and Nevada. While several sites have existing wet pools that could be used for short-term storage of FRR SNF, the Barnwell Fuel Receiving and Storage Station (FRSS) adjacent to the Savannah River Site is seismically qualified, suitable, and available for long-term wet storage. Analyses indicate that the FRSS can accommodate all of the expected FRR SNF.

CONCLUSIONS AND RECOMMENDATIONS

The applicability of SNF storage technology was evaluated as part of DOE's ongoing EIS on foreign research reactor fuels. All currently available technologies, including wet pools, dry vaults, and dry casks, were found to be amenable for the safe storage of FRR SNF. A well developed commercial industry indicates ample availability of designs and hardware, and implementation time should be minimal. The analyses also identified existing facilities that could be used in whole or in part for FRR SNF storage.

ABSTRACT

Preliminary accident analyses and radiological source term evaluations have been conducted for transuranic waste (TRUW) as part of the U.S. Department of Energy (DOE) effort to manage storage, treatment, and disposal of radioactive wastes at its various sites. The approach to assessing radiological releases from facility accidents was developed in support of the Office of Environmental Management Programmatic Environmental Impact Statement (EM PEIS). The methodology developed in this work is in accordance with the latest DOE guidelines, which consider the spectrum of possible accident scenarios in the implementation of various actions evaluated in an EIS. The radiological releases from potential risk-dominant accidents in storage and treatment facilities considered in the EM PEIS TRUW alternatives are described in this paper. The results show that significant releases can be predicted for only the most severe and extremely improbable accidents sequences.

INTRODUCTION

Transuranic waste (TRUW) is waste contaminated with alpha-emitting transuranium radionuclides with half-lives greater than 20 years and concentrations greater than 100 nCi/g of waste at the time of assay (1). Packaged TRUW with surface dose rates less than 200 mrem/h is categorized as contact-handled (CH); that with surface doses greater than 200 mrem/h is categorized as remote-handled (RH). TRUW results from a variety of activities, including the processing and handling of plutonium and plutonium-contaminated materials. Principal sources are research and development, special nuclear materials recovery, weapons manufacturing, decontamination and decommissioning (D&D), and disposition of plutonium-bearing residues. Most residue is in solid form such as contaminated protective clothing, paper trash, glassware, tools, and machine parts. At the end of 1991, there were approximately 65,000 m3 of CH TRUW and 4,300 m3 of RH TRUW. Most TRUW is stored in 55-gal drums or standard waste boxes on asphalt pads within weather-protective structures, earthen berms, or concrete structures. Estimated inventory and generation rates for major storage sites, derived from data in the Interim Mixed Waste Inventory Report (2) and the Integrated Data Base for 1992 (3), are provided in Hong et al. (4).

To support analyses for the U.S. Department of Energy (DOE) Office of Environmental Management Programmatic Environmental Impact Statement (EM PEIS), Argonne National Laboratory (ANL) has developed an integrated risk-based approach for evaluating the source terms from radiological releases from postulated facility accidents (5). The methodology has been developed in accordance with the latest DOE guidelines, which consider the spectrum of possible accident scenarios in the implementation of various actions evaluated in an EIS. This approach allows comparisons of facility accident impacts on EM PEIS strategies for consolidating the storage and treatment of TRUW at sites throughout the country. Accidents considered in this analysis include operational (scenarios such as handling accidents, facility fire, and facility explosion) and severe external events (such as earthquakes, tornadoes, and airplane impacts). This paper analyzes the radiological releases from potential risk-dominant accidents in storage and treatment facilities considered in the EM PEIS TRUW alternatives.

TRUW MANAGEMENT ALTERNATIVES OVERVIEW

Under DOE's current management program, retrievably stored and newly generated TRUW are to be prepared (characterized, segregated, packaged and/or certified for transport and disposal) and stored pending transport to the planned Waste Isolation Pilot Plant (WIPP) facility in New Mexico. The DOE has entered a WIPP test phase to evaluate long-term repository performance and subsequent acceptability for disposal. During this phase, limited quantities may also be located at the WIPP. Additional storage facilities may be required, depending on the timing of retrieval operations and the WIPP schedule. Other sites that generate TRUW, including that from D&D will have to store on-site, contract for commercial storage, or transport to one of the nine current storage sites. All sites are responsible for minimizing the quantities of waste generated. The current strategy is to treat TRUW to meet WIPP waste acceptance criteria (WAC) (6) and dispose of it at the WIPP under the Resource Conservation and Recovery Act (RCRA) "no migration" determination rule. However, treatment might be required, under RCRA, Title 40, Part 268 of the Code of Federal Regulations (CFR) (7), to remove or reduce the hazardous components to acceptable levels to meet the hazardous land disposal restriction (LDR), or to meet the radiological requirements of 40 CFR Part 191 (8), before WIPP disposal. These requirements depend on results of the test phase, a WIPP disposal performance

assessment, and the establishment of U.S. Environmental Protection Agency (EPA) criteria for compliance certification.
Four alternatives are considered in the EM PEIS: no action, decentralization, regionalization, and centralization. Decentralization and regionalization each have several cases that may result in distinct inventories for treatment at each site. In addition, three treatment options are considered. In the first, TRUW is treated to meet the minimum requirement for WIPP-WAC namely, liquid absorption, compaction, immobilization, and repackaging. The second option considers an intermediate treatment level beyond WIPP-WAC that includes shredding, grouting, and changing containers to reduce gas generation. In the third option, TRUW is treated to meet LDRs. Detailed descriptions of TRUW treatment processes are provided in Hong et al. (9).

METHODOLOGY AND MODELING CONSIDERATIONS

The volumes, physical characteristics as defined by treatability categories, and radiological composition of the sites' TRUW inventories have been compiled in the ANL WASTE_MGMT computational model (10,11). Each site's facility throughput used for determining source term information was obtained directly from the ANL computational model. The data used included unique volumetric inventories and physical, radiological, and chemical compositions for each waste treatability category at each site for each alternative. Information on accident sequences, such as initiating frequencies, damage fractions (DFs), probabilities, respirable airborne release fractions (RARFs), and leak path factors (LPFs), are also compiled in the ANL accident analysis computational model (12).
The DF is defined as the fraction of the total inventory of waste in a facility or particular operation at risk involved in the accident sequence and actually susceptible to airborne release. The LPF is the fraction of the airborne inventory that passes through the containment barriers and filters to escape to the atmosphere. The RARF is the fraction of the potentially available inventory rendered airborne and having particulates with aerodynamic equivalent diameters below 10 micrometers at the point of the accident. The values of RARFs are a function of the physical form of the material rendered airborne, which varies by the treatability category of each waste stream, and are based on the work of Mishima (13).
Preliminary consequence factors from unit-radionuclide releases at all sites were obtained from ORNL and incorporated into the accident analysis computational model to screen the accident sequences on the basis of risk, defined here as the consequence times the frequency of the accident sequence. Chemical releases for mixed TRUW were considered in the EM PEIS but are not discussed in this paper.

Storage Facility Accidents

TRUW is typically packaged in drums or canisters and stored in concrete structures, weather-protective sheds, below-grade caissons, or earthen berms. Most TRUW is stored in facilities with minimal containment. Accordingly, in this analysis, the use of a generic storage structure was assumed to represent facilities with minimal confinement or with confinement that would likely fail under severe external challenges. To ensure conservatism, no credit was taken for filtration or containment integrity in the accidents postulated for storage, although DOE sites are increasingly moving toward development of qualified TRUW storage. Because special provisions have been made for storage of RH wastes that involve much more robust containment (e.g., underground caissons), the storage accidents investigated here cover only CH wastes.
Although the inventories, physical forms, and radiological and chemical compositions of waste stored at each site were characterized for the EM PEIS and the data then used in the ANL WASTE_MGMT model, compilation of analogous information for individual facilities on each site is beyond the scope of the EM PEIS. A unit inventory approach was used to develop source terms on the basis of waste generation and inventory data at each site. All storage facility accidents reported here assume an inventory of 2,000 m3 (10,000 drums) with a site-dependent radiological and physical composition derived by volume-weighting the inventories of the treatability categories within each waste type at that site. Scaling of these unit source terms will be required to account for actual facilities.
The storage accidents investigated include handling accidents, operation-induced facility fires, and external-event-induced fires and explosions. Representative handling accidents involve a single drum and assume that 25% of the drum inventory is affected and subject to stresses capable of rendering the contents airborne. The

representative operation-induced fire scenario assumes that 10% of the facility inventory is affected. The earthquake was selected as a limiting surrogate for other natural phenomena because of its overriding damage potential. All external-event source term parameters vary according to the particular sequence. Aircraft (small or large) impacts were analyzed at selected sites, depending on their importance to risk.

Treatment Facility Accidents

In the minimal treatment (WIPP-WAC) option, retrieval drums and packages are opened and inspected in a glovebox (CH) or hot cell (RH). Absorbers are added for any free liquids, and compaction, immobilization, and/or repackaging are performed as required. The intermediate treatment option involves essentially the same operations except that all waste is treated and repackaged. The LDR treatment option includes incineration, evaporation, and various RCRA contaminant treatments.

Although several treatment operations may present potential exposure hazards, incineration was assessed to be the treatment technology most likely to dominate risk to facility and site staff and the surrounding general population. This is because incineration has key process characteristics affecting the potential for airborne release, including high temperature; the presence of fuel and fuel feed lines; the presence of combustible input feed waste (combustible solid waste, organic liquid waste, and organic sludge); the potential for overpressurization or explosion; and the high dispersibility of the ash by-product, which has radionuclide concentrations two orders of magnitude higher than the input feed waste. The focus here is on radiological accidents with sequences involving fires and explosions capable of producing large airborne releases of the ash present in storage or filtration systems.

A generic treatment facility was defined for all options for assessing a range of radiological releases from treatment process accidents. Each generic facility consists of a series of linked process modules that provide a specific treatment process. A DOE Hazards Category of 2 and concomitant performance requirements were assumed for the generic facilities. Double high-efficiency particulate air (HEPA) filtration systems are assumed to be in place.

Treatment facility accidents analyzed include (1) a fire in the baghouse area of the incineration facility, failing the filtration systems completely (LPF = 1.0) and affecting 3% of the total amount of ash existing in the facility (DF = 0.03); (2) an incinerator ash explosion caused by combustible gas buildup that affects the existing ash in the rotary kiln (12% of the total in the facility [i.e., DF = 0.12]) and partially degrades the filtration system of the facility (LPF = 0.001); and (3) external events leading to a fire. Aircraft (small or large) impacts were analyzed at selected sites, depending on their importance to risk. The earthquake was selected as a limiting surrogate for other natural phenomena because of its overriding damage potential. All external-event source term parameters vary according to the particular sequence.

RESULTS AND CONCLUSIONS

Preliminary results of the accident sequences for various site consolidation cases for each EM PEIS alternative were reviewed for risk importance in terms of the frequency-weighted dose (risk) to the maximally exposed individual. These sequences were then grouped into four annual frequency categories: anticipated (greater than 1.0E-02), unlikely (between 1.0E-02 and 1.0E-04), very unlikely (between 1.0E-04 and 1.0E-06), and extremely unlikely (less than 1. 0E-06). Representative source terms for the important sequences were then selected as the bases for health effects calculations, which are now being considered as part of the risk impact calculations performed for the EM PEIS. Generic CH TRUW storage facilities were analyzed at the nine major sites. Representative estimated total releases for each accident and its frequency group are provided in Table I for selected storage facility accidents. These accidents assume a generic 10,000 drum facility with site-specific waste composition.

Incineration facility accidents were analyzed for three cases under regionalization: treatment at five sites (ANL-E, Hanford, INEL, LANL, RFETS, and SRS), treatment at three sites (Hanford, INEL, and SRS), and treatment of RH waste at two sites (Hanford and ORNL); and one case under centralization: treatment at one site (WIPP). Representative estimated total releases for each accident and its frequency group are provided in Table IIa,b for selected incineration facility accidents. Detailed radionuclide release data for all accidents can be found in Mueller et al. (14).

These accidents assume the generic source term parameters discussed above, with facility inventories defined by the EM PEIS alternative.
Uncertainties in the inventories, source term parameters, and frequencies of accidents imply that absolute source terms are highly uncertain and should be used cautiously. In addition, the results presented here are based on the unit storage facility size or treatment throughput inventories. Nevertheless, with appropriate weighting by the ultimate inventories to be stored or treated at the various sites, these results allow the relative importance of accident source terms to be calculated with sufficient accuracy to provide a measure of comparison among the EM PEIS alternatives.

RADIOACTIVE WASTE MANAGEMENT IN LITHUANIA
Saulius Kutas
Ministry of Energy
ABSTRACT
Lithuania generates more than 80 per cent of power energy based on nuclear fuel. Nuclear fuel as well as the greater part of fossil fuels are imported. This shows that nuclear energy is a highly significant energy sector and the overall economy

branch in Lithuania. Two RBMK-1500 type reactors operate at the Ignalina Nuclear Power Plant. The first one was launched in 1983. Plenty of measures have been implemented and will be undertaken in future to increase reactors safety operation. A technical and financial assistance is rendered from the Western states, especially from Sweden, European Bank for Reconstruction and Development, IAEA, others. It is projected Ignalina Nuclear Power Plant to operate a designed life time. In Ignalina low enrichment uranium is used. Spent nuclear fuel is stored at water basins built at the vicinity of reactors. While designing this power plant it was considered to export spent nuclear fuel to a Russian reprocessing plant, however, no refineries were constructed thus causing spent nuclear fuel from Ignalina Nuclear Power Plant to remain at the site. At present basins are almost totally exhausted. The international tender had evaluated 8 companies proposals and the German company GNB was accepted to store spent nuclear fuel at metal containers within power plant's site. Currently these containers are underway of manufacturing, however, they are highly costly. It would be acceptable to use technology of concrete transportable containers or concrete module storage, which could enable to reduce costs for spent nuclear fuel management and to use local production and engineering potential.
Low radioactive waste is stored in two places in Lithuania, i.e. in the Ignalina Nuclear Power Plant and in a storage for non-energy radioactive waste.
Sufficient reservoirs are installed for low radioactive waste at the Ignalina Nuclear Power Plant where cementation and bituminization undergo. The non-energy waste storage was built more than 20 years ago and it should not be used any longer.
As well as elsewhere in the world, Lithuania has not solved yet a radioactive materials and first of all spent nuclear fuel final disposal issue. Obviously, this issue is a concern of every country, despite that trans-boundary aspects of this problem cannot be neglected.

ENERGY CHARACTERISTIC

Only 3 to 4 percent of Lithuanian primary energy resources in the energy balance is local, including hydroenergy, peat, fire-wood. Other energy resources as nuclear fuel, oil, gas are imported. If total power plants within Lithuania capacity is used, around 30 billion kWh of electricity can be produced, whereas 50 percent goes from the Ignalina Nuclear power Plant. However, due to 1991-1993 economical crisis impeded by industrial products decrease, primary energy resources, especially fossil fuel, drastical increase of prices, electricity export reduction to Russia and Byelorussia as a reason of economical disorder, electricity production in Lithuania decreased in 1993 by 14,1 TWh, including 12,3 TWh generated in the Ignalina Nuclear Plant. Thus, more than 80 per cent of power energy produced in Lithuania is based on nuclear fuel.
Unit 1 at Ignalina NPP was launched at the end of 1983. Today two RBMK-1500 type units are operating at the plant. These reactors have been designed and produced in the former Soviet Union. In chanal type reactors uranium of low enrichment is used as fuel, moderator - graphite.
Before Lithuania regained independence in 1990, regulations, standards and licensing procedures for nuclear facilities and activities were the same as valid elsewhere in the Soviet Union. The system was strongly centralized and local authorities were not consulted or even informed. This means that Lithuania after having declared its independence, has to face the task to built up a new national legal and regulatory system for radioactive waste management.
When Lithuania restored State power and independence, all operational issues at the nuclear plant had been transferred under the auspices of the Lithuanian State. Ignalina NPP itself became on operator, the State Atomic Energy Safety Ispectorate - VATESI was established, scientific institutions dealing with nuclear energy issues had been strengthened. Though earlier RBMK reactors safety operation was doubtful, the Chernobyl accident forced to review their safety issues.
Striving to improve units safety, at Ignalina NPP the total capacity was reduced to 2 500 MW, as well as other safety measures were accomplished. The construction of the Unit 3 was ceased regardless the used investment of approximately 80 per cent.
In the former Soviet Union nuclear power plants were very closed factories. After collapse the Soviet Union with western countries assistance studied the Ignalina NPP project in detail as well as its operational status, safety improvement possibilities. Programs for further safety improvement have been prepared. Assistance was provided by many European and American countries; a particularly great contribution allocated by the Government of Sweden should be mentioned.

Meanwhile 18 projects for safety improvement are underway, financed from the Nuclear Safety Account through EBRD, total grant sum of 33 ml. ECU. When these and other projects are completed, Ignalina NPP safety requirements will comply with Western standards in an acceptable level.
Following the Energy Strategy approved by the Government in 1994, it was anticipated that both Ignalina NPP units would operate the designed life time if measures for safety improvement were undertaken and the license received. It is not expedient to allocate huge investment seeking to prolong the designed retirement.

RADIOACTIVE WASTE MANAGEMENT

Ignalina NPP is the dominant generator of radioactive waste in Lithuania. A minor part of radioactive waste comes from nuclear applications in research, medicine and industry. The dominating part of the short-lived waste comes from the Ignalina NPP. During operation and maintenance the following types of low and intermediate level waste form: evaporation concentrates, ion - exchange resins and solid scrap and trash.
After evaporation the concentrate is temporary stored in tanks. From the storage tank the concentrate is transported to a bituminization facility. From there the solidified product is pumped to storage basins made of reinforced concrete. The inner surfaces of the concrete are covered with 4 mm thick steel plates. Average annual production of bituminized concentrate in the two reactors is of about 750 m. No arrangements for new basins are necessary.
Granual ion exchange resins with the inorganic filter aid Perlit are used for treatment of the reactor water. So far the resin Perlit mixture has been transported to a storage tank in a liquid form. No treatment measures have been taken except dewatering after sedimentation. As the sludges have been stored in the tank for several years without any agitation, a fairly thick layer of sediments with a very low viscosity has assembled on the bottom of the tank. No arrangements for emptying the tank are made, and special measures for making the sediment slurry transportable will have to be taken. The storage tank will be completely filled in the near future. Additional storage capacity is planned to be obtained by using one of the tanks adjusted for evaporation concentrates. This, however, is a provisional solution awaiting the installation of a solidification facility probably using cement as solidifying material. The procurement process of such a facility is presently in progress. The annual production is estimated to about 200m/year.
The solid waste generated at Ignalina NPP is divided into three groups according to surface dose-rate. Waste with dose-rate below 2.6 Sv/h is considered as non-radioactive. Presently the solid waste is dumped in reinforced concrete troughs with removable roofs. The design of the troughs are somewhat different depending on the type of waste to be dumped. There is no conditioning of the solid waste before dumping. The intention is to install a bale compactor in the near future and thereby reduce the volume of this kind of waste. The procurement process is in progress. The annual quantities of solid waste are about 1500 m3 and mostly of group I with low surface dose rate.
Radioactive waste generated after use of radionuclides in research, medicine and industry are subjects of radiological center of Health. Most of those, however are probably not generating any radioactive waste but using X - Ray equipment. On the medical side using radioisotopes for diagnostic purposes and for therapy are all the RMI waste generated up to 1989 is disposed in the repository for low and intermediate level waste at Maishiogala. The repository is disposed in a concrete vault, designed in the early 1960s. Repository in Maishiogala is absolutely filled. Since 1989 all RMI waste is collected by the Institute of Physics and transported to the Ignalina NPP and is stored in the vaults used for the waste from the power plant. During this time volume of solid waste transported to Ignalina NPP was 8m3.

SPENT NUCLEAR FUEL MANAGEMENT

The enrichment of the fuel is 2 per cent and the average burn-up is given 20.000 MWd per tonne. Spent fuel elements are stored in their full length in a water pool at the reactor unit for about one year. Then the elements are taken to a hot cell, where the central support rod as well as two end pieces are cut off. This leaves two fuel bundles and some metallic radioactive waste to be taken care of. The fuel bundles are placed in cages, each one of 102 bundles, which are taken to a pool for continued storage.
These pools at the moment are almost totally exhausted. Pursuant to the preliminary project it was anticipated to construct a centralized reprocessing plant in the

Soviet Union for spent fuel from RBMK type reactors, however, later this project was rejected and every plant individually had to solve a spent fuel storage and disposal issue. The project prepared by the Russian engineers on Ignalina NPP spent nuclear fuel wet storage technology was rejected. When 1993 international tender was announced, a Germany company GMB proposal was accepted for Ignalina NPP stock fuel stockpiling at the metal containers in the open site. This project is underway now. Each container can store 51 fuel bundles; these containers are transportable, they are safe and licensed in Europe. However, containers are expensive. Currently possibilities to reduce spent nuclear fuel management costs are under consideration. From that standpoint attractive proposals happen to be while placing fuel into the concrete transportable containers or module fixed concrete facilities. The basic prerequisite is that when the final disposal issue is solved for spent nuclear fuel, these filled containers could be taken out from the plant site without any complicated fuel bundles overloading to transportable containers procedures. A very similar technology is offered by Canadian AECL.

A plant, operating under present loading, needs approximately 1000 fuel bundles per year. Taking into consideration the previous yearly generation of 16 TWh of electricity and that designed life time is between 2004 and 2007, there will accumulate around 35-40 thousand fuel bundles of spent nuclear fuel. Many states, including Lithuania, have approved laws which ban to import radioactive waste. Economically it is not attractive to reprocess low enrichment spent nuclear fuel, thus it is hardly possible that in the nearest future in Lithuania or any other country it might be processed. Provisory appraisals showed that a direct nuclear fuel disposal from the economical point of view is more than two folds as efficient as its reprocessing.

DISPOSAL OF RADIOACTIVE WASTE IN LITHUANIA

The short-lived wastes will lose most of their radioactivity, the requirement on reliable demonstration of long-term good function and stability of the barrier system are much more demanding. Among other things this implies, that the host rock for a spent fuel must be selected with a higher degree of discrimination and, that the choice may by fairly limited. It also implies, that substantial efforts will be needed for characterization work and evaluation of possible disposal concepts. The geology of Lithuania is characterized by thick sedimentary rocks overlying a submerged crystalline basement. The bedrock surface is generally flat and covered by quaternary deposits consisting mainly of till and sand with a thickness between 10 and 300 m. The basement rock is dipping at depth of 200 m while the depth is more than 2000 m. The geological conditions in Lithuania seem to favor the choice of repository for the short-lived waste. As there is only one nuclear power station it is natural to try to find a suitable site for a repository at or in the vicinity of the Ignalina NPP site. The site investigations should include geological mapping including geomechanical and geohydrological properties, recording of the ground water level and its seasonal variations and geohydrochemical conditions. Repository for long term waste (spent fuel) will be needed after 30 or more years. On the other hand it is of interest to get an apprehension of feasibility and costs as soon as possible. Lithuania primarily works on a national solution but at the same time attentively follows up the possibilities for international solutions. Lithuania with its limited financial resources can not afford to build up a full competence of its own at the same extent as a bigger country with a solid economy. A large portion of the necessary knowledge and experience is today from various countries. Spent nuclear fuel disposal technical as well as legal problems shall be solved by every state, notwithstanding that in compliance with inter-governmental aspects of nuclear threat high level radioactive waste disposal should be treated as the world-wide objective in future. In the IAEA yearbook 1992 was mentioned "Interest is expected to grow regarding co-operation between countries having small nuclear programs in developing regional or international management facilities for high lever waste and spent fuel".

LEGISLATIVE BACKGROUND FOR RADIOACTIVE WASTE MANAGEMENT

Lithuania today does not have the accomplished legislative base which regulates nuclear use. However, Draft laws of the Republic of Lithuania: Energy Law, Nuclear Energy Law, Radiation Protection Law are under preparation. Some regulations are issued by the Government. In 1991 Lithuania accessed to the Nuclear Weapon non Proliferation Treaty, has co-ordinated the Safeguard Agreement with IAEA. Lithuania has accessed or is intending to access to international conventions and agreements:

Vienna Convention on Civil Liability for Nuclear Damage and Vienna and Paris Joint Protocol (1993), Convention on Physical Protection on Radioactive Material (1993). Convention on Early Notification (1994), etc. We signed or are going to sign bilateral agreements with Canada, Denmark, Norway, Poland, Russia, Byelorussia etc. Lithuania has to face the task to built up a new legal and regulatory system and requires consultative assistance while it implements the legislative establishment programs.
Implementation of a national program for the management of radioactive wastes requires a careful planning. A radioactive waste management program is not only a matter of solving technical issues, it must investigate and demonstrate to the decision-maker and the public how the demands on safety and radiation protection are to be satisfied both in a short and in a very long term perspective. The Lithuanian Ministry of Energy and Swedish Nuclear Fuel and Waste Management Co SKB signed an agreement on the preparation of an Overall Plan for Radioactive Waste Management in Lithuania. This Plan must be flexible and maintain a preparedness to modify the plan for best adaptation to current circumstances. To implement different projects have been and will be prepared tenders. With regard to radioactive waste management there should be made a clear distinction between the implementing party and the regulatory, supervising and licensing authority. The restrictive factor for an optimal and timely accomplishment of radioactive waste management a plan in Lithuania is to create such funds controlled by a national authority.
Experience of 1986-1991 anti-nuclear movement in Lithuania demonstrated that public opinion has big influence on the governmental decision-makers. The lack of understanding may seriously disturb the activities related to radioactive waste management. An open and consistent information to the public as well as comprehensive consultation with local organizations primarily concerned will therefore be an important issue in radioactive waste management program. The information should be open, reliable and consistent, should be given an early stage, initiated by the disseminator of information. Information must be passed to Seimas (parliament) political parties, local politicians and public organizations, the scientific community, teachers and young people at schools.
CONCLUSIONS
Intensive surveillance is undertaken in Lithuania and Ignalina NPP targeting to upgrade radioactive waste management.
There is prepared overall Plan for Radioactive Waste Management in Lithuania.
The key assumption for a successful solution of this issue is the national legislative background.
Seeking to achieve accurate radioactive waste management it is indispensable to study overall states experience within mentioned scope. Long term waste, especially spent nuclear fuel disposal is an inter-government issue, which requires co-ordination of appropriate activities.

THE DISPOSAL FACILITY MOCHOVCE - STATUS AND ISSUES
Peter Salzer
Nuclear Regulatory Authority of the Slovak Republic
Trnava
ABSTRACT
Low-level Radioactive Waste Repository in Mochovce was planned and constructed since end of seventies under unfavorable conditions: On-site storage after waste treatment during all plant operational time as the basic approach for waste management on power plants, no existence a quality assurance system applicable to the waste management, no legislative oriented specially to waste management, economical, social and political conditions. Nuclear Regulatory Authority of the Slovak Republic (NRA) has been requested for facility licensing to operation. Paper contains a description of repository various aspects: hydrogeology, seismicity, design and construction, acceptation of waste. NRA approach, IAEA Waste Management Assessment and Technical Review Program peer review team recommendations and their implementation to NRA requirements is discussed below.
BRIEF HISTORY
The initial strategy for nuclear power plants radioactive waste management in former Czechoslovak federation valid to the end of seventies envisaged for a storage of waste after treatment in inside basins and vaults for all living time of plants.

Decision for shut-down of NPP A-1 (HWGCR, 150 MWe) after accident in 1977 was the first motive, which induced a state to interesting in disposal of low-activity waste. A basic goal of activities was following: disposal of low-level waste from NPP A-1 and also operational waste from constructed and planned WWER (PWR, 440 MWe) power plants.
Selection of locality for disposal was done by state bodies for land planning from cca 30 alternatives. They decided for localize a repository close to Mochovce Nuclear Power Plant building site.
It is necessary to mention a political, economical and social climate of that time. Decision and information from nuclear energy area fell among extremely secret. All of activities were done under dictate of state and political administrative. Public had not any possibilities to express of opinion about nuclear programs. State was sole owner of all facilities, thus a competing business, which would have been an inherent guaranty of maximal work quality did not exist. A strategy of use of nuclear energy and radioactive waste management basically copied east model; any other alternative was not possible from political reasons.
The basic legislative existing within the given period which should have been met during siting were:
  Regulation of the Federal Ministry of Technical and Investment Development No. 85/1976 on detailed procedure for siting
  Edict of the Czechoslovak Atomic Energy Commission No. 4/1979 on general criteria of nuclear safety assurance in siting of nuclear power facilities.
On September 1, 1981, after having been assessed of Introductory Safety Report prepared by the repository designer (1), Czechoslovak Atomic Commission issued an approval with decision on siting. An underestimate of detailed hydrogeological investigation was a fundamental deficiency of this license procedure step. In next it has been an important source of problems.
The application for a construction license attached with Preliminary Safety Report was submitted to Czechoslovak Atomic Commission at 1984. The Czechoslovak Atomic Commission issued an approval with the construction license, but with many conditions. The final stage of complementary safety report was being prepared during the construction, which started at 1985 and finished at 1990. The disposal facility design assumpted a compacted clay layer as a fundamental engineering barrier and disposal of 200 l drums with bituminized waste into concrete vaults (2).
The quality assurance system underestimate besides existing political and economical relations caused recurring problems with quality during construction works.
During repository construction, several changes have been proposed and after having been approved also implemented. Some of them resulted from solving partial problems and impreciseness of the design, another were initiated during inspections of Czechoslovak Atomic Commission. Following changes were important:
  the change in technology of compacted clay sealing placement
  the changes in drainage systems
  the change in the technology of radwaste placement
  the change in control system.
When the works on Preoperational Safety Report (PSAR) started, the new Regulation No. 67/1987 (about safety assurance on radioactive waste management) had been already valid 3).
Detailed investigation of locality started during the PSAR preparation. The content of PSAR revised version based on above mentioned regulation, preceding discussions with Czechoslovak Atomic Commission representatives as well as American recommendation (4), was approved on November 1992. A fundamental change in disposal waste form was done approximately at the same time. Waste would be disposed in fibre-reinforced concrete containers (inner volume 3.1 m3). Waste conditioned into the containers will be produced in Bohunice conditioning centre; its operation has beginning at 1996-97.
Third version of PSAR was submitted to NRA in October 1993. This version contains the evaluation of detailed hydrogeological and seismological investigation. A` posteriori determination of waste acceptance criteria is the most important contribution of PSAR safety analyses.
DESCRIPTION OF REPOSITORY
Surface type low-level radioactive waste repository is built-up in northeast direction, approx. 1.5 km from nuclear power plant Mochovce (PWR, 4 x 440 MWe, under construction) - see Fig. 1.

Site Geology and Hydrogeology (5)

The Mochovce repository was built at the end part of the headwater area of nameless dextral affluent of the Telinsky stream, directly on the flood plane situated on both banks of the intermittent stream bed. The flood depression is filled with deluvial and flood loams (good or semi-permeable quarternal soils of the upper pleistocene). The loam thickness is somewhere between several decimeters and 4-6 m, in the repository southern part up to 10 m.

Brackish sediments from the earliest Miocene period, i.e. middle to upper Sarmat in the underlying Quaternary loams appear. Pelite and even aleuropelite layers (slightly consolidated in some places) are found between layers of silty and fine-grained sands. All the above rocks are primarily lenticular in shape.

The deeper underlying rock at the repository site and its surroundings is formed by volcanic andesite, agglomerated andesite and andesite tuff to tuffite. The andesite complex is analogous to farther places of occurrence of lower Sarmat origin.

In the Mochovce repository locality, permeable and impermeable layers (aquifers, aquitards and isolators) interchange in Sarmat sediments. There is often a smooth transition between these layers in the vertical direction and also sidewards. The layers dip generally coincides with the gradient and direction of stream bed. The conditions for appearance of partial hydrodynamic systems with groundwater free surface as well as artesian groundwater table arise. The only contact with the earth surface and surface or rainfall water occurs in places, where the aquifers comes out to the surface.

On the valley axis where the repository is situated, under Quaternary earths a fine and even silty sand layer with considerable areal spread and small thickness changes are found. This layer of permeable sands is identified as the main H aquifer. In the repository southern part under H aquifer another 2-3 aquifers are found without a stable stratigraphic level and with rapid pinching near at least some wells. The aquifer close under the H aquifer is identified as the P1 aquifer and the underlaying as the P2 aquifer. Both underlying aquifers (P1 and P2) merge southward and they form so called unified P1 + P2 aquifer.

It was found, that contingent groundwater contamination by leaching radioisotopes from the repository vaults might be spread only through the H aquifer. Contaminants in water solution would have to pass through unsaturated zone at first, its thickness is varying from 8 m (western part of vaults) to 4 m (eastern part). Infiltration through the unsaturated zones place is passed in vertical direction with minimum hydrodynamic dispersion.

After reaching a groundwater free surface the infiltrating contaminated water would mix with the uncontaminated water from the layer and they would flow together in the direction of maximum hydraulic gradient, thus causing hydrodynamic dispersion of contaminants. Groundwater from H aquifer is passing to the surface stream southern of the repository site.

Seismic Conditions and Geotechnical Characteristic

No tectonic fault has been proud to exist directly at the repository site. The nearest faults have been found west from the western repository border about 250 m in the S-N direction and parallel one about 600 m east from the eastern border. Recent movements have not been proud at these faults. In conclusion it can be assumed that the confined floe is compact and no faults are occurred under the repository within this floe.

The seismic risk estimated on the geological and seismological basis results the maximal intensity 6 - 6.5 oMSK-64 with return period once through 10 000 years and maximum developed peak ground acceleration is not overcrossing the value 0.06 g. A related risk of the sand liquefaction in the subsoil is not imminent. Risk resulting from soil properties in the subsoil and artificially installed sealing clay layers round the repository have not been proved. As conclusion of geotechnical studies and assessment of concrete structures of the repository including embankments it was follow that repository is safe and can guarantee a functional capabilities during waste disposal as well as after final coverage.

Design and Construction

The basic design of repository is a shown on Fig. 2 & Fig. 3. The structure of repository consists itself from 2 concrete double-rows with vaults. Each single row consist from 20 vaults with inner dimensions 17.4 x 5.4 x 5.5 m. The vaults in single row are grouped by 4 into dilatation units. Ninety fibre-reinforced containers can be situated to each vault, on three level.

The reinforced concrete skeleton, in this case, is not taken as barrier, which is able to prevent radionuclide release into environment. This function is fulfilled by the compacted clay sealing installed under repository (1 m thick) and on both sides (3.5 m thick). The clay bath layers were compacted to the Proctor Standard 96 % and hydraulic conductivity 10-9 ms-1.
The drainage system has been built to enable testing in case of an accident and radioactive material penetration into groundwater and subsequent radioactive waters collection. The drainage is divided into 2 systems:
"checking" drainage for drains collection and monitoring in drainage layer (space between concrete bottom of vaults and clay layer)
"observed" drainage has been installed with the aim to catch contingent infiltrating water from the space outside clay bath.

Acceptation of Waste

Limits and safety parameters of accepted waste were derived from various limiting requirements:
from performance assessment
from way of disposal
used waste form
design solutions
requirements from geotechnic stability evaluation
packaging of waste
recommendation of international and abroad bodies and operational experiences of similar type repositories
"classical" regulatory requirements (free liquids, content of phyrophoric, toxic materials, etc.)
meteorological conditions at the disposal operation
radiation protection.

Some of limits and safety important parameters are connected with operational procedures, some of them are the acceptance criteria of waste. Total activity and specific activity limits are the most important and discussed acceptance criteria formulated in PSAR.
They were computed by using of various radionuclide pathway scenarios. The general overview of calculations is shown in Table I.
The results of calculations in total acceptance activity, mean specific activity for single vault and maximum specific activity terms are shown in Table II. Because in Slovak Republic the institutional control period is not done in any regulatory requirements, the calculations had been done in two alternatives: 300 and/or 500 years. However, results are different only for Cs-137 and Sr-90.

WATRP MISSION

In December 1993 the NRA requested the International Atomic Energy Agency, Vienna, to review the Mochovce Radioactive Waste Disposal Facility within the IAEA's Waste Management and Technical Review Program (WATRP). A review meeting between international WATRP team and Slovak specialists was held at the Mochovce in May 1994. NRA obtained the official version of WATRP team report in December 1994 (6).
Some notable recommendations of WATRP team were:
a more integrated approach to safety of the disposal facility
a program should be instituted to ensure that there is a thorough identification, characterization and categorization of waste streams
the list of radionuclides considered in the safety analysis should be expanded
safety assessment for the operational phase of repository should be done
additional scenarios should be considered in the safety analysis
the maximum duration of the institutional control period which the applicant take credit for in the safety analysis should be determined by the regulatory body
a separate licensing process should be established for the disposal facility closure, on a basis of preclosure safety report
additional geotechnical tests should be made to ensure the reliability of the design assumptions
particular attention should be given to the design and construction of the various cap clay layer to ensure proper performance.

The summary number of recommendations (some of those are oriented also to the national waste management system) is 70.

NUCLEAR REGULATORY AUTHORITY STANDPOINT

The NRA standpoint to operator request for permission of operation based on the PSAR

reviewing, has been prepared at the last days. The WATRP Report recommendations and also recommendations of other Slovak specialists, who evaluated the separate chapters of PSAR, were generally adapted to the this standpoint.
NRA standpoint is divided to five parts:
- requirements concerning to repository stability
- requirements concerning to design and construction improvement
- requirements concerning to a safety analyses
- requirements for another revisions of PSAR
- quality assurance area.

In the first part NRA requires additional analysis of data to ensure of repository stability from geotechnical, seismic, erosion points of view. Principal requirements in second group are:
- drainage system improvement to obtain a possibility to drainage of individual vaults during the institutional control
- change in placement of waste containers and backfilling to obtain an extractability of containers.

In the safety analyses area NRA requires more systematic approach to selection of radionuclides, scenarios and pathways to the environment.
Requirements in fourth group are oriented to better and critical evaluation of all aspects of repository quality. The necessity of detailed procedure for waste control on disposal facility place and/or on producer part and analyses for extend of repository is also required.
Requirement for independency between producer of waste and disposal facility is principal in the last group of these.

CONCLUSION

Mochovce repository operation safety beginning has been evaluated as a basic condition for acceptation of nuclear activities by public. Overworking of PSAR and better ensure of disposal facility stability and safety is required. It is possible to assume that the first radioactive waste will be accepted to dispose at 1997.

RADIOACTIVE WASTES STORAGE IN ROMANIA

T. Burtic
G. Rotarescu
Institute for Physics and Nuclear Engineering
Bucharest, ROMANIA

ABSTRACT

The objective in wastes management in Romania is to ensure that there will no significant effects to man and environment from such wastes. In this paper storage and disposal for the long term of low and medium level radioactive wastes generated from diverse applications of nuclear material in industry, medicine and research in the repository from Baita-Bihor are described.

INTRODUCTION

The appearance and development of nuclear energetics together with the wide penetration of nuclear technologies and techniques in the economic and social life led to the on ever increased production of radioactive wastes.
These wastes are produced along the whole cycle of the nuclear fuel starting with the uranium extraction and ending with the used fuel reprocessing. An important problem is therefore to find the adequate methods to keep nuclear wastes away from

disturbing or affecting human activities. The most dangerous ones are the long lived radioisotopes.
The main purpose of nuclear wastes handling and processing is to protect the environment and the population by a continuous monitoring of the nuclear activities and their pollutants production.
Final deposit of radioactive wastes was subject of many papers and communications at international conferences in the field (1-5). A valid solution is far from being found, each case presenting its specificities.
The difficulty of the problem comes from the large amount of the actually produced nuclear wastes and from the large variety already applied solutions.
In order to protect the population and environment against nuclear radiation effects, in Romania has been prepared a repository in geological formations for long term storage of low and medium radioactive wastes.

SITE CHARACTERIZATION

The repository for the long term storage of low and medium level radioactive wastes has been sited in consideration of geological, hydrogeological, seismic, meteorological and mining studies at the premises of a currently extinct uranium mining enterprise Baita, Bihor county (6). The site is at 840 m above sea level and at geographical coordinates X=46020', Y=22023'.
Geologically, the site features crystalline rocks of high toughness, coming in bulky, compact formations that provide a solid ground and good vertical shielding. The rocky compound has a low porosity (<3%), good chemical homogeneity and impermeability and keeps these qualities over considerable horizontal and vertical spans.
The site is at about 8 km from the nearest community. Within its perimeter there is no shallow underground water and practically no risk of floods (8oo m height).
From the seismic standpoint, the zone's history is quite scarce in events. According to Romania's seismic map, the maximum expected intensity at the site would not exceed 6 (Mercalli).
The underground compound of the repository was sized for 20,000 standard containers, 200 l each. This would ensure a 30-year storage capacity for radioactive wastes originating from scientific research and nuclear techniques applications in industry, health care and biology (sources other than the nuclear plants).
The repository was committed in 1985. Proper approvals were secured at the time, from the institutions and bodies that had a legal say to this effect (the National Commission for Nuclear Activities Control-NCNAC, the Departments of Health and of the Environment, the Bihor County Authority and the Municipality of the local town-Nucet).
The geological environment and the mining opportunities technically approachable at the site would allow in principle an extension of the repository's capacity-if and when deemed appropriate-up to 150,000-200,000 standard containers.
In the year 1990 the repository at Baita-Bihor was inspected by an IAEA Expert Team under a WAMAP (Waste Management Advisory Programme) Mission in Romania. The Mission issued a favorable appraisal on the Repository's technical design and storage strategy implemented by the Operator-the Institute of Nuclear Physics and Engineering-INPE Bucharest. Recommendations were also made in regard to in situ tightening of the already deposited containers, geomembranes and upgrading of access routes.
It is of great importance to chose some optimal indigent sorts of natural ion changers that can be used as effective barriers against the migration of radionuclides deposited in natural geological formations. In this respect, the volcanic tuff and bentonites existent in a series of ore deposits from Romania were studied (7).
For the studied sorts of ion changers it turned out that, for the same working conditions (pH, mass to volume ratio, time of contact, etc.) the retention capacity has the following trend: 137Cs>60Co>51Cr>65Zn>131I>82Br with equilibration times ranging between 48 and 72 hours. An increase of the mass to volume ratio leads to a decrease of sorbtion-desorbtion processes. It was also observed that:

- the retention capacity of the studied ion changers is higher for cationic radionuclides (Zn2+, Cr3+, etc.) than for the anionic ones (Br-, I-),
- the higher the zeolites content in volcanic tuff and the sodium content in bentonites, the higher is the retention capacity of these indigent ion changers.

On the basis of these data, for the confinement of nuclear wastes were chosen the

volcanic tuff with 65% zeolites from Salaj region and bentonites with 90% sodium.

EFFECTS ON THE ENVIRONMENT

With the purpose of monitoring the radioactivity level in the protection zone of Baita-Bihor radioactive wastes repository, samples of soil, water and vegetation were prelevated and analyzed (8,9). The prelevation places and frequency were agreed with the local authority for environment protection.

The analysis of data gathered since the commissioning of the repository in 1985 shows that the radioactivity level is in limit of natural background determined before 1985 and that increases of radioactivity level due to the depositing activity were not observed in the zone of geological formation at Baita-Bihor.

The gamma spectra of the samples reveals the presence of U, Th and their descendants. Their presence is explained by the fact that the geological formations at Baita-Bihor were former uranium mine (10).

CONCLUSIONS

By realizing of this repository all the radioactive wastes coming from the nuclear units in Romania other than Cernavoda Nuclear Plant are collected and processed at the Radioactive Waste Treating Unit and finally deposited in the National Repository.

This measure leads to the diminishing of the risk of radioactive contamination in Romania due to technical and technological applications of nuclear energy in social and economical life.

The studies concerning the introduction in the technologic flux of radioactive wastes depositing of mineral absorbants that have the role of retaining possible uncontrolled migration of radionuclides from the deposited containers as well as for in situ consolidating of containers lead to the conclusion that using for this purpose bentonites and volcanic tuff has the benefit of diminishing the risk factors for the environment in the repository region in our particular case the geological formations at Baita-Bihor.

This fact was demonstrated also by the evolution of radioactivity level in the repository's surroundings as resulting from the analysis of soil, water and vegetation samples a long seven years of the mentioned repository.

Nuclear Waste Management Group
Bhabha Atomic Research Centre
Bombay-400 085, India.

ABSTRACT
In India, today, three types of Nuclear Reactors, i.e. research rectors with metallic fuel, power reactors with oxide fuel and a fast breeder test reactor with mixed carbide fuel, are in operation. Besides this, to attain self sufficiency, necessary facilities have also been established to cover all aspects of the nuclear fuel cycle including the back-end. Even though a wide spectrum of wastes are generated from these activities, and technics for their management have been developed, special attention was required on the design and development of immobilization process technology for the safe ultimate disposal of high level liquid wastes.
On the basis of indigenously developed matrices and processes, the first waste immobilization plant was constructed at Tarapur. This plant which is currently in operation, uses borosilicate glass as matrix in a pot melter for the immobilization of HL waste. A second plant at Trombay is in an advanced stage of completion wherein a calciner has been incorporated followed by a metallic melter. A third plant is under construction at Kalpakkam which not only incorporates some design changes based on feed back from operating plants but also has a modified process scheme using ceramic melter.
For the management of intermediate and low level liquid wastes, the process technology has already been successfully demonstrated and is in continuous use for over three decades now and has adequately met the regulatory requirements with respect to effluent discharges. The treatment techniques adopted include chemical precipitation, ion-exchange and evaporation.
Extensive research and development work is currently in hand on the development of various other matrices for the fixation of high level waste and for the separation of actinides from high level wastes. Result obtained in these studies are very encouraging. This paper deals in detail the processes and technologies adopted in the management of high and intermediate level radioactive wastes in India.

INTRODUCTION
In India, today, three types of nuclear reactors, i.e. research reactors with metallic fuel, power reactors with oxide fuel and a fast breeder test reactor with carbide fuel are in operation. Total installed capacity of nuclear power is about 2000 MWe. Besides reactors, to attain self sufficiency, necessary facilities have also been established to cover all aspects of nuclear fuel cycle including the back-end. Considerable expertise has been achieved in all these steps vis-a-vis uranium mining & milling, fuel fabrication, reactor technology, reprocessing technology etc. The success of nuclear technology lies in the safe management of various radioactive streams. Top priority has been accorded to waste management since the very inception of nuclear program. Annual waste generation rates from various stages of nuclear fuel cycle for generation of 1000 MWe are presented in Table I. The philosophy adopted for radioactive waste management has been to concentrate and contain as much radioactivity as possible and activity releases to environment are kept far below limits prescribed by regulatory bodies. Strategies adopted for management of high and intermediate level wastes are described in this paper.

MANAGEMENT OF HIGH LEVEL WASTE (HLW)
A three stage program has been devised for management of aqueous high level waste generated during reprocessing of spent fuel containing more than 99% of the radioactivity associated with entire nuclear fuel cycle. In the first stage the HLW is immobilized in inert solid matrices. A wide range of matrix formulations are developed to suit different waste characteristics, which include ceramics, titanates and vitreous (borosilicate) matrices. The borosilicate matrices selected for immobilization on industrial scale are presented in Table II. Some of the early HLW streams contain considerable amount of sulphates for which special lead borosilicate matrices have been developed.
Flowsheet adopted for first waste immobilization plant at Tarapur envisages concentration in thermosyphon evaporator by factor of two. The concentrated waste and inactive slurry containing glass formers are metered to an inconel process pot heated in a multizone induction furnace. Off gas clean up system consists of line cooler, condenser, wet scrubber, Ru adsorber, prefilter and HEPA filter.
It is well known that metallic melters have throughput limitations. The maximum energy consumption step in vitrification is evaporation. Hence, for the second immobilization plant being set up at Trombay, a modified flow sheet has been adopted

to isolate evaporation/calcination from glass melting. This is achieved by incorporation of a rotary calciner for HLW and dry frit feed system for inactive glass formers.
Operation/Design feed backs of Tarapur and Trombay plants were used while developing flowsheet for third immobilization plant to be set up at Kalpakkam. The simplified vitrification process flowsheet is presented in Fig. 1. In this plant joule heated ceramic melter will be employed in place of metallic melters.
A prototype ceramic melter being tested at Trombay is shown in Fig. 2. Indigeneously available fusecast AZS refractory has been employed as glass contact refractory. However for actual melter, crome bearing refractory will be employed.
For the first time acid recovery system has been planned with intention of reusing the decontaminated acid for reprocessing. This serves dual purpose of resource recycle and reduce waste generation. Unlike earlier plants, this plant has provision of treating in-house generated wastes and what goes out of the plant is within exempt limit for direct disposal.
In the second stage of HLW management, the vitrified high level waste is stored in stainless steel (SS 304L) canisters. Two such canisters after remote welding of caps are decontaminated and enclosed in secondary carbon steel overpack for storage in air cooled vault for interim period. A stack induced air cooled vault has been commissioned at Tarapur. Schematic of air cooled vault is shown in Fig. 3.
In the third stage, these high level waste canisters are planned to be disposed of in deep geological repositories. A conceptual design of such repository in deep granitic formation is shown in Fig. 4. Investigations for site selection and other thermomechanical, geohydrological, geochemical studies are going on.

MANAGEMENT OF LOW & INTERMEDIATE LEVEL WASTES (LLW & ILW)

For the management of low and intermediate level liquid wastes, the process technology has already been successfully demonstrated and is in continuous use for over three decades. Our earlier preferred matrix for fixation of intermediate level waste had been bitumen. Extensive R & D efforts have resulted in development of modified cement formulations with superior product characteristics. Cementation being simpler and safer process, future plants are being designed for fixation of intermediate level waste in modified cement matrices. As an alternate to cement matrix, a program is evolved for fixation in polymer matrices. A campaign had been undertaken in Tarapur, some time back wherein about million liters of low heat generating waste was immobilized in situ in polyester styrene matrix. Prior to immobilization, various treatments such as chemical precipitation, evaporation are imparted to reduce the volume of the ILW to be solidified.

RESEARCH AND DEVELOPMENT

Extensive R & D activities are also on hand with respect to long term durability of high level waste forms in view of the extended period of their isolation from biosphere. For vitrified waste products, temperature and radiation induced degradation are being evaluated by microstructural characterization. Alternate waste forms with improved long term durability such as synroc, ceramics are also being investigated.
Partitioning of actinides from HLW using newly developed solvents like CMPO is also under investigation as an alternate strategy. Studies on development of ion exchangers for selective removal of specific radionuclides like Cs137, Sr90 and Ru106 from liquid effluents are also being pursued.

CONCLUSION

Much of our future program on the treatment of waste will relate to high level and alpha bearing wastes. One of the problem areas to receive attention concerns the development of improved matrices for incorporation of high level waste, particularly in respect of long term stability of the solidified product, in the face of radiation and ageing. Another aspect of work to be undertaken in the field of radioactive waste management would be to develop techno-economically viable processes to deal with alpha bearing radionuclides present in the high level wastes; this work will assume greater significance in the near future when India's fast reactor program gets underway.
Our efforts in future will also be directed towards the demonstrations required, with field experimental data, to establish an adequate degree of confidence in deep geological disposal of vitrified products of high level wastes.
Our experience in managing low and intermediate level wastes has been good and it is expected that our present schemes of management of high level wastes will also be

a step forward in fulfilling our objectives.

RADIOACTIVE WASTES IN THE REPUBLIC OF KAZAKSTAN AND SOME PRINCIPLES OF ITS ISOLATION

Askar K. Dzhunusov
Ergali M. Bayadilov
Dostai T. Ramankulov
Atomic Energy Agency of the Republic of Kazakstan

ABSTRACT

Radioactive wastes (RW) in the Republic of Kazakstan are generated from the following sources:
- uranium mining and processing enterprises;
- raw material or wastes (from ore mining and processing enterprises) which are characterized by increased contents of natural radio nuclides
- locations of nuclear explosion tests;
- nuclear power plant and research reactors; and
- enterprises using sealed radioactive sources.

Enterprises of the Republic of Kazakstan have ability to store all RW located on its territory with safe isolation. After preliminary cooling, spent nuclear fuel is shipped to Russia for storage.
There are safety rules for handling RW, and now the legal system of regulations is being created. Safe storage of RW is provided by plant safety services, and will be supervised by national control bodies.
For the creation of a national system for RW disposal, three main approaches will be used. The experience of the uranium industry will be used and developed. Regional collection centers for RW of low and medium activity with shortlived radio nuclides (less than 30 years) will be created. Highly radioactive RW and RW with long lived radio nuclides (more than 30 years) will be stored in special storehouses until further decisions about their disposal are made.

INTRODUCTION

After the collapse of the USSR a sovereign state - the Republic of Kazakstan - was formed. This new state inherited on its territory portions of an economic complex which included processes which used radioactive materials. For disposal of radioactive wastes the complex included:
1) along with advanced systems of safety for handling RW , there are separate elements of a national system of collecting, transporting and disposal of RW;
2) there are rules for safe handling of RW and control of the execution of those rules, a legal base is being created and a state control system is being formed.
The project "Concept of RW disposal in the Republic of Kazakstan" and the laws of the Republic of Kazakstan "About handling with RW" are now being developed. Acceptance of these documents will be a legal base for the creation of a national management system with supervision in this area as well as creation of a national system of handling for RW. This article is written as a result of discussion of the mentioned documents.

RW SOURCES

The Republic of Kazakstan contains more than 230 millions of tons of radioactive wastes (RW) with an activity which exceeds 13 million Curies. They are characterized by origin:
- uranium mining and processing plants;
- ore mining and processing enterprises, raw material or wastes of which are characterized by increased contents of natural radio nuclides.
- locations of execution of nuclear explosions;
- nuclear power plant and research reactors;
- enterprises using sealed radioactive sources [1].

There are 529 declared locations of storage and disposal of RW on the territory of Republic. These locations include:
127 - in the uranium mining and processing plants;

76 - ore mining and processing enterprises;
16 - locations of nuclear explosions execution;
5 - in the nuclear facilities;
301 - in the plants involving sealed radioactive source production
According to the regulations of the territory of Kazakstan, all locations used for storage or disposal of RW should be registered and supervised.
CHARACTERISTICS OF SOURCES AND EXISTING FORMS OF RW ISOLATION
RW from uranium mining and processing plants
During prospecting, mining, and processing more than 219 million of tons of RW with activity more than 250 thousand Curie were created. RW from the uranium mining and processing industry have low activity levels, the most significant volume (93 % of the total RW volume) and are widespread on the territory of Kazakstan. Two storehouses were created in the plants of the uranium mining and processing industries for RW storage. They contain:
- rock wastes; and
- special surface storage of low level activity wastes (tail storages).

The project for tail storage does not provide for the construction of special engineering buildings. The isolation of the stored radionuclides is provided by choice of location (location with low level of ground waters), availability of waterproofing and anti erosive protection. The surface of the tail waste floor is covered by a layer of waterproof ground or special waterproofing cover. The surface of the tail waste is covered by road bitumen or other waterproofing. Above this surface, the tail store is covered by earth, the thickness is sufficient for protection from plant life root system penetration.
After the tails storage is filled and ready for reclamation, it should be made even, planed, and then covered by binding material (clay, etc.), a road bitumen layer, and a layer of clean earth (fill). Waste sites positioned far from populated places (not closer than 5 km) are not required to be made level.
At the present such forms of disposal are not unequivocally equated as the final form of safe disposal for RW. The locations of tail storages and recultivated waste are fenced in or are posted depending on the distances to populated areas and they remain under supervision. The supervising bodies impose restrictions on uses of these grounds.
RW from non uranium ore mining and processing enterprises
In Kazakstan, we have a series of deposits containing uranium. During mining assorted byproducts are extracted and often go to waste or tails. On some coal deposits, the top parts of the coal layer are accompanied by uranium radionuclides. This coal is not used as fuel and is subject to storage as RW. In the oil industry there are also present soils, equipment, and pipes which are polluted by natural radionuclides. The RW weight of this group is 1.57 million tons with an activity total of 519 Curie. These wastes (98 %) are formed by the oil trade. It stores them on specially allocated platforms under the supervision of the enterprises which produced them.
RW from nuclear explosions
The RW produced from nuclear explosions is estimated to be 12 million tons with an activity of 12,9 million Curie. Of this total, 6.5 million of tons is attributed to underground explosions. Wastes in cavities of explosions classified as medium activity and wastes on the earth's surface classified as low activity add to activities of 11.6 thousand Curie, they consist of less than 0.1 % of the RW activities of this group. Though the wastes of underground explosions are isolated in melted rocks, it now should not be unequivocally equated to their final safe disposal. It seems that the locations of nuclear tests will be restricted areas, supervised and investigated for a long time. RW from nuclear explosions are located within the limits of nuclear test site areas and are under the supervision of government agencies.
RW from nuclear power plant and research reactors
On the territory of the Republic of Kazakstan, we have one power nuclear plant of the BN-350 type in Aktau and four nuclear research reactors (three in Kurchatov and one in Almaty).
The weight of medium activity RW of this group is about 9 thousand tons with an activity of 26.6 thousand Curie. The weight of low activity RW is about 3 thousand tons with an activity of 50 Curie. The spent nuclear fuel departs for storage in Russia after preliminary cooling with subsequent reprocessing in Russia. RW from

regeneration of spent fuel will be returned in the Republic of Kazakstan. Besides that by 2005 occurrence of high active RW is expected as a result of scheduled decommission of power nuclear plant BN-350. All of these nuclear facilities are supplied with special storehouses for average and low activity RW. These storage facilities are surface concrete buildings with technological capacities for RW storage.

RW from enterprises using sealed source production

There are to 100 thousand assorted sealed sources in Kazakstan. Annually more than 10 thousand pieces go to disposal. For example in 1991, enterprises in Kazakstan have sent to disposal 11603 pieces of sealed sources with an activity of 1274 Curie. Surplus declarations on the first of January 1992 identified 11362 sealed sources with an activity of 32389 Curie.

According to regulations of the Republic of Kazakstan, enterprises do not have the right to store spent sealed sources and are obliged to declare locations of permanent disposal. Due to administrative reasons in 1992 the work on utilization of spent sealed sources were not executed according to schedule.

CONDITIONS OF NATIONAL SYSTEM OF COLLECTING, TRANSPORTATION AND DISPOSAL OF RW

In the former USSR there were specialized enterprises which worked with RW, nowadays they belong to Russia. The Republic of Kazakstan has not had regional points of disposal. Till 1992 the work was conducted by specialized enterprises of the Russian Federation. After the Russian Presidential Decree which prohibits disposal of non-Russian RW on the territory of Russia, disposal of Kazakstan's RW was stopped (mainly, work on disposal of spent sealed sources).

The special storehouse in Kurchatov is now ready for action for long-term storage of spent sealed sources from the enterprises of the Republic of Kazakstan (it will be the regional point of storage). The storehouse has surface concrete buildings with special technological capacities for storage of RW. It is suitable for low and medium activity RW, and has special chambers for transhipment and identification. It allows safe storage of all spent sealed sources from enterprises of the Republic for a long period of time (100 years).

Part of the work dealing with collecting and transportation of RW can be performed by special teams from various enterprises in Kazakstan. However, there are some needs, for example recharging of apparatuses in oncologic institutes, where sources with residual intensity to several thousands Curie. These needs will be addressed by personnel from Russia under contract to industries of Kazakstan.

MAINTENANCE OF SAFE HANDLING WITH RW

The main supervising bodies in the national system are:

1) Bodies of sanepidiomilogical control (BSC) at the Ministry of Health - these supervise the observance of rules and norms of radiation safety for the protection of life and health of population and staff.

2) Ministry of Ecology and Bioresources - this national body of management and control of the environment gives permission for RW disposal.

3) Atomic Energy Agency (AEA) - executes the supervision of nuclear safety and the licensing of all kinds of nuclear work, including work on handling with RW.

Safe handling of RW is provided by safety services of each enterprise. These services are obliged to guarantee the safety of staff at execution of work and completely exclude irradiation of the general population. Moreover, the enterprise executes tracking for radiation conditions of object and around it. For these purposes health physics devices are used which measure fields gamma-radiation. For supervision of the conditions of underground water, measurements are performed around the objects in drilled boreholes. The quality of this work is supervised by BSC, the Ministry of Ecology and Bioresources and the AEA pursuant to the authorities.

LEGAL BASE

There are nuclear and radiation safety rules and separate rules of handling for RW on the territory of the Republic. At the same time, the legislative base for the handling of RW is absent. Till acceptance of appropriate laws, activities proceed under the "Temporary regulation about use of nuclear energy, nuclear activity, handling with radioactive wastes and spent nuclear materials, maintenance of radiation safety of population of the Republic of Kazakstan". This temporary act was authorized on April 1994 by decree of Cabinet of Ministers of the Republic of Kazakstan.

At the present, a project of the law "About handling with radioactive wastes" has

also been created under temporary status. This project established priority of protection of person and environment and obligatory indemnification of damage caused by RW. The following principle is used -whoever made the pollution should pay restoration money. This project fixed procedures of control and established the creation of a new body of national management for the handling of RW. This provided for separate functions of state management and state supervision. This project requires the ecological examinations during the creation of disposal points of RW or at the creation of large waste producing enterprises. The state accounting of all RW of the Republic will be established, including final disposal. The current law provides for the refusal to process spent nuclear fuel.

APPROACHES TO CREATION OF THE NATIONAL SYSTEM OF RW ISOLATION

In the future the following groups of RW can be allocated:

1) RW from uranium and non uranium mining and processing plants;
2) RW of low and medium activities with shortliving radio nuclides (less than 30 years);
3) special class of RW with long living radio nuclides (more than 30 years) and high active RW.

For RW isolation of the first group we will rely on the experience of our uranium mining and processing industry. Earlier , we described the principles of storage and disposal of RW of this branch. Probably technologies of disposal of these wastes will be developed in the direction of optimum choice of material and thickness of bottom cover and surface cover and stabilization of surfaces. And the procedures of supervision and control will be amplified and extended. It is not decided yet how long land used for RW disposal of this group will be excluded for human activity. It is possible, that with development of novel technologies for RW disposal, additional measures of protection will be needed or on the contrary the total safety of these disposals will be recognized.

The creation of regional points of disposal on the territory of the Republic of Kazakstan is under discussion. These sites could meet requirements for the final disposal of RW of the second group. After RW disposal, these sites will be not used for human activity for approximately 300 years. The sites will be observed, and final disposal of RW of this group will not present significant danger. The creation of such waste storages requires in the design stage a combination of natural and engineering barriers capable to supply reliable isolation of radio nuclides during waste storage operation and its supervision after disposal. Till creation of regional waste storages, wastes of this group will be stored in RW special storehouses of enterprises. All spent sealed sources will be stored in a regional storehouse of spent sealed sources in Kurchatov.

The decisions about RW disposal of the third group of RW is not under discussion and planning at the present time. In the interim, they are in special storehouses. There is a task of designing safe storage for high active RW which will need resolution after 10-15 years.

There is a well known necessity for development of RW processing before disposal. Currently, hardening of liquid RW for disposal is prohibited. Technologies enabling facilities to lower the volumes of RW and the inclusion of radio nuclides in matrix for decrease of their mobility are of interest. There is no experience in these technologies in RW disposal in the Republic of Kazakstan yet.

CONCLUSION

The Republic of Kazakstan has conditions for the safe and secure storage of RW containing low and medium activity levels. The problem of utilization of spent sealed sources will be solved by entering into agreements about the operation of a regional storehouse of spent sealed sources in Kurchatov.

After 10-15 years a solution for high active RW will be needed. For now, no safe permanent storages are created.

The Republic does not have facilities for storage of spent nuclear fuel. After preliminary cooling it departs to Russia. The processing of spent nuclear fuel will be made by facilities in Russia. RW from processing will be returned to Kazakstan. Now the future development of power in the Republic of Kazakstan is under discussion. Hereinafter, an increase of nuclear technologies will appear to require independent storage of spent nuclear fuel and its processing. The project of the law of the Republic of Kazakstan "About handling with RW" provides the opportunity to refuse the reprocessing of spent nuclear fuel on a temporary basis. To discuss these problems is premature until other issues are resolved.

The development of disposal technologies is required for good safety practices. Appropriate modern requirements for the final disposal of RW will follow. The development of a scientific base which designs or introduces new disposal technologies for RW is necessary and a scientific evaluation of the safety of existing are required simultaneously. At the present time, the Republic of Kazakstan begins with control and documentation of all existing locations for the storage and disposal of RW.

ABSTRACT

One of the prominent environmental and safety issues facing the Hanford cleanup effort is the highly radioactive wastes stored in 177 underground tanks. Before waste retrieval and long-term isolation efforts can be initiated, safety issues, including the flammability and toxicity of tank-headspace vapors and gases, must be addressed. While other species can contribute to flammability and toxicity, this paper describes only the analysis of the organic vapors and permanent gases in the tanks. Gas and vapor concentrations exceeding allowed flammability and/or toxicity limits may potentially be caused by 1) evaporation of semivolatile organic wastes, 2) generation of organic vapors by radiolytic and chemical degradation of organic wastes, and 3) generation of inorganic gases and vapors, such as hydrogen and nitrous oxide, by the waste.

To support Hanford tank vapor characterization, Pacific Northwest Laboratory set up a dedicated laboratory to identify and quantify permanent gases and volatile organic compounds in tank headspaces. Whole air samples are collected in SUMMATM passivated stainless steel canisters using two described methods. The variety of polar and nonpolar organic compounds found in tank-headspace samples required that modifications be made to the U.S. Environmental Protection Agency compendium method TO-14. This modified TO-14 method is now routinely applied to the analysis of tank-headspace samples. Roughly 200 organic compounds and permanent gases have been identified and quantified in the tank-headspace samples analyzed to date. Some compounds found in tank headspaces, such as the semivol atile normal paraffin hydrocarbons and tributyl phosphate, were constituents of waste sent to the tanks. The majority of volatile compounds found in the tank headspaces, including the homologous series 3 to 10 carbon alkanes, alkenes, alcohols, aldehydes, ketones, and alkylnitriles, are thought to be chemical and/or radiolytic degradation products of the semivolatile normal paraffin hydrocarbons and tributyl phosphate. Nitrous oxide and hydrogen are typically the most abundant species found in SUMMATM canister analysis. Nitrated organic compounds have also been found at low concentrations.

INTRODUCTION

Bounded on two sides by the Columbia River, the Hanford Site covers 560 square miles of southeastern Washington State. Between 1944 and 1988, Hanford supplied weapons-grade plutonium to United States national security efforts. After five decades of service, the end of the Cold War brought the plutonium-production mission to a close, leaving a legacy of environmental problems.

One of the most prominent environmental and safety issues facing Hanford cleanup efforts is the highly radioactive wastes stored in underground tanks. About 60 million gallons of high-level waste and 260 million curies of radioactivity are stored in 177 tanks that hold between 55,000 and 1.1 million gallons each. The long-term strategy is to reduce the volume of tank wastes, remove organic constituents, and separate remaining wastes into low- and high-level components for permanent isolation.

Several safety issues of immediate concern must be addressed before waste retrieval and long-term isolation can begin. These issues include the potential flammability and toxicity of waste-generated hydrogen, nitrous oxide, and organic vapors in the tank headspaces. Tools to characterize these tanks are available, but are incomplete (1). We have evaluated available methods and chose to modify them from U.S. Environmental Protection Agency (EPA) TO-14 to meet the needs of this program.

Westinghouse Hanford Company (WHC) directs the Tank Characterization Program, which conducts the vapor sampling and contracts sample analysis. WHC is responsible for sampling-methods development and sample collection. Pacific Northwest Laboratory (PNL), Oak Ridge National Laboratory, Sandia National Laboratories, and Oregon Graduate Institute of Science and Technology have assisted the program in the past year by developing and applying analytical methods. In this effort, PNL set up a dedicated laboratory to identify and quantify permanent gases and volatile organic compounds in tank headspaces sampled with SUMMATM passivated stainless steel canisters (2). The goal of this laboratory is to provide timely identification and quantification of permanent gases and volatile organic compounds in tank headspaces.

While it would be desirable to use only established methods to analyze the tank gases and vapors, the broad range of analytes found in the tank headspaces precludes this. For example, U.S. Environmental Protection Agency (EPA) compendium method TO-14 was developed and validated to analyze 40 volatile organic compounds in ambient air (3). This method is based on the use of SUMMATM passivated stainless steel canisters to collect whole air samples. Samples are analyzed by using a NafionTM dryer to dewater the sample, followed by cryogenic preconcentration and gas chromatography/mass spectrometry (GC/MS) analysis. The following issues have limited the direct application of this method to the Hanford waste tanks headspace vapor analysis:

- the TO-14 method was originally designed for ambient and not source-level sample analysis;
- of the 40 compounds that have been validated by the TO-14 method, only a few have been found in the tanks sampled to date;
- the NafionTM dryer used for sample dewatering in the TO-14 method will also scavenge many of the polar oxygenated compounds known to be present in the tanks.

We have successfully applied new vapor-analysis methods for analyzing tank headspaces over the last year (4). This paper provides a review of the tank-headspace sampling and analysis methods developed under this program and a summary of data derived from the application of these methods to various Hanford waste tanks. Finally, the composition of headspace vapors is explained in terms of known liquid waste streams and radiolytic decomposition processes.

TANK-HEADSPACE SAMPLING

Two techniques are used at the Hanford site to collect vapor samples from the waste tanks. The first method, in situ sampling (ISS), is a relatively simple technique in which sorbent traps attached to plastic tubing are lowered into the tank headspace and a measured amount of headspace air is pulled through them. Permanent gas, organic gases, and volatile organic vapors samples are collected in SUMMATM passivated stainless steel canisters via open-ended teflon tubing from the same headspace location. The second method transports headspace air, gases, and vapors via heated tubing to a remote sampling manifold. The heated sampling probe inside the tank headspace, the transfer tubing, the sampling manifold, and all associated pressure, flow, and temperature monitoring instrumentation comprise the vapor sampling system (VSS). Huckaby et al. describe the application of both the ISS and VSS methods to resolve vapor issues with tank 241-C-103 at the Hanford Site (5)

In Situ Sampling System

The ISS system is a site-developed method used to collect tank-headspace vapors from high-level waste tanks. It consists of a weighted sampling head connected to unheated flexible tubes, rotometer flow meters, needle valves, and a vacuum pump. The sampling head, in which the sorbent traps and an open tube for the collection of

SUMMATM canisters reside, is lowered into the tank headspace, as depicted in Fig. 1. After the open tube has been well purged with tank air, the vacuum pump is isolated, and samples are collected into evacuated SUMMATM canisters at the surface. The ISS equipment is constructed from commercially available components and mounted on a 2-wheeled hand cart. The advantage of this system is its simplicity and cost, allowing several of these generally robust sampling systems to be operational at any one time.

Fig. 1. Illustration of Waste Tank Sampling Methods Showing the Mobile Vapor Sampling System (VSS) and the In Situ Sampling System (ISS). In the VSS, SUMMATM and sorbent tubes as well as mass flow controllers and vacuum pumps are located and/or controlled inside the tanks.

Vapor Sampling System

The VSS consists of a mobile laboratory, a hot-water-jacketed stainless steel probe that is inserted into the tank headspace, and heated transfer tubing that connects the mobile laboratory with the probe. Sample air is drawn from the tank headspace and through the transfer tubing and sampling manifold by an air pump. Air flow within the VSS is directed by electrically activated, pneumatically actuated valves. Instrumentation housed in the mobile laboratory provides system temperature monitoring and controlling, absolute and differential system pressure monitoring, mass flow metering and controlling, and hydrocarbon vapor monitoring. Mahon et al. describe the VSS, its performance, and its operation in detail (6).

A key feature of the VSS is its use of heated sample transfer tubing and a heated sampling manifold. Maintaining the system temperature at an electronically controlled, elevated temperature prevents vapor condensation and reduces vapor adsorption on surfaces exposed to sample air. Mahon et. al describe various tests and observations that indicate the VSS sample transfer efficiency is consistently high (6).

The VSS sampling manifold has two sampling stations for sample collection. One station is set up for collecting tank vapor samples using evacuated SUMMATM canisters. The second station is equipped for collecting vapor samples on a variety of sorbent traps. To prevent condensation and to minimize adsorption of vapors during SUMMATM canister sampling, the connection tubing between the sampling manifold and the canister itself, as well as the mechanical valve on the SUMMATM canister, are heated with electrical heat tape. Mass flow controllers are used to measure and control the sample flow rate for sorbent-trap sample collection. These are located downstream of the sorbent-trap station and downstream of in-line dryers that remove water vapor from the air before it is metered. The sorbent trap station allows collection of two samples simultaneously, and most samples are taken in pairs.

TANK-HEADSPACE ANALYSIS

The PNL Vapor Analysis Laboratory currently analyzes SUMMATM samples for permanent gases and volatile organic hydrocarbons. An additional method for the determination of total nonmethane organic compounds (NMOC) has been developed. The total NMOC method will be used in the future to screen samples and determine if additional speciation and quantification of the volatile organic constituents is necessary. Figure 2 provides the SUMMATM analysis scheme from sample media preparation through sample analysis.

Fig. 2. SUMMATM Analysis Scheme for Permanent Gases, Total NMOC, and Volatile/Semivolatile Organic Compounds.

Permanent Gas Analysis

Several permanent gases are quantified in tank samples. These include hydrogen, carbon monoxide, carbon dioxide, methane, and nitrous oxide. The analysis method, developed using a gas chromatograph-thermal conductivity detector instrument {Hewlett Packard (HP) 5890 series II GC-TCD} with gas sampling and column switching valves, is typically capable of detecting analyte gases to 80 ppmv. This instrument has been recently modified with the addition of a mass selective detector (HP 5972 MSD) that allows mass-spectral identification of analyte gases and reduces detection limits to about 10 ppmv for carbon monoxide, carbon dioxide, methane, and nitrous oxide. The hydrogen detection limit is reduced to about 40 ppmv. Gases are sampled directly from the SUMMATM canister using a syringe to withdraw a 5-mL aliquot. No preliminary sample preparation is necessary for this analysis. A 1-mL gas-sampling loop is subsequently filled from the syringe and injected directly into the GC-TCD. The individual gases are separated on a 25 m x 0.5 mm PoraPLOT Q coupled with a 5

MolSieve Plot column. A 10 m x 0.53 mm HP-1 is used as a blackflushed sample precolumn to eliminate potential interference and contamination from the volatile and semivolatile organic compounds also present in tank vapor samples.

Total Nonmethane Organic Compound Analysis

In addition to the permanent gas and speciated organic compound analysis methods, we have recently configured one of our cryogenic preconcentration systems to determine the total NMOC concentration in a tank-headspace vapor sample. The method is adapted from the EPA Compendium Method TO-12, (3) and was optimized for samples in which significant quantities of semivolatile organic compounds, such as normal paraffin hydrocarbons (NPH) are found. The use of total NMOC concentration data as a screening mechanism can substantially reduce the cost and complexity of laboratory analysis and reporting through eliminating the speciation and quantification stages used in our modified TO-14 analysis. This method employs an EnTech 7000 cryoconcentrator system coupled to an HP 5890 gas chromatograph equipped with a flame ionization detector. The cryoconcentrator is coupled with a 16 position SUMMATM canister autosampler for automated analysis. Canisters, transfer lines, and gas sampling valves are heated to 120C to ensure recovery of polar and semivolatile compounds. Compounds are quantified by using a multilevel calibration curve with a propane standard reference material from the National Institute for Standards and Technology (NIST) as recommended by EPA method TO-12.

Volatile/Semivolatile Organic Compound Analysis

The PNL Tank Headspace Analysis Laboratory uses methods derived from the EPA Compendium Method TO-14 (3). The TO-14 method was originally developed and validated by the EPA to analyze hazardous VOCs in SUMMATM-collected ambient air samples. The method has EPA approval for 40 organic compounds that have been successfully collected in pressurized canisters and subsequently quantified at the parts per billion by volume (ppbv) level. Several instrument and method modifications were required to apply this technique to Hanford waste tank-headspace analysis. These modifications have allowed us to overcome analytical problems associated with the high concentrations of semivolatile organic compounds typically found in tank vapor samples and allow us to analyze a large number of targeted polar constituents.

The PNL analysis method employs an EnTech 7000 cryoconcentrator and an HP 5890/5972 GC/MS system for tank-constituent speciation and quantification. Each preconcentration/analysis system is fitted with a 16-canister autosampler, allowing the system to operate overnight without intervention of the bench scientist. The autosamplers meter in analytical standards, internal standards, and samples, preflushing and purging sample lines and traps as required. During analysis, the SUMMATM canisters are heated to 120C in specially constructed heating mantles to ensure recovery of polar and semivolatile compounds. The cryogenic concentration/sample dewatering front end operates on the principal of a microscale purge-and-trap system. Using a cryogenically cooled glass bead trap, sequentially followed by a Tenax adsorbent trap, this technique successfully dewaters the sample while allowing relatively polar compounds such as ketones, alcohols, aldehydes, nitriles, and nitrates to be concentrated from the air volume and subsequently analyzed. All transfer lines and sample contact surfaces are heated to 120C and the SILCOSTEELTM (Restek Corp.) is treated to minimize sample sorption. After the preconcentration stage, the organic constituents are separated on a 60 m x 0.32 mm J and W DB-1 capillary column with a 3 m liquid-phase coating. Target analysis compounds include the 40 VOCs listed in the TO-14 method (3) and 15 additional compounds selected by a toxicology review panel as being representative of tank-related compounds. Standards are prepared by diluting certified gas standards and/or using a Kin-Tech permeation tube standard generation system.

Compounds detected in tank vapors that are not on the target analysis list are tentatively identified by standard GC/MS analysis. These are further quantified through comparison with the response factor of the nearest eluting internal standard. An experienced mass spectrometrist reviews the mass spectrum of the unknowns using conventional mass spectral interpretation techniques and visual/computer comparison with the NIST/EPA/NIH (65,000 spectra) and Wiley (120,000 spectra) mass spectral libraries. If an unknown cannot be tentatively identified by conventional 70 eV electron ionization GC/MS, chemical ionization is used to obtain additional molecular-weight information. In addition, the PNL Tank Safety and Characterization programs have a wide variety of analytical tools to further the identification process if more information is required. These include a GC/atomic

emission detector, a four-sector high-resolution mass spectrometer with numerous ionization and MS/MS capabilities, a Fourier transform infrared (FTIR), and a Laser-Raman FTIR.

Laboratory Data Integration

Analyzing SUMMATM samples for TO-14 list organic compounds, additional Hanford tank-headspace analytes, and permanent gases is a highly automated process. Using an HP-UX chemserver workstation has enhanced productivity and data quality in several ways. First, the use of Thru-Put System's Target3 and ReportWriter software permits a high throughput of complex data analysis, meeting contract laboratory program (CLP)-type reporting and quality assurance/quality control (QA/QC) requirements. Production control is maintained by evaluating calibrations and sample analysis immediately after the GC/MS data are available. Calibrated compound data are processed using software that was developed and validated for reporting TO-14 gas-analysis results. Final concentrations are based on the volumes analyzed, dilution factors used, and molecular weights of each of the target analytes. All calculations are made by the data system, minimizing transcriptions and the associated potential for transcription errors. Molecular weights for non-target compounds are taken directly from the NBS mass-spectral database and used in the final calculation of concentrations when expressed by volume. Calibrations are performed directly on-column, which permits direct evaluation of whether a sample analysis falls within the calibration range. Data are fully auditable from sample preparation and analysis to reporting. The system tabulates both target and non-target tentatively identified compound (TIC) data , eliminating the potential for errors due to compiling and transcribing multiple sample-results data. Data for TO-14, TO-12, and permanent-gas analysis are processed and archived in a consistent and systematic manner.

RESULTS AND DISCUSSION

The headspaces of over 30 tanks have been sampled in the past year with the two described methods. The advantages of the ISS method include 1) it is relatively simple, 2) it consists of low-cost hardware that can be moved quickly from site-to-site, and 3) transfer tubing wall adsorption of constituents is eliminated for sorbent trap samples. Sampling setup and tear-down time are relatively short. One disadvantage is that unheated sample lines are used to bring the sample from the tank dome up to the surface for collection into evacuated SUMMATM canisters. Depending on the difference between the tank-headspace temperature and the ambient temperature during sampling, cold trapping of higher molecular weight compounds can influence results. This is generally not as severe a problem during summer months, but it is a concern during the colder winter months. Another disadvantage is that in the currently used configuration, flow regulation and measurements are somewhat crude, and there is no automated data logging during sample collection. Current plans are to correct some of these deficiencies by adding field-stable mass-flow meters and flow totalizers.

The advantages of the VSS are that it provides high quality samples with tight control over hardware performance, sample manifold heating, sample-collection flow rates, and sample-collection time. Much of the sampling process can be automated and recorded through integrated process-control/data-logging technology. Potential cold trapping zones have been eliminated through carefully heating all areas of the sampling manifold and sample-transfer line. The system is less susceptible to outside temperature fluctuations as it is housed in a climate-controlled vehicle. It also permits the use of limited real-time analysis techniques. However, the sophistication of this system does lead to some disadvantages, such as relatively time consuming setup, tear down, and cleanup stages. Extended equilibration times are also required to ensure that all adsorptive surfaces are in equilibrium with the tank vapors, and thus, staff members must spend long hours manning the sampling stations. These sampling times are of special concern when staff are required to dress out in full sets of radiation-protection clothing.

The analysis methods described were applied to vapor samples collected from over 20 different tanks representing 4 different tank farms. The initial focus was to develop and apply the methods for the speciation of the organic constituents; we have recently added the permanent gas and total NMOC methods. Over 200 organic compounds and several permanent gases have been identified and quantified in the tank-headspace samples analyzed to date. While a complete evaluation of these results is outside the scope of this paper, we would like to summarize the results

from tanks analyzed. Table I presents a overview of the classes of compounds that have been identified and the observed concentration ranges.
The chemical composition of tank headspaces is directly related to both recent and historical usage. Tank farms contain groups of tanks that are regionally located in conjunction with various facilities associated with different stages of the plutonium production, extraction, and finishing processes. Tanks in a particular farm have similar histories and therefore often share similarities in the composition of stored wastes. This appears to be especially true in the cases where tanks are linked together through cascading overflows. Tank vapors are generally comprised of varying concentrations of a homologous series of alkanes, alkenes, alcohols, aldehydes, ketones, and alkylnitriles. We have observed that these series often extend from C3 to C10. It is possible that other homologues are also present but not observed under current procedures. Nitrated organic compounds are also found, but generally at sub parts per million by volume (ppmv) range. Nitrous oxide and hydrogen are consistently above ambient levels.
Compounds found in tank headspaces are present because they were constituents of waste from plutonium-extraction processes or because they are formed through the oxidative and reductive radiolytic decomposition of process materials (7,8). The concentration of many organic compounds, especially the n-alkanes, can range over 4 or more orders of magnitude when comparing one tank to another. This can be explained by differences in the degree of venting, the amount of radioactivity in tank wastes changing the rate of waste aging, and the presence or absence of floating organic liquid layers. The semivolatile NPHs, ranging from C11 to C15, are examples of common extraction-process parent materials. The NPHs were constituents of diluents used with tributyl phosphate (TBP) to extract plutonium from spent uranium fuel. DecalinTM, which is a mixture of decahydronaphthalene and substituted decahydronaphthalenes, was also used as a TBP diluent. Both NPH and DecalinTM, as well as many of their radiolytic decomposition products, have been found in several tanks. Butanol, the main volatile decomposition product of TBP under alkaline conditions, is usually also found at relatively high concentrations when present.
Our laboratory has successfully analyzed vapors from Hanford waste tanks. The approach described in this paper describes tools used to characterize these vapors. The methods used have allowed flammability and toxicity issues to be resolved. The data from these analyses have helped in classifying and evaluating the Hanford tanks. This is a small but significant step toward complete tank waste characterization. Vapor sampling and analysis have been relatively easy and inexpensive when compared to the sampling and analysis of liquid/solid waste samples from these tanks. This difference is largely due to the high radioactivity and complexity of the wastes.
The procedures followed in our laboratory are well suited to Hanford waste tank analysis. These waste tanks are typically warm (ambient to 100C) because of the radioactivity of the constituents. The warmth allows semivolatile components to become vaporized and available for release to the atmosphere. Thus, both volatile and semivolatile components can contribute to flammability and toxicity. Because many of the standard methods available for sampling and analyzing organic vapor components are tailored to volatile components, we have added appropriate modifications to include both semivolatile and polar compounds.

ABSTRACT
The conversion of an ultimate waste form into a stable, inert product is a beneficial operation, especially in the case of potentially toxic waste materials. One widely recognized approach today is vitrification, in which a glass or crystalline material is fabricated from a particular waste composition. This is a high-temperature process involving the use of selected additives - notably silica - to form a glass network. The waste is thus contained in a stable, inert and nontoxic material suitable for safe disposal; the process also generally results in a significant volume reduction that has a decisive effect on disposal costs.
The nuclear industry was a forerunner in this area. Research on containment of uranium fission products began in 1957, and has been extensively developed in France, where industrial vitrification facilities are now operating at Marcoule and La Hague. Glass is now a universally recognized containment medium.
Research is continuing in France, not only to enhance the quality of the matrix and increase production capacities, but also to extend the process to low and intermediate level radioactive waste produced in nuclear power plants. New melting equipment has been designed to implement a "cold crucible" melting technique, in which glass is heated by induction inside a cooler solidified layer of the same material. Recent work by SGN, an engineering subsidiary of the CEA and COGEMA, substantiates the technical and economic advantages of vitrifying this type of waste.

INTRODUCTION

Nuclear power today represents a significant fraction of the world's energy balance. It accounts for about 17% of the electricity generated worldwide, including 35% in the European Community and over 75% in France.
Nuclear power produces practically no gaseous wastes that would represent an environmental hazard, resulting in acid rain or affecting the climate. This does not mean that it produces no waste at all, however, but in fact it produces very little. Nuclear wastes are separated from fissionable material by fuel reprocessing, and may then be confined in a suitable containment matrix. In France, for example, 99% of the waste produced by a nuclear reactor consuming 35 tons of fuel each year can be contained in less than 4 m3 of glass, a stable, insoluble matrix. Fuel reprocessing and waste containment operations are performed in France in the UP2 and UP3 plants operated by COGEMA at La Hague, on the English Channel.

THE NUCLEAR WASTE PROBLEM

Most nuclear waste - the 99% mentioned above - are present in concentrated high-level solutions containing uranium fission products. The remaining 1% include low and intermediate-level liquid waste, ion exchange resins used for liquid decontamination, and incinerable waste.

Processes are now available to treat all types of waste. Fission product solutions are vitrified to form stable, compact and insoluble glass packages. Other conditioning processes are also used for lower-level waste, generally bituminization or cement encapsulation, although these processes involve a weight and volume penalty.

The Commissariat l'Energie Atomique (CEA), together with the Socit Gnrale pour les Techniques Nouvelles (SGN), is currently investigating new enhanced techniques, notably high-temperature processes: incineration combustible waste materials, followed by ash melting, for example, to achieve a significant volume reduction and improved containment quality; or melting of incombustible materials to obtain the most stable oxide form.

EXISTING TECHNIQUES

Vitrification

Vitrification produces a glass or vitrocrystalline material from a specific waste composition to obtain a stable, compact solid waste form that ensures radionuclide containment and mechanical strength, and meets applicable standards for handling, interim storage and final disposal. Since the first nuclear application in France in 1957, vitrification has been adopted world-wide for containment of high-level radioactive waste; today in France and other industrialized countries, the scope of this technique is being extended to other waste categories, including toxic industrial waste.

Vitrification is now implemented at industrial scale to solidify concentrated fission product solutions produced by reprocessing spent reactor fuel. A pressurized water reactor with an electric power rating of 1300 MW and a nominal burnup of 33,000 MWd.t-1 consumes 35 metric tons of fuel annually, producing 1200 kg of fission products in the form of concentrated nitric acid solutions containing precipitates. France and the United Kingdom are the only countries in the world where such solutions are now vitrified industrially. The plants operated by COGEMA at La Hague in France, and by BNFL at Sellafield in the UK both implement the French two-step continuous vitrification product to convert the feed solution into a stable material of significantly smaller volume.

The process has been widely discussed in the literature (1,2). A rotating kiln first evaporates the solution and calcines the dry residue; the calcinate is then heated to 1150C in an induction-heated metal melter together with glass frit and suitable additives to obtain a glass melt of the desired composition, which is cast at regular intervals into a metal canister. The calcining step also generates dust that is trapped and recycled in the process by a scrubbing column, making the process particularly clean and simplifying the off-gas treatment system (which includes simply a condenser, a nitrogen oxide absorption column and an absolute filter). All the process equipment is maintained under slight negative pressure.

By the end of 1994, the three French vitrification units had solidified over 4000 m3 of solutions in nearly 2000 metric tons of glass, filling more than 5000 canisters and isolating over 1.5 x 109 curies (Table I). Vitrification has thus largely proved its capacity to dispose of concentrated fission product solutions. In the near future, the process will probably also be applied to other types of low or intermediate-level waste.

Incineration

Another waste treatment and conditioning technique is incineration. Although currently implemented industrially to very limited extent in Europe and in the USA, it is increasingly seen as an advantageous alternative to encapsulation and other low-temperature conditioning processes.

The CEA has developed a process designed to incinerate highly contaminated combustible-bearing waste, i.e. containing large amounts of plutonium (3,4). This is a two-step process involving pyrolysis of previously ground waste material at 550C under argon to form pitch, which is then calcined into ashes at 900C in oxygen-enriched atmosphere. Both steps are carried out in resistance-heated rotating tubular kilns. A third step, which could be performed on-line, is vitrification of the ashes to reduce the waste volume ten-fold, by increasing the specific gravity of

the material from 0.25 (ashes) to 2.5 (vitrified waste form).
The off-gas treatment system naturally includes a preliminary afterburning step in a vast, resistance heated refractory chamber; the gas stream is then cooled, preferably by dilution in air, water quenching or in a simple heat exchanger, before filtration by bag filters or electrostatic filters specially designed for the low process flow rates, and finally by absolute filters. The off-gas treatment also comprises a dechlorination treatment and maintains the system under negative pressure.
The incineration process is suitable for highly -contaminated waste, which is generally produced in small quantities; the design capacity is therefore limited accordingly. A nonradioactive solid waste incineration research prototype (IRIS) has been operating for several years at Marcoule with a throughput of 4 kg.h-1. Two industrial facilities have already been planned: one, with a capacity of 7 kg.h-1, is nearing completion and is scheduled to begin operating in 1996 at the Valduc military site; the second, with the same capacity, should be commissioned after the turn of the century at Cadarache, where incinerable -bearing waste from all CEA facilities is consolidated for processing.
This incineration process could also be used for waste, and could be scaled up to handle several hundred kilograms of waste per hour with no serious difficulties. Compared with conventional burners, this process has a number of significant advantages for highly contaminated waste:

The very limited gas flow during pyrolysis, which releases only the gases generated, and during incineration in oxygen-enriched air, minimizes entrainment of radioactive particles in the off-gas stream: less than 1%, compared with 5% or more in conventional incineration processes. The total off-gas decontamination factor may therefore reach 1011!

The process is suitable for highly chlorinated waste. A typical feed stream contains 50% polyvinyl chloride; the chlorine is released during pyrolysis at 550C, a temperature at which its corrosive action is very limited.

The carbon content of the ashes can be minimized by adjusting the ash residence time in the incineration step: after 3 hours the residual carbon concentration in the final ashes is well below 1 wt%. As carbon is a chemical reducing agent, limiting the carbon content allows the use of oxidizing processes to recover plutonium from the ashes.

The modular process design allows the use of compact equipment items, and facilitates monitoring of plutonium retention, minimizing the criticality hazard.

INCINERATION AND COLD CRUCIBLE MELTING

For many years the CEA has been investigating the potential of induction heated cold crucible melters (CCM) for waste conditioning, and the processes developed are now reaching maturity, due in part to the experience acquired and to recent progress in electric power technology. The same technique is now being applied to glass melting in non-nuclear industries.
This is an ingenious and apparently simple technique, requiring only relatively simple equipment (Fig. 1). An electromagnetic field oscillating at high frequency within the glass is created in a sectorized water-cooled metal crucible. The electric currents induced in the molten glass dissipate considerable power by Joule effect. A solidified glass "skull" forms between the melt and the cold wall, protecting the crucible from damage by the molten glass. A layer of solidified material above the melt also lowers the surface temperature, and very effectively limits the release of volatile elements.
Several melters of this type have already been built, notably by the CEA, although they are only nonradioactive prototypes 50 to 60 cm in diameter with capacities of about 50 kg.h-1. The principal advantage of this type of melter, other than its extended service life due to the virtual absence of corrosion, is its ability to reach very high temperatures - well above 1500C if necessary. In this diameter range, the melters operate at a frequency of 200-300 kHz and routinely achieve 70% efficiency. They may be scaled up to larger dimensions and capacities with few problems, and mechanical stirring provisions would allow even higher capacities to be reached.
The CEA is currently investigating several approaches:

Permit operation of this type of melter in the existing La Hague vitrification facilities by nuclearizing the process equipment for use in hostile environments.

Scale up the current melter design to obtain higher capacities.

Adapt the process for application to other types of waste, such as low and intermediate-level radioactive solutions from reprocessing plants or nuclear power stations (6).

Adapt the process to vitrify fuel waste incineration residues immediately after the incineration phase, notably for ion exchange resins from nuclear power plants. If direct incorporation into molten glass proves feasible, this would allow waste processing and conditioning in a single operation, inside a single highly compact unit that is not subject to corrosion.

THE ECONOMICS OF LOW-LEVEL WASTE VITRIFICATION

Low-level waste vitrification can only be considered if the technology is cost-effective, i.e. if the overall waste treatment cost is no higher than with conventional concrete grouting or bituminization processes.

The improved containment integrity of glass is an undeniable advantage of vitrification. A containment matrix must meet the conditioned waste acceptability criteria specified for a final repository site; the enhanced quality of glass packages constitutes a qualitative advantage with regard to public acceptance or to more stringent regulatory requirements in the future, but it is impossible to quantify objectively and was therefore disregarded in this economic assessment.

Another hypothesis concerns the ultimate destination of the conditioned waste package, which should be compatible with near-surface disposal. This is a conservative hypothesis in that it limits the quantity of radionuclides incorporated in the glass, but it also allows comparison with conventional processes.

Finally, vitrification is applicable only if contact maintenance is feasible after source removal. This is the case for liquid waste containing up to about 108 Bq.l-1. The cold crucible itself requires no maintenance; relatively thin biological shielding around the melter allows direct maintenance operations on peripheral components.

Based on these considerations, the comparative cost of vitrification and of cement encapsulation was assessed, including not only treatment and conditioning costs (capital, operating and maintenance costs), but also transportation and final disposal costs. The study was conducted for concentrated borate solutions from VVER reactors in eastern Europe, for capacities ranging from 200 to 1200 m3 per year; high capacities requires a preconcentration step before the calciner/melter or the mixer. The main specifications taken into account are indicated in Table II.

The overall waste treatment cost is shown in Fig. 2 for the two extreme capacities considered in this assessment: a) 200 m3 and b) 1200 m3 per year, with the depreciation time plotted along the X-axis.

The depreciation period necessary to obtain identical costs for concrete encapsulation and vitrification range from 2 years for a capacity of 1200m3/year to 7 years for 200 m3/year. With low capacities, the cost difference remains relatively low for periods exceeding 7 years, while for higher capacities the differences becomes more significant after 2 years. Any increase in the disposal cost would constitute a further argument in favor of vitrification.

These findings were supplemented by a sensitivity study covering final disposal costs (+100%), the capital cost of the vitrification facility (+30%) and the cost evaluation basis (data corresponding to central and east European countries). The results did not change the preceding conclusions.

Economic assessments are still in progress, focusing on very low capacities. The vitrification process has been modified accordingly, notably including provisions for supplying waste directly to the cold crucible to vitrify incineration ashes, for example.

CONCLUSION

Nuclear waste disposal problems have been taken into account from the outset by the CEA, and research continues with the objective of ensuring waste treatment and containment under optimum technical and economic conditions. After developing and implementing high-level radioactive waste containment jointly with SGN at industrial scale in the reprocessing plants operated by COGEMA at Marcoule (UP1) and La Hague (UP2 and UP3), the CEA is now orienting its research effort toward increasingly effective and reliable processes that are also applicable to other waste forms which, although less radioactive, warrant enhanced conditioning as part of an optimized overall nuclear waste management strategy. The CEA, COGEMA and SGN are working together to mitigate the waste produced by an advanced nuclear industry.

ABSTRACT
The Island of Rhodes was the jewel of the Dodecanes Islands. It rivaled Athens in 300 B.C. The people of Rhodes built the Colossus of Rhodes in 283 B.C. The Colossus spanned the harbor entrance. It was 105 feet tall, a statue of the sun god Helios, the deity of the island. The statue stood for 56 years and was considered to be "The Seventh Wonder of the Ancient World." It collapsed during an earthquake and was sold for scrap and carted off by 980 camels, an ignominious ending for a wonder of the ancient world. The statue was built for approximately $2 million in 1993 dollars. Now how does this compare to the "Hanford Tank Remediation"? Hanford may not be the "Seventh Wonder of the World," but it is probably the most underrated "First Wonder of the Engineering World." The cost of remediating the tank farms is currently estimated at $53 billion in 1995 dollars. The Hanford site will have existed for 56 years when tank remediation starts, and was toppled by the Peace Initiative earthquake that changed the economics of the Tri-Cities area. If one extrapolated the cost of the Colossus to the cost of Hanford remediation in 2025 dollars, one could build the Colossus over the Straits of Gibraltar at its 8 mile width. Hanford could be considered a monument to the sun god, if one could relate the explosion of the first hydrogen bomb to the energy of the sun. The Hanford production site produced the resources to provide almost 20,000 suns.
The Hanford tank waste remediation project is probably the most underrated engineering marvel of the 21st century. It exceeds the engineering required for the Manhattan Project, the Nuclear Navy, the Polaris Missile Program, even the Mercury Space Program and placing a man on the moon. One can visualize 30 Trident submarines, the total fleet of nuclear carriers and their weapons systems, the total cost of the Suez and Panama canals, the Golden Gate, George Washington, Brooklyn and Straits of Mackinaw Bridges, the Channel under the English Channel. The amount of engineering at Hanford boggles the technical mind but is being treated as just another DOE project even though it exceeds the dollars and engineering of all the previous programs. In 1989, DOE signed a Tri-Party Agreement with the state of Washington, Region 10 EPA and DOE. The agreement originally required operation of a high-level waste vitrification plant to treat the high-level waste in 28 double-shell tanks by 1999. DOE recognized in 1990 that: 1) the higher risk

vulnerabilities were the 149 single shell tanks and 2) the ability to retrieve and process the waste had not been evaluated sufficiently to achieve these dates. After significant negotiation, the date for some form of vitrification has been revised to 2009 and a major effort is being devoted to waste retrieval technology and aqueous processing.

In April 1994, DOE initiated a "Call for Interest and Qualifications for Lead Organizations for the High Level Waste Tank Remediation Area." In this document, the DOE identified its objectives as stakeholder involvement, expediting regulatory constraints on technology, insuring DOE cross complex technology demonstrations, validating pretreatment technology needs, and immobilization as the key areas of concern by the interested parties. In response to the inquiry, a lead team was identified composed of the Hanford operations contractor, Pacific Northwest Laboratory and the Oak Ridge, Idaho Engineering Laboratory and the Savannah River Laboratory. As part of an "integration meeting", over 200 areas of "Need" were identified in the areas of: Waste Characterization and Analysis, Retrieval Technology, Waste Pretreatment, Waste Processing, Regulatory Uncertainties, Waste Stabilization, and Site Closure.

In conjunction with the seven major areas identified, more than 500 technology priorities were tabulated. The experience with DOE existing vitrification projects were major inputs into the 500 technology areas. The West Valley Demonstration project is presently four years behind its original vitrification schedule of vitrifying 600,000 gallons of commercial high-level waste. Also factored into the technology needs were 62 areas still to be resolved at Savannah River where the Defense Waste Processing Facility is 5 years behind its original schedule and a factor of 2-3 above original cost estimates to start vitrification.

Figure 1 displays the scope of the problem in the site technology problems

Safety

Characterization

Retrieval

Pretreatment

Immobilization

Stabilization & Closure

The figure is only a listing of the major technology initiatives. Thus, there are the 200 individual technology needs identified by Savannah River, West Valley, Oak Ridge, INEL and Hanford. When this is combined with over 500 serial, parallel and conflicting priorities, the initial scope of the challenge starts to be visualized. Once you realize that the cost of only the Hanford segment of this program is greater than $50 billion in 1995 dollars, the emotional and economic issues start to surface. In addition to the Hanford costs, Savannah River is estimated at $300+ million per year, West Valley is $120 million per year and INEL will require a $1 billion capital expenditure and $100 million per year operating expense at some period in the post 2003 time frame. The magnitude of the project becomes mind-boggling when one considers the diversity of managing contractors, the demands of the stakeholders, the regulatory overlap and conflicting scheduling demands, combined with the conflicting reinvention and decreasing budget availability.

DOE has identified a conceptual organization alignment shown in Figs. 2 and Fig. 3. The organization consists of a lead team, two interface steering groups, a management team, an implementation team and an economic development board. An ancient technology warrior once said "If you can't find the individual in charge, nobody is in charge." Figure 4 is the conceptual communications model which includes one committee, three teams, two groups, one council and three related management organizations.

Figure 5, "the decision making process" consists of one committee, three deputy assistant secretaries, two teams, one group, three headquarters program managers, and five site inputs. In Ref. 1, N. Nohria and James D. Berkley wrote an interesting article, "Whatever Happened to the Take Charge Manager?" (1). If one looks back on major projects of a similar nature-i.e., the Manhattan Project, the Nuclear Navy, the Polaris Missile programs--each program had a specific "take charge" manager in control and initially the programs were not as complex as the Hanford Tanks. General Groves, Admiral Rickover, and Admiral Rayburn were take charge types and the programs achieved their goals because of take charge focused decision making.

As seen in Fig. 1, there are enormous technology demands, hundreds of technology uncertainties, multi-year financial uncertainties, diverse interest groups and a

changing regulatory environment that is more politically driven then ecologically-health risk justified. In order to achieve decision closure, a key road map is needed that parallels the:
1. West Valley Program Schedule
2. Savannah River DWPF
3. Oak Ridge TRU Tank Program
4. INEL High Level Waste Program
5. Hanford Tank Focus Area
This road map needs to address West Valley as a bench scale initial research demonstration to identify problems and solutions to high level waste tank retrieval and small scale vitrification. Unknowns and needs for Savannah River, Oak Ridge and Hanford should be clearly identified for resolution in certain West Valley operations.
Next Hanford's needs and unknowns must be clearly identified in the Savannah River DWPF program. And the tank analysis, characterization and retrieval at Savannah River must clearly be part of a prototype project for Hanford technology resolution. The ORNL TRU tank retrieval program is a parallel extraction chemistry project that is directly applicable to Hanford TRU extraction and separation chemistry. Figure 2 illustrates the tank focus area proposed organizational interaction.
In Fig. 3, when one examines the diversity of unknowns that are interrelated, the multiple parallel programs communicating at Savannah River, West Valley, and INEL that will directly effect 2025 dollars of $200 billion, one understands the then the need for a more efficient decision making organization. It is clear that paramount to the success of the Hanford program is a simple chain of command. Although stakeholder participation appears to be a primary issue at Hanford, the need to address the total technical issue so that it can be presented to stakeholders, their constituents and their independent technical specialists in a credible way appears to be the initial feature to any successful dialogue. Even more important to a program that will require $200 billion dollars of potential expenditure is a leadership that will be recognized in Congress as technically, institutionally, and economically credible and one that would be accountable for such an expenditure of government and taxpayer resources.
Figure 4 was the illustration used in the Tank Focus Area Proposal on how decisions would be made by a committee, two teams, side bar management, a group and five sites.
Figure 5 identifies a simplified organization structure that meets the direct line of decision, responsibility and accountability that is considered to achieve an initial programmatic credibility requirement for early program direction and decision. The organization requires accountability at the top and responsibility for the implementation, and limits the responsibility of decision making to a limited number of individuals and organizations while still providing external review and support.
Figure 6 minimizes the circular decision process, provides input to EM-1 who Congress believes holds the responsibility for direction to the Hanford site manager and ultimately the program manager.
Congress will demand headquarters responsibility and continuity of management for a program with the potential of $200 billion expenditures. EM-50 will be the focus of continuity to Congress even though a field laboratory is providing technical research. Congress needs a headquarters technology guru who can convince them that the process will achieve the programmatic goals for the dollars expended. The state of Washington will look to the Hanford Operations Manager for regulatory and safety responsibility. All of the interested stakeholders, Congress, HQ, state of Washington, EPA, etc., will be looking to the Program Implementation Manager as the focal point of field accountability. Figure 6 reinforces the simplicity of the decision making process that will insure decision authority and responsibility. The DWPF, West Valley experience will help to convince Congress and the stakeholders that resolution of unknowns, the cost benefit, safety and regulatory decisions, and the warm feeling of someone being in charge will achieve success.
The lack of a single chain of responsibility inferred in Fig. 2 through Fig. 4 would cause Congress, the Defense Nuclear Safety Board and regulatory agencies to have significant qualms in continuity of direction and decision. Again, as Admiral Rickover would say, "If you can't point to the person in charge, no one is in charge."

The Hanford program needs to develop the following:
1. Program road maps with prime and alternative paths.
2. Technology availability and needs analysis.
3. Priorities of needs and availability.
4. Research flow diagram and technology availability.
5. Scheduled compatibility analysis.
6. Uncertainty analysis on meeting technology, research, scheduling and economics.
These areas must be fully integrated with West Valley, Savannah River, Oak Ridge, INEL and Hanford to insure that the projects are visible and clearly under control of the Department of Energy.
The Hanford project is greater, far greater, than Gibraltar, the colossus of Rhodes and the Pyramids, and needs to be recognized as such in the engineering and science communities to achieve success. There are no $200 billion 2025 dollar projects in either the private sector or the federal sector that approach the complexity of the Hanford Tank Focus Area, and the support of Congress and stakeholders will only be achieved through credible, visible leadership, expeditious decision communication and financial control and schedular success that can only be achieved through performance by take-charge leadership.

ABSTRACT
The U.S. Department of Energy's Hanford Site, located in southeastern Washington State, contains the largest amount and the most diverse collection of highly radioactive waste in the United States. High-level radioactive waste has been stored at the Hanford Site in large, underground tanks since 1944. Approximately 217,000 m3 (57 Mgal) of caustic liquids, slurries, saltcakes, and sludges have accumulated in 177 tanks. In addition, significant amounts of 90Sr and 137Cs were removed from the tank waste, converted to salts, doubly encapsulated in metal containers, and stored in water basins.
The Tank Waste Remediation System Program was established by the U.S. Department of Energy in 1991 to safely manage and immobilize these wastes in anticipation of permanent disposal of the high-level waste fraction in a geologic repository. Since 1991, significant progress has been made in resolving waste tank safety issues, upgrading Tank Farm facilities and operations, and developing a new strategy for retrieving, treating, and immobilizing the waste for disposal.
INTRODUCTION
The U.S. Department of Energy's (DOE) Hanford Site, located in southeastern Washington State, contains the largest amount and the most diverse collection of highly radioactive waste in the United States. The Tank Waste Remediation System (TWRS) program was established in 1991 to safely store, treat, and dispose of those wastes. This paper provides an update on the progress of the TWRS program.
BACKGROUND
High-level radioactive waste (HLW) has been stored at the Hanford Site in large underground storage tanks since 1944. Approximately 217,000 m3 (57 Mgal) of waste have accumulated in 177 tanks. These caustic wastes consist of different chemicals, including liquids, slurries, saltcakes, and sludges.
The radioactive waste stored in these tanks came from different sources, including: 1) three plutonium and uranium recovery processes from approximately 100,000 metric tons uranium (Mtu) of irradiated fuel; 2) three radionuclide recovery processes from waste; and 3) miscellaneous sources (e.g., laboratories and reactor decontamination solutions). These wastes were then concentrated and mixed in order to minimize the

number of storage tanks required. The neutralized wastes include sodium nitrate/nitrite, sodium hydroxide, sodium aluminate, sodium phosphate, the hydrous oxides of iron, chrome, and other transition metals, large amounts of organics, and approximately 250 MCi of radionuclides.

The wastes are stored in 149 single-shell tanks (SSTs) and 28 double-shell tanks (DSTs). The SSTs are made of reinforced concrete with a carbon-steel liner and can hold 208 m3 (55,000 gal) to 3,800 m3 (1 Mgal) of radioactive waste. The DSTs consist of a carbon steel tank within a steel-lined concrete tank, and have a nominal capacity of 3,800 m3 (1 Mgal), as shown in Fig. 1. Of the SSTs, 67 have leaked or are suspected to have leaked a total of approximately 3,800 m3 (1 Mgal).

No waste has been added to the SSTs since 1980. The pumpable liquids are being removed from the SSTs and are being sent to DSTs, so that the remaining waste is mostly sludge and saltcake. There is no evidence to suggest that any of the DSTs have leaked.

In addition to the waste stored in the tanks, significant amounts of 90Sr and 137Cs were removed from the tank waste, converted to salts, doubly encapsulated in metal containers, and stored in water basins. There are approximately 1,900 6.7-cm (2.6-in.)-diameter x 52-cm (20.5-in.)-long capsules containing approximately 160 MCi total.

TWRS PROGRAM DESCRIPTION AND STATUS

The Tank Waste Remediation System's mission is "to store, treat, and immobilize highly radioactive Hanford Site waste in an environmentally sound, safe, and cost-effective manner." Systems Engineering techniques are being applied to TWRS to establish functions and requirements, to identify all its relationships to other programs, and to evaluate alternatives for accomplishing the TWRS mission. This systematic, disciplined, and documented approach is an effective way to manage this large, complex Hanford Site waste management program, which will require many years to complete.

A technical strategy for storing, treating and disposing of the tank waste has been developed, and the strategy has been agreed upon through extensive interaction with the public, other public interest groups, and regulatory agencies. This strategy is shown in Fig. 2 and described in the following sections.

TANK FARM OPERATIONS

Newly generated wastes continue to be received in the double-shell waste tanks, and approximately 4 million gallons of liquid waste are yet to be pumped from the SSTs to the DSTs to reduce the risks of leaks. Continuous surveillance and monitoring of the 177 underground tanks is necessary to ensure the waste is safely stored. Significant progress has been made in the past year on improving tank farm operations to increase safety and cost effectiveness.

Safety statistics have improved in all categories, as shown in Fig. 3. The number of lost and restricted work case injuries decreased by more than 60% and the total number of days lost was reduced by 75%. During this same time period, the maintenance productivity increased 50% and the backlog of corrective maintenance work was at an all-time low.

The 242-A Evaporator was restarted, and recovered more than 19,000 m3 (5 Mgal) of DST space during two processing campaigns. The lessons learned and implemented from Campaign 94-1 made Campaign 94-2 even more successful. No safety incidents or personnel contaminations occurred during Campaign 94-2, and only one administrative-based occurrence report was issued. The Campaign 94-2 maintenance outage was completed 30% faster than scheduled, production targets were exceeded, and the overall campaign was completed well ahead of schedule.

The SST pumping program, for the first time since the early 1980's, was actively removing liquid waste from 6 SSTs at one time. More than 760 m3 (200 Kgal) of waste was transferred to DSTs during the year. This included pumping two tanks that were "assumed leakers."

The plan is to continue improving tank farm operations to increase productivity and keep the workplace safe.

TANK FARM UPGRADES

Many of the Hanford Site facilities and much of the equipment at the tank farms are 40 to 50 years old and have not been well maintained. Upgrading the tank farms is a high priority, because the tank farms will continue to provide interim waste storage for many years until disposal of the waste can be achieved. Upgrades include: new

safety analyses; replacing old instrumentation, equipment, and ventilation systems; constructing new waste transfer lines; removing obsolete contaminated equipment; and removing contaminated soil.

SAFETY ISSUE RESOLUTION

The highest TWRS program priority is resolution of waste tank safety issues. The safety issues of primary importance are summarized below.

Flammable gas concentrations in 25 tanks (SSTs and DSTs). The flammable gas tanks safety issue involves the potential release of flammable gases in concentrations above the lower flammability limit. The worst tank, 101-SY, has been successfully mitigated with a mixing pump. The pump is operated up to three times a week to mix the waste and release gas.

Hydrogen monitors are being installed on all 25 flammable gas tanks. A better understanding of the physical properties of the tanks will be gained using a retained gas sampler, a viscometer, and void fraction devices. The void fraction test instrument has been successfully demonstrated in tank 101-SY. This monitoring data will be used, along with knowledge acquired during the process, to determine if any tanks other than 101-SY require active mitigation for safe storage. Documentation to close the 101-SY Unreviewed Safety Question was submitted in 1994.

Potentially explosive mixtures of sodium nickel ferrocyanide and sodium nitrate and nitrite in 18 tanks. In certain concentrations, these chemicals are known to react exothermally at high temperatures. Extensive testing of waste samples and simulants, along with temperature measurements and modelling, suggests that these wastes are safe and can continue to be safely stored for many years. Six of the original Ferrocyanide Watch List tanks have been removed from the Watch List based on records that showed no ferrocyanide had been added to these tanks. (Watch List tanks are those that the Secretary of the DOE reports on to Congress because of potential safety concerns.) The understanding and evaluation of this safety issue have progressed to the point that the Ferrocyanide Unreviewed Safety Question was closed in 1994.

The potential for exothermic nitrate-nitrite organic chemical reactions in SSTs. The organic tanks safety issue involves the potential for uncontrolled exothermic reactions of organic chemicals and nitrates/nitrites and for vapors from semi-volatile organics entrained in waste to exceed the flammability limits (4). Recent laboratory tests showed that fuel concentrations and temperatures required to support propagating exothermic reactions are comparable to those for ferrocyanide. Ten tanks that received organic complexants were added to the Organic Tanks Watch List following a review of sampling data and waste transfer records (5,2). Vapor sampling and safety analyses were completed and formed the basis for closing the Unreviewed Safety Question concerning flammability of the floating organic layer in tank 103-C (3).

Mitigation of worker safety concerns resulting from the random release of fugitive noxious vapors from passively ventilated SSTs. These vapors have a strong odor and, on occasion, have made some workers ill. A health and safety plan that includes appropriate sampling/respiratory requirements has been implemented.

High-heat load in SST 241-C-106 requiring periodic addition of water to provide evaporative cooling. Because many of the SSTs have leaked, attempts are underway to remove as much liquid from them as possible. Currently, the liquid cannot be removed from tank 241-C-106 because the tank would overheat, potentially damaging its structural integrity. Therefore, plans are underway to remove the waste from this tank, and a project has begun to provide the facilities and equipment to start sluicing the waste from this tank in 1996.

WASTE CHARACTERIZATION

Waste characterization data must meet the needs of safety, waste treatment, and disposal program elements. The waste core sampling equipment is being improved and additional systems have been placed in service. Additional analytical laboratory hot cells are under construction, faster and more accurate analytical methods and instruments are being developed, and the laboratory data management system is being upgraded. In response to Defense Nuclear Facility Safety Board Recommendation 93-5, waste sampling and characterization for safety issue identification and resolution will be accelerated. This acceleration includes screening all single-shell tanks over the next three years to determine if any other tanks have safety concerns that may require resolution.

WASTE RETRIEVAL

Waste will be retrieved from all the tanks for treatment, immobilization, and disposal; the waste in some safety issue tanks may be retrieved in order to resolve the safety issues. Hydraulic sluicing has been the method used to retrieve waste from underground radioactive waste tanks at the Hanford Site and elsewhere. While sluicing is the preferred method of waste retrieval, it may not be acceptable in single-shell tanks that leak, and it may not remove some of the hard sludges. A robotic, long-reach arm with an assortment of tools is being developed to solve these problems. Design of the first SST sluicing system (for tank 241-C-106) is in progress. Subsurface containment barriers, which could be installed around and beneath the leaking tanks, are also being considered.

WASTE PRETREATMENT

The waste retrieved from the tanks will be separated into two fractions so that most of the radionuclides, and only a small part of the waste volume, are in the HLW fraction. The HLW will be vitrified and shipped offsite for disposal in a geologic repository. The bulk of the chemicals, and only a small amount of radionuclides, would be in the low-level waste stream that will be vitrified and disposed of near the surface onsite. The strategy is to use proven separations technology, to the fullest extent possible. More advanced separations technologies will be developed, but will only be implemented if needed to achieve the required level of radionuclide removal or an acceptably small volume of HLW. The pretreatment processes will include:

Solid-liquid separation, and sludge washing and leaching, with the soluble liquid fraction destined to be the low-level waste stream. A sludge settling test in tank 241-AZ-101 was initiated.

Radionuclide removal from the soluble liquid fraction to assure the waste can be categorized as low-level waste. Ion exchange processes are planned to remove 137Cs and possibly 90Sr, which will be routed to the HLW stream. Removal processes for long-lived mobile radionuclides (e.g., 99Tc) will be developed as a contingency.

Enhanced sludge washing, leaching, and blending to minimize the amount of high-level waste.

Technology development for selective sludge dissolution and advanced radionuclides separation processes, continued as a contingency. These technologies may be needed if the amount of vitrified HLW to be produced is not acceptable to the repository or if there is an economic reason to reduce the amount of glass.

Organic destruction process development, continued as a contingency for resolution of waste tank safety issues or, if needed, to achieve radionuclide separation.

LOW-LEVEL WASTE IMMOBILIZATION

The low-level waste will be vitrified and disposed of onsite near the surface, in a retrievable form. The existing grout immobilization process and the disposal system will be maintained as a contingency for freeing up DST space if required. The low-level waste vitrification facility will have a capacity of approximately 100 tons of glass per day. Standard glass industry melter technology may be adapted for this application, and the radiation level of the waste stream should be low enough to allow minimal shielding. Some melter tests have been conducted, and an aggressive program of waste form development and vendor melter tests must be carried out to meet the Tri-Party Agreement (1). Neither the final vitrified waste form (large monoliths or small pieces) nor the disposal container have been selected.

HIGH-LEVEL WASTE VITRIFICATION

Vitrification as borosilicate glass is generally accepted as the method that will be used to immobilize high-level waste. The TWRS strategy is to provide a high-level vitrification capacity that will be able to vitrify all of the high-level waste in 20 years. This will require a melter capacity of approximately 15 tons per day. A high-capacity melter development program is being conducted. A stirred melter and a high-temperature melter are being acquired for testing. The number and size of melters that will be installed in the HLW vitrification facility will depend upon the results of the development program.

The waste container capacity and configuration will be optimized considering such factors as the vitrification plant, interim storage, and the geologic repository. This may include a larger HLW "package" (e.g., 10-m3 container) to reduce the cost of disposal at the repository.

INTERIM HLW STORAGE

HLW containers will require onsite storage for many years until a geologic repository is ready to accept them.

137Cs AND 90Sr CAPSULES

The 137Cs and 90Sr capsules will be stored until they can be packaged and shipped to the geologic repository for disposal. Overpacking multiple capsules in a canister is the reference plan. If the overpacked capsules do not meet repository acceptance criteria, the 137Cs and 90Sr capsules will have to be processed and vitrified with other HLW.

SCHEDULE

The schedule for carrying out the TWRS program includes: 1) completing retrieval of all SST waste by 2018; 2) closing all SST farms by 2024; and 3) completing all waste vitrification by 2028. The major milestones embodied in a recently approved amendment to the Tri-Party Agreement (1) are listed in Table I.

CONCLUSION

The Hanford Site TWRS program is a large, complex program that will require many years to complete. Acquiring the funding and stakeholder commitment to conduct this program will require a national consensus that this work is necessary and is being done in a cost-effective manner. In order to significantly decrease the budget requirements, an ongoing process is in place for review of options from single processing lines to commercialization. Privatization of selected processing units could reduce the funding needs even more. We must continue to review each option's level of risk while achieving the program objectives with significantly fewer dollars. It is imperative to work safely, protect the public, seek the best technology, and use national expertise in planning and conducting the TWRS program. The DOE is committed to an open, responsive policy and encourages public participation in Hanford Site cleanup discussions. The Hanford Site has been selected as a place to test the Clinton administration's thrust to "reinvent government." This designation is particularly appropriate because cleaning up the Hanford Site is estimated to cost tens of billions of dollars.

ABSTRACT

This paper summarizes recent progress toward resolving Hanford Site high-level radioactive waste tank safety issues, including modeling and analyses, laboratory experiments, monitoring upgrades, mitigation equipment, and developing a strategy to screen tanks for safety issues.

BACKGROUND

Interim storage of alkaline, high-level radioactive waste, from two generations of spent fuel reprocessing and waste management activities, has resulted in the accumulation of 216 million liters (57 million gallons) of waste in Hanford Site single- and double-shell tanks. Before the 1990's, the stored waste was believed to be: 1) chemically unreactive under its existing storage conditions and plausible accident scenarios; and 2) chemically stable. This paradigm was proven incorrect when detailed evaluation of tank contents and behavior revealed a number of safety issues and that the waste was generating flammable and noxious gases.

In 1990, the Waste Tank Safety Program was formed to focus on identifying safety issues and resolving the ferrocyanide, flammable gas, organic, high heat, noxious vapor, and criticality issues. The tanks of concern were placed on Watch Lists by safety issue.

To ensure continued safety until needed data were collected and interpreted, the tanks associated with safety concerns were placed under stringent operating controls.

Data from extensive work done in the last few years (2) have reduced uncertainties and allowed closure of several unreviewed safety questions. Technical findings, which resulted from laboratory studies on waste simulants and actual waste, accomplished the following: 1) identified and bounded the energetics of the fuel-rich materials added to the tanks; and 2) determined that waste aging processes over the last 30 to 40 years due to waste chemistry and tank physics reduced the potential risk. Waste aging processes have led to dispersion or degradation of these fuel-rich species (3).

RECENT PROGRESS AND PLANS TO RESOLVE SAFETY ISSUES

Ferrocyanide. The ferrocyanide safety issue involves the potential for uncontrolled exothermic reactions of ferrocyanide and nitrate/nitrite mixtures (19). Laboratory studies show that temperatures must exceed 250C for a reaction to propagate. The hottest tank's temperature is currently 54C and decreasing.

Moisture levels above 20% will prevent reactions from propagating regardless of fuel concentrations. Current plans were to take two core samples from each of 18 tanks to determine ferrocyanide levels and moisture content. However, recent laboratory work with simulants confirmed that ferrocyanide fuel content decreases over time in intense radiation fields (16,17). Core sampling will be used to confirm aging in the tanks projected to have the highest ferrocyanide concentrations and exposed to the lowest radiation field and/or alkali concentrations. The sampling results are expected to show that the ferrocyanide has aged to levels low enough to resolve the safety issue. Six of the original Ferrocyanide Watch List tanks have been removed from the Watch List based on records that showed no ferrocyanide had been added to these tanks.

Organic Tanks. The organic tanks safety issue involves the potential for uncontrolled exothermic reactions of organic chemicals and nitrates/nitrites and for vapors from semi-volatile organics entrained in waste to exceed the flammability limits (21). Recent laboratory tests showed that fuel concentrations and temperatures required to support propagating exothermic reactions are comparable to those for ferrocyanide. In addition, moisture levels above 20% will prevent reactions from propagating regardless of fuel concentrations.

In prior years, work controls were implemented to prevent introduction of ignition sources to these tanks. Vapor sampling and safety analyses were completed and formed the basis for closing the Unreviewed Safety Question concerning flammability of the floating organic layer in tank 103-C (20). Ten tanks that received organic complexants were added to the Organic Tanks Watch List following a review of sampling data and waste transfer records (22,12).

Aging processes have destroyed or significantly lowered the energy content of the organic tanks. Recent laboratory work (1) demonstrates that in the presence of alkaline aluminum salts and radiation, complexants such as hydroxyethylethylenediamine triacetic acid (HEDTA), ethylenediamine triacetic acid, and glycolic acid decompose to form less reactive fragments, ultimately creating a mixture of sodium formate and sodium oxalate. During this aging process, hydrogen, nitrogen, nitrous oxide and ammonia are evolved. This finding has been confirmed by studies on tank 241-SY-101 waste (9) that found the HEDTA had almost disappeared. Other complexants had partially degraded to sodium oxalate and formate and a complex mixture of degradation products such as the sodium salts of ethylenediamine diacetic

acid and nitrilodiacetic acid.
Recent laboratory findings (5) indicate that the more energetic complexants and the primary degradation products of tributyl phosphate (TBP) are water soluble in saturated nitrate-nitrite salt solutions and would a large percentage have been removed from the single-shell tanks when they were saltwell pumped.
In conclusion, the combination of waste aging, waste dissolution and dispersion appears to bound the inherent risk in fuel-rich nitrate-nitrite systems. When work on waste surrogates and simulants is completed, limited core sampling in bounding tanks will be used to verify the conclusions derived from these conceptual models of waste behavior.
Flammable Gas Tanks. The flammable gas tanks safety issue involves the potential release of flammable gases in concentrations above the lower flammability limit. In prior years, work controls were instituted to prevent introduction of spark sources, and evaluations were completed to ensure that attached equipment was intrinsically safe.
The worst tank, 241-SY-101, has been successfully mitigated with a mixing pump. The pump is operated up to three times a week to mix the waste and release gas.
Hydrogen monitors are being installed on all 25 flammable gas tanks. The Standard Hydrogen Monitoring System consists of a cabinet equipped with piping and instrumentation that support an on-line hydrogen detector and a "grab sampler." The cabinet isolates the equipment from the environment. The hydrogen detector is presently a Whittaker electrochemical cell, but other detectors can also be installed into these cabinets. The grab sampler allows gas samples, captured during a gas release event, to be removed from the tank for highly detailed analyses using state-of-the-art gas chromatograph and mass spectral analysis techniques. A better understanding of the physical properties of the tanks will be gained using a retained gas sampler, a viscometer, and void fraction devices. The void fraction test instrument has been successfully demonstrated in tank 241-SY-101. This monitoring data will be used, along with knowledge acquired during the process, to determine if any tanks other than 241-SY-101 require active mitigation for safe storage. Documentation to close the Unreviewed Safety Question in SY tank farm was submitted earlier this year.
High-Heat Tanks. The high-heat tanks safety issue concerns tank 241-C-106, a single-shell tank that requires water additions for evaporative cooling. Without the water additions, which would be discontinued in the event of a tank leak, the tank could exceed structural temperature limits, resulting in potential tank collapse. Tank 106-C is on an accelerated program for early retrieval to a double-shell tank. Double-shell tanks handle heat-bearing materials better than single-shell tanks, thus lowering the potential hazard from a structural failure if, in the event of a tank leak, cooling water additions to the tank are discontinued. Tank 106-C retrieval is scheduled to begin in late 1996. A process test and considerable thermal analyses were completed on tank 106-C to evaluate alternate cooling approaches. The studies concluded that the tank could be adequately cooled using an air chiller.
Criticality. The criticality safety issue involves the potential for criticality in tanks. Tank criticality prevention controls have been strengthened by improved administrative procedures and training, and the Unreviewed Safety Question was closed (6) using analyses that showed criticality during storage was highly unlikely. All the single- and double-shell tanks at the Hanford Site contain sufficient neutron absorbers to ensure safe storage; however, additional sampling or controls will be required for retrieval and pretreatment-related activities.
Noxious Vapor Concerns. The noxious vapor safety issue involves potential health and safety issues related to toxic vapors that may be present in some of the high-level waste tanks. The issues stem from an insufficient understanding of the causes of reported exposures of tank farm personnel to unacceptable levels of noxious vapors, and the concern that until the vapors in the waste tanks are well characterized, the risks to worker health and safety cannot be determined or controlled (18,13). In prior years, worker protection controls were instituted to prevent worker exposures, and a program was implemented for routine workspace air monitoring and periodic personnel dosimetry.
In-tank vapor sampling equipment has been developed and tested. Two methods are used to collect vapor samples from the waste tanks (14). The primary method employs: heated transfer tubing; a heated sampling manifold; temperature, flow control, and

valving technology; and an air pump to draw air, gases, and vapors out of the waste tanks. This method currently requires that a customized vapor sampling probe be installed by crane into a tank riser. This integrated equipment is referred to as the vapor sampling system (VSS). The VSS was specifically designed to collect representative samples from warm, moist tanks, even if a fog exists in the tank headspace.

A second method for collecting vapor samples from the waste tanks is referred to as in situ sampling (ISS). Rather than transferring the air, gases, and vapors to be sampled to a remote location, the sampling devices themselves (specifically sorbent traps) are lowered into the tank headspace. This minimizes the loss of constituents by adsorption on transfer tubing walls, and circumvents the need for heated probes, heated transfer tubing and a heated sampling manifold. Currently, the ISS equipment consists of a simple manifold and air pump mounted on a two-wheeled hand cart. Small bundles of about eight sorbent traps are lowered into the tank headspace, each sorbent trap having its own 0.64-cm (0.25-in.) plastic tube connection to the sampling manifold. The current sampling manifold is capable of collecting four samples simultaneously, and uses needle valves to control flow rates and a rotameter to monitor flow rates. In the ISS method, constituents that are not amenable to sorbent trap sampling (e.g., gases such as H2, N2O, and CH4), are sampled using an unheated plastic tube that transfers sample from the headspace to whole-air sampling devices (e.g., SUMMA1 canisters) located outside the tank. By the end of 1994, 18 high-level waste tanks had been vapor sampled.

UPGRADED APPROACH TO WASTE TANK SAFETY SCREENING

In 1990, all Hanford Site high-level waste tanks were segregated into four different categories based primarily on historical and monitoring information. These tanks were placed on "Watch Lists" to ensure increased attention and monitoring. In mid-1993, a program was initiated to screen all single- and double-shell tanks using core sample data. This program is being updated to take advantage of recent improvements in vapor sampling capability and an improved understanding of conditions necessary for selected chemical reactions.

Key changes in the revised safety screening strategy will include placing flammability controls on all tanks until associated sampling is complete, and using vapor sampling to help determine tank contents. Rather than initially sampling the waste to determine fuel content, as was the past strategy, evaluation and/or checking of moisture levels will be performed. If moisture levels are above 20%, fuel-rich propagating reactions will not occur.

Figure 1a, b shows the logic chart for the proposed safety screening. Key steps include:

Perform tank-by-tank evaluations of historical records (including past sampling results, laboratory waste testing, tank-specific modeling, and monitoring records), assessment of the adequacy of present monitoring systems, and tank-specific safety bases.

Vapor samples will be used to check for flammable or explosive gases. Headspace samples will be evaluated for hydrogen, organic gases and vapors, including ammonia, and nitrous oxide levels. If concentrations exceed pre-determined requirements, additional monitoring, waste or vapor sampling, or mitigation using enhanced ventilation or inserting, may be required.

Vapor samples will also be used to help identify the presence of volatile reactive materials and might be used to identify changes in waste chemistry resulting in significant changes in overhead gas compositions.

Vapor samples will be further used to check for noxious vapor sources. Treatment systems may be required if vapors are detected in the tank headspace above levels immediately dangerous to life or health.

Visual inspections will be used as an initial screening for moisture. For tanks with continuous aqueous layers (all double- shell and about five single-shell tanks), no additional sampling will be required. Other tanks will require either evaluation or near-surface samples to determine moisture content. If moisture levels are 20% or higher, no further safety screening sampling will be required.

If moisture levels are not adequate, fuel levels will be determined by near-surface sampling, or a low-cost mitigation process will be implemented to increase moisture levels.

This sampling program is expected to greatly accelerate tank safety screening, with considerable cost savings.

This new approach will require vapor sampling of all passively ventilated tanks (26 have already been completed) and near-surface moisture sampling of up to 70 tanks. Either auger samples or an in situ device will be used to determine moisture. An auger sampling device is like a drill bit that is rotated into the waste to obtain the sample. Auger samples are much easier to obtain than core samples; however, sample recovery may not be adequate. Commercially available devices such as an electromagnetic induction moisture monitor could be modified and used in a penetrometer. Some limited core sampling will be required to support the technical basis for the new strategy.

TECHNICAL BASIS FOR UPGRADED SCREENING STRATEGY

To provide greater assurance that all tanks with safety issues have been identified, a safety screening will be conducted to determine whether any other tanks generate flammable gases or noxious vapors above limits, or if conditions exist that would support exothermic propagating reactions due the fuel and oxidizers mixtures, or if surface combustion could occur due to entrained or pooled organic solvents.

Previous testing with vapor sampling has demonstrated that waste tank headspaces are essentially homogeneous (15). In addition, near-surface moisture levels are believed generally high enough to reduce the number of waste samples required for adequate moisture assessment to reasonably attainable levels, particularly for sludge-containing tanks.

Ferrocyanide and organic chemicals act as a fuel when combined with an oxidizer, and nitrate salts (an oxidizer) have been precipitated in the tanks. These compounds have the potential for propagating exothermic reactions between fuel and salts of sodium nitrate and sodium nitrite. Two types of propagating exothermic reactions are possible in fuel-rich wastes: 1) bulk runaway reactions, in which an entire tank's contents reach a critical temperature and then self-heat; and 2) propagating reactions in which the reactive zone spreads at a measurable rate as the result of a localized initiator (11).

For a bulk runaway reaction to occur, a major fraction of the waste would have to be heated to above 250C (Fauske 1994). Heat loads in most of the Hanford Site tanks are low, and temperatures are declining with time. In addition, most single-shell tanks are passively cooled (10). Bulk heating of waste to 250C is not credible.

For a propagating reaction to occur, a mixture of fuel-oxidizer must be heated to high temperatures or energized by applying an ignition source (7). Because specific conditions of fuel, moisture, and temperature are all required to support a propagating reaction, screening criteria have been set based on extensive energetics studies on waste stimulants. For the ferrocyanide safety issue, these results have been confirmed on actual waste. Safety screening criteria for the propagating exothermic reactions in the condensed phases are listed in Table I.

All double-shell tanks contain adequate moisture levels to prevent propagation. Ferrocyanide fuels are found only in sludges in single-shell tanks. Organic fuels may be in sludges or saltcakes and in double- or single-shell tanks. Most sludges, except for those in shallow tanks or high-heat tanks, contain adequate moisture to prevent propagating exothermic reactions and will remain adequately moist indefinitely unless temperatures increase above 90C. Considerable research work has shown that formation of dry regions due to local hot spots in sludges is not credible. In addition, no credible mechanisms exist to raise temperatures inside wastes to reaction levels. Therefore, only external initiators are credible. Several potential external initiators have been evaluated, including instrumentation, cameras, pumps, core samplers, vehicles, and lightning strikes.

The maximum waste temperature criterion of 90 C reflects the need to preserve existing waste moisture contents. It is important to note that this is a bulk waste temperature, and that point source temperatures (e.g., from rotary core sampling) are allowed to be only as high as 150C, well below the critical ignition temperature for a propagating reaction (Fauske 1994)(23). Experimental work at Fauske and Associates (Fauske 1994) measured the actual energies released for a variety of bounding organic-nitrate-nitrite-containing surrogates, and bounded the actual propagating energy ranges and conditions for a variety of mixtures containing organic complexants, TBP and related materials. Fauske and Associates is completing documentation of the quenching effects of moisture on such systems.

Evaporation of saturated salt solutions in the passively ventilated tanks is slow; therefore, extensive dryout of the tanks is an improbable event.

Operational upsets were considered by using a "what if" approach that focused on

upset conditions that would significantly increase the amount of energy deposited in the tank or waste. Heating a small portion of dry, reactive waste to fuel-nitrate ignition temperatures could initiate a sustainable rapid exothermic fuel-nitrate reaction accident if the waste were reactive. The potential for tank farm equipment and operations to heat a portion of waste to ignition temperatures has been evaluated in (4). Energy from external initiators and natural events such as lightning strikes were also considered. Lightning was the most energetic, and therefore was used to bound the maximum depth that an external initiator would penetrate the waste surface.

Given that credible initiators transfer their energy to the waste surface, sufficient fuel and oxidizer must exist near the surface in order for a propagating chemical reaction to be induced. Conversely, if insufficient fuel and oxidizer exist in a surface layer that could be heated by an initiator, then it is physically impossible to initiate a propagating reaction.

In addition, preliminary work by Camaioni and Samuels (8) has confirmed the general findings on complexant decomposition and also demonstrated the facile destruction of TBP and its primary hydrolysis product sodium dibutyl phosphate. Only normal paraffinic hydrocarbon, which would evaporate or boil out of hot waste, was resistant to gamma-radiation-induced aging under initial test conditions.

Further insight into the distribution of organic material was gained from a series of solubility studies by Barney (5). Accurate data have been obtained for solubilities of selected organic compounds in tank supernate solutions. Initial research resulted in development of a model for fuel distribution in saltcake that shows the more energetic species to be soluble in the aqueous-saturated waste solution and thus susceptible to removal when drainable liquid is removed from the single-shell tanks by saltwell pumping. Work is continuing to determine whether the salts of calcium, aluminum and/or iron form insoluble precipitates of complexants leading to their deposition in saltcake (creating localized concentrations of fuel). In the absence of localized insoluble salts, a case can be made that organic complexants are dispersed in the aqueous phase.

In summary, the presence of separable organic liquids can be quantified from concentration data obtained from headspace air. Because the energy required to ignite an entrained solvent is likely to be small, it is likely that mitigation efforts such as inerting the tank headspace (e.g., with nitrogen replacing air) may be necessary. Meanwhile, as mentioned earlier, flammability controls will be applied, not just to known Watch List tanks, but to all tanks.

CONCLUSION

Westinghouse Hanford Company and supporting organizations and laboratories have made remarkable progress toward resolving waste tank safety issues. Three unreviewed safety questions were closed in 1994, the worst tank was successfully mitigated, understanding chemical reactions limits has improved dramatically, instrumentation to enhance understanding of tank conditions is being installed on an accelerated schedule, and an innovative cost saving approach has been developed to screen all of the tanks.

OPERATIONAL EXPERIENCE IN MITIGATING FLAMMABLE GAS RELEASES FROM HANFORD TANK 241-SY-101

J. W. Lentsch
H. Babad
N. W. Kirch
Westinghouse Hanford Company
P.O. Box 1970
Richland, Washington

ABSTRACT

Flammable gases consisting of hydrogen, nitrous oxide, ammonia, and methane are periodically released from Hanford Site waste tank 241-SY-101 at concentrations above the flammable limit. A large mixer pump installed in the tank in 1993 has effectively mitigated this problem by continuously releasing small amounts of the flammable gases at the rate they are generated.

BACKGROUND

Since its original fill in 1980, Hanford Site high-level underground waste tank 241-SY-101 has periodically released flammable gases as a result of a buoyant rollover of the lower viscous layer of waste. At intervals of approximately 100 to 150 days, the flammable gases hydrogen, nitrous oxide, ammonia, and methane evolve episodically from the tank at concentrations above the flammable limit. Because of the potential consequences of ignition, this problem has received a high national priority for mitigation.

In July 1993, a large mixer pump was installed in tank 241-SY-101 to test whether mixing could mitigate the episodic hydrogen releases. The results of initial testing were reported in February/March at Waste Management '94 by Lentsch et al. (1). In April 1994, a series of full-scale tests were completed, and the pump was placed into routine operation.

TANK AND MIXER PUMP

Hanford Site tank 241-SY-101 and the mitigation mixer pump are shown schematically in Fig. 1. The tank is 23 m (75 ft) in diameter and contains 4,163,953 L (1.1 million gal) of caustic sodium nitrate/nitrite/aluminate waste with 3% to 5% organic complexants. Approximately 3 million curies of radioactive Cs137 in the tank generates 40,946 Btu/hr (12 kW) of decay heat, resulting in an average waste temperature of approximately 49C (120F). Overall waste depth is 1,016 cm (400 in.); the lower 635 cm (250 in.) consists of non-convective settled solids with a specific gravity of 1.7, covered by approximately 254 cm (100 in.) of convective saturated solution with a specific gravity of 1.4. A 102 to 127-cm (40 to 50-in.) layer of solid crust floats on top of the waste.

Prior to mixer pump installation, gases formed by radiolysis were retained in the lower (non-convective) waste layer. Every 100 to 150 days, the gas inventory built up to the point where the lower waste layer was less dense than the upper layer. The waste would then "roll over" or "burp," releasing the gas inventory to the dome of the tank, over a period of a few minutes, at concentrations above the lower flammability limit.

The mixer pump shown in Fig. 1 is a 150-hp, submersible, centrifugal unit that draws waste from the middle of the tank at 660 cm (260 in.) and discharges it through opposing 7-cm (2.6-in.)-diameter converging nozzles at 71 cm (28 in.) off the bottom at a maximum velocity of approximately 20 m/sec (65 ft/sec) and flow rate of 10,599 L/min (2,800 gal/min). The pump nozzles can be rotated through a 360-degree sweep. The mixer pump is located in a tank riser located 3 ft off center in the tank. Two multi-function instrument trees (MITs) are located at distances of 8.5 and 9 m (28 and 30 ft) from the pump to measure the vertical temperature profile of the waste at .30 to .61-m (1 to 2-ft) intervals. These two MITs provide the best measure of the degree of mixing taking place in the tank.

Tank 241-SY-101 is also equipped with multiple high-sensitivity gas monitoring systems and level detection systems to measure the quantity of gas that is retained in and released from the waste.

TEST AND OPERATIONAL RESULTS

The best measure of the effects of pump mixing on gas retention in the waste is waste level. A graph of the waste level before and after mixer pump operation is shown in Fig. 2. Prior to pump installation, the waste level grew at a rate of about 0.25 cm (0.1 in.)/day as gas accumulated. Following the rollovers, or burps, the waste level dropped 0.30 m (1 ft) or more after the gases were released. Then the cycle took place again. This behavior has not occurred since the pump was installed in July 1993. The first 4 months after the pump was installed, it was only operated for 5 to 10 minutes per day maximum. This operation was adequate to keep the pump nozzles from clogging with the viscous waste at the bottom of the tank. During this period, the waste level grew 5 to 8 cm (2 to 3 in.), but at a reduced speed. As more aggressive mixing was performed (up to 3 hours per day with 360-degree sweeps of the tank), the tank level was knocked down to a historical low value of 400 in.

Fig. 2. Tank SY-101 Surface Level.

Following demonstration testing in 1993, gas was allowed to regrow into the waste

during early 1994 to show that mixing had not altered the waste or created any safety issues. During February-April of 1994, full-scale testing was performed. Daily test sequences of 5-minute, 1-hour, and 3-hour runs and 360-degree directional sweeps were performed to determine the minimum pump operation necessary to control gas releases, and to assess how deep the pump jets were penetrating into the waste. From the full-scale tests and experience gained since then, it has been determined that the mixer pump should be operated at a speed of 1000 rpm for 25 minutes three times a week. Figure 2 shows that since the summer of 1994, the waste level has been closely controlled at 1,013 to 1,016 cm (399 to 400 in.) by this pump operating frequency. This frequency has also been shown to effectively prevent clogging of the pump nozzles.

Figure 3 shows a plot of hydrogen release data during a typical month of pump operation. Hydrogen is measured continuously with electrochemical cells and with gas chromatographs. Each 25-minute operation of the pump typically causes an increase in hydrogen concentration of 50 to 200 ppm. These values are not only controllable, but are far lower than the concentrations of up to 50,000 ppm that were seen during the naturally occurring, uncontrollable burps prior to pump operation.

Fig. 3. Hydrogen Releases from Tank SY-101 During Mixer Pump Operation.

Since September 1994, a steady state has been maintained using mixer pump operation. An average of approximately 3 m3 (100 ft3) of total gas is released each day. This amount corresponds with the approximately 100 ft3 of total gas that is estimated to be generated by radiolysis in the tank.

Concentrations of other gases in the tank dome exhaust are measured continuously with a Fourier transform infrared analyzer. Concentrations of the oxidizer gas nitrous oxide show close correlation with hydrogen at approximately 1.5 times higher values than hydrogen. Ammonia, on the other hand, shows a more steady release of roughly 35 to 50 ppm with only small increases of 10 to 15 ppm during pump operation. Much higher concentrations of ammonia (to 2,000 ppm) were seen during burps prior to pump installation). Only trace amounts of methane have been detected at concentrations of 1 to 2% of the nitrous oxide concentration.

JET PENETRATION

Waste temperature profiles were used to measure how deep the pump jets are penetrating into the waste. Figure 4 shows graphs of waste vertical temperature profiles from the thermocouples of one of the MITs (this tree is located 8.5 m [28 ft] from the pump). Profiles are shown for a date prior to pump installation, and for a recent date during steady state pump operation. The parabolic temperature profile shows that prior to pump installation, the lower 635 cm (250 in.) of waste are unmixed (non-convective). With pumping, only the lower 4 ft of waste is non-convective. Further, when the pump is running, the temperature reading on the very lowest thermocouple on this tree (10 cm [4 in.] from the tank bottom) clearly increases when the warmer pump jet passes by.

Fig. 4. Tank 241-SY-101 Multi-Instrument Tree Riser 17B Temperature Profile.

The other MIT, located 30 ft from the pump in the opposite direction, shows less than 41 cm (16 in.) of unmixed waste. However, each successive operation of the pump further reduces the thickness of the unmixed waste.

Recent operation of a newly-developed instrument for measuring the fraction of gas voids in the waste has confirmed the mixing depth inferred from the MITs. Also, infrared photogrammetry of the primary tank wall was performed from the tank annulus. The tank wall temperature was shown to be vertically uniform before and during pump mixing. From this and thermal calculations it has been inferred that the waste is vertically well mixed all the way out to the cylindrical tank walls, at a distance of 10 to 12 m (34 to 40 ft) from the pump.

The mixer pump cannot be operated continuously due to thermal operating limits. However, the continued systematic operation at 3 days per week is expected to eventually mix all of the tank waste all the way to the bottom in all directions.

PUMP REPLACEMENT

Because of the proven success of the mixer pump for mitigating tank 241-SY-101 flammable gases, keeping a pump operating in this tank at all times has become essential. Thus, a spare pump has been fabricated and is ready for installation in case the current pump fails. The estimated lifetime of the current pump is approximately eight years, based on its current duty factor, operating temperature, and radiation exposure.

Removal of the current pump, in case of a failure, is expected to be a difficult

task involving radiation levels up to 50 R/hr. The pump is nearly 21 m (70 ft) long and weighs approximately 9,072 kg (20,000 lb). Remote equipment to decontaminate, monitor, and contain the pump during withdrawal is currently being tested, and a special shielded container and hydraulic trailer assembly have been built to contain and transport the pump after removal. Detailed plans and training are being developed to assure that a failed pump can be removed and a new pump installed within 30 to 60 days of a failure, before hydrogen builds back up to unacceptable quantities.

Testing is also underway to determine what amount of dilution of tank 241-SY-101 would be required to "passively" mitigate the tank (thinning the waste to the point where it no longer retains gas). A 1:1 dilution (diluent: waste) might be needed. At this time, there is insufficient tank capacity in the West area at Hanford to accommodate the additional waste volume that would result from dilution.

CONCLUSIONS

The mixer pump in Hanford Site tank 241-SY-101 has been in operation for 20 months. It has effectively eliminated the episodic release of flammable quantities of hydrogen and other gases. Although the pump is only operated about 1% of the time, it has been shown to mix most of the viscous settled solids in this tank. A steady state has been reached where the pump releases gases at the same rate as they are generated.

ABSTRACT

A dynamic event simulation model for the Hanford Tank Waste Remediation System (TWRS) top-level functions has been developed for the in-tank enhanced sludge wash option. The model simulates the expected activity occurring between the 177 underground waste storage tanks during the waste remediation campaign period of about 30 years for the current TWRS baseline case. An animation is also developed which shows the material flow of tank farm waste from storage tank through processing to treated waste form. Preliminary results are reported.

INTRODUCTION

The primary mission of the Hanford site is waste clean-up and site remediation. A major aspect of the remediation is long-term protection of the environment from hazardous waste stored in 177 underground tanks at Hanford's 200 Area plateau. The hazardous portion primarily consists of longer-lived fission products from reactor fuel processed during various separations campaigns over the past 40 years. Remediation involves retrieving, treating and immobilizing the waste in a highly stable glass material for safe disposal in an isolated underground location. The activities and functions necessary to accomplish tank waste remediation in a timely/cost-contained manner are being studied to support the Tank Waste Remediation System (TWRS) Program at Hanford (1).

To assist with the study, a dynamic simulation has been developed to help predict how process and logistic assumptions influence behavior of the system. The

simulation tracks tank waste volume from storage tank to final treated waste form. Tracking involves numerically simulating the intermediate processes which change and transfer waste. Therefore, the primary dynamic variables are the waste volumes contained in the 177 underground storage tanks. The primary processes which are modeled and thereby control the dynamics are the following:

1) Concentration of dilute liquid waste in the double shell tanks (DST) to provide space for storage and processing,
2) Retrieval of the waste from remaining DSTs and from single shell tanks (SST),
3) Separation of liquid and solid portions of retrieved waste,
4) Pretreat liquid portion to remove higher activity aqueous components,
5) Vitrification of the solids and separated aqueous components, and
6) Concentration and vitrification of the pretreated liquid portion in LLW glass facility.

The interrelationships of the various processing activities are shown schematically in Fig. 1. The simulation model estimates flow rates, capacities, and interdependencies associated with the boxes in Fig. 1 to estimate the time dependence of waste moving through the system (2).

The model is organized such that storage capacities are fixed and preassigned rather than floating. Therefore, the delays caused by throughput bottle-necks are computed by the model and can be displayed in the animation. There is no strong advantage to this organization for performing sensitivity studies; but, it is necessary to drive an animated representation of the simulation.

Fig. 1. Top-level processing activities.

General tank farm information used by the model is contained in three text files which are read during program execution. Initially, all waste volumes are set by two of these data files to the current double and single shell tank waste inventory reported by Hanlon (3).For the SSTs, the third data file contains a retrieval schedule which directs the removal of waste from the tanks to designated transfer annexes. The schedule is based on a modification of the retrieval sequence outlined by Williams (4) to reflect the recent Triparty Agreement (5) (TPA) goals. Retrieval is one of the first activities to occur and continues well into the simulation when other activities are concurrently being performed. Even though a relatively fast retrieval rate is conceivable, transfers are constrained by the available volume in designated target tanks and by other processing activities involving those tanks. Since the model accounts for this type of intertank dependency, the retrieval schedule is best understood as tentative - the actual retrieval date is tentative, yet the retrieval sequence is preserved. As already mentioned continued retrieval of the SST wastes is postponed until a certain number of DSTs become available for storage and for performing the in-tank wash. Additionally, dependence on the operation of new (to-be-built) facilities coming on-line will also affect the actual time of retrieval during the simulation. Presently, the simulation assumes the existence of transfer annexes, cross-site transfer line and 2 new 1 Mgal double shell tanks. The assumptions are consistent with the TPA milestones (5), since the simulation starts in the year 2003. The time at which particular resources and facilities become available can be easily varied in a sensitivity study.

On the 200 East side, waste received from the B and C-Farm annexes is stored directly in the A-complex DSTs which also serving as feed for the in-tank wash. On the 200 West side, waste received from T, U, and S-Farm annexes is stored in the 3 SY-Farm DSTs, the 2 new 1 Mgal capacity DSTs. When one or more of the 1 Mgal DSTs are full, a cross-site transfer to 200 East Area is attempted. Cross-site transfer is allowed, if space in AN or AW-Farm is available. As waste slurry is transferred from the transfer annexes to the DST system, in-tank washing of dispersed solids begins becomes the rate limiting process in the simulation.

The most complex intertank dependence in the model occurs within the in-tank sludge wash process. This process allows the possibility of requests for transfers from multiple tanks to a single tank and/or partial transfer from a single tank to multiple tanks.

SIMULATION MODEL ASSUMPTIONS AND SELECTED RESULTS

LIQUID-SOLID SEPARATION/SLUDGE WASHING

To reduce the fraction of waste going to HLW vitrification a multitank settle/decant of retrieved waste slurry and sludge washing of dispersed solids is considered. The first wash effectively occurs during retrieval as insoluble solids are mobilized and dispersed through the retrieved waste slurry. Retrieved waste is stored in 101-102AN

and 103AW tanks which supply feed to settle/decant tanks. An exception is made for retrieved waste with less than 0.2 wt.% solids in this case the waste is sent directly to feed for low level pretreatment. For example, retrieved TX farm saltcake will completely by-pass sludge washing. Since only tanks with small amounts of sludge are retrieved before 2009, no significant accumulation of solids occurs in settle decant tanks before 2009. Figure 2 shows the (4 tank case) volume of total waste and of sludge in a first stage settle decant tank over the entire processing time.

For this study, it is assumed that settle/decant and washes occur within the same tank. Other schemes involving waste transfers could more effectively accomplish mixing and chemical additions, but overall timings are not expected to change significantly. Notice that the first cycle of Fig. 2 is extended because of the small amount of solids introduced for early times. Similar behavior occurs for other settle/decant tanks. Subsequent cycles show a mild variation based on the retrieval sequence. The timing and number of cycles depends on the batch size as well as the fraction of solids assumed for the settled sludge.

Fig. 2. Volume of waste in a 1st stage S/D tank.

The details of a typical cycle can be seen in Fig. 3. The first full cycle of Fig. 3 shows available waste added to a settle/decant tank in the beginning of 2012. At the end of the 30 day settling period, 250 kgal of sludge has settled to 20 wt.% within the tank. The supernatant liquid is decanted and additional waste slurry is added to obtain the specified 10 ft (330 kgal) of settled sludge batch for washing. Caustic is added (1:1 by liquid volume) to the sludge with a 30 day mixing period followed by a 30 day settling period. It is assumed that 30 % of the solids are dissolved (6,7). The wash is decanted and three additional water washes (2:1 by volume) are performed to remove interstitial sodium from the sludge. Since the density of the interstitial liquid is reduced by removal of sodium, the volume of the sludge increases slightly during the water washes. Finally, water is added to transfer the sludge to high level waste accumulation tanks (101-102AZ,101-102AY, & 107AN).

Fig. 3. Typical volume cycles for a 1st stage S/D tank.

Table I summarizes the processing steps and timings assumed for the simulation. While 20 wt.% solids in settled sludge is taken as the base case, the precise value will depend on specific waste characteristics, settling time, and chemical additions. A fixed settling time of 30 days is assumed in the model (of course longer settling occurs if space limitations restrict decanting). Table II shows the end dates for sludge washing for various solids/sludge fractions for two different batch sizes.

For 4 tank case at 100% TOE, Table II shows that the sludge wash operation completes in 2020. This is almost two years after the completion of SST retrieval, since the final years are spent processing waste within the DST system. The actual retrieval completion dates for the calculation of Table II occur about 2 years earlier. In following sections, additional calculations are made for retrieval progress which apply an overall 60% TOE to the timings presented in Table I.

INITIAL CONDITIONS AND DST ASSIGNMENTS

The start time of the simulation is assumed to be the beginning of CY 2003. While numerous tank transfers and use of 242-A evaporator occurs prior to 2003, the net effect of those activities is approximated. This net effect includes the presence of 8 Mgal of 7 M Na waste stored in AP farm as feed for low level pretreatment and 4 Mgal in 200 West area resulting from 101SY and 103SY retrieval. As low level pretreatment starts-up late in 2004 (processing feed at 30 gpm), AP farm tanks become available. The seven tanks 102-108AP continue to serve as feed (lag storage) to low level pretreatment. Once emptied, 101AP along with 104-106AW are assigned as second stage settle decant (S/D) tanks. For first stage S/D tanks, 103-106AN and 101-102AW are assigned, yet Table II assumes only four first stage S/D tanks are used. If the use of 242-A evaporator continues beyond 2004, 102AW and 106AW may not be available for these assignments.

The DST sludges remain in 101-102AZ, 102AN, 107AN, and 101AY; additionally, it is assumed that retrieved solids from 106C are contained in 102AY. Retrieval of the six DST`s with sludges begins in 2009 with the availability of high level vitrification. After their retrieval, 101-102AY, 101-102AZ, and 107AN are used for sludge accumulation, while 102AN becomes a receipt tank for retrieved SST waste. Tanks 101AN and 103AW are also assigned for receipt of retrieved SST waste. When available, cross-site transfer can be made to any of these three receipt tanks, but

it is assumed that 200 East area retrieval of SST`s is restricted to 103AW and 102AN. Effectively, 101AN is exclusively reserved for cross-site transfer.
Two new DST`s are assumed for 200 West area for retrieval of 101SY and 103SY; they continue to serve as storage of retrieved SST waste prior to cross-site transfer. No new DST`s are assumed for 200 East area from in-tank processing considerations.

SST RETRIEVAL

The retrieval of each of 149 single shell tanks containing distinct wastes is considered. While a large range of chemical constituents are contained in the tanks, only sodium, unidentified anions (mostly nitrates), water and solids are represented in the simulation. Hydraulic retrieval (or sluicing) is assumed in each case. In the simulation, this is accomplished with 5 waste receiver facility (WRF) annexes (each containing four 75 kgal tanks) distributed among the 12 single shell tank farms (9). Table III shows the grouping of SST farms with the five WRF annexes.
A given WRF may services more than one SST at a time from it`s assigned farms. The historic retrieval rate has an average instantaneous value of 14.4 m3/day of sludge or saltcake (6). Assuming this rate for four sluicers with a 70% equipment availability along with an overall 70% efficiency, each waste receiver facility has the retrieval rate capability of (0.49)14.4 m 3/day or 28.2 m3/day of sludge or saltcake. It should be mentioned that these assumed rates may be overly optimistic, since (without bottlenecks) a single WRF could retrieve all SST waste in 14 years. This is purposely imposed to insure overall process timing is controlled by sludge washing rather than by retrieval. Water addition is calculated on a tank-by-tank basis for a dilution to 5 M Na or 10 wt.% solids. Overall, the 36 Mgal of SST waste is diluted to 143 Mgal.
In 200 West Area, waste is stored prior to cross site transfer in two new 1 Mgal DSTs and in previously retrieved SY Farm tanks. When one million or more gallons of retrieved waste is accumulated, a cross site transfer to 200 East area is sought. Transfer is made at 200 gpm when one or more targeted AN Farm DSTs become available. For 200 East Area, waste is transferred from the WRF directly to 102AN or to 103AW. The choice of the retrieval sequence will effect process timing. Low level pretreatment is available to process supernatant liquid by 2005, yet space for additional sludge accumulation dose not appear until after 2009. Therefore, prior to 2009 the following tanks containing primarily saltcake are specified for retrieval: 110TX, 111TX, 112TX, 113TX, 114TX, 115TX, 116TX, 117TX, 118TX, 102TX, 104TX 105TX, 106TX, 107TX, 108TX, 109TX, 102TY, 109SX, 102BY, 103BY, 112BY, 101A, 101AX, 102S, 105S, 108S, 112S, 102U, 103U, 105U, 106U, 107U, 108U, 109U 111U.
Processing saltcake early in the retrieval sequence offers an additional advantage---the reduced dilution of sludge for later retrieval times will reduce the cycle time for sludge accumulation in a settle decant tank. Any further study attempting to optimize process times for sludge washing will need to consider retrieval sequence variability.
With the retrieval assumptions outlined, Fig. 4 show retrieval progress for 100% and 60% TOE for three cases in which 4, 6, and 8 DSTs are assigned as first stage settle decant tanks.
Fig. 4. SST Retrieval with 60 % TOE for Sludge Wash
Notice that significant differences in retrieval progress do not occur until after 2009 when full cycles for sludge washing become routine. Assuming the overall 60% TOE applied to the timings of Table I, Fig. 4 shows that 6 first stage settle/decant tanks just miss the SST retrieval TPA milestone. At the 60% TOE, 7 DSTs are sufficient to meet the SST retrieval milestone.

SUMMARY OF RESULTS

A dynamic event simulation model for the Hanford Tank Waste Remediation System has offered valuable insight for process timing and system performance behavior. System performance studies with respect to a few parameters are compared with milestone expectations of the Hanford Tri-Party Agreement. Assuming a 20wt% fraction of solids in sludge settled for 30 days, 7 existing DSTs are sufficient to perform the in-tank settle-decant/enhanced sludge washing and meet the TPA requirements for SST retrieval. Naturally, more tanks are required if smaller weight fractions or longer settling times are assumed.

PERFORMANCE AND RISK ASSESSMENT OF SUBSURFACE BARRIERS FOR SINGLE-SHELL TANK WASTE RETRIEVAL

Foster Wheeler Environmental Corporation

ABSTRACT

Subsurface barriers are among various alternatives under evaluation to mitigate the threat of leakage from the Hanford Site's 149 single-shell high-level radioactive waste tanks. The Tank Waste Remediation System (TWRS) division of Westinghouse Hanford Company is conducting this evaluation of subsurface barriers and other alternatives, focusing on risk and cost as performance measures.

A number of alternative retrieval/closure approaches were evaluated in terms of risks (carcinogenic and toxicological) to a postulated maximally exposed individual. In addition, worker and accident risks were evaluated and factors developed for each alternative on a relative basis. The work performed to date indicates the use of subsurface barriers may potentially reduce public risk by limiting contamination of groundwater below the Hanford Site; however, the cost in terms of actual funding and in elevated worker risk is significant. The analyses also assume certain performance levels for technologies that have not been demonstrated in field conditions similar to Hanford Site tank farms.

The evaluations summarized herein are being used to support a decision by representatives of the U.S. Department of Energy, Richland Operations Office, the Washington State Department of Ecology (Ecology), and the U.S. Environmental Protection Agency (EPA) regarding potential further development of subsurface barrier technology.

BACKGROUND

The Hanford Site's 149 single-shell tanks (SSTs) currently store approximately 140 million liters (37 million gallons) of high-level radioactive liquid waste. Objectives for environmental cleanup of the Hanford Site include retrieving, treating, and disposing of the SST waste in an acceptable manner. The TWRS program is responsible for achieving these objectives in accordance with the Tri-Party Agreement, U.S. Department of Energy (DOE) orders, and state and federal regulations applicable to environmental clean-up.

Historically, tank wastes have been released to the ground from leaks from SSTs, and associated transfer lines, and other miscellaneous spills. Sixty-seven SSTs are assumed to have leaked a total volume of approximately 2,271 to 3,407 m3 (600,000 to 900,000 gal). Several studies have indicated that the contaminants present in this

volume of leakage could cause violation of groundwater quality standards, once the contaminants migrate through the vadose zone to the groundwater.
The Hanford SST tank farms were constructed from 1943 to 1964. Retrieval of waste from the SSTs is currently scheduled for a 15-year processing campaign beginning in 2003 and ending in 2018. One tank, C-106, is planned for retrieval in 1997 to provide a demonstration of retrieval technology. Accordingly, the SSTs will be 60 to 75 years old at the initiation of retrieval, depending on the sequence for individual tanks.
Hydraulic sluicing is the primary approach currently envisioned for retrieval of the SST waste. The sluicing operations will typically add some level of working liquid to the tank to mobilize the solidified salt cakes and sludges. The design life of the tanks has expired, and the integrity of the tank containment boundaries is in question. The age of the tanks and the fact that leakage paths exist in a number of tanks already strongly indicates that sluicing retrieval operations will likely cause additional leakage of tank waste to the surrounding soil unless preventive actions can be taken.
The concerns of environmental impact due to migration of the contaminants that have already leaked from the tanks and the potential for additional leakage during retrieval have driven the initiative to evaluate alternatives for leakage mitigation. The TWRS program is investigating a number of options to mitigate past and potential future leakage from the SSTs. The evaluation and decision processes are reflected in the following Tri-Party Agreement milestones:
M-45-07A Complete Evaluation of Subsurface Barrier Feasibility (September 1994)
Complete a feasibility study of barriers to accomplish the following:
1. Estimate the potential environmental impact of waste storage and retrieval activities without the application of barriers.
2. Establish functional requirements of barriers to minimize the impact associated with the waste storage and retrieval activities.
3. Evaluate the application of existing subsurface barrier technologies to meet functional requirements of barriers and the potential reduction in environmental impacts from the application of barriers to SST waste storage and retrieval activities.
M-45-07B Reach Decision on Whether to Proceed with Demonstration (January 1995)
Based on the results of the subsurface barrier feasibility study, Ecology, EPA, and DOE will make a decision on whether to proceed with a sub-scale demonstration. If the decision is negative, then interim milestone M-45-07 will be considered complete.
EMERGING TECHNOLOGIES
A number of subsurface barrier development projects are active in the DOE Office of Technology Development (EM-50) Program under the Crosscutting Technology, Plumes, and Landfills Focus Areas. Industry has made a number of proposals to DOE-Headquarters and the field in technologies such as a heated, continuous air barrier and a cryogenic soil freezing system. The continuous air barrier concept is designed to stop/prevent leaks by crystallizing salt in the soil pores by evaporation, thereby sealing the soil from further leaks. The soil freezing system is designed to create a basin of ice beneath the tank, thereby providing a mechanism for capturing any leaked waste. The Underground Storage Tank - Integrated Demonstration tasks conducted in fiscal years 1992 and 1993 (TTPs RL421210 and CH321203) began work on an instrumented test facility and evaluated several barrier systems. The proponents of a number of these subsurface barrier systems, including the air barrier, frozen soil basin, and a technology that provides a physical barrier adjacent to and beneath the tank, claim that they are "ready for demonstration."
The Plumes Focus Area is supporting ongoing research and development of materials that may serve as effective solid barriers around tanks and other waste sites. These materials include organic polymers, cementitious grouts, and paraffins. While several of these materials appear promising, methods of injecting the materials into the soil to effect a seal around tanks are largely untested. Several fiscal year 1995 projects will focus on deployment of subsurface barriers below waste sites. One

example is called the horizontal soil saw, a device that is pulled below the waste site by cables previously placed in directionally drilled holes. As it moves through the soil, a rotating "grouting bar" both cuts the soil and injects barrier-forming grout or other material.

The Hanford Site's TWRS Program has conducted several studies and workshops to evaluate the potential application of subsurface barriers at the tank farms. Based on this work, three subsurface barrier concepts have emerged for consideration: 1) injected or infused material barriers, 2) cryogenic barriers, and 3) desiccant barriers. These barrier types may be installed in two configurations: close-coupled (against the tank structure) and stand-off (with a soil layer between the tank(s) and barrier).

PERFORMANCE AND RISK ASSESSMENT

The overall objective of the feasibility evaluation was to analyze a logical set of subsurface barrier technologies in terms of overall system performance, as measured primarily by public risk reduction, worker and accident risks, and cost.

Integrated Alternatives

To compare the various alternatives on an even basis, integrated alternatives were constructed by assuming a retrieval method, the use or nonuse of subsurface barriers for leakage mitigation, and several closure methods. A total of fourteen alternative retrieval/leakage mitigation/closure approaches were evaluated. Figure 1 provides a flow chart that depicts the integrated alternatives.

The evaluation process required that a number of assumptions be made regarding performance of the alternative concepts. Key assumptions included the performance of the retrieval system in terms of the percentage of waste removed from the tanks, and the effective recharge rate of the tank farm and vadose zone soil system (with or without a surface barrier) following retrieval.

Public Risk

The public risk assessment was performed as a two-step process: the first step estimated the inventories of contaminants of concern in the various sources, then estimated the rates and durations of the releases to the vadose zone, and the second step modeled the transport through the vadose zone and aquifer to obtain potential exposure to a hypothetical maximally exposed individual (MEI).

The analyses assumed a hypothetical tank farm consisting of 12 tanks with a capacity of 3,785 m3 (1 million gallons) each. The waste composition was assumed equal to the average of the 149 SSTs. Soil chemistry and lithology representative of overall Hanford Site properties were assumed. The SST waste inventory includes more than 150 chemicals and radionuclides; however, a relatively small subset of the constituents are sufficiently toxic and mobile that they can produce a significant public risk impact. Eight constituents of concern were retained in the analyses as the dominant contributors to public risk.

The dominant sources in terms of contribution to the public (MEI) risk values were residual waste in the tanks following retrieval and the contamination resulting from old and new leaks. However, other sources resulted in substantive contributions; other sources analyzed included: waste trapped between steel and concrete, residual waste that diffused or advected into the concrete, residual waste that diffused or advected into barrier material (if applicable).

The Multimedia Environmental Pollutant Assessment System code was used to model the contaminant transport through the vadose zone to the aquifer and to compute risk factors to the MEI resulting from use of the groundwater. Cancer risk factors were calculated for exposure to carcinogens, and hazard index (HI) factors were calculated for exposure to noncarcinogens. The receptor was assumed to have a 70-year lifetime. Exposure pathways included drinking water ingestion, crop ingestion, and animal product ingestion.

The transport and risk calculations were run over a 30,000-year postoperational period. The duration of this model was needed to show the magnitude and time of the peaks in risk to the MEI. Figures 2 and 3 show the carcinogenic and HI curves for all alternatives.

Worker and Accident Risks

Potential risks to worker health and safety were evaluated by further defining the alternatives in terms of individual technology options. The work force needed to support each option was estimated on a life-cycle basis and included technology readiness, capital, operating and maintenance, and decontamination and decommissioning. The risk factors were formulated to address exposure to radioactive

and hazardous materials and physical hazards associated with the activities. Table I shows the results of the evaluation.

Cost/Cost Benefit

Cost estimates were developed for each of the alternatives based on recent engineering studies and other data. The cost estimates were based on the life cycle elements as described in the worker safety analysis. The cost benefit for each alternative was based on risk reduction versus cost. Table II presents costs as total net present worth (TNPW). The relative risk value is the peak carcinogenic risk calculated for the postoperational phase (Fig. 2). Cost benefit (based on carcinogenic risk) is calculated using Eq. 1.

Eq. (1)

The cost-benefit factors calculated based on hazard index are numerically different; however, the relative changes between alternatives would lead to the same conclusions as the values based on carcinogenic risk shown above. To provide clearer resolution among the various technologies, an incremental risk reduction value was calculated using Eq. 2:

Eq. (2)

Table III presents the incremental risk values based on implementation of individual technologies.

Sensitivity of Results

A five-phase analysis was performed to examine the sensitivity of the results to the following: variability in performance of subsurface barriers, variability in geology and waste composition, variability in release rate of constituents, the affects of high leakage and variation in performance of the surface barrier and soil flushing, and variability in vadose zone water potential due to leakage. The analyses concluded the results are highly sensitive to the assumptions regarding performance of the protective surface barrier to limit the affects of recharge to the tanks and vadose zone soil system. The results are also highly sensitive to the assumption that the tanks will be reasonably effective in containing the waste inventory during sluicing operations. Other variations had little affect on results.

CONCLUSIONS

The results of the feasibility evaluation support the following conclusions:

Taking no action would result in risks approximately three orders of magnitude higher than the assumed upper limit (10-4) of the target risk range.

Taking no action other than capping a tank farm with a surface barrier capable of limiting recharge to 0.05 cm/year (0.02 in./year) may result in acceptable risks for some tanks, but only if collapse of the tank domes could be prevented.

The use of either traditional sluicing (assumed capable of achieving 99% tank waste retrieval), robotic sluicing (99.9% retrieval), or mechanical retrieval (95% retrieval), in combination with stabilizing the structure of emptied tanks and using a surface barrier, appears potentially capable of attaining the target risk range for most tanks.

The use of any of the subsurface barrier concepts (chemical, freeze wall, and circulating air in close-coupled and standoff configurations) in general applications to tank farms would result in a relatively small incremental reduction in the risk level achievable using baseline technologies. (Baseline technologies include traditional sluicing, emptied-tank stabilization, and surface barriers.)

Uncertainty in the performance of subsurface barriers is high, but because the impact of subsurface barriers on risk and cost-effectiveness is very low, even best-case assumptions of subsurface barrier performance have a relatively small effect on improving overall risk and cost-effectiveness of SST disposal options.

Stand-off barriers offer no benefit in terms of reducing public risk unless soil flushing or excavation is used in conjunction. The requirement for soil flushing in the stand-off barrier alternatives results in a large cost impact.

The use of a close-coupled barrier to support clean-closure activities may be cost-effective in comparison to the clean-closure alternative without a barrier because it would limit the volume and reduce the cost of contaminated soil requiring excavation and treatment, while reducing risk.

Except for the clean-closure application, cost-effectiveness of subsurface barrier technologies is essentially equal and relatively low. The cost-effectiveness of the subsurface barriers, calculated by the method most favorable to subsurface barriers, is about 0.0001 times that of surface barriers, and 0.01 times that of the set of baseline technologies.

The retrieval of all tank waste, including tank structures and contaminated soil to effect clean-closure, would likely result in bettering the public risk range. The landfill created to contain washed, retrieved soil and debris from the tank farm would represent a new, but relatively small source of risk.

The clean-closure alternatives would be about as cost-effective as other tank waste retrieval alternatives assuming that all recovered contaminants of environmental concern would be destroyed or treated and disposed offsite in a federal repository, and assuming that benefit can be represented as a ratio of initial risk to achieved risk. If benefit is represented by the difference in these risks, the cost-benefit is two to eight times lower than for the other retrieval alternatives.

Worker risks of the baseline alternative are 2 to 5 times lower than subsurface barrier alternatives and about 10 to 15 times lower than the clean-closure alternatives.

Functional requirements have been established in Functions and Requirements for Single-Shell Tank Leakage Mitigation (1). All functional requirements potentially can be satisfied using any of the subsurface barrier options evaluated.

These conclusions are based on the ability of subsurface barriers to reduce risk and improve cost-effectiveness in general-use applications to tank farms. A broader set of values beside risk and cost-effectiveness should be considered. Conclusions presented here may be modified as a result.

The risk and cost factors and the methods of their calculation used in the evaluation process were developed using the most recent information available, given the available resources and schedule. The evaluation team considers the approach taken to be correct and defensible. However, there is no set standard for this kind of evaluation and decision process. This paper is a very cursory summary of the work performed. Individuals with an interest in reviewing the detailed information may contact the authors to obtain the supporting documentation (2,3).

STATUS AND PROGRESS IN SLUDGE WASHING: A PIVOTAL PRETREATMENT METHOD

W. Blaine Barton

ABSTRACT

Separation of the bulk soluble chemical salts from the insoluble metal hydroxides and radionuclides is central to the strategy of disposing Hanford tank waste. Sludge washing and caustic leaching have been selected as the primary methods for processing the 230 million L (61,000,000 gal) of Hanford tank waste. These processes are very similar to those selected for processing waste at the West Valley site in New York and the Savannah River Site in South Carolina. The purpose of sludge washing is to dissolve and remove the soluble salts in the waste. Leaching of the insoluble solids with caustic will be used to dissolve aluminum hydroxide and chromium hydroxide, and convert insoluble bismuth phosphate to soluble phosphate. The waste will be separated into a high-level solids fraction and a liquid fraction that can be disposed of as low-level waste after cesium removal. The washing and leaching operations involve batchwise mixing, settling, and decanting within the existing underground storage tanks.

PROCESSING PLANS

The waste will be retrieved from the single-shell underground storage tanks with as much blending as possible. The retrieved waste will be accumulated in million-gallon underground storage tanks to a volume of approximately 1 million L (300,000 gal) of

settled solids. The waste sludge will be processed through a series of leaches using 3-molar caustic, followed by inhibited water washing. Because methods for retrieving single-shell waste are still being developed, early sludge washing will be performed on selected double-shell tank waste with limited blending.

The first sludge to be washed is the neutralized current acid waste (NCAW) that was generated during the first solvent extraction cycle in the plutonium-uranium extraction (PUREX) process. The radionuclide inventory consists of fission products (primarily Cs-137 and Sr-90) with significant amounts of transuranic elements. With the exception of Cs-137, the fission products have low solubility in the alkaline solution and are present in the solid phase. Transuranic compounds as well as aluminum, iron, and zirconium compounds are also present as solids. Soluble components consist of nitrate, nitrite, hydroxide, carbonate, aluminate, and sodium ions.

The NCAW is stored in two 3.8 million-L (1 million-gal) tanks. Both tanks will be decanted using a floating suction pump down to a level of 30 cm (12 in.) above the sludge, or until the suspended solids concentration in the pump discharge exceeds 100 ppm. The first wash water will consist of 3 million L (800,000 gal) of dilute liquid waste, which will be mixed for 7 to 10 days using 300-HP mixer pumps. The contents of both tanks will be combined, mixed with mixer pumps for 7 to 10 days, and allowed to settle for 1 month. The solids will be washed once more with 2.3 million L (600,000 gal) of water and decanted.

It is estimated that washing the two tanks together will remove 97% of the soluble salts while only 0.4% of the insoluble solids will be carried over with the supernatant. A total of 10.2 million L (2.7 million gal) of supernatant solutions are generated, but these will be concentrated by evaporation to 3.8 million L (1 million gal). Thus, the two tanks containing NCAW will become one tank containing washed sludge ready for vitrification and one tank filled with solution ready for cesium removal.

The above outline plan was initiated as the "AZ-101 Sludge Washing Process Test," began when the airlift circulator operation in the tank was terminated on August 4, 1993. The next phase is to install a decanting pump, a control system, and instrumentation, then decant the supernatant to another storage tank. The final phase is to install and test two, 300-HP vertical centrifugal mixing pumps.

Airlift Circulator Operation

Every tank at the Hanford Site designed to contain PUREX high-level waste contains 22 airlift circulators. These circulators mix the tank contents to prevent insoluble solids from settling. If the solids settle and compact, the possibility exists that the high-heat-generating solids can cause steam to form in the sludge layer. Trapped steam might accumulate until it is released suddenly, resulting in a burp or steam bump. Such an event has the potential of adverse consequences due to overpressurizing the tank, thus causing potential airborne release of small quantities of radionuclides. In the case of a large burp, the physical damage may influence the integrity of the tank structure.

In-tank washing or leaching of insoluble solids requires that the solids be allowed to settle so that the solutions can be separated by decantation. This requires that airlift circulator operation be discontinued during the settling period. There was concern that a steam bump could occur during the settling period. Therefore, a computer model was developed to simulate the tank dynamics (1), and a process test was carried out to determine if a bump could occur in the tank with the highest heat-generating rate (2).

The test consisted of turning off the airflow to all the circulators in tank AZ-101. The temperature readings from the many thermocouples permanently installed in and around the tank were monitored and recorded. It was found that the average temperature of the solution increased about 11F, from 136 to 147F. The average sludge temperature increased about 13F, from 141 to 154F, with a maximum temperature of 190F near the tank center when the annulus ventilation system was not operating. With the bubble point of the solution being about 220F at the waste surface and 260F at the bottom, the formation of steam was not possible. The results of the test agreed well with the predictions of the computer model discussed later in this report.

Decantation of Waste Tank AZ-101

To decant tank AZ-101, a decanting pump, instrumentation to measure suspended solids concentrations and the sludge interface level, and a control system were needed.

These have been designed, procured, and fabricated for installation. The total system has been tested at the Sulzer Bingham Pump Co. facility in Portland, Oregon. A drawing of the tank with equipment and instrumentation and including the mixing pumps is shown in Fig. 1.

The decanting pump is a modified vertical turbine pump with a floating suction intake. A flexible metal hose is attached to the intake at one end, and the stainless steel float is attached to the other end. A cable attached to the float controls the position of the float, and allows the float to be pulled up out of the waste. A load cell is used to measure and control the tension on the cable, and an encoder or resolver measures the unreeled cable length.

The pump operation is controlled by a Siemens Power Corporation programmable logic controller, with a remote operator station located outside the tank farm fence line. There is instrumentation to measure the pump discharge flow rate, the discharge liquid turbidity (calibrated in ppm suspended solids with a waste simulant), a tank turbidity profiler, and a buoyancy liquid level monitor. This instrumentation will be wired into the controller so that the pump can be automatically switched between recycle back to the tank and transfer out of the tank or turned off. The position of the diverter valve or on-off status of the pump will be based on discharge flow and turbidity as well as tank waste liquid level and sludge/liquid interface level.

When the decant pump system is installed, tank AZ-101 will be decanted to about 0.3 m (1 ft) above the sludge layer. Then the tank will be refilled with a very dilute wastewater from another tank to reduce radiation exposure for the installation of two vertical centrifugal mixing pumps. This dilute waste will also be used for the first wash of the waste after the pumps become operational. The mixing pumps will be the first installed at the Hanford Site for the purpose of mobilizing and washing compacted waste sludge.

Future Test Plans

Following the testing of the mixing pumps, it is planned to decant a neighboring PUREX high-level waste tank (AZ-102) and pump the contents of tank AZ-101 to it. The combined sludge from the two tanks will then be washed and stored as feed for the future high-level waste vitrification plant. The washed sludge will also be available for laboratory or pilot-scale vitrification tests.

Also planned is a test of in-tank leaching and washing of single-shell tank waste that is scheduled for removal and transfer to a double-shell tank. This waste sludge contains a substantial amount of strontium-90 and large amounts of iron, aluminum, silicon, and phosphorus. It is an ideal waste to demonstrate the caustic dissolution of aluminum and methasis of phosphate to hydroxide. The waste will be sluiced from the single-shell tank C-106 into double-shell tank AY-102, which is in close proximity to tanks AZ-101 and AZ-102.

LABORATORY STUDIES

Laboratory studies have been conducted with both simulated waste and real tank waste. These studies were designed to:

1. Evaluate the efficiency of washing and caustic leaching the waste to separate alkaline water soluble nonradioactive species from radioactive species
2. Determine the settling characteristics of simulated waste, including the effects of high-heat generation in the sludge and pumping the waste through mixing pumps.

These studies were conducted by the Pacific Northwest Laboratory for Westinghouse Hanford Company.

Leaching and Washing of Actual Waste

Samples of waste taken from several single-shell tanks were subjected to a series of water washes and alkaline leaches with sodium hydroxide solutions (3). This was done to determine the solubility of aluminum, chromium, phosphate, and other species in 3 M OH^- solution and water.

Tables I, II, and III data indicate that much of the aluminum and phosphorus, and some of the chromium, can be leached out of tank waste with hot caustic soda solutions. The amount varies with each tank waste because the chemical composition varies from tank to tank. Overall, the majority of the aluminum and phosphorus compounds, and some of the trivalent chromium compounds, can be leached from the sludge with 3 M NaOH solution. Computer simulation of these processing experiments is discussed in a following section.

Settling and Washing of PUREX Waste Simulant

Experiments were conducted to determine the unhindered and hindered settling rates and supernatant clarity of a simulated PUREX waste (4). The experiments were carried

out in a 26-L (7-gal) tank, using 19 L (5 gal) of slurry. The experiments were also designed to measure the effect on settling of natural conduction caused by heat generation in the settled sludge, and to determine if a steam bump could occur. This was done by placing a spiral heating coil on the bottom of the tank. The effect on settling of pumping the slurry through a centrifugal pump was also studied. Preparations were made to test various flocculants as settling aides, but the tests were not carried out because very clear settled solutions were obtained during the experiments without flocculants. Initial settling rates were found to be around 1 cm/h, and supernatant clarities were less than 10 nephelometric turbidity units. Heating the sludge layer increased the settling rate, presumably because the temperature of the solution was increased, thereby decreasing the viscosity and density. Washing the sludge with alkaline, inhibited water also resulted in higher settling rates, possibly again because of a decrease in density. The slurry was pumped through a centrifugal pump with the same impeller tip speed as planned mobilization mixing pumps. No effect was observed on the settling characteristics of the slurry.

The conclusions from the experiments with the PUREX simulant is that flocculants will not be needed to gravity separate tank waste insoluble solids and solutions. Neither radiological heating in the sludge layer nor water washing the sludges will adversely affect the separation. The effects of shearing the slurry through mixing pumps is not expected to affect the settling properties.

THERMODYNAMIC SIMULATION

To predict the results of full-scale leaching and washing of various mixtures or blends of tank waste, a method to simulate processing with computers is necessary. A licensed process simulator can calculate activity coefficients and, thus equilibrium concentrations, for mixtures of aqueous and nonaqueous solutions, solids, and vapors. This simulator, produced by OLI Systems and called Environmental Simulation Program (ESP), includes extensive data banks for aqueous, organic, solid, and vapor phase species. It is being used at the Hanford Site to simulate a wide variety of processing. Two examples are discussed in the following sections.

Leaching and Washing of Actual Waste

Waste samples are taken from Hanford Site storage tanks by coring the tanks in a manner similar to geological coring. These samples are analyzed in a variety of ways. As discussed earlier, they are also processed in the laboratory by leaching and washing to obtain data on the solubility and leachability of the various constituents. A large amount of very valuable data comes from these laboratory leaching and washing experiments. However, because the results are for a single tank waste and are experimental, it is not easy to extrapolate the results to waste mixtures.

The ESP is being used to simulate the leaching and washing experiments. In ESP, the extensive data banks are searched for all species that possibly exist in equilibrium with the input species. Semi-theoretical methods are then used to calculate activities and concentrations for all the species. If the results of the laboratory tests can be predicted with reasonable accuracy, then the results from processing mixtures of tank waste can likely be predicted.

Simulations have been completed of the first three tank waste leaching and washing experiments (5). These simulations were for tanks B-110, C-109, and C-112. Comparisons between the laboratory results and ESP simulations are shown in Tables I, II, and III. The ESP simulations, in general, agree well with the laboratory results.

Sludge Washing Process Test

As discussed earlier, a full-scale process test of sludge washing is in progress in Hanford Site tank AZ-101. In preparation for this test, an ESP simulation was run of the separation and combining of waste that will occur as part of the decanting and refilling of the tank. This simulation was valuable for assessing whether any safety problems could exist, and for determining phase material balances during processing.

COMPUTATIONAL FLUID DYNAMICS SIMULATION

To evaluate the effects on safety of performing various operations in Hanford Site double-shell waste storage tanks, a tool has been needed to simulate the transport phenomena in the tank systems. Of particular concern has been the effects of heat-generating radionuclides, which can cause steam generation and possible "bumping" of the tanks. This need has lead to the development of computational fluid dynamics (CFD) models to simulate waste tank dynamics and heat transfer. The GOTH

computer code has been adapted to simulate the dynamics in a PUREX waste storage tank and ventilation system (1).

Fluid Dynamics in Tank AZ-101

As discussed earlier, the operation of the airlift circulators in tank AZ-101 was discontinued as the initial step in the sludge washing process test. Before shutoff of the circulators, a CFD simulation was made of the tank waste and vapor space dynamics to determine if steam could accumulate in the sludge and then be released suddenly. For this to occur, the transfer of heat from the sludge to the ventilated air space above the tank would have to be slower if the airlift circulators were not operating. This, in turn, would mean that the rate of heat transfer from the sludge layer to the liquid surface is faster when the circulators are operating.

The simulation was designed to simulate the heat, mass, and momentum transfer in the liquid and vapor phases as a function of time. The initial conditions used were those measured in tank AZ-101 with the circulators on. The simulation was then run until near steady-state conditions were reached. GOTH solves for the local fluid velocity, pressure, and temperature in the liquid and vapor space of the tank.

The results indicated that the supernatant solution temperature would rise about 10F, but that the bubble point would not be reached anywhere in the tank after the circulators are shut off. The temperatures in the sludge layer varied, but again, the bubble point of the solution in the sludge was never reached. When the actual test was performed and the circulator operation was stopped, the temperature changes corresponded well to what was predicted by the CFD simulations.

Decantation of Tank AZ-101

There was concern that when tank AZ-101 was decanted, the temperature of the remaining sludge and solution might rise and possibly boil. This decanting process was simulated with the GOTH model to determine what temperatures are predicted to be reached. The results were that as long as some liquid covered the sludge there will be very little change in temperature (6). This is because the force-ventilated vapor space remains well mixed, even when the tank is nearly empty. Thus, the rate of transfer of water vapor, and therefore latent heat, from the liquid surface to the vapor space remains relatively constant during decanting. The CFD model showed that most of the heat removal is through evaporation.

ENGINEERING EVALUATIONS

Although separation of metal hydroxide sludges traditionally has been performed by sedimentation because of the very small particle size, examination of other methods to accomplish the sludge washing process has recently been initiated. If a large radioactive processing facility is required it might make either economic or operational sense to perform this processing on a semi-continuous basis using centrifugal or filtration methods. A study has shown that it may be possible to use a crossflow filter for washing and separating the insoluble solids. This would be accomplished by continuously circulating waste slurry through the filter while adding water to it to maintain a constant suspended solids concentration.

The feasibility and efficiency of both the in-tank and crossflow filter processes needs to be demonstrated.

CONCLUSIONS

Sludge washing and leaching is central to the Hanford Site's approach to disposal of the tank waste. All experimental and analytical work done to date supports the feasibility of washing and leaching the tank waste currently stored at the Hanford Site using an in-tank process. An approach using computer simulation, physical simulant testing, and in-tank testing is being pursued and is providing validation of planning assumptions. By continuing to look at alternative methods it is expected that Hanford Site tank waste will be processed in the most cost-effective manner to allow disposal in accordance with legal commitments.

THE SORT ON RADIOACTIVE WASTE TYPE MODEL: A METHOD TO SORT SINGLE-SHELL TANKS INTO CHARACTERISTIC GROUPS

J. G. Hill
G. S. Anderson
Pacific Northwest Laboratory
Richland, Washington
B. C. Simpson
Westinghouse Hanford Company
Richland, Washington

ABSTRACT

The Sort on Radioactive Waste Type (SORWT) Model is a method to categorize Hanford Site single-shell tanks (SSTs) into groups of tanks expected to exhibit similar chemical and physical characteristics based on their major waste types and processing histories. The model has identified 24 different waste-type groups encompassing 133 of the 149 SSTs and 93% of the total waste volume in SSTs. The remaining 16 SSTs and associated wastes could not be grouped according to the established criteria and were placed in an ungrouped category. A detailed statistical verification study has been conducted that employs analysis of variance (ANOVA) and the core sample analysis data collected since 1989. These data cover eight tanks and five SORWT groups. The verification study showed that these five SORWT groups are highly statistically significant; they represent approximately 10% of the total waste volume and 26% of the total sludge volume in SSTs. Future sampling recommendations based on the SORWT Model results include 32 core samples from 16 tanks and 18 auger samples from six tanks. Combining these data with the existing body of information will form the basis for characterizing 104 SSTs (70%). These 104 SSTs represent 79% of the total waste volume, 63% of the total sludge volume, and 88% of the salt cake volume.

INTRODUCTION

Between 1943 and 1964, 149 SSTs were constructed to store liquid and solid radioactive wastes generated during the production of plutonium at the Hanford Site. Over 36 million gallons of wastes are currently stored in SSTs. Before the last tanks were removed from active service in November 1980, various waste volume reduction programs were undertaken to minimize the amount of occupied tank volume. These programs involved intertank transfers, evaporation, and chemical alterations of the waste. These actions, combined with the ongoing chemical and radiolytic in-tank processes, have changed the character of the waste in the SSTs over time. Characterization of these wastes is currently a top priority to alleviate safety concerns and to support the development of retrieval, pretreatment, and disposal systems for the tank wastes.

The wastes in the SSTs originated from a limited number of chemical processes and waste solidification schemes. However, because of the complex physical and chemical history of the tank waste, especially when several different waste types were mixed or processed together, the model does not attempt to predict the precise composition of a tank. Instead, the sorting method concentrates on the different types of waste introduced into each SST, each waste's distinct contribution to the known properties, the individual significance of each waste type, and the process history of each tank. Although the actual chemical reactions and phase equilibria may be unknown when two waste types are combined in an SST, it can be assumed that similar reactions and equilibria occur in other SSTs when the same two waste types are mixed. Therefore, tanks that received the same waste types in the same approximate proportion and had a similar processing history will be more similar to one another than SSTs that received several different waste types in varying amounts and had a relatively unique process history. This forms the basis of the SORWT Model.

Validation of the SORWT Model indicates that a limited number of tanks (representatives of their corresponding SORWT groups) could provide sufficient information to begin developing pretreatment and disposal systems, assuming the selected tanks provide an accurate representation of the conditions within the SSTs.

DATA SOURCES FOR THE SORWT MODEL

The principal source of information used by this model is A History of the 200 Area Tank Farms (1). This document contains much of the available processing history for each of the 149 SSTs from 1944 until 1980. However, the historical records used to generate A History of the 200 Area Tank Farms were often inaccurate and/or incomplete. The methods used to measure accumulated solid and liquid volumes during the early history of the Hanford Site produced inconsistent estimates of inventories. Indeed, solids inventories were not routinely taken until the mid-1950s, and tank transfer information was often missing. Despite these inconsistencies, it is still one of the best sources of SST historical information, and it is believed a qualitative assessment of the principle solids-forming waste types contained in each SST can be accurately determined from this information.

The volume of waste contained in each SST was obtained from the Tank Farm Surveillance and Waste Status Summary Report (2). These values include, on a per-tank-basis, total waste volume, volume of salt cake, volume of sludge, and volume of supernatant liquid. It is assumed that these values are more accurate than those final values found in A History of the 200 Area Tank Farms because they were obtained more recently; however, it is understood that these values have deficiencies because of the limited access to the tanks.

SORWT MODEL ASSUMPTIONS

The underlying assumptions used by the SORWT Model are as follows:

The information contained within A History of the 200 Area Tank Farms is sufficient to qualitatively identify and rank, relative to one another, the waste types that contributed to the accumulated solids in each SST.

Primary solids-forming and secondary solids-forming waste types were responsible for the majority of the physical characteristics and chemical compositions of the waste remaining in each SST.

Supernatant wastes that were not allowed to remain in a tank for a long period of time and were later pumped out of the SST had less influence on the physical and chemical character of the waste than did the insoluble solid waste types that remained in the tank.

Tanks were often sluiced at some time during their processing history. Sluicing involves removing solids from waste tanks using high-pressure water jets. Waste types present in the tank prior to the most recent sluicing were not considered relevant by this model.

Using a broad-ranging, less descriptive waste type such as noncomplexed waste (NCPLX), complex concentrate (CCPLX), evaporator feed (EVAP), and/or double-shell slurry feed (DSSF) was avoided whenever possible. Process-specific nomenclature was preferred, if available; however, a broad category identifying the tank waste as either noncomplexed, complexed, or ferrocyanide-scavenged waste has been included in the SORWT Model to aid in evaluating the results of the model.

SUMMARY OF SORWT MODEL RESULTS

The SORWT Model has predicted the existence of 24 groups ranging from a high of 22 tanks per group to a low of two tanks per group. These 24 groups encompass 133 tanks and 93% of the total waste volume. An additional group contains the 16 SSTs which could not be grouped with any other tanks based on their primary and secondary waste types. Table I presents a summary of the SST groups predicted by the SORWT Model. A review of Table I quickly reveals that Group I is by far the most significant group. This group includes 22 tanks, 37% of the total salt cake volume, and over one quarter of the total waste in all 149 SSTs. The first three groups represent over one-half of the total waste volume in all 149 SSTs. This categorization demonstrates the potential usefulness of the SORWT Model in making management decisions. Table I also identifies groups that have relatively no significance, such as Groups XIV and XVIII, which contain almost no waste. This information can be used in allocating time and resources for characterization activities, pretreatment, and immobilization development.

Larger families of related tank groups may exist. Examples of potential families are Group I (R, EB) and Group IX (EB, R). The relative differences between these two groups are due to their respective designation of which of the two waste types is

primary and secondary. These differences may be small when compared with the overall group variability. Identifying larger families of tanks will reduce the overall number of different groups being evaluated and the corresponding number of sampling and analysis events.

STATISTICAL VERIFICATION OF THE SORWT MODEL

Approach to Verification of the SORWT Model

First, the analytical results were arranged into groups as predicted by the SORWT Model, then an ANOVA was performed on the grouped data for a selected number of analytes. An ANOVA is a quantitative method to test the significance of the effect a particular treatment has on the response or dependent variable. In the SORWT Model verification study, the treatment being studied is SORWT groups, and the dependent variable is analyte concentration. The ANOVA method was used to test whether the mean concentration of a particular SORWT group is statistically significantly different from the mean concentration of other SORWT groups. The null hypothesis tested by this statistical model was as follows:

The deviations between the means of the different groups were due only to random variation within the entire data set.

If the null hypothesis was proved valid, then no group effects were present, and the SORWT Model would be discredited. However, if the null hypothesis was proved incorrect, then the converse would be true (i.e., group effects are present and the SORWT Model methodology is supported by the data). If significant group effects were observed, a Tukey pairwise comparison was conducted to investigate the groups that differed significantly from one another.

Analytical Data Sources for the Verification Study

The analytical results data used in the SORWT Model verification study were obtained from the official core sample data packages produced by the Hanford analytical laboratories in support of the Westinghouse Hanford Company Tank Waste Characterization Program. The SSTs and SORWT groups that were used in the verification study are presented in Table II.

The core sample data packages contain a great deal of analytical data measured using several alternative digestion methods and analytical instrumentation. These measurements were often taken both on segment level aliquots and on core composites, which represent the nominal or average composition of an entire core. Because the SORWT Model verification study compares the differences between the mean nominal compositions of one group and the mean nominal composition of other groups, only core composite data for the analytes that significantly contribute to the overall character of the waste were considered. The analytes included in the verification study, along with the sample preparation method and analytical instrumentation, are presented in Table III.

Graphical Description of the Verification Data Set

The data set used in the SORWT Model verification study consists of 109 separate cases with 22 total measurements per case for a total of 2,398 pieces of information. This is a rather large amount of information to comprehend and only a small subset of the total data available. A useful tool for summarizing and understanding large data sets is a box plot, which is a graphical representation of the spread or variance in a given data set. Figure 1 is an example box plot for sodium (Na).

The example box plot shows the spread in the Na data for the five different SORWT groups to be tested in the verification study. The vertical axis is Na concentration presented in units of mg/g. The horizontal axis represents the five different SORWT groups. The spread in the data is depicted by a box and whiskers plot. The median of a set of data is marked by a horizontal line in the box. The lower and upper hinges are the edges of the central box. The median splits the ordered set of data in half such that 50% of the values are above the median and 50% of the numbers are below. The hinges split the remaining halves in half again such that the interior of the box represents 50% of the data. If we define the hinge spread as the absolute value of the difference between the two values of the upper and lower hinges, the whiskers show the range in values that fall within 1.5 hinge spreads of the hinges. Any data farther than 1.5 hinge spreads from the hinges are outliers and plotted as asterisks (*). Values that are more than three hinge spreads away from the hinges are considered far outliers and plotted as open circles. Examples of both of these outliers can be seen in Fig. 1.

As can be clearly seen in the figure, the median value and range of values for Na in

some of the SORWT groups are substantially different from other SORWT groups. It is also clear that not all groups are necessarily different from one another. It appears that Groups XII and XVI show comparable Na concentrations and that Groups VII and XV are indistinguishable from one another. However, the spread of values from Groups XII and XVI does not approach the spread of values in Groups VII and XV. Group IV appears to be different from all the other groups presented.
Similar box plots were generated for each analyte included in the SORWT Model verification study and are included in The Sort On Radioactive Waste Type Model: A Method to Sort Single-Shell Tanks into Characteristic Groups (3).
Analysis of Variance (ANOVA) of SORWT Groups
The ANOVA performed for each analyte included in the SORWT Model verification study used the general linear model of the SYSTAT for Windows(a) statistical data analysis software package. If a significant grouping effect was observed, then a Tukey pairwise comparison was also conducted for each analyte to determine which groups were significantly different from the others. The output reports generated by the statistical software for each analyte are presented in The Sort On Radioactive Waste Type Model: A Method to Sort Single-Shell Tanks into Characteristic Groups (3).
The ANOVA provides two estimates for the variance, one between groups and one within groups. If the null hypothesis (i.e., no differences among SORWT groups) is accurate, then the estimate for the between-group variance should be similar in magnitude to the within-group estimate of the variance. Conversely, if the between-group estimate of the variance is significantly greater than the within-group estimate, the null hypothesis would be untenable, and some of the between-group variation must be caused by real differences between treatment groups. A summary of the ANOVA results for each of the analytes tested is presented in Table IV. The F-Ratio is defined as the ratio of the between-treatment variance (mean sum of the squares) and the within-treatment variance. This ratio should follow an F distribution for the appropriate numbers of degrees of freedom. The significance of the F-Ratio is called a P-value and can be determined from the relevant F distribution. The significance is the fractional probability of the F-Test ratio occurring only by random chance. The benchmark probabilities typically used to test the significance of differences between means are 5% and 1%, which correspond to significances of 0.05 and 0.01. For the purposes of the SORWT Model verification study, the 5% benchmark was selected. If the significance is greater than the benchmarks, then the differences between treatment means can be explained by random chance. If the significances are below the benchmarks, then the discrepancies between treatment means cannot be explained by random chance, and real differences exist between the subject groups.
As shown in Table IV, all 22 analytes and measurements listed have a significance well below the benchmark 5% level. In fact, all but two analytes have a significance below 0.1%. Table IV indicates there is virtually no probability that the differences between the means of the SORWT groups are due only to random chance. Therefore, the null hypothesis is invalid, and the data strongly support the premise that SORWT groups provide meaningful information about waste characteristics.
Because a significant grouping effect was observed, a Tukey pairwise comparison was performed to identify the groups that were significantly different from one another. The Tukey pairwise comparison first generates a matrix of pairwise mean differences. These are the differences between the mean concentration of a pair of groups. The routine then compares this difference to the mean square error for the analyte calculated from the ANOVA table and calculates a P-value (probability) that the difference between the mean concentration of any two groups is due to random chance. Table V presents a summary of the Tukey pairwise comparisons. The analytes that vary significantly between groups and the total number of significantly different analytes are listed. As shown in Table V, 18 out of 20 analytes were significantly different in Group IV than in Group VII. The smallest number of analyte differences between groups was eight between Groups XVI and XII. More than half the analytes considered in this study were significantly different for 7 of the 10 pairwise comparisons. This is another strong indication that the grouping methodology used by the SORWT Model predicts real differences between the characteristics of tank groups. Density and pH were not included in these Tukey summary tables.
RECOMMENDED TANK WASTE SAMPLING
Tanks recommended for sampling based on the results of the SORWT Model are listed in Tables VI and VII. The list takes advantage of the SORWT Model groups to establish a

substantial amount of characterization information from a relatively small number of core and auger samples. Thirty-two core samples and 18 auger samples are recommended. If this new sampling and analysis information is combined with the existing data, nominal compositions of 104 tanks (70% of the SSTs) could be established. This would represent approximately 79% of the total waste volume, 63% of the total sludge volume, and 88% of the salt cake volume.

ADDITIONAL INFORMATION

Information included in The Sort On Radioactive Waste Type Model: A Method to Sort Single-Shell Tanks into Characteristic Groups (3) but not presented in this report includes the following:

Descriptions of waste types used in the SORWT Model. The waste types are general categories based on process history rather than chemical or physical properties.

Descriptions of the 24 groups predicted by the SORWT Model. A brief history of the tanks included in each group and general comments about similarities between them.

Nominal compositions of the five SORWT groups included in the verification study. Mean concentrations of each analyte were calculated for each SORWT group included in the verification study. These mean concentrations, along with the current waste volume inventories, were used to project an inventory of each chemical analyte over the entire group.

Results of a pairwise comparison of expected and observed analyte concentrations between groups. A semi-quantitative comparison of analyte concentrations between groups was made based on estimated analyte concentrations in various waste types. A similar comparison was made based on the projected nominal compositions of the groups.

RELATED STUDIES

Two additional studies are currently underway to investigate the SORWT Model's effectiveness in grouping SSTs with similar waste types. One study focuses on the physical and rheological properties of the tank waste. It is assumed that tank waste with similar process histories will have similar physical and rheological properties and may therefore be grouped together. The other study is based on chemical analytes; however, the data set used for the verification study will be much more extensive than the one used in The Sort On Radioactive Waste Type Model: A Method to Sort Single-Shell Tanks into Characteristic Groups (3).

THE NEW GERMAN APPROACH TO WASTE MANAGEMENT AND FINAL DISPOSAL

Jrgen P. Lempert

Woltorfer Str. 74, 31224 Peine
Federal Republic of Germany

ABSTRACT

By enacting an amendment to the Atomic Energy Act, the German Parliament has recently added a new alternative of waste management to the nuclear fuel cycle back end. The former Atomic Energy Act wording, with its implicit commandment to reprocess all spent fuel, is now complemented to allow long term interim storage and direct disposal of spent fuel as alternatives. This new development is expected to have a substantial impact on all future activities of the fuel cycle back end. During the last 15 years, direct spent fuel final disposal was the subject of an important long term R&D programme. Since final disposal technology is meanwhile

virtually fully developed, real options are available. Policy decisions on waste management can be made now and in the future on a sound, objective basis.

INTRODUCTION

In June 1994 a new waste management option was legalized in the Federal Republic of Germany. By an amended to the valid version of the Atomic Energy Act of July 15, 1985, direct disposal of spent nuclear fuel is now permitted. Research and development work in this field started already in 1979, and it took 15 years from the initial steps to the legal effectiveness.

At the end of the seventies, the International Fuel Cycle Evaluation (INFCE) task force was set up by an initiative of US President James Carter with experts from 60 countries and five international organizations. This task force (INFCE) considered basically the question how the peaceful use of nuclear energy could be made available to all countries to cover their electrical energy needs and at the same time, how the proliferation of nuclear weapons could be reliable precluded. Among the variants analyzed for the back end of the fuel cycle, both reprocessing and direct disposal were considered. The misuse of facilities for peaceful application of nuclear energy to produce or to divert weapon-grade nuclear materials is in principle possible, but it can be however prevented by technical means, safety inspections, and administrative measures.

In May 1979 the Federal Government expressed again that it will adhere to the disposal concept with spent fuel being reprocessed. Nevertheless, it concluded to support investigations of waste management alternatives, like direct disposal of spent fuel, and to evaluate all available options on the basis of INFCE's experience while also considering the national context. This policy was also strongly supported by the Heads of the Federal States Governments. A long term research and development program was set up and launched, with the purpose of developing direct disposal in suitable steps up to technical maturity and evaluating possible advantages regarding safety and fuel cycle economics. At that time first evaluations were expected by the middle eighties.

REVIEW OF DIRECT DISPOSAL DEVELOPMENT

A first study called "Comparison of Different Disposal Alternatives and Evaluation of their Feasibility" was commissioned in 1979 by the Federal Minister for Research and Technology (BMFT) to the Karlsruhe Nuclear Research Center (KfK). Broad participation of other research institutes and the industry was recommended. The study compared final disposal after reprocessing with direct disposal of spent fuel considering technological, ecological, safety and energy policy aspects. A possible proliferation of weapon-grade materials had also to be considered. At the end of this first phase a concluding overall evaluation was found to be not sufficiently feasible, since several important issues remained open.

To resolve these particular remaining questions further research and development concentrated on "Other Disposal Technologies" during the period 1980 to 1985. The main objective was to find out whether direct disposal of spent fuel yields significant safety advantages not to satisfy political requirements.

During the development of a conceptual design for direct disposal of spent fuel a significant amount of technical documents was prepared. In many cases these documents already had a degree of details as required for the safety analyses to license a final repository. With regard to the comparison of both options for the back end of the nuclear fuel cycle a series of evaluation criteria was set considering main criteria as e.g. safety, technical feasibility, nuclear material safeguards and additional aspects, as economics and resource consumption.

Taking into account that such a comparison of complex and different alternatives should support political decisions reaching far into the future, it was necessary to consider not only existing facilities and fully developed technologies.

Consequently, the likely evolution of the state-of-the-art was considered as far as possible and it was assumed that future commercial-scale facilities with a yearly processing capacity of 700 metric tons of heavy metal are applicable. This seemed to be sufficient at that time for the NPP installed capacity forecasted for Germany by the end of the century, of some 25 to 30 GW.

In addition, a conceptual design for a second generation, an advanced reprocessing facility was developed, which should be built at the beginning of the next century. The experience gained during operation of a smaller plant, should be transferred to the final solution. Furthermore, it seemed not to be adequate just to compare different options for the fuel cycle back end standing alone, i.e. reprocessing and

direct disposal. Because of possible changes at the front end, of the fuel cycle such as the use of mixed-oxide fuel, additionally needed front end facilities were considered.
The analyses of several possible variants, led to a reference concept which was selected and developed in detail by companies of the nuclear industry. This concept of direct disposal was compared with the reprocessing path. Evaluation criteria were basically operational and long term safety, nuclear material safeguards and in addition also fuel cycle economics and energy policy issues.
With regard to operational and long term safety both options resulted to be nearly equivalent. The detailed analysis at that time clearly demonstrated a cost advantage for direct disposal, and that at present and for the foreseeable future. No macro-economical consequences were identified, but in the long term and from the view point of technology and energy policy reprocessing was still regarded very important. The final recommendation of the study was to stick to the reprocessing, and to continue developing direct disposal to technical maturity.
At the beginning of 1985, the results were evaluated by the Federal Government. Further development of the direct disposal technology was initiated, to achieve a technical level that fulfills all licensing requirements. Simultaneously, the Federal Government gave to understand that essential impulse for further development and application of these technologies should come from the industry, and especially from the utilities. According to the Atomic Energy Act, the Federal Government would limit its financial support to the field of final disposal.
In addition to the realization of the reprocessing path, direct disposal was further developed up to technical maturity by means of an extensive R&D programme aimed at providing an objective decision taking basis.
Until some months ago reprocessing of spent fuel has been considered as the only legal concept for the back end of the fuel cycle in Germany. The high level waste (HLW) resulting from reprocessing is to be vitrified and, after an interim storage period lasting some decades to allow a first reduction of the decay heat, disposed of in boreholes in a final repository. With the present legal option for final disposal of spent fuel, this fuel must be adequately conditioned and packed prior to final disposal.
A first reference concept consists of the following alternatives: either the fuel rods of disassembled fuel elements or the intact fuel assemblies are packed into self-shielding casks of the POLLUX type. These casks are transported to the repository site, via the shaft hoisted to the underground repository mine, transferred to the disposal position on a railbound carrier, and emplaced in a drift by a remote operated handling system (ELVIS). The remaining void space around the cask is subsequently backfilled with crushed salt.
Disposal of nuclear waste in deep geological formations has been chosen in Germany as the best solution to protect man kind and the environment from the radioactivity present in spent fuel and high level waste. The repository design assures that after closing and abandoning the repository no surveillance or any type of corrective or protective measures are needed. Different concepts have been proposed in several countries, to achieve this, all of them following the basic idea of a multiple barrier system. The multibarrier system is conceived and engineered in such a way that even after failure of some of the barriers the safety is still assured by the remaining barriers.
The barriers are either engineered ore natural. The engineered barriers are tailor made to fit into the site geology to enhance and complement the overall safety. The consideration of natural and man made barriers differs substantially due to the geological conditions of repository sites in various countries. In some concepts the repository safety relies more upon the engineered barriers, in others their role is of minor importance, because of the entrusted isolation function to the natural features of the site geology.
Fortunately, in Northern Germany exists a large number of salt domes with huge dimensions, many of them in principle adequate to host a repository. Due to the unique geohydrologic, thermal, and geomechanical properties of rock salt, as a self-healing impermeable rock, rock salt was very early selected as the preferred host rock for a repository for heat generating wastes. In the German concept the natural barriers are expected to assure by their own the long-term safety of the repository for most of the post-closure period. Engineered barriers enhance operational safety prior to repository closure and provide additionally required

redundancy during some time after the repository decommissioning.
It is important to mention that the advantages of rock salt as a host rock remain fully present for direct disposal of spent fuel. The benefits of salt compared to other host rocks are:

The spent fuel cooling time in interim storage can be minimized since rock salt can sustain a considerably higher thermal load than other host rocks

The viscoplasticity of the salt, enhanced by the waste decay heat, effectively closes all void space remaining in the backfilled drifts, compacting the crushed salt as backfill material after a period of some tens to a few hundreds of years. The backfill has then similar permeability as the original rock salt.

In order to develop the spent fuel direct disposal technology to technical maturity it was necessary to carry out a comprehensive series of demonstrations tests. The target of these tests was to prove the feasibility and safety of the proposed technical solutions. In addition, the results of these tests should provide all information required for licensing this new back end technology, satisfying the legal requirements for a German final repository. It is essential to mention that the required systems and components for the final repository may have to be tested by inactive and active demonstration tests.

In the framework of the mentioned long-term R&D effort DBE was contracted, besides the repository planning, with carrying out tests to prove the technical feasibility of systems and components under realistic conditions. The program which was set up had to supply comprehensive solutions for all relevant open questions with regard to the licensing of components and systems. It covered waste package handling and emplacement technology for drift and borehole disposal. The main objectives were:

construction and test of newly developed mechanical and mining components and systems for disposal technologies;

demonstration of safe handling for waste packages under realistic conditions;

ALARA-aspects, as calculation of radiation exposure to the operating personnel;

verification of temperature field and thermo-mechanical calculations for drift disposal by in situ tests.

One major aspect with regard to a new set of requirements was the handling of the POLLUX cask which will have a weight of 65 metric tons fully loaded with spent fuel. All necessary handling steps for drift disposal were demonstrated in separate test facilities. These are partly finished others are still under investigation:

Thermal Demonstration of Drift Disposal

This test started in 1990, and has now been running for more than four years. The drift disposal test is being carried out in the Asse salt mine at a depth of 870 m by using electrically heated waste POLLUX mock-ups. Among many other parameters the data sampling equipment records the temperature transient at the cask surface, drift convergency, backfill compaction, backfill porosity and permeability, displacements around the drifts, gas generation and release. Before starting the simulation, preliminary tests for selecting a suitable backfilling technique and a comprehensive geotechnical data sampling program were carried out. The test is planned to last until end of 1998. The results at present demonstrate clearly, that specifically the temperature is well within the required limits.

Handling Tests for Drift Disposal

These tests were accomplished to demonstrate safe underground transport, handling, and final disposal of the 65 tons self-shielding waste package of POLLUX type under realistic conditions. It allows to draw conclusions on operation, handling, equipment wear, reliability and availability. The tests were finished by the end of 1994. More than 2000 operating cycles have been performed under realistic conditions. The result was a clear confirmation of the newly designed equipment under normal and faulted conditions.

This test was a major step towards the future realization of the underground emplacement techniques.

Shaft Hoisting Test

Shaft hoisting systems for the handling of radioactive wastes are very sensitive pieces of equipment in a final repository. They are important to safety since a failure can eventually lead to detriment to personnel and to a possible release of activity into the environment. All shaft equipment must therefore be designed to satisfy highest safety standards.

The shaft hoisting demonstration test was run to demonstrate the technical feasibility of a shaft hoisting system for payloads up to 85 metric tons,

including all essential components. Radiological aspects where an essential issue during these tests. The mentioned payload corresponds to the weight of a POLLUX cask and of the flat cask carrier used for the internal transport in the repository. The tests provided conclusive evidence that the designed facility complies with all requirements of conventional and nuclear regulations. The results today are that such a system can now be licensed for a repository.

A shaft hoisting system was designed for a shaft diameter of 7.5 m, a maximum depth of 1000 m, and 85 metric tons payload taking into consideration the relevant boundary conditions, the applicable technical rules, and the operational and safety requirements. The hoisting facility design, and the design of the shaft cage loading and unloading systems on surface and underground as well, were performed with the view to safely prevent all accidents which may lead to a release of radioactivity or to cause severe detriment to the personnel.

Among many other details worth to be mentioned is the airlock door at the surface shaft station, which was designed as a redundant shaft safety gate. It is not only electronically monitored and interlocked, but also equipped with an additional mechanical system to prevent the accidental drop of a loaded cask carrier into the shaft. The shaft cage itself has a unique design, equipped with a movable floor which rests on the cage frame during hoisting and which can be fixed to the loading and unloading stations on surface and underground during loading and unloading. This system allows a very slow and smooth transfer of the payload to the cage ropes, which are tensioned by slowly rising the shaft cage with the hoisting machine.

The single tests carried out comprised a considerable number of loading and unloading cycles for obtaining statistically significant reliability data and the testing of all equipment and devices important to safety. Separate tests were run to simulate operational disturbances. The design of all components with regard to their mechanical stability was verified under normal and faulted operations. All tests have been completed and the final report is close to completion.

Active Handling Experiment

By using active neutron sources the neutron radiation dose around a POLLUX cask mock-up was measured. Special attention was paid to scattering effects in the underground environment. The test, was started with an above ground measurement campaign and continued during the fall of 1994 with underground measurements in the Asse mine. The main target is the validation of the existing calculations for cask shielding and radiation exposure of personnel during operation. These tests are scheduled to end during the current year.

CONCLUSIONS

Successful realization of the above mentioned tests has proven the technical feasibility and licensability of all key system and components of the German spent fuel direct disposal concept. The shaft hoisting test series was a key element since a payload of 85 metric tons had never been hoisted before. Meanwhile, the German Commission for Reactor Safety (RSK) confirmed the feasibility of direct disposal in a recommendation to the Federal Authorities issued on December 8, 1993, and underlined that the test results so far obtained and those of the still running tests enable industry and government to license and construct safe systems for spent fuel conditioning and final disposal.

The mentioned test results were technical preconditions for the authorities to accept direct disposal as a valid waste management option. After the law had passed the German Parliament, the Bundestag, it became effective on July 20, 1994. Hence, now there are in Germany two alternatives available for the fuel cycle back end, spent fuel reprocessing and direct disposal of spent fuel.

STORAGE/DISPOSAL STRATEGIES IN UN MEMBER STATES

R.E. Gerton
S.T. Burnum
USDOE
D.J. Squires
VECTRA GSI

ABSTRACT

As of the end of 1993, 32 UN Member States had electricity-generating nuclear power reactors in operation or under construction. There are currently 429 operating units worldwide, with a total capacity of about 337 gigawatt-electric (GWe). In addition,

there are 67 units under construction, which would bring the total electrical generation capacity to about 391 GWe.
Generating electrical power, whether the energy source is coal, oil or nuclear, results in a by-product. In the case of nuclear power, the by-product of concern is radioactive waste.
The management of radioactive waste is not a new concept. It has been safely practiced for low- and intermediate-level wastes (LLW/ILW) for almost 40 years. For high-level waste (HLW), including spent nuclear fuel, many countries with nuclear power are developing strategies, approaches and technologies for its disposal. Disposal facilities for low- and intermediate-level waste and other short-lived wastes are in operation. Currently, there are three common disposal options for these types of waste, ranging from direct land disposal to near-surface facilities and geologic repositories.
There is agreement that interim storage will be an important component of the waste management system - most countries plan to store spent fuel and/or vitrified HLW for at least 20-50 years prior to disposal Presently, spent fuel is being stored by some Member States, at the reactor or at a separate storage facility, with the intent for its direct disposal; others are reprocessing the spent fuel and storing the HLW from the reprocessing. The reprocessed waste product will be placed in canisters in a borosilicate glass form and placed in interim storage, with eventual disposal in a geologic repository. To date, about half the countries with nuclear power are planning for direct disposal of conditioned spent fuel.

INTRODUCTION

The use of the atom has come a long way since that famous day in December 1942 in Enrico Fermi's lab. Since then, the atom has been applied to many uses, including the eradication of worms and flies, shelf-life extension of fruits and vegetables, medical research and therapeutic applications, and most notably, generation of electricity. Nuclear power in 1993 supplied over 23% of the total electricity in OECD countries and about 17% worldwide.
However, using the atom creates a by-product of concern: radioactive waste. Although all activities generate some waste, most comes from nuclear fuel cycle activities that support nuclear power plant operations. These activities include four main categories, which are uranium or thorium mining and milling; fuel conversion, enrichment and fabrication; nuclear power plant operations; and decontamination and decommissioning. The types of waste generated are diverse in terms of levels of radioactivity, physical characteristics and volumes.

QUANTITIES OF RADIOACTIVE WASTE

As mentioned earlier, the majority of the radioactive waste arises from the generation of nuclear power. Thus, if nuclear energy is to achieve its potential, countries with or planning nuclear power must develop effective waste management programmes that will safely immobilize and isolate radioactive wastes from human beings and the environment.
While the actual volumes of waste generated from nuclear energy are small relative to other energy industries and alternatives such as coal-burning power stations, one of the major concerns of nuclear energy is the long period of time that radioactive wastes can pose radiological risks to man and the environment. Although the larger portion of the radioactive waste generated has a relatively short half-life (20 to 30 years), there are some elements of the waste product that have half-lives of hundreds to thousands of years.

DISPOSAL STRATEGIES FOR LOW AND INTERMEDIATE LEVEL WASTE

The management and disposal of low- and intermediate-level waste (LLW/ILW) in Member States with nuclear power plants has been established and proven during the past 40 years. In the early days, LLW/ILW were usually disposed of in near-surface disposal facilities, sometimes referred to as shallow-ground burial sites, with little or no treatment and conditioning. However, as national programmes developed a better understanding of the effects and impact of LLW/ILW disposal, many countries have redefined their disposal strategies and practices.
In most Member States, the disposal strategy for LLW/ILW includes near-surface disposal facilities and geologic repositories. In some countries, the present strategy is to dispose of these wastes in deep rock formations. The four major options currently used or planned by countries for waste disposal are: 1) near-surface disposal facilities, 2) rock cavities, 3) sea coastal facilities, and/or 4) geologic repositories.

Status of Low- and Intermediate-Level Disposal Programmes
By the end of 1992, significant progress in a number of UN Member States had been achieved, and LLW/ILW disposal facilities began operations in Finland, France, and Spain.
A disposal facility (Centre de L'Aube) near Soulaines, France, located approximately 200 km southeast of Paris, received its first shipment of waste in January 1992 (operating authorization was received in late 1991). The disposal facility at (L'Aube) will have a disposal capacity of at least 1.2 million cubic meters of packaged short-lived LLW/ILW. The Centre de L'Aube will replace the Centre de La Manche, which has been in operation since 1969. Closure of the La Manche disposal facility will not occur for a number of years. The waste volume at the La Manche facility is expected to be about 500,000 cubic meters of short-lived LLW/ILW.
In early 1992, the Finnish utility TVO completed construction of a final LLW/ILW repository at Olkiluoto, the location of the first Nuclear Power Plant site in Finland. A cave was excavated in the bedrock to a depth of about 70 meters. Waste from TVO's Olkiluoto Nuclear Power Plants will be stored in 200 liter-drums and 1000 liter boxes in the two rock silos. The repository's total capacity is 15,000 drums and 1000 boxes. A second repository of similar design, which is to be located near Loviisa the second Nuclear Power Plan site, started construction in February 1993, and is expected to initiate operations in 1996. The overall capacity of the new repository will be about 113,000 cubic meters. This facility is being built on the Finnish Island of Hastholmen.
Spain's final storage/disposal facility for LLW/ILW at El Cabril in the Andalucia region began operating in 1992. Spain's disposal model is very similar to that being used by ANDRA in France, which is the near-surface disposal concept with engineered barriers for LLW/ILW. The first phase of El Cabril has a capacity of 60,000 cubic meters, sufficient to last until the year 2000. In Spain, ENRESA is responsible for radioactive waste management, including the storage and disposal of radioactive wastes.
The LLW generated by Belgium's seven nuclear power plants is treated and temporarily stored onsite. Solid LLW/ILW is temporarily stored in a storage facility at Mol until the repository is available in the mid-1990s.
The LLW generated by the 18 nuclear power plants in Canada is temporarily stored onsite. A surface land disposal facility is in operation at Chalk River, Ontario, and is used by AECL and Ontario Hydro for LLW disposal. A facility at the Bruce Nuclear Complex in Tiverton, Ontario, is used for the storage of ILW. The storage units are either in-ground concrete-tiled trenches or above-ground concrete quadricell units. The Canadian government is currently dealing with the political and financial issues of implementing the IRUS (Intrusion Resistant Underground Structures) system. The system stores LLW and ILW in resistant concrete vaults for 500 years, when the radioactivity in the waste has been reduced to acceptable levels.
Site investigations are underway in China to locate and build 10 waste storage and disposal facilities in the Sichuan, Gansu and Zhejiang Provinces. Other storage locations for LLW and ILW will be identified on an as needed basis. The current concept, includes disposal in near surface facilities and rock cavities.
In accordance with the Czech Republic Atomic Energy Commission Waste Management Act, all radioactive waste from nuclear power plants must be converted to a solid form prior to disposal at one of the two regional near-surface disposal sites, which are located at Dukovany and Mochovce. Short-lived wastes that are low-active and low-leachable are disposed of in landfills.
In Germany, notification of intent to develop the Konrad iron mine as a site for a LLW/ILW repository has been filed; site studies are continuing, however, construction of underground facilities as part of the repository has not started. The current schedule calls for a full license review to be completed in early 1995, and operations of the repository are expected to be initiated within 3 years after the approval of this action. The capacity is expected to be about 650,000 cubic meters. LLW/ILW was disposed of in the Asse salt mine from 1967 until 1976, and more than 42,000 cubic meters of LLW was placed in the mine. In addition, the Mosleben disposal facility, located in Eastern Germany, initiated operations in 1993 after a 2 year shut down to evaluate safety of the facility. It is expected to operate until about the year 2000.
A shallow land disposal site for industrial and institutional LLW has been in

operation in Hungary for about 12 years. A number of locations are being considered for siting a geologic repository including a clay formation in the southwestern part of Hungray, an old abandoned uranium mine, the PAKS Nuclear Power Plant site, and others. Research programmes will be conducted at these locations to determine site suitability. Decisions covering site selection are considered long term.
India's strategy is to dispose of short lived LLW/ILW in near-surface disposal facilities, and long-lived ILW (such as alpha-bearing wastes) in deep geological formations. LLW disposal facilities are engineered to meet site specific conditions and are located at BARC and at the nuclear power stations near Tarapur, Rajasthan and Madras, and the reprocessing plant at Kalpakkam.
Japan Nuclear Fuel Limited (JNFL) was authorized in late 1992 to begin operation of its disposal facility for low level waste from the country's nuclear power plants. The disposal facility is located at Rokkasho in Aomori Prefecture. Construction of a repository for 50,000 drums (200 liters each) was completed in November 1992. The facility is to be enlarged gradually to hold up to one million drums of waste - with an ultimate target of three million drums.
Korea's strategy to dispose of LLW includes evaluation of shallow-land disposal, engineering-trench burial and disposal in a mined-out cavity in granite. From the analysis performed, the underground "engineered cave" concept was selected, and engineered barriers will be used to minimize waste migration. Of the 25 sites that were considered, three were selected for further evaluation. As a result of public reaction to considering the disposal site on the uninhabited island of Anmyon, continued search for a disposal site has been delayed. The LLW/ILW disposal facility will have an initial capacity of 500,000 drums of waste, with a final placed volume estimated to be at least one million units.
The storage facility for LLW in the Netherlands, which was built near the village of Borssele, initiated operations in 1992. This is also the location of the 450 MWe PWR-1 reactor. The municipality was one of two in the country that agreed to store nuclear waste in its territory. LLW/ILW will be stored for at least 50 years prior to disposal.
The Swedish Final Repository (SFR) for LLW and ILW at Forsmark began operating in 1988 and is considered by some to be one of the industry's most successful operating facilities. The solid LLW from power plants is segregated, and the combustible materials are incinerated in an excess air-shaft-type furnace. The ash is then cemented in 200-liter concrete shielded drums. Arisings at Oskarshamm and Ringhals Power Plants are solidified using cement in concrete boxes with an internal volume of 900 liters. These wastes are then transported to Forsmark for disposal. The current capacity of Forsmark is 90,000 cubic meters; however, space can be made available to dispose of all reactor wastes from D&D, which is estimated to add about 100,000 cubic meters of LLW.
In 1988, the National Cooperative for the Disposal of Radioactive Waste (NAGRA) in Switzerland, received approval for Project Gewahr from the Government. The approval authorized NAGRA to select and construct a facility for LLW/ILW. The current design concept envisions a disposal facility inside a mountain with horizontal access. The disposal area will be several hundred meters below the surface of the mountain, its design capacity is expected to be about 100,000 cubic meters of waste, which corresponds to 40 years of operation. Successive and independent multiple barriers will be used for long term protection and isolation of the radioactive waste from man's environment.
A LLW/ILW disposal site has been in operation for over 30 years at Radon, which is near Zagorsk, Russia, about 30 kilometers northeast of Moscow. About 5000 cubic meters of waste is received at Radon for disposal each year.
Since 1959, the U.K. has disposed of more than 700,000 cubic meters of LLW in eight trenches at the Drigg Low-Level Waste Disposal Site near the Sellafield Nuclear Complex. Seven of the eight trenches are direct land disposal units; and number eight is an engineered concrete barrier unit, constructed as three separate bunkers, whose overall size is about 220 meters long, 60 meters wide and 5 meters deep. The facility is expected to operate beyond 2020. The Drigg Disposal Site occupies about 107 hectares, of which about 40 hectares are used for disposal of waste.
The radioactive waste management company Nirex is considering Sellafield in Cumbria as a site for a LLW/ILW geologic repository. Test drilling at Sellafield has been under way for several years. Based upon data collected and current studies being performed, indications are that the site is suitable for further investigations and

characterization.
The U.S. Low-Level Waste Policy Act (LLWPA) of 1980, as amended in 1985, mandated that each state, either individually or in compact agreements with other state(s), must have a plan for a LLW disposal facility by January 1993 and in operation by January 1996. In June 1992, the U.S. Supreme Court ruled that the LLPA of 1980 was not valid or binding; therefore, LLW disposal site investigations were not necessary, and individual states were free to develop their own programmes and determine methods for disposing of the waste. There are two commercial LLW disposal sites in operation in the U.S.: they are located at Hanford, Washington and Barnwell, South Carolina. A third site located at Beatty, Nevada receives only hazardous wastes, which began this mode of operation in January 1993. However, due to the political and institutional concerns raised within each of these states, waste receipts from other states may be restricted or stopped at any of these sites.
DISPOSAL STRATEGIES FOR HLW AND SPENT FUEL
Radioactive waste disposal systems are designed to isolate the waste from humans and the environment for the necessary time frames to ensure that no potential future releases of radioactive substances would constitute an unacceptable risk. Such systems have been built at or near the surface for low-level and short-lived wastes, and are widely envisaged to be built deep underground in geological formations for high-level and long-lived wastes. Disposal of HLW in deep geologic formation has received strong support from the scientific and technical experts for more than 35 years. In 1957, the U.S. National Academy of Sciences issued a report that stated that HLW should be disposed of in a deep salt formation. The position, that HLW can be safety disposed of in a deep geology, has been supported by many organizations. In 1991, the NEA Radioactive Waste Management Committee and the IAEA International Radioactive Waste Management Advisory Committee issued the report "An International Collective Opinion on the Disposal of Radioactive Waste: Can Long-Term Safety be Evaluated?" which states that the methods, techniques and analytical tools are in place to determine the long-term safety for disposing of HLW in a geologic repository, and which also notes that this action should be pursued.
Research and Development Activities
In conjunction with the Commission of European Communities (CEC), the Hades underground research laboratory (URL) near Mol, Belgium, was constructed in clay in 1984. Since 1984, the Nuclear Research Center (CEN/SCK) has conducted various tests and investigations to develop a technology for disposal of ILW, HLW and TRU. One of the main objectives of the research center is to evaluate the geology for long-term disposal of HLW in clay. Galleries (drifts) have been excavated at a depth of 225 meters. Various tests are under way (some have been completed), including thermomechanical heating, demonstration of excavation techniques and waste-handling methods.
Investigations are under way on the island of ASPO, with the drilling and mining of a shaft for access to the Swedish URL, to evaluate the granite for a possible geologic HLW repository. The URL is expected to be operational in 1995.
The Waste Isolation Pilot Plant (WIPP) in Carlsbad, New Mexico, suffered a series of setbacks in 1988 - awaiting the official transfer of land from the Bureau of Land Management to the DOE, certification of the TRU-PACT canister, and a hazardous waste permit from the Environmental Protection Agency, thus delaying its experimental schedule for a number of years. The original plan called for waste acceptance in October 1988. It is expected that delivery of waste to the WIPP will not occur until at least 1995-96.
Status of HLW Disposal Programs
To date, most countries with nuclear power are developing and implementing programmes that will safely and effectively manage HLW and/or spent fuel.
China's national programme for HLW disposal has four discrete phases: 1) technical preparations for site screening, 2) geologic research and site characterization, 3) in-situ testing and URL experiments, and 4) repository construction. China is currently in the first phase.
In accordance with a HLW management bill passed by the French Senate and the National Assembly in 1991, ANDRA (Agence Nationale pour la Gestion des Dechets Radioactifs) is continuing detailed geographical investigations at four candidate sites (granite, clay, salt and schist). Upon completion of the site surface work, one or more sites will be selected for construction of an underground research laboratory. Studies and investigations will aim at characterizing the local geology,

radionuclide migration and developing waste emplacement and backfilling techniques, to determine if the site(s) is suitable. Construction of a repository would begin in 1995 for ILW, with scheduled operation around 2000. Emplacement of HLW would start around 2010 if studies confirm the site's suitability.
Out of 100 sites screened, Finland has narrowed the number to three for conduct of site studies to determine site suitability for disposal of HLW and/or spent fuel. A programme to conduct site investigations and confirmation studies until 1997 is planned, and should lead to the identification of a suitable geologic media by the year 2000. A design specific to the selected geology and completion of confirmation studies is expected by the year 2020. Operation of the repository is targeted for the year 2050.
Germany's construction of the Ahaus interim storage facility for HLW was completed in 1991. In June 1992, the facility received its first shipment of fuel from the shutdown THTR-300 high temperature gas reactor. Construction of shaft one at the Gorleben site resumed in March 1989. A final evaluation to examine the legal, technical and organizational impacts of the May 1987 mining accident was completed. Both shafts have been drilled and lined to a depth of 450 meters, which penetrates the salt dome about 100 meters. As currently envisaged, the Gorleben repository is scheduled to begin operations in the year 2008.
For HLW, a geological survey has been conducted at Horonobe in Hokkaido, on the northern tip of Japan. However, due to many siting problems with locating a HLW repository, interim storage facilities (dry storage cask units) may be used. Japan is continuing investigations as to the feasibility of sub-seabed disposal for radioactive waste.
Geological disposal of radioactive waste in the Netherlands may be in salt domes. The Netherlands and the Energy Research Foundation (ECN) are conducting preliminary research evaluating potential suitable sites and repository concepts; however, there are no firm plans at the present to dispose of the radioactive wastes by geologic disposal. A national storage facility at Borssele became operational in 1992. The facility has a capacity of 110,000 cubic meters for LLW and ILW, and 24,000 cubic meters for vitrified HLW and 5000 tonnes of spent fuel.
Spain's current HLW strategy includes: increasing spent fuel storage capacity until a disposal facility is available; selecting a site for disposal in a geologic formation (clay, salt or granite); and, developing an URL pilot facility (IPES) in granite in collaboration with the CEC.
In Sweden some of the spent fuel will be reprocessed, resulting in a small amount of HLW to be stored-disposed of as vitrified glass. The remaining spent fuel will be disposed of in multiple encapsulated copper-clad waste packages. Spent fuel is currently being stored at the CLAB facility. Investigations are under way at ASPO, which is about 20 km north of Oskarshamn, with the drilling and mining of a shaft for access to the URL to evaluate the granite for a possible geologic HLW repository. The URL is expected to be operational in 1995, with about 15 years of testing to follow before a final decision is made as to suitability of the site for a repository.
In Switzerland, NAGRA is now proceeding with a site selection programme, taking into account four candidate sites for a HLW repository. A site in crystalline rock in northern Switzerland is being considered in addition to sites in the central part of the country, and investigations in the Jura Mountains area are also being conducted.
In Russia, spent fuel is to be returned by foreign customers; however, it is to be stored by the customer for at least 5-10 years prior to its return. Due to experience obtained in reprocessing WWER440 fuel, a large-scale plant for WWER-1000 fuel is being built. Industrial-scale reprocessing plants with annual capacities of about 1500 tonnes uranium will be built on an as-needed basis. The resulting HLW will then be immobilized in a glass matrix and stored until a permanent disposal facility is available.
In the United Kingdom, at the present time, there are no plans for HLW disposal in a deep geological repository. Vitrified HLW will be stored for at least 50 years.
The Nuclear Waste Policy Amendments Act (NWPAA) of 1987 designated Yucca Mountain in Nevada as the sole candidate site for detailed characterization as the United States first HLW and spent fuel repository. The NWPAA directed DOE to prepare a site characterization plan (SCP) to determine suitability of the Yucca Mountain Site. DOE published the voluminous SCP for Nuclear Regulatory Commission (NRC) review in December 1988. The SCP describes all the site work completed to date, but more

importantly, all of the geotechnical and engineering test programmes required to determine the site's suitability. The SCP also includes a repository conceptual design, waste package performance criteria, exploratory shaft test programme, levels of quality assurance to be applied for the test programme, repository engineering and performance needs, and plans for engineering, construction, operation and closure of the repository. Exploratory Studies Facility Startor Tunnel Construction was started in 1993. This activity continues underground site suitability studies in the proposed repository block area. The tunnel boring machine was delivered in April 1994 for on-site erection and follow-on operations, which is part of the site characterization activities.

SUMMARY

The disposal of low and intermediate level waste has been practiced in a number of countries for about 40 years. At present, countries are continuing to rely on a mix of near surface and subsurface disposal facilities for disposal of LLW/ILW, but increasing their reliance on the use of engineered barriers to isolate the radioactive materials. Some countries such as Finland and Sweden have constructed disposal facilities at greater depths, and a number of other Member States are leaning towards deep geologic disposal for all radioactive wastes. Even though there are no deep geologic disposal facilities on-line for disposal of HLW, most Member States with nuclear power programmes are evaluating potential repository sites for HLW. In continuing the development of radioactive waste disposal facilities, the IAEA, in response to requests by Member States, is developing standards, guides, practices, etc., which should lead to the harmonization of approaches to radioactive waste management at the international level. In addition, safe and effective waste management practices can be implemented by means of open coordinated national programmes, and exchange of ideas and experiences with the technical community, politicians, media and the public, leading to closer collaboration and cooperation with these groups at all levels.

RETHINKING THE STRATEGY FOR MANAGING LOW-LEVEL RADIOACTIVE WASTE

Joseph A. Coleman

Germantown, MD

ABSTRACT

While it remains the Department of Energy policy to transition as promptly as possible from waste acceptance to disposal, a variety of circumstances in the last decade have resulted in extensive delays in establishing new disposal and treatment capabilities for managing significant portions of the Department's radioactive

waste. As a result, waste management programs are experiencing extended and unexpected storage requirements. Moreover, this situation has delayed the development of disposal waste acceptance criteria and specifications. The combination of contending with expanded long-term storage and the uncertainty about the waste form and packaging to use for such storage in order to avoid further processing and repackaging for disposal has resulted in the need for consideration of more robust components for the waste management system, e.g., waste packages that exhibit enhanced waste containment characteristics and greater flexibility to perform well in all reasonable storage and disposal environments.

This experience is not unique to the Federal waste management program; similar delays and uncertainties exist with efforts in the private sector to establish new waste management capabilities. These circumstances have inspired several efforts to demonstrate and advocate technologies that would provide more conservative and robust systems for managing low-level and low-level mixed radioactive waste. However, there has been little overall system life cycle cost-benefit analysis of deploying the more robust pre-disposal components of the system pending the availability of a disposal capability. To adopt a more conservative and robust strategy introduces certain policy issues, such as the merits of Federal and private sector sharing of selected waste treatment capabilities as a means of reducing capital costs for new or improved facilities and the possible use of lower risk, long-term storage to facilitate a more conservative and structured approach to establishing a disposal capability with approvals by all appropriate stakeholders.

INTRODUCTION

The Department of Energy's Office of Waste Management has a program vision statement that reads:

The Waste Management Program permanently protects people and the environment from the hazards of DOE wastes by providing an effective and efficient system that minimizes, treats, stores, and disposes of DOE waste as soon as possible.

For purposes of the arguments presented herein the operative words of the vision statement are "as soon as possible." Disposal is defined as the least health and safety risk, least cost isolation of the waste from the human environment that can be realized with the resources, technologies, regulations and schedules provided for the waste management programs. An obvious advantage for disposing any hazardous waste as promptly as possible is the reduced risk for human exposures and environmental impacts by isolating the materials from the biosphere. Recognition of this fact is reflected in the regulatory principle of discouraging long-term storage of radioactive waste in favor of early disposal.

Transitioning from waste acceptance to waste disposal is not occurring as expeditiously as expected for large segments of the Department of Energy's radioactive waste inventory. Such delays, which are occurring for a variety of reasons, are having an impact on the strategy for managing all phases of the waste management system. This situation is not unique to the Department's program for managing its waste; the "commercial" low-level waste management programs are experiencing similar difficulties.

The strategy for managing any class of waste with its inherent radiological, physical, and chemical characteristics is predicated on the functional objectives to be achieved by the elements of the management system and the technological, legal, regulatory, and fiscal constraints with which the system must comply. The strategy must also consider the views of legitimate stakeholders as a prerequisite to receiving public acceptance.

For purposes of a common perspective, the key functional elements of a waste management system include:

- Waste acceptancecharacterization, packaging and certification for transfer by the generator;
- Storagean interim function pending treatment and/or disposal;
- Transportationshipment usually for treatment, storage or disposal;
- Treatmentfor storage, transport and/or disposal; and
- Disposal.

TRADITIONAL MANAGEMENT STRATEGY

Once a waste stream is characterized and classified, the traditional approach to defining and implementing a strategy for managing the waste is to identify the method for disposal of the waste, define the criteria and specifications for acceptance of the waste for disposal (e.g., the waste form and packaging

requirements), and to use these considerations as the principal "drivers" for determining critical requirements applicable to each pre-disposal phase in the management system, i.e., acceptance, treatment, storage, and transportation.
This approach to managing the waste has been generally acceptable since it was felt one could identify preferred generic methods of disposal for the principal classes of waste. For example, the bulk of the waste characterized and classified as low-level radioactive waste qualifies for disposal in near-surface land disposal systems that have been demonstrated in practice with both commercial and defense-generated waste. Long-lived and/or highly radioactive high-level and transuranic waste generally require isolation in deep geologic repositories. Since the regulatory performance requirements have been established for these preferred generic disposal systems, and since it was felt one could identify technically acceptable sites for these disposal systems, then one could with a reasonable degree of confidence plan and project schedules for the availability of the necessary disposal capabilities. Armed with the source term inventory for disposal and the characteristics of the host site for the disposal facility, an assessment of the long-term performance of the disposal system could establish the criteria and specifications for acceptance of the waste for disposal. With this information, one could develop the design and performance requirements for the remainder of the waste management system, i.e., the pre-disposal phases.

EXPERIENCE IN IMPLEMENTING THIS STRATEGY

The employment of this strategy for the management of both "commercial" and DOE low-level waste enjoyed reasonable success for over two decades. Disposal capabilities were established on relatively prompt schedules, thereby avoiding prolonged storage of the waste packages. There have been six LLW disposal facilities sited, developed, licensed, and operated by the private sector over the past three decades. Over the same period, DOE operated six major sites with low-level waste disposal capability.
Experience in operating and monitoring the performance of these disposal facilities added greatly to knowledge about the use of enhanced waste forms and packages as well as the potential advantages of engineered barriers to migration of hazardous components. There have also been improvements in modeling the performance of LLW disposal systems and in the codes used for quantitative assessments of the disposed waste in interacting over the long-term with the man-made and natural occurring environment in which the waste is emplaced.

RECENT DIFFICULTIES IN IMPLEMENTING STRATEGY

It would appear, therefore, that with the emergence in the early 1980's of the need for establishing a new generation of LLW disposal facilities in the U.S., the responsible parties could build on this extensive experience base in a reasonably expeditious and straightforward manner in establishing the necessary new LLW disposal capacity. Unfortunately, this has not been the experience of the past decade. Even though 11 States are currently identified to host new "commercial" LLW disposal facilities pursuant to the terms specified in the Low-Level Radioactive Waste Policy Act in 1980, there has not been a new disposal facility brought into operation to date. In fact, in spite of extensive efforts and expenditures of resources, construction has not been initiated on a single new disposal facility to serve non-DOE LLW generators, nor has final approval been obtained for a site to host one of these facilities. Over the same period, there have been only 3 new DOE LLW disposal facilities brought into operation and two of those were technology demonstration projects of limited duration (i.e., the Savannah River Site concrete vaults, the tumulus facility at the Oak Ridge Reservation, and augured boreholes at the Nevada Test Site).
In an effort to promote progress in the establishment of new "commercial" LLW disposal capacity by the States, Congress amended the Low-Level Radioactive Waste Policy Act in 1985 to provide incentives for the States to comply with Federal policy. One of the more compelling incentives was authorization for the three operating disposal facilities in the States of Washington, Nevada, and South Carolina to deny access to their facilities after 1992 by generators outside their specific compact regions as ratified by the Congress. As a result of this provision and the continued delays in opening new disposal facilities, only generators in the 8 States of the Southeast regional compact and in the 11 States in the Northwest and Rocky Mountain compacts served by the disposal facilities in Barnwell, South Carolina, and Richland, Washington, respectively, have access today to disposal

facilities. Approximately 47% of the LLW being generated currently by NRC and Agreement State licensees is being stored, pending the availability of a licensed disposal capability.

As noted above, DOE also has had only modest success in recent years in providing improved or new LLW disposal capacity. There are some common factors that have limited progress in both the "private" and DOE programs. They both have experienced difficulties and associated delays in siting new facilities. In most cases, there have been no unusual problems associated with the process of selecting a preferred site by the responsible organization in its application of such technical criteria as hydrogeologic conditions, avoidance of wetlands, and access to appropriate transport routes.

The difficulties and delays usually occur after selection of a preferred site. Three reasons appear to be the cause of such delays. First, sufficient technical information is not obtained by site developers. Second, technical information, including risks and benefits, are not adequately conveyed to State officials and regulators. Third, local publics will not accept a disposal facility regardless of the adequacy of the technical and regulatory validity of the information. This could be due to a general lack of trust and confidence by the public and the lay decision-makers in the developers and promoters of radioactive waste disposal facilities.

Changing regulations also play a role in opening new disposal facilities. Recently two regulatory uncertainties have emerged that could have significant implications for siting and development of design requirements for new LLW disposal facilities. The NRC is planning to formally propose a revised Branch Technical Position for conducting performance assessments of LLW disposal systems. It will employ probabilistic risk assessment methodology with increased emphasis on uncertainty analyses. The net result will reflect a more rigorous and conservative approach to assessing the performance of the LLW disposal system which is also likely to result in more stringent acceptance criteria and specifications for the disposal facility. Concern has also been expressed by some private sector facility developers that application of the NRC-proposed methodology will make risk communication more difficult to convey and thereby jeopardize the schedule of the licensing process.

The second new development emerging in the regulatory field with potential adverse implications for existing and planned LLW disposal facilities is EPA's draft LLW standards (40 CFR 193) planned for publication in April of this year. These standards include a provision for protection of underground sources of drinking water which is keyed to the maximum allowable contamination limits for drinking water. Options under consideration for this standard may significantly limit operations at some existing disposal facilities and limit siting options for new facilities.

A direct consequence of these delays in realizing adequate disposal capability for low-level waste is either to invoke extended storage of waste or to curtail operations that generate the waste. This assumes that access to an alternate disposal capability is not available, which is the prevailing situation for many private sector waste generators in the country.

Off-site disposal options may or may not be available for DOE generators with waste that is not acceptable to current on-site disposal facilities. If DOE's degrees of freedom for transferring waste among its sites are significantly limited, the Department may have to rely on a strategy of complete waste management self sufficiency for LLW at each major site. Given the wide range of characteristics associated with the low-level class of waste and the quite different site-specific characteristics of the Department's arid and humid sites, cradle-to-grave management of LLW at the site of generation would impose significant economic penalties on DOE environmental restoration and waste management programs. It would also result in extended periods of storage for portions of the LLW inventory at most of the large DOE sites pending the availability of necessary on-site treatment and/or disposal capabilities.

In any case, both licensed and DOE LLW generators that do not currently have access to a disposal facility are confronted with uncertainties about how long this situation will persist during which storage of the waste will be necessary. This leads to further uncertainties and questions about the adequacy of existing storage capacity, what waste forms and containers should be employed for storage in view of the uncertainties about the term of storage, and what will be the resource

requirements for these additional functions. If the wastes are generated as a result of services rendered, one must also consider how best to pass these additional costs to the beneficiaries of the services. Concern has been expressed that the additional costs resulting from the inaccessibility of a waste disposal capability could force the discontinuance of some services using radioactive materials, such as industrial and medical research, diagnosis and therapy, which are deemed important to society. Those organizations confronted with indefinite storage of their waste must ensure that the waste form and container provide the necessary containment integrity over the term of storage. Moreover, they would like the storage package to qualify for acceptance by the disposal facility without further processing or repackaging, thereby avoiding additional costs as well as additional exposure risks to workers and the public.

Preoccupation with this concern about selecting appropriate waste form and packaging for storage has been apparent in workshops on temporary storage of radioactive waste provided to the States and regional compacts by the Department's National Low-Level Waste Management Program over the past couple of years. Among the first to reflect interest in this subject were generators in the State of Michigan who lost access to a "commercial" LLW disposal facility in 1990. Additional workshops on this subject are scheduled in 1995 at the request of States and their waste generators. It is a concern for both the generators and the regulators.

The most obvious response to these concerns would be to store the waste in stabilized forms and containers that comply with the current acceptance criteria at the operating disposal facilities. This may or may not be adequate for the planned new generation of LLW disposal facilities. These facilities with their new designs may require waste packages of new configurations to be compatible with the waste emplacement cells and modes of closure. More stringent waste form/package performance standards may result from planned changes in the regulatory standards governing release rates of radionuclides from disposal facilities. Moreover, the long-term storage facilities may place certain special demands on the waste packages for handling and maintenance of long-term containment integrity.

These considerations could be particularly relevant for managers of DOE LLW. They would prefer to minimize storage while avoiding expenditures of resources on improving or establishing new waste management capabilities that may not comply over the longer term with resolution of their current set of uncertainties:

The degree of flexibility DOE will have in transferring waste between sites for treatment or disposal;

The extent to which different and possibly more stringent regulatory requirements will govern the management of DOE's LLW as a result of the following current regulatory-type initiatives:

- EPA's proposed LLW management standards;
- Revision of the Department's Order 5820.2A that applies to management of radioactive waste;
- The Department's programmatic environmental impact statement that pertains to management of radioactive and mixed waste; and
- The on-going debate as to whether or not external regulatory authority should be imposed upon DOE's nuclear programs, including waste management.

Possible changes in acceptance criteria and specifications for several of DOE's LLW disposal facilities as a result of performance assessments for these facilities having been conducted recently;

Potential policy changes with implications for the long-term strategy for managing waste that could result from periodic changes in the senior Department managers; Resource availability beyond the current fiscal year; and

The uncertain nature and volume of waste to be generated by the environmental restoration program in cleaning up and decommissioning a multiplicity of sites and facilities contaminated with radioactivity materials.

In this latter connection, the cleanup standards, which are still somewhat uncertain, could have a significant impact on the amount of waste to be generated and, therefore, on the capacity requirements for the elements of the LLW management system.

NEED FOR MODIFIED STRATEGY

In addition to the uncertainties noted above, several other known factors contribute to the need for reexamination of the practice of predicating the LLW management strategy on prompt transition from waste generation to waste disposal.

Whatever the result of the debates over the public policy issues of:

The continued use of nuclear energy for generating electrical power;

The continued generation and use of radioactive materials for various industrial, research, and medical applications; and

The continued use of nuclear materials in the U.S. national defense systems;

there remains the need to safely and effectively manage the very large amounts of radioactive wastes already generated by these programs, as well as the waste from the cleanup and decommissioning of sites and facilities that have possessed radioactive materials. However, the experience of the past decade indicates that under today's circumstances the establishment of new LLW disposal sites involve very long lead times. In addition, recent performance assessments of some DOE LLW disposal facilities have resulted in more stringent waste acceptance criteria. As a consequence, some of the waste streams expected to qualify for disposal on-site no longer have an identified place for disposal. An example are waste streams containing transuranic nuclides ranging in concentrations from 10 to 100 nanocuries per gram of waste that are no longer acceptable for disposal in current facilities at certain DOE sites. These wastes will be stored until a disposal facility with suitable containment is established at the site of generation or they can be transferred to another DOE site with a LLW disposal facility that can accept such waste.

Given these facts, one can only conclude that the strategy of transitioning on a reasonably timely schedule from low-level waste generation through any necessary treatment and storage to disposal is no longer viable. This has been a long-recognized fact in the management of DOE's transuranic and high-level radioactive waste. Extended and uncertain periods of storage will likely be the rule rather than the exception for the foreseeable future.

In light of this situation, are there initiatives that can and should be taken by DOE waste managers that provide an enhanced level of confidence in:

a) The integrity of the system to contain the radioactive waste during the lengthy pre-disposal phases of management; and

b) The stored waste package qualifying without further processing for acceptance at the disposal facility when one becomes available.

Such initiatives to modify the strategy for managing the waste must pass the test of providing net overall benefits in terms of public health and safety and life cycle costs.

The most obvious initiative to ensure integrity of a waste storage system for containing the radioactive constituents over whatever time period is necessary while awaiting the availability of a disposal capability is to provide very robust components for each pre-disposal phase of the waste management process. The components in question are primarily the waste form and the waste container. The term robust is intended to mean the application of conservative requirements for the waste form and for the waste container thereby exhibiting a high degree of containment in any likely storage and disposal environment. The bounding case would be design requirements for containment over the 500-year lifetime of the waste package as contemplated by 10 CFR 61.

An additional characteristic of the robust system would be a high degree of flexibility exhibited by the system components to be compatible with and to perform well in a broad spectrum of storage and disposal environments. Just how robust the waste form and how high the integrity of the container may have to be determined at each DOE site in terms of the circumstances that prevail in the candidate options for managing its LLW. For example, the characteristics of the waste streams and engineering judgements about the disposal acceptance criteria and specifications for a specific DOE site (humid or arid) should provide a basis for selecting conservative performance and design requirements to provide a sufficiently robust waste form and container.

To varying degrees a recognition for the need of a more conservative approach is beginning to occur at the major DOE sites as they are confronted with new challenges, constraints, and delays in managing their LLW. This trend should be examined in terms of the need for a strategic principle(s) that would be applied across the entire DOE complex with respect to harmonizing and optimizing the LLW forms and containers for all components in any candidate waste management system. The intent would be to recognize and take into account any uncertainties associated with the disposal and treatment technologies, the schedules on which they can be

deployed, and the associated spectrum of fiscal, regulatory, and institutional constraints when deciding the waste form and container requirements of the system. This process is essentially the general application of system engineering principles.

Several initiatives have been taken in recent years by the Department's Office of Waste Management that will contribute to the more disciplined and fully integrated approach embodied in the application of system's engineering methodology to the management of waste across the DOE complex.

A DOE-Headquarters coordinating manager has been designated for each class of waste, with each chairing a Steering Committee having representation from DOE Operations Offices. Together they maintain a current snapshot of the state of the Department's waste management systems, compile projected waste volumes and the capabilities required to manage these volumes in a manner consistent with the goals to be achieved with time and in compliance with the multitude of regulatory, institutional, and fiscal requirements and constraints on the system. The major system issues requiring resolution should be identified in these studies. A target product of these efforts is the development of a long-term strategic plan for management and disposal of each class of waste.

The DOE regulations covering the management of the Department's various classes of waste products are set forth in DOE Order 5820.2A, "Radioactive Waste Management." This Order is currently being revised to reflect the experience and changes since it was initially promulgated in 1988.

A separate but related study has been recently initiated by the Department's Office of Waste Management pursuant to a recommendation by the Defense Nuclear Facilities Safety Board. It constitutes a survey of all facets of the management of low-level waste across the DOE complex, including the identification of issues and options for their resolution. Elements of the Department's practices will be compared to those of the private sector.

TRENDS IN COMMERCIAL PROGRAMS

A similar situation exists in the management of low-level waste in the private sector. Given the delays in access to a disposal facility and uncertainties about what waste forms and containers will be acceptable when a disposal capability is available, each generator is attempting to ensure access to adequate interim storage under affordable terms and conditions. If generators are providing an in-house storage capability, they are also facing the question of what waste form and container to use and the availability of any necessary treatment capability to produce the preferred waste form.

Some private entrepreneurs have apparently concluded that licensed generators, facing these uncertainties, will opt for more robust waste forms than generally employed in the past. According to recent reports in the trade journals, several projects have been initiated that are designed to provide
more conservative and robust waste forms. These efforts have included the initiatives listed in Table I.

TRENDS IN DOE PROGRAMS

We have seen a similar trend toward conservative waste forms emerging in the management of DOE LLW. As various DOE sites have been confronted with increasing external influences on aspects of managing their LLW, such as tripartite agreements among DOE, the host State, and EPA, they have encountered significant uncertainties about the schedules and technologies for treating and disposing of their LLW. As a result of these uncertainties, there have been case-by-case conservative decisions or considerations given to the adoption of more robust waste forms for certain waste streams. For example, a vitrified waste form has been a prime candidate for stabilizing the low-activity waste stream that will result from processing the HLW at one of the Department's production sites.

Other developments or issues currently under consideration that are conducive to adoption of a DOE strategy to deploy a more robust LLW management system include:

Savannah River Site is eliminating use of engineered earthen trenches for disposal of low-level waste in favor of using concrete vaults. Specially formulated concrete is used to resist cracking and erosion. A waste/grout slurry will be introduced into a vault for in-place solidification (1).

Low-level waste generated in processing Hanford high-level waste is expected to be vitrified rather than stabilized with grout for disposal (2).

- DOE has contracted to demonstrate for vitrification of liquid low-level waste at

Hanford.

Vitrification of residual waste from operation of the proposed Idaho Waste Processing Facility is planned when treating mixed alpha-low level waste (3).

Use of sulfur polymer cement has been proposed for solidifying and stabilizing radioactive and mixed low-level waste, particularly those with high concentrations of toxic metals and salts resulting from high-temperature treatment processes (4).

Pilot-scale tests have been conducted for the use of an existing electric arc melter to evaluate vitrification processes for low-level and transuranic mixed waste similar to those occurring at the INEL (5).

Oak Ridge National Laboratory plans to demonstrate in 1995 a ceramic waste form for nitrate salts (2).

Proof of concept tests were completed in 1993 at INEL for a fixed hearth plasma thermal treatment unit, thereby demonstrating the ability of this process to turn compacted waste drums and buried waste into a vitrified product that complies with Federal and State laws for disposal (2).

Based on past experience and current considerations, one can identify advantages of extended duration and uncertain disposal criteria:

Provides an additional margin of safety and confidence in the containment integrity of the waste package if the term of storage is extended;

Results in a storage waste form acceptable for disposal over a broader range of acceptance criteria, thereby minimizing adverse schedule and cost impacts due to possible changes in regulatory performance requirements and more stringent waste acceptance criteria;

Likely reduced total life-cycle costs, reduced worker exposures by avoiding further processing and packaging operations, and increased safety margins for potential public exposures;

Provide enhanced confidence in and acceptability of proposed waste management system by the public and host State officials; and

Reduction in potential adverse implications from changes in the planned configuration of TSD facilities across the DOE complex resulting from host State equity decisions, PEIS results, or changes in DOE policies.

On the other hand, there may be disadvantages associated with the more robust system to be considered:

There would be increased near-term capital outlays for the more expensive treatment, storage, and/or disposal components of the system; and

There could be higher unit costs than originally projected for management of the waste.

Both of these potential disadvantages may be more than offset by use of the more robust system, thereby avoiding additional costs and personnel exposures associated with a future need to further treat and repackage the stored waste to comply with more stringent requirements.

If the Department adopts a strategy of reliance on more conservative and robust systems for management of its low-level radioactive and mixed waste, it would also be useful to consider other policy issues including:

1. Should there be some degree of accessibility for low-level waste generators to treatment and perhaps even to disposal facilities between the Federal and the private sector waste management systems? Such an approach could be conducive to harmonizing waste management practices and associated risks on a national scale and could be cost effective for both sectors in terms of minimizing the number of capital projects, optimizing land use, and economies of scale.

2. Should DOE rely on "privatization" as a means of establishing selected low-level waste treatment and disposal capabilities, thereby taking advantage of the experience of private industry with the more conservative and advanced engineered disposal technologies, use of high-integrity containers, and stabilized waste forms customized to specific waste streams, which are required by some State waste disposal requirements.

3. Should external regulatory authority be applied to the Department's waste management operations? An affirmative resolution of the two aforementioned policy issues would certainly be conducive to a similar resolution of this issue.

4. Should the Department's regulations include prescriptive performance requirements for low-level waste forms and container integrity in terms of radionuclide confinement (release rates)? Given the progress in RD&D for the long-term performance of concrete structures for low-level waste disposal applications (1) and

the advances in high-integrity waste forms and containers, should consideration be given to adopting a system performance objective of zero release for the first 300 years. Such a requirement, if realistically achievable, would minimize concerns about siting disposal facilities on DOE reservations, even if the more stringent low-level waste standards proposed by EPA in 40CFR193 become a reality. It could also result in portions of the GTCC LLW qualifying for disposal in the near-surface low-level waste disposal facility.

HUNGARIAN STRATEGY FOR MANAGEMENT OF RADIOACTIVE WASTE OF NUCLEAR POWER PLANT ORIGIN

Peter Ormai
Paks Nuclear Power Plant Ltd.
Jzsef Solymosi
Ivn Gresits
Budapest Technical University
Hungary

ABSTRACT

In Hungary, no long term strategy has been worked out yet for the waste coming from the nuclear power plant operation and decommissioning - a strategy that covers all important questions related to the problem.
The original Soviet concept for low- and medium level radwaste storage - i.e. the storage of the radwaste in the plant site -till the time of decommissioning was refused by Hungarian authorities as early as in 1977. The proposed new concept - to dispose of the cemented waste into trench - type facility at a distance of less than 100 km from the NPP - remained only an idea after the 1990 January ministerial refusal concerning the planned site and repository.
The recognition that to solve the safe, socially acceptable final disposal of the radwaste generated in the NPP - which provides almost one half of the Hungarian electrical energy production -needs a complex (scientific, economical/technical social, legal and financial) activity went into operational program at the beginning of 1992. The Hungarian Atomic Energy Commission in his resolution related to this topics deemed it important to launch an inter-departmental Task Project aiming at finding solution for the final disposal of the NPP radwaste. Within this Project - called National Project - a comprehensive strategy had to be established covering all the low-and medium level waste produced during the whole life of the plant and the back-end of the fuel cycle, handling and disposal of the waste coming from the plant decommissioning, and implies technical, licensing, regulatory activities, the financial solutions and public relation issues.

INTRODUCTION

The concept laid down in the late 1960s for the management of wastes at WWERs was to store the arising wastes on site and to postpone the decisions on conditioning and disposal until the decommissioning stage so that wastes from operation and dismantling can be handled together. Waste collection and storage systems were developed to accommodate ten years' treated operational wastes with possible extension of storage capacities. The only exception were very low level solid wastes where on-site disposal was proposed.
A truly remarkable feature of the concept was the return of the spent fuel to the USSR where it would be reprocessed and the arising wastes would be disposed of. No reprocessing wastes were to be sent back to the operators of the reactors. However, after the political and economic changes in Russia, this practice may not continue and probably new arrangements will have to be made.

Due to differences in design and operating philosophy from those practiced in Western Europe, the waste management systems at power plants with WWER reactors have to deal with relatively large volumes of waste. This resulted in the accumulation of large amounts of radioactive wastes stored at the sites of the NPPs and has increased the risks of radiological incidents and contamination of the environment. Now, following the political changes in Eastern Europe, there is an intensive re-evaluation of the safety of WWER reactors under way. This program also deals with the waste management practices at these power plants. During the IAEA's Technical Assistance Regional Project on Advice on Waste Management at WWER type reactors, the lack of effective waste management strategies has been identified as the most significant common problem apart from the need for further technical improvements. Nuclear activities in Eastern European countries are carried out on the basis of nuclear energy acts which only define general principles. Application of these principles would require a more detailed system of regulation which is not available yet. In most cases only the period of the NPP's operation is covered and the problems connected with decommissioning and final disposal of all types of wastes remain to be resolved. Furthermore, in the centrally planned economies the state was responsible for all decisions concerning the financing of these activities and now there is an urgent need to reallocate the responsibilities between the state and the operators according to the needs of the new economic system. As the IAEA experts put it, the safe and reliable management of radioactive wastes is only possible within the framework of a clearly defined national waste management strategy which covers all of the long term aspects of waste management.

The main requirements for such a strategy should include:

- a legal framework;
- a clear structure and division of responsibilities between operators and national authorities at all levels;
- national regulations for the releases of radionuclides into the environment and exemption limits;
- key decisions on the type of disposal for low and intermediate level wastes arising from operation and decommissioning;
- evaluation of solutions for the back end of the fuel cycle (duration of and technologies for intermediate storage, preparation for geological disposal of spent fuel or high level reprocessing wastes);
- timing and extent of decommissioning activities;
- long-term liabilities, financial arrangements and insurance for all waste-related activities.

However, the development of the individual countries' waste management systems were also influenced by their own regulatory authorities, the performance of the plant, and previous waste management experience. Many of the power plants have changed the original system arrangements or some of its components.

NATIONAL PROJECT

On 28 February, 1992, the Hungarian Atomic Energy Commission (HAEC) declared in a resolution that the safe and socially acceptable disposal of radioactive waste required the co-ordination of complex scientific, economic, technological, social, legal, financial and international activities.

It was found that the most appropriate means to achieve this was the establishment of an interdepartmental project in which all the organizations concerned would be involved. Basically, this resolution represented a realization that since the reliable operation of the nuclear power plant was a national interest, the company could not be left on its own in its attempt to find a solution to the radioactive waste disposal problem.

To implement this resolution, a proposal was prepared by the representatives of several ministries and Paks NPP.

The starting point taken in the proposal was that the project should be realized as a part of the new tenders program of the National Committee of Technical Development and thus the tasks of the project must essentially be commissioned through the invitation of tenders.

According to the proposal, the Project was to be funded primarily by the Paks NPP Ltd. although substantial contribution would come from central resources as well. The setting up of an appropriate fund or other financial arrangement to cover the costs of the waste disposal was also scheduled to be done in the framework of the Project.

When discussing the proposal, the Hungarian Atomic Energy Commission considered it very important that a complex strategy be elaborated that would cover all the issues related to the management and final disposal of the low and intermediate level radioactive wastes arising during the operation of the plant, the wastes resulting from the closing of the nuclear fuel cycle (spent fuel and perhaps high level reprocessing waste) and finally the wastes coming from the decommissioning of the plant.
It was emphasized that the strategy would have to deal with the different options of the technical realization of the disposal facility (near surface or geological disposal), the economic conditions of the disposal, the licensing and regulating activities of the authorities, and the question of public acceptability.
On 26 February, 1993, the Ministry of Industry and Trade, the Ministry of Public Welfare (the successor of the Ministry of Health and Social Affairs), the Ministry of Environmental Protection, the National Committee of Technical Development, the State Holding Company (which is responsible for the proper management of state owned enterprises as a trustee), the Hungarian Electricity Works Ltd., and the Paks Nuclear Power Plant Ltd. signed a Co-operation Agreement to solve the handling and final disposal of radioactive wastes of nuclear power plant origin.
According to the agreement, the National Project, which is aimed at the establishment of the repository for low and intermediate level radioactive wastes, will be carried out in two phases. The complex strategy will be worked out in the first phase (1993-94). This phase will provide the basis for the decision on the siting of the facility and the invitation of tenders for its realization. The second phase is the actual realization of the facility.
The costs of the project will be covered by the fulfillment of the economic conditions that are to be worked out in Phase 1.
Informing the public about the National Project, the results of its implementation and other issues that might arise during the process was considered as a high priority and a decision was made to carry out these activities in a co-ordinated manner.
The responsible organization for the realization of the Project is the Paks Nuclear Power Plant Ltd. The first phase of the Project is jointly funded by the company and the Central Technical Development Fund.
The following tasks of the Project are listed in the supplement of the agreement:
  elaboration of a complex strategy for the management and final disposal of radioactive waste;
  siting of radioactive waste repositories;
  having the site and the facility accepted by the public;
  selection and implementation of waste handling and volume reduction technologies;
  drawing up the conceptual design of the facility for the disposal of low and intermediate level radioactive waste;
  preparation of the engineering report, licensing and construction of the facility.

COMPLEX STRATEGY

The complex strategy was worked out on the basis on the following principles:
  Radioactive wastes generated should not hamper the operation of the NPP during its whole life.
  At the plant site radioactive wastes shall be stored in the possible lowest amount and volume.
  Pre-disposal conditioning of the radwaste and the final disposal itself has to be solved within the shortest time possible.
  By examining the alternatives of the technical solution, a complex evaluation shall provide a framework for the further tasks that later would be submitted to tenders for design and construction of the facilities.
  By designing the final disposal of the radwaste, not only the waste from the plant in operation, but that from a contingent further one shall be considered.
  For selecting the technical solution, the experiences of the countries that are advance of us have to be used and provide the proper references.
In Hungary - as previously mentioned - no long term strategy has been worked out yet for the waste arising from the nuclear power plant operation and decommissioning - a strategy that covers all important questions related to the problem.
The original Soviet concept for low- and medium level radwaste storage - i.e. the storage of the radwaste in the plant site -till the time of decommissioning was refused by Hungarian authorities as early as in 1977. The proposed new concept - to

dispose of the cemented waste into trench - type facility at a distance of less than 100 km from the NPP - remained only an idea after the 1990 January ministerial refusal concerning the planned site and repository.
Since 1983 the Paks NPP has been sending low activity solid radwaste to Central Radioactive Waste Processing and Storage Facility at Pspkszilgy - a disposal facility built for receiving radioactive waste of non-nuclear fuel cycle - with the consent of its constructor, the Hungarian Atomic Energy Commission and with permission of the health authorities.
Long term concept of the Paks NPP fuel back-end - to ship back the spent fuel to the Soviet Union as made previously - has became rather uncertain because of the radical changes in foreign policy and economical environment in the ex-SU.
The complex strategy was worked out on the basis on the following principles:
Radioactive wastes generated should not hamper the operation of the NPP during its whole life.
At the plant site radioactive wastes shall be stored in the possible lowest amount and volume
Pre-disposal conditioning of the radwaste and the final disposal itself has to be solved within the shortest time possible.
By examining the alternatives of the technical solution, a complex evaluation shall provide a framework for the further tasks that later would be submitted to tenders for design and construction of the facilities.
By designing the final disposal of the radwaste, not only the waste from the plant in operation, but that from a contingent further one shall be considered.
For selecting the technical solution, the experiences of the countries that are advance of Hungary shall be used.
The first version of the complex strategy outlines the work to be performed by considering the knowledge available at the time of compilation and the previously declared and approved ideas, giving the priorities for the participants in the Project and for the experts getting in touch with it (Authorities and decision makers etc.). At the end of the first stage of the Project, on the basis of the decisions and the knowledge acquired in the meantime, the first version of the strategy is to be reviewed and finalized focusing on long term tasks for each decision-making and executive level.
The structure of the complex strategy goes along with the logical sequence radwaste treatment and disposal and assigns the tasks required from the origin through the treatment, packing, transport up to the final disposal according to this sequence.
Basic premises of the approach applied for solving the problems are as follows:
Elaboration of a coherent international recommendation system related to waste management as a whole is currently in progress. Principles and the requirements are laid down, they can be applied in Hungary, too.
Operation and economical electricity production of the Paks NPP is of a national interest. So it is not solely the Paks NPP's interest to solve the waste management problems.
Treatment of the nuclear power plant wastes means a very complex system. Arrangement of some single elements (solving the problem of partial areas) results not necessarily the optimum of the whole system. In decisions, the "system view" and the avoidance of "irreversible" alteration shall dominate.
As a part of the "safety culture" a change in the way of thinking should be reached, where the success were not measured by solving the known and urgent problems in short range but - by seeing the waste management as a process - favors the forming and implementation of such procedures that provide adequate handling for both the known and the - for the time being - unknown problems.
Having the priorities of the partial areas scrutinized, the following statements can be made:
Source - side reduction of the waste produced is a general requirement.
A further general requirement is to avoid the long living radioactive isotopes getting into the waste stream, or at least to minimize this process.
Without the availability of waste disposal facilities, the waste management is unsolved. Disposal for the low - and intermediate level radioactive waste has to be constructed even in the operational period, and it should have the capacity also for housing the decommissioning waste. Therefore design work shall account both with the operational and decommissioning waste.
It should be set as a requirement to carry out developments programs of the Paks

NPP technological system in such a way (the availability of the intermittent storage capacities included) that results a minimal amount but conditioned waste suitable for disposal.
By taking into account the above principles and objectives a hierarchically arranged proposal for the tasks to be performed are as follows:
The following questions should be discussed in a government-level submittal
a) Acceptance of areas proposed for detailed site survey and that of the disposal concept
b) Proposal for establishing a national waste management agency
c) Settling the long term financing and liability problems
d) Ideas for the nuclear power plant decommissioning:
- alternatives of the total decommissioning or further utilization as a nuclear site;
- the time scheduling of decommissioning.
e) Principles of the high activity waste disposal
- Reprocessing or direct disposal
- Intermittent storage, the program scheme of the final disposal with decision making, time schedule and cost estimation
Problems requiring authority regulation or further development of the regulation:
a) Relation between waste classification and solutions for disposal (adaptation of the IAEA proposals is suggested)
b) Determination of the limits of exemptions
c) Determination of the waste acceptance criteria
d) Settling the waste qualification - and requalification procedure
e) The problems of waste disposal to be regulated include the site selection requirements, settling the safety requirements on dose - or risk basis, establishing
the licensing scheme and system of terms up to the end of institutional surveillance,
as well as integration of the aspects of the public needs and concerns.
Questions belonging basically to the Paks NPP authorization area:
a) Source side minimization
b) Expand the storage capacities or improvement of their maneuverability
c) Apply the waste volume reducing technologies
d) Liquid waste conditioning
e) Preparations for decommissioning waste treatment

SUMMARY

In 1993 a National RW Management Project was launched to solve handling and disposal of LLW/ILW of the Paks Nuclear Power Plant and to elaborate a complex strategy for the management of radwaste from the NPP, including HLW, spent fuel and wastes from the decommissioning. It was intended to realize the project so as to have selected the possible site (or sites) for the LLW/ILW waste repository. The nation-wide screening for suitable areas and the comparative evaluation process to select potential sites for a surface or geological LLW/ILW disposal facility is under progress. International tenders were issued to find the most appropriate technology to reduce the quantity of liquid and solid radwaste in the Nuclear Power Plant. Their results will provide a better basis for planning the characteristics and quantity of radwaste. The applications revealed that supercompacting can be ordered as a service, when need arises thus it was possible to re-allocate the funding foreseen for the equipment to treat solid wastes. Great importance is attached in the Project to public acceptance and PR activity. An expert organization was selected in a two-phase bidding process, and it was decided that detailed exploration of a potential site will take place only if public acceptance is assured. The original program of the Hungarian RW Management Project was extended in 1994 to make on-site underground investigations with Canadian support in a silt-stone formation. The first results confirm that this is a potential site for deep geological disposal of HLW. The financial and legal framework of the RW management is also to be solved. The new law on nuclear energy now in preparation will deal with that problem in one of its most important chapters, defining the responsibilities for RW management and the sources of funding.

EXPERIENCES, CONCEPTS AND STRATEGY WITH THE MANAGEMENT OF RADIOACTIVE WASTE MATERIALS IN FR YUGOSLAVIA

Aleksandar Peric
Ilija Plecas
Institute of Nuclear Sciences "Vinca"
P.O.Box 522
Belgrade, Yugoslavia

ABSTRACT

From the early fifties, when the first research reactor started with operation inside the "Vinca" institute site, parallel started generation of the radioactive waste materials. These materials had been generated in the industry and nuclear medicine, as well, where the radionuclides found their useful application. All these materials were transferred to the covered interim storage on the Institute site, that was built in early seventies, whether they were in liquid or solid form. Compressible solid waste materials were introduced to the 50 tone hydraulic press, for the volume reduction purposes. Capacity of the facility is five thousand drums. Main radionuclide presented in the most of the drums were 14C and 3H. Dose rate in the storage does not exceed 5 mSv/h. This storage facility was fulfilled, and in the early eighties, second interim storage facility was built. Liquid radioactive waste materials, that were generated in the research reactor, were transferred, using specially manufactured pipeline, to the four stainless steel reservoirs, each of 300 m3 capacity. As concepts for immobilization processes of the generated and stored radioactive waste materials, cementation and bitumenization processes are adopted. These two processes are suitable for immobilization of different types of the radioactive waste materials, depending on the radwaste material origin and structure. Pilot bitumenization plant was built in the "Vinca" institute, and the experiments were carried out with three types of the Yugoslav produced bitumens, used as an inactive matrices. Optimization was performed on the basis of the lowest level of the radionuclides leaching from the matrix-radwaste form, as well as on the other physico-chemical and mechanical characteristics. Cementation facility is under construction. In the technological procedure of the radwaste materials chemical pretreatment and treatment before the cementation, several steps were taken into account, such as: concentration, chemical precipitation, phase separation with or without evaporation. As a concept for the final disposal system of such prepared solidified radwaste-mixture forms, engineer trench system is adopted. This system consists of four barriers to the influences that might occur to and from the trench environment, and they are: immobilized matrix-radwaste mixture form, solidified inside 200 l metal drums or in concrete made containers, depending on the applied immobilization technique, drainage materials and trench walls, made of the concrete of the high mechanical strength characteristics. Engineer trench system will be divided into section, each representing independent trench system, with the control possibility of the system potential damages, expressed as radionuclide presence in the drainage network system, that goes under the trenches and collects liquids that might penetrated through facility. All R&D work that is performing in the "Vinca" institute, dealing with the treatment and management of the radioactive waste materials has its final goal in constructing the Yugoslav radwaste materials final disposal centre.

INTRODUCTION

Since early fifties, when the "Vinca" nuclear research reactor of 5 MW power started with operation, as a product in the nuclear fuel cycle, radioactive waste materials of different levels of specific activities, were generated. Simultaneously with research rector operation, laboratories for fuel reprocessing, radiation chemistry

and application of radioisotopes in nuclear medicine, industry and agriculture, started with work. In the same time, in the "Vinca" Institute, the Radiation and Environmental Protection Department was established. Its primary task was collecting, conditioning and storing of the generated and accumulated radwaste materials, on the site of the "Vinca" Institute,in absence of a final storing centre,being in project stage.

Quantities and nature of radioisotopes presented in collected radwaste materials until nowadays, have established a task in front of the "Vinca" Institute investigators, to solve the problems that are arising from the collected radwaste materials in their safety handling, treatment, conditioning, storing and final disposal.

All the accumulated radioactive waste materials should be treated due to the international regulations and recommendations of IAEA and ICRP (1,2). Quantities of the accumulated radwaste and a level of bonded activities, ordered necessity of safety handling of these materials, as well as development of appropriate technologies, which have to provide final products of the immobilization processes to be safely stored and disposed.

Numerous procedures that are adopted in developed countries, having a great deal of experience in the radwaste materials management, were adopted in the earliest stages of our investigations. First of all, we had to established types and quantities of the radwaste already stored on the "Vinca" institute site, their generating frequency and to adopt safety procedures related to their handling in transport, immobilization, storing and final disposal. Due to these safety procedures, we were obligated to confirm safety of an each step in the radwaste materials management. This task was related to an investigations of the radwaste materials chemical and mechanical treatment, before their introduction to an immobilization processes and treatment of the mixtures of radwaste materials and matrix materials, as well as materials that are anticipated for the final disposal facility construction on prospecting their physico-chemical and mechanical characteristics. Processes of radwaste materials pretreatment and treatment of the radwaste materials are depending on their form and phase, as well as on possibility of recovering the valuables components, that are presented in the bulk radwaste form, using one of the appropriate methods (1).

SOURCES, TYPES AND QUANTITIES OF RADWASTE MATERIALS AND MANNER OF THEIR STORING

Radioactive waste materials that arised as off-products in the work of research reactor, as well as in industry and medicine, were interim stored on the Institute site. All these materials were transferred to the covered interim storages on the Institute site, that was built in early seventies, whether they were in liquid or solid form.

Liquid Waste Materials

For the purpose of collecting of the liquid waste materials, generated in the research reactor, four stainless steel reservoirs, each volume of 300 m3, were built. These underground basins were connected with reactor building through a special net work system. The main radioisotopes in these reservoirs are: 137Cs, 60Co and 3H, where the specific activity of the liquid is about 4 KBq/ml. The other source of the liquid radwaste materials is radioisotopes production laboratory. These radwaste materials have different radionuclide composition from the materials of the first group, and the preconcentration of liquid is usually done before its introduction to the underground reservoirs. This group of radwaste is divided into two subgroups, due to half-life of the radioisotopes present. The third source of the liquid radwaste materials arising from the isotopes application in research, medicine and industry.

Radioactive waste materials arising from radionuclide application in medicine and industry, are temporary stored inside the storing facilities on the site of the "Vina" Institute. Liquid radwaste materials are placed mainly in the plastic made barrels, V=50 l. Liquid radwaste materials collected in the underground reservoirs are periodically inspected on pH value and specific activity. Building of the facility for the liquid radioactive waste materials treatment, is in progress.

Solid Waste Materials

Solid radwaste materials are generated from the sources already discussed, as well as from collection of the spent sealed and unsealed sources, fire alarms, radioactive lightning rods, radium needles and discarded filters from the ventilation systems. These materials are divided into two groups: compressible and

incompressible materials. If the materials from the both groups are valuable, they could be decontaminated in the first treatment step. These materials are stored in the 200 litres steel barrels, with or without interior concrete shield. The annual production of these materials till 1990 was about 70 m3, depending on intensity of work in the nuclear program. For the volume reduction of the compressible waste in drums, 50 tone press was used. At the beginning, drums were stored on the uncovered storage, where they were under the destructing influence of corrosion.
In early seventies, first covered interim storage was built, with the capacity of 5000 drums. The main radionuclides in almost 50% of all drums are 14C and 3H. Dose-rate in this storage does not exceed 5mSv/h. In 1984., the new interim storage shed was built. In this facility, 1500 drums are stored and the great deal of the stored radwaste materials are spent sealed sources from medicine and industry, dominantly containing 60Co, 137Cs and 153,154Eu.

EXPERIENCES

When the row radwaste material is conditioned mechanically and chemically in aim to decrease the volume of the waste form, such a treated material is immobilized in the inactive matrix. In our investigations, as a matrix, domestic cements and bitumens were used. After solidification of the radwaste-matrix mixture form, hardened monoliths are obtained. These solidified radwaste mixtures are investigated on their physico-chemical and mechanical properties. Good experimental results of the investigations, performed in aim to confirm good embedding properties of the matrix-radwaste mixture forms, which could guaranty stability of the solidified waste forms during the operations of their transport, storing and final disposal, even in the elapsed periods of time.

Research and Development Work (R&D)

Even the regulatory bodies of the Yugoslav government imposed temporary prohibition of nuclear power plants building, objects for treatment, storage and disposal of radioactive waste materials were excluded and we were in position to continue with our R&D work, in attempts to start with the preliminary works of the first Yugoslav radwaste disposal facility and all activities, that are related to this goal. This work is related to the procedure steps in treatment of solid and liquid radwaste materials, before they are introduced into the immobilization processes, developed until nowadays in the "Vinca" Institute: cementation and bitumenization (3,4,5,6). Immobilization processes in which two component resins were applied as matrix materials were neglected in the early stages of the matrix material selection, mainly because of expensive immobilization process, as well as some weak physico-chemical characteristics. Developed immobilization processes have, as a final goal, production of the solidified radwaste-matrix mixture form that is easy for handling, and that satisfy safety requirements for interim storage and final disposal of such materials, on the appropriate sites. Shallow land burial engineer trench system, as a concept of the final disposal system for low level radioactive waste materials, is adopted. Following this strategy, materials that the engineer trench system consists of: mortar or bitumen as matrices, concrete for containers and trenches, back fill and drainage materials, were investigated. Research was done in aim to define the most important physico-chemical properties, that characterized implemented materials as barriers to the radionuclide migration from the trench system to an environment. Optimization of the matrix materials, either mortar and bitumen, were performed, as well optimization of the concrete formulations for containers and trenches in aim to promote the best physico-chemical characteristics of the materials applied in three stage barriers concept for radwaste materials final disposal system.

Experimental Work Related to the Radwaste Management

Testing methods, which are applied mainly in radwaste-mortar mixture form properties examinations, are:

- leaching test in static conditions,
- leaching test in static semi-real conditions,
- leaching test in dynamic conditions,
- leakage test,
- test of radwaste-mortar mixture form accelerated ageing,
- testing of mechanical characteristics,
- permeability measurements.

All the experiments were ruled up to the IAEA recommendations and standardized procedures (1,2,7).

The most important characteristics that were investigated for each material in the final disposal system, are: main radionuclides leach-rates and adequate diffusion coefficients, permeability, porosity, compressive strength, resistance on freezing and open flame. One of the specific investigation methods that was developed in the "Vinca" Institute was "leakage"-test, that should simulate radionuclides migration from the encapsulated solidified radwaste-mortar mixture form through the well defined inactive barriers of the final disposal system, into the inactive environment, e.g., distilled water in these experiments. One of the aims of the R&D work is, by using the results of the performed experiments, to be in the position to predict behaviour of each segment of the future disposal system, especially solidified waste-matrix mixture, in the prolonged periods of storing time, in normal and accidental conditions on the disposal site. In this manner, experimental results for prospected radionuclides leach-rates, as well as their efficient coefficient of diffusion, obtained in leaching-test, using Standard Hespe`s and modified, accelerated and Soxlet`s methods, were used as input parameters in the mathematical modelling of the phenomena of radionuclide leaching from the matrix materials to the environment (3,4,7,8,9). For this purpose, modified program packages are used. Results of the experiments, performed in a period of 3 to 5 years shown good accuracy of the applied mathematical models to the experimental results, when simulating the radionuclide leaching from the inactive matrices in the prolonged time periods (5,6,8,9,10).

FINAL DISPOSAL SITE CONCEPT

Radioactive waste materials generating in FR Yugoslavia established a task in front of the organizations responsible for handling with the hazardous and radioactive waste materials, starting with development of an idea project in such hazardous materials safety treatment in collection to a final disposal.

As a concept for the final disposal system of such prepared solidified radwaste-mixture forms, engineer trench system is adopted. This system consists of four barriers to the influences that might occur to and from the trench environment, and they are: immobilized matrix-radwaste mixture form, solidified inside 200 l metal drums or in concrete made containers, depending on the applied immobilization technique, drainage materials and trench walls, made of the concrete of the high mechanical strength characteristics. Engineer trench system will be divided into the sections, each representing independent trench system, with the control possibility of the system potential damages, expressed as radionuclide presence in the drainage network system, that goes under the trenches and collects liquids that might penetrated through facility. All R&D work that is performing in the "Vinca" institute, dealing with the treatment and management of the radioactive waste materials has its final goal in constructing the Yugoslav radwaste materials final disposal centre.

STRATEGY

In our attempts to prepare all the pre-work that is necessary for a future Yugoslav final disposal centre for the low and intermediate level radioactive waste materials, we decided to established National Agency for Radioactive Waste Management (NAROM). This body of the national importance will have its main task in planning and leading all the actions that are related to the radioactive waste management, such as: making a decision on the final national disposal radwaste materials disposal centre, concerning the disposal site and techno-economical aspects of the facility, and it will have advisory role for all aspects of the radioactive waste management: appropriate pretreatment, treatment and immobilization techniques for the certain waste materials, manners of solidified waste materials transport, storing and disposal, etc.

Figure 1 graphically represents concept of the organization of the Yugoslav agency for the radioactive waste management.

CONCLUSION

Preliminary investigations and research work related to the final disposal site for the future Yugoslav radwaste disposal site is in progress. Until the final decision concerning facility site is made, all the other, necessary previous step should be finished, having a common goal in being positive about quality of the all applied processes and techniques in radwaste management. Optimization of the chosen techniques in treatment, conditioning, immobilization and storing the radwaste materials is nearly completed and great deal of the work is almost done. Investigations are still carrying out on materials that are adopted as components of

the engineer trench system, in aim to improve their physico-chemical properties, mainly retention the radionuclides release from the disposal facility to environment, as well as their mechanical characteristics. Parallel, collection of the new generated waste materials and their interim storing at the site of the Institute "Vinca" is continuing.

ABSTRACT

High density storage racks (HDSRs) have been, and will be installed to alleviate the saturated condition of spent fuel pool storage capacity in some operating nuclear power plants in Korea. Korea Power Electric Company (KOPEC), the A/E, has been performing the technical support in the reracking projects for Korea Power Electric Corporation (KEPCO), the utility. This paper presents the experiences and some issues encountered from previous and current reracking projects. The prospects for future reracking projects and the design of spent fuel pool under consideration are also discussed focusing on the work to be performed by KOPEC.

INTRODUCTION

In Korea, nuclear power plants have been an important role of the national energy system since the first commercial operation of KORI-1 in 1978. Since then, the nation's nuclear power program has continuously expanded. At present, Korea has nine nuclear power plants (8 PWRs and 1 CANDU) in operation with generating capacity of 7,616 MWe. The nuclear share of total installed electrical capacity is about 36%

which requires approximately 180 MTU of PWR fuels and 100 MTU of CANDU fuels every year. Seven(7) nuclear power plants, with capacity of 6,100 MWe, are currently under construction with an additional 7 more nuclear power plants, with capacity of 6,700 MWe, planned by the year 2006.

There are several long-term issues to be resolved in order to continue Korea's nuclear energy policy as planned. The major issue is the radioactive waste management which includes interim spent fuel storage, and low- and intermediate-level radioactive waste disposal. The spent fuel storage capacity of most of the nuclear power plants operating in Korea will be nearly saturated by 2000. To resolve this issue, the Korean Atomic Energy Commission, the governmental regulating authority, decided in 1988 that a central away-from-reactor interim storage facility for spent fuel will be constructed by December 1997. Several studies on the interim storage of spent fuel have been performed. However, the construction of an interim storage facility has been delayed due to the difficulty of site selection. Therefore, reracking projects to increase the at-reactor storage capacity of the spent fuel are under consideration since the utility is still responsible for the at-site storage of spent fuel until the time the interim storage facility is constructed.

In this paper, the experiences and technical problems encountered from past reracking projects, will be reviewed and future plans will be discussed.

RERACKING PROJECTS FOR OPERATING PLANTS IN KOREA

Spent fuel storage racks ensure a safe storage of spent fuelunder normal and postulated accident conditions. The fuel storage racks are designed to withstand operating loads (dead loads of fuel assemblies) as well as safe shutdown earthquake loads, as required by Category I seismic requirements of Regulatory Guide 1.29.

As of November 1994, the number of discharged spent fuel assemblies is 3,155 for 8 PWRs and 57,196 fuel bundles for the single CANDU unit. A dry storage facility was installed to increase the storage capacity for the CANDU spent fuel in 1992. However, there are no dry storage facilities for the PWRs, therefore several reracking projects have been completed to increase the at-site storage capacity of PWR spent fuel since UCN-2 (Ulchin Unit 2) reracking in 1990. KOPEC, the A/E, has been performing the engineering work, including technical specification preparation, bid evaluation, reviews of manufacturer's documents, and licensing support, for the reracking projects of KORI-3, UCN-1, UCN-2, KORI-4, YGN (Younggwang)-1 and YGN-2. In the reracking project of UCN-2, KOPEC only prepared technical specifications and performed the bid evaluation. In Korea, to rerack existing spent fuel racks and install High Density Storage Racks (HDSRs) requires approval of regulatory body, KINS (Korea Institute of Nuclear Safety). The utility must amend the related section of FSAR, submit all licensing analysis and resolve all questionnaires raised by KINS. KOPEC and manufacturer also resolve the problems encountered in licensing procedure to support the utility. Companies which participated in reracking projects and their respective work scope, are summarized in Table I.

The outline of reracking projects performed or under consideration is described below.

UCN-2 (ULCHIN UNIT 2) RERACKING

UCN-2 is a 3-loop pressurized water reactor designed by Framatome, and has been in commercial operation since 1989. The core is sized for 157, 17x17 fuel assemblies. The original storage capacity of 472 fuel assemblies was expanded to 893 fuel assemblies by completely replacing the old austenitic stainless steel racks with newer boraflex HDSRs of region I type in 1990.

As of November 1994, UCN-2 has stored 252 spent fuel assemblies in its spent fuel pool. It is expected that the storage capacity will be saturated in 2005. However, the plant is expected to be reracked again by replacing partially (about one and a half core) of existing boraflex HDSRs with the boral HDSRs of region I type to accomodate fuels of high enrichment. After the second reracking, the spent fuel pool will consist of two regions, boraflex HDSR and boral HDSR. The remaining boraflex HDSRs of region I type will be used as region II racks. The two region concept permit increased spent fuel storage by the use of denser fuel storage array for full burnup fuel assemblies. Region I has no restriction on burnup history of stored fuel assemblies. However, region II is restricted for use with fuel having a minimum cumulative burnup, which is dependent on the initial enrichment for each fuel assembly. Design parameters for each spent fuel pool for respective plants are summarized in Table II.

KORI-3 RERACKING

KORI-3 is a 3-loop pressurized water reactor designed by Westinghouse and has been in commercial operation since 1985. The core is sized for 157, 17xl7 fuel assemblies. As shown in Tables I and II, the spent fuel storage capacity was expanded from 746 fuel assemblies to 1201 fuel assemblies by installing an additional 455 borated stainless steel HDSRs of region II type in empty space of spent fuel pool. The old austenitic stainless steel racks is used as region I rack which can only store no
burnup fuel of 4.2 w/o initial enrichment.

As of November 1994, KORI-3 has stored 444 spent fuel assemblies from its own core and 156 spent fuel assemblies discharged and transported from KORI-1 in 1991 because the storage capacity of
KORI-l was nearly saturated at that time. KORI-3's storage capacity is expected to reach saturation in 2001.

UCN-1 RERACKING

UCN-1 is a 3-loop pressurized water reactor designed by Framatome and has been in commercial operation since 1988. The design parameters of the plant are the same as those for UCN-2. As of November 1994, UCN-1 has stored 265 spent fuel assemblies. As shown in Tables I and II, the storage capacity of UCN-l's spent fuel pool will be expanded from 472 to 1114 fuel assemblies by completely replacing the existing spent fuel racks with boral HDSRs in 1995. Without reracking in 1995, the plant will lose full core reserve capacity. The new boral HDSRs consist of 264 racks of region I and 850 racks of region II. Both region I and II storage racks are designed to accommodate fuel assemblies with initial enrichment up to 5 w/o U-235.

In UCN-1 reracking, two divers will remove seismic bracings and cut off the rack interlock connections in spent fuel pool. After reracking, the storage capacity will ensure unit operation until 2005.

KORI-4 AND YGN-1 & 2 (YOUNGGWANG UNITS 1 & 2) RERACKING

Design parameters of KORI-4 and YGN-1 & 2 plants are same as those of KORI-3. Both KORI-4 and YGN-l have been in commercial operation since 1986 and YGN-2 has been in operation since 1987. As of November 1994, KORI-4, YGN-l and YGN-2 have stored 388, 400, and 360 spent fuel assemblies, respectively. It is expected that the storage capacity of KORI-4 and YGN-l will be saturated in 1997 and that of YGN-2 will be saturated in 1999. Therefore, to increase the storage capacity, the installation of HDSRs is is scheduled for 1996 through 1997 for all three units. The HDSRs will be installed successively in non-racked (empty) space of spent fuel pools for the three plants. Since the spent fuel pool of three plants are identical, a single contractor will be selected, by competitive bid, to complete the work on all 3 units. It is anticipated that project cost and licensing uncertainty will be reduced since it is a blanket contract and licensing application.

For these 3 units, the utility and the A/E are planning to remove some of the spent fuel pool cooling piping and supports which would interfere with the HDSR installation to maximize the space in which HDSRs are to be installed. Generally, in Korea, such piping and supports are maintained and the contractor is required to work around the interference. The piping and supports will be removed by underwater divers after the range of pipe to be cut is determined and the maintaining of structural integrity and sufficient cooling capability is proved by all analysis needed. The removal of cooling pipe and supports is a common practice in countries other than Korea. Particular emphasis will be placed on thermal-hydraulic, criticality, structural/seismic, radiological, and mechanical accident analysis.

There are many alternatives in HDSR design and arrangement in spent fuel pool, but according to KEPCO's requirements, the new HDSRs to be installed in empty space of pool will be designed as region I racks. Existing racks will be designated as region II. When the reracking is completed, at least 400 spaces for each plant will be available for the spent fuel storage. Design parameters for the spent fuel pools using HDSR are summarized in Table II.

In Table III, differences between poisoned-rack (HDSR) and non- poisoned rack are summarized.

DESIGN IMPROVEMENTS FOR PLANTS UNDER CONSTRUCTION AND CONSIDERATION

As described above, four PWRs (YGN-3 & 4, UCN-3 & 4) and three CANDUs (Wolsung-2, 3 and 4) are under construction. Four PWRs are planned to be commercially operated in 1995, 1996, 1998 and 1999, respectively and three CANDUs in 1997 through 1999. YGN-3 & 4 were designed by Combustion Engineering, while UCN-3 & 4 were designed using the

Korean Standardization Plant design, which incorporates the results of standardization study and experiences gained from YGN-3 & 4. Nuclear power plants under construction were designed to ensure the spent fuel storage for at least 10 years.

The spent fuel storage racks of YGN-3 & 4 and UCN-3 & 4 consist of nine 10x12 modules. The spent fuel, which is CE standard fuel, will be stored in two regions of the pool. Region I provides core off-load capability for 252 spent fuel assemblies (equivalent to one core and maximum refueling batch plus spares). This is achieved with 50% density storage in checkerboard array using "L" inserts in the usable cells. The "L" insert is a non-poisoned stainless steel insert which provides the needed flux trap water gap. It also provides additional metal thickness for neutron absorption and limits the displacement between the fuel assemblies and the rack wall, which minimizes loads due to seismic acceleration. New fuel assemblies placed in the spent fuel pool in preparation for a refueling outage are located in region I. Region I also includes storage space for failed fuel assemblies. Region II provides 75% density storage for 426 spent fuel assemblies. "L" inserts are required in the region II cells to provide a flux trap water gap. The cells that are not used are blocked to prevent improper storage. A total of 678 storage locations are thus provided. This capacity allows storage for approximately 11 years of unit operation (380% of a full core). The structural design of future spent fuel racks includes provisions for accepting spent fuel with 100% storage using neutron poison inserts for future expansion potential (approximately 600% of a full core).

Nuclear power plants which are under consideration, including YGN-5 & 6 will be constructed incorporating the latest high density storage techniques. To this end, the responsibility for design of spent fuel storage rack was transferred from NSSS scope to A/E scope. Planned storage capacity will allow storage for at least 20 years of unit operation. Therefore, in the plants, the partial storage concept of spent fuel, designed by CE, will be changed to the full storage concept using HDSRs. Spent fuel storage racks will be designed for extended burnup fuel of 5 w/o initial enrichment in nuclear power plants under construction and consideration.

DESIGN REQUIREMENTS FOR NEXT GENERATION REACTOR

Korea is studying the design of an advanced reactor, often called the Korean Next Generation Reactor, having increased safety and improved economics. The basic design requirement of the spent fuel pool storage capacity for the Korean NGR is that it will only ensure the storage of spent fuel discharged for 10 years plus one core reserve as described by K-SRED (Korea Standard Requirements Document). However, if we consider the future improvement of storage technology, including boron credit, poison rack, and/or rod consolidation, the spent fuel pool storage capacity of the Korean NGR will have sufficient capacity for the lifetime of the unit.

CONCLUDING REMARKS

The issues of radioactive waste management should be resolved to drive actively the national nuclear energy policy in Korea. Specifically, the major issue to be solved immediately is that of spent fuel storage since the spent fuel storage capacities of several operating plants are nearly saturated and construction of away-from-reactor interim storage facility has been delayed. The utility, KEPCO, reviewed the alternatives for spent fuel storage since the utility is responsible for the storage of spent fuel until an interim storage facility is constructed.

Their review concluded that the reracking was the first option to increase the at-reactor spent fuel storage capacity. Thus the spent fuel pools of UCN-1 & 2 and KORI-3 have been reracked and reracking of KORI-4, YGN-1, and YGN-2 is under consideration with bid evaluation process in progress. CANDU spent fuel is stored in dry storage facility after being cooled for 10 years in wet storage pool. Future nuclear power plants will be designed to guarantee sufficient spent fuel storage capacity (more than 20 years).

If an interim storage facility for spent fuel is not constructed by the early 2000's, additional reracking or at-reactor dry storage facility is inevitable. KOPEC is expected to play an important role in this facet of nuclear power.

THE INSTITUTIONAL BARRIERS TO PUBLIC PARTICIPATION

Don Beck
Acting Deputy Director
Office of Public Accountability
U.S. Department of Energy
Deirdre McCarthy Gallagher
Jason Associates Corporation
ABSTRACT
In the past twenty years, the mission of the Department of Energy (DOE) has evolved from national defense to environmental clean-up. The Cold Was nearing an end, the Department had begun shifting its priorities from nuclear materials production for nuclear weapons to management of the resulting waste and contamination. The culture of the Department of Energy has evolved along with its mission. Once a bastion where secrecy prevailed, the Department is now changing, opening up to allow citizens to impact DOE's decisions. The cultural change - still underway - has come slowly, due to institutional barriers at the Department. This paper examines some of these barriers and the methods employed to overcome them.
INTRODUCTION
The primary barrier to institutionalizing public participation at DOE has been the prevalence of the old culture. Chipping away at the old culture has involved two major initiatives. The first is the publication of the DOE Public Participation Policy, which defines and communicates the new culture and direction of the Department. The second - and probably, the most important - is ensuring that commitment to public participation comes from the top down. A recent study of DOE and DOE contract employees revealed that the only factor which predicts an employee's predisposition toward public participation was the stance of his/her manager on public participation. Senior managers are the decision-makers and role models at federal agencies; as such, their behavior should reflect the new direction of the agency.
So how to ensure that senior managers will be committed to practicing public participation? Communication. Explain to managers what effective public participation really means. It does not mean relinquishing the Department's decision-making authority to the public; DOE is still the ultimate decisionmaker. Public participation is reaching out and educating the public so they can provide guidance and input to the Department on strategic decisions. It is then taking this input, incorporating it (or not), and letting the public know why.
Two realities about public participation must be communicated to senior managers and agency officials. The process of public participation is one which will likely increase controversy, not decrease it. If the Department is opening up the decision-making process, it will become apparent that many of DOE's decisions are based on value judgements. This will outrage and impassion people - and the Department will hear about it. But this does not mean that a decision will never be made. An informed, involved public is much less likely to challenge a decision than an excluded public. The Bonneville Power Administration case clearly illustrates this premise. If an agency can document that it went the extra mile to promote education, outreach, and involvement efforts, and made the best decision it could based on these efforts, then people - and judges - although upset with the decision, are more likely to accept it.
Another important tool for institutionalizing public participation - not just at the senior manager level, but throughout the Department - is an effective training program. The Department offers informal lecture series on public participation to all DOE employees and contractors. DOE has also organized a half-day training program on public participation for senior managers and a two-day training program for program managers and below. The training programs are crucial to the ultimate success of DOE's public participation efforts. Most of the people at DOE were not recruited to do public participation. Many of them were recruited due to their backgrounds and disciplines: geography, water resource management, nuclear engineering...To expect these people to go out to the public and deal with outraged community groups, or Native American tribes, or environmental groups, is unfair. Education and training is necessary to prepare DOE representatives to effectively deal with and involve the public.
Finally, the Department is working to generate some incentives for public participation efforts. Performance standards have been develop which evaluate employees on their accomplishments and initiative in the public participation arena.

A public participation awards program has also been instituted, which recognizes outstanding efforts in the public participation realm.
Changing the culture of an agency is not an easy task, especially when the culture is imbedded in the system, as is the case with the Department of Energy. It will be a long process, but the culture will change - and continue to evolve in response to the changing times.

ABSTRACT
The U.S. Department of Energy's (DOE's) Environmental Management Program is committed to creating a working relationship with its stakeholders by sharing information about its activities and inviting public input. Successful stakeholder involvement results in decisions that are technically and economically feasible and environmentally sound, that protect health and safety, and that address public concerns and values. Public involvement is a legal requirement in many cases, but DOE is committed to moving beyond required involvement to provide a wide range of opportunities that are tailored to DOE's individual stakeholder groups. The purpose of this paper is to describe the efforts of DOE's Environmental Restoration (ER) Program to characterize the types of information and participation techniques that are used at its more than 130 sites, and to begin developing qualitative measures of success for its stakeholder involvement programs.
INTRODUCTION
DOE's activities directly affect public health and safety and the environment-for which DOE must exercise stewardship and be responsive to the public interest. Citizens have the right to influence decisions about matters that effect them, and public participation rights have been codified in many of the environmental laws with which DOE activities must comply. As a result, DOE needs broad-based support and participation in order to implement its environmental programs effectively. DOE plans and implements the ER Program, and serves as the lead agency in making decisions at most ER sites. However, it does so within a complex web of organizations that have roles in authorizing, overseeing, regulating, funding, reviewing, and participating in ER activities. These organizations, which include the U.S. Congress, the U.S. Environmental Protection Agency (EPA) and State regulatory agencies, and Site-Specific Advisory Boards (SSABs), are key ER stakeholders.
The ER Program has several objectives for its public and stakeholder involvement efforts:
Solicit the public's help in identifying ER site problems and issues;
Solicit the public's involvement in identifying the full range of approaches for addressing those problems and issues, and working towards a broad-based consensus early in the cleanup process;
Increase public understanding of the complex regulatory, political, technical and funding environment in which ER decisions are made, as well as the need to balance a variety of often competing interests and considerations;
Coordinate, integrate, and communicate information about ER program activities and participation opportunities;
Provide a range of participation opportunities that are tailored to meet the needs and interests of ER site-specific communities;
Provide timely feedback on how input was considered in the ER decision making process; and
Meet the letter and spirit of all laws, regulations, and negotiated agreements relating to public and stakeholder participation.
In meeting these objectives, the ER Program works closely with DOE's Office of Public Accountability, which serves as the central coordination point for public participation activities among all Environmental Management (EM) program offices, with other DOE offices, and between EM Headquarters and field offices.
The Need To Define Terms

DOE often uses the terms "customer," "stakeholder," and "public" interchangeably when describing its participation programs. Similarly, the terms "participation" and "information" are often confused. The ER Program uses the following definitions to guide its public and stakeholder involvement programs:

Customer: one who directly benefits (or should benefit) from an ER product or service; may be external or internal to the ER Program.

Stakeholder: any group or individual who is affected by or who can affect the future of the ER Program-as a subset of "customer" includes customers, employees, suppliers, owners, other agencies, Congress, the public at large, supporters, and critics.

Public Participation: meaningful opportunities to take part or share in the ER program decision making process; a two-way exchange of ideas, concerns, and issues with the goal of impacting outcomes. Example activities: public meetings and hearings, advisory boards, and comments on technical and programmatic documents.

Public Information: communication and receipt of data, facts, messages, and knowledge regarding the ER Program; materials prepared by the ER Program that inform stakeholders and enable them to participate effectively in ER decision-making. Example tools: fact sheets, newsletters, exhibits, and videos.

The ER Program believes there are clear differences among these terms, and that different approaches should be used depending on the audience and the intended outcome of the activity.

Conflicting Stakeholder Needs and Desires

In one sense, the ER Program's stakeholders include not only citizens who live near sites or in the same State, but every taxpayer in the Nation. Trying to reach and satisfy a group as large and diverse as this is difficult; compromises must be made and site decisions must be carefully negotiated and clearly communicated.

Each of the more than 130 ER sites has a different set of interested publics. For example, stakeholders at one of ER's largest sites in Washington State include two States, three separate counties, several Indian Tribal Nations, as well as regulators, Members of Congress, environmental groups, agricultural interest groups, labor groups, and a variety of community action groups. While some of the concerns of these different groups are similar, each has a different approach for resolving its concerns. For example, some groups are looking to DOE for money to fund their participation efforts. Other groups want information so they can provide more meaningful input into ER decisions. While others want to scrutinize Departmental actions with an eye towards impacting how DOE spends its ER dollars.

In addition, each stakeholder group has a preference for how it wants to participate in DOE's decision making process. In response, the ER Program provides a wide variety of information and participation opportunities, including numerous publications describing the Program in general as well as site-specific activities; site tours, public meetings and workshops; traveling exhibits describing ER accomplishments and priorities; Site-Specific Advisory Boards; information repositories; and many other mechanisms.

ER's challenge is to develop public information and participation programs and tools that are tailored to these varied groups. If ER is successful, the Program can help facilitate a broad-based consensus on the ER Program's objectives and how to achieve those objectives. With a successful program, DOE/EM may overcome the public skepticism that has resulted from decades of secrecy and public mistrust, and may be able to create new relationships with its stakeholders that are built on common trust and a dedication to solving environmental problems.

ER's Customer Focus Analytical Team

In the Spring of 1994, DOE's Office of Environmental Restoration developed six functional Analytical Teams for the purpose of conducting program-wide, crosscutting analysis. The purpose of these teams is to enable the ER Program to better focus its efforts on meeting EM's six goals. The analyses conducted by these teams will enhance the overall communication and programmatic understanding among individual ER projects and between the ER Program and other EM programs. The six Teams parallel EM's six major goals, as follows: 1) Technical Scope, 2) Program Management, 3) Technology Applications, 4) Risk Management, 5) Health and Safety, and 6) Customer Focus. Each Team has broad representation across the Office of Environmental Restoration, and has coordinated extensively with other EM offices, other DOE organizations, other Federal agencies, and private sector companies.

The Customer Focus Analytical Team (CFAT) is aligned with EM's Strategic Goal 6:

Develop Strong Partnerships Between the DOE and Its Stakeholders. CFAT is chartered to analyze and recommend to the ER Program a process to ensure that ER hears its customers; supports its customers with accurate, timely, and helpful information; and provides opportunities for their involvement. To fulfill this charter, CFAT has embarked on a series of analyses:

Development of a baseline of information and participation techniques and tools used by the ER Program and an analysis of trends in their application;

Benchmarking of current ER customer support and stakeholder participation efforts against other Federal agency and private sector practices;

Coordination with the Office of Public Accountability and other DOE offices in assessing customer and stakeholder satisfaction with ER Program activities;

Coordination with the Office of Public Accountability in developing a performance measurement and evaluation system to ensure that ER Program customer support and stakeholder participation efforts continuously improve; and

Development of specific recommendations to improve ER Program information and participation processes and activities, when necessary.

To date, CFAT has completed an inventory or baseline of information and participation activities across ER sites. In addition, the Team has begun to identify the attributes and techniques of "Best in Class" public participation programs and compare how these attributes and techniques have been adopted by the ER program.

ATTRIBUTES AND TECHNIQUES OF SUCCESSFUL STAKEHOLDER PARTICIPATION PROGRAMS

The first analysis conducted by CFAT was to identify the specific activities that DOE uses to inform the public and other stakeholders and gain their participation in the ER Program. To gather this information, CFAT interviewed program managers from 24 ER sites and reviewed numerous public participation/community relations plans. CFAT determined that the ER Program supports at least 12 unique participation or information programs, encompassing more than 145 activities. Eight of these programs, comprising 82 activities (57%), are considered information programs. These information efforts include routine newsletters and fact sheets that help the public acquire the understanding they need to become more informed participants. Four programs, comprising 63 activities (43%), provide participation opportunities. These participation opportunities include SSABs, tours, workshops, and meetings, all of which enable stakeholders to engage in a dialogue with DOE on issues that concern them. Fifteen sites reported that they either have or are in various stages of establishing an SSAB. Three sites (Kansas City, Mound, and Pinellas) concluded with the help of their stakeholders that a formal SSAB was not required at this time. For example, instead of an SSAB, the Mound site is using "Mound Action Consortia," small focus groups set up for limited periods to address specific issues. Figure 1 summarizes the types of activities that are being conducted across the ER Program.

Attributes of "Best in Class Programs"

As a follow up to this inventory of ER Program stakeholder involvement activities, CFAT investigated and developed a preliminary list of attributes and techniques most widely cited as characteristics of "Best in Class" public participation programs. The Team then evaluated whether these attributes and techniques are characteristics of ER Program stakeholder participation efforts. The Team has not yet assessed the quality of individual information or participation techniques nor evaluated the impact each technique has had on the overall level of customer satisfaction.

CFAT's analysis determined that the ER Program exhibits many of the attributes cited for "Best in Class" organizations, with less emphasis, however, on evaluation activities. This analysis also shows that the ER Program is utilizing all of the top ten successful public participation and information techniques that are being used by the external organizations that were investigated. In fact, the ER Program utilizes a variety of innovative public participation and information techniques that are not widely utilized by other organizations.

The methodology used to conduct this analysis involved three activities: 1) an extensive literature search of more than 16,000 titles and the review of information on effective public participation programs and practices and improvement methods of "Best in Class" and award winning private sector companies; 2) interviews with professional and trade associations, private industry, and other Federal and local government agencies; and 3) interviews with EM Public Participation Coordinators. The information collected by CFAT is considered representative of the types of approaches and techniques being used by the various organizations. The data are not

comprehensive of all outreach and participation techniques that are being used in the public and private sector.

CFAT identified several common attributes or characteristics of successful outreach and participation programs. These attributes are broad in nature and provide generic guidelines for the development and/or assessment of information and participation programs. The Team organized the attributes logically within the chronological life cycle of a program: research, planning, execution, and evaluation. Figure 2 summarizes the key attributes.

Information and Participation Techniques That Work

In addition to identifying the attributes of successful public participation programs, CFAT has identified and begun to assess specific information and participation techniques that are used by the "Best in Class" programs. As shown in Tables I and II, there are few techniques which are unique to any one organization. The private sector companies that were contacted reported fewer techniques, with an emphasis on print and broadcast publicity campaigns and citizen advisory boards. Private industry also does not appear to consider hearings/meetings/workshops as key to the success of their programs. This type of participation is viewed as a regulatory requirement rather than a tailored outreach approach. One notable exception is the use of public debates, through which industry provides a public forum for open discussion of a particular technology or other area of citizen concern.

Insert Tables I and II

Industry, particularly the chemical industry, has been employing citizen advisory boards for more than five years. The boards are viewed as a key connection to the community. Some companies that have had boards in place for several years reported that the current challenge is keeping the board members interested and involved, since much of the mystery and secrecy of plant operations has been erased. Print and broadcast campaigns are used to acknowledge the efforts of the citizen advisory boards and increase general awareness of plant operations. Private industry also uses exhibits at trade shows, public libraries, and other public venues to encourage partnerships with the community in conducting plant activities.

Cable information shows have been used at only one EM facility, with limited duration and mixed results. One of the private companies contacted by the Team produced a cable television show for a six-month period. While viewer ratings were high, the company could not continue to justify the high production costs and canceled the effort. Alternatively, one local government that was contacted reported using cable access as a way to announce and describe special programs and new opportunities for citizen involvement. ER was unique in its development and application of interactive simulation games like the "Priority" game and "Cleanopoly," which may represent an innovative tool that could be adopted by other government agencies, as well as the private sector.

Three Innovative Techniques

In many ways, DOE has been more aggressive, innovative, and responsive in developing and implementing tailored public information and participation tools when compared to many of the external organizations that CFAT reviewed. For a program that is only 5 1/2 years old, EM/ER has accomplished a great deal in providing a variety of options for citizen involvement. The following three examples highlight the creative thinking of EM/ER public involvement professionals.

The "Priority Game"

This interactive board game was invented by the DOE/ER Program's Site Manager at Mound. The game was introduced at a December 2, 1993, Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) Quarterly Public Meeting to inform stakeholders about the impact of budget reductions on the ER Program and about ER activities and their costs, and to gather stakeholder input on which activities to prioritize with the available funding. The game board itself resembles the well-known Monopoly Game. Each square on the game board represents a planned Fiscal Year (FY) 1994 operable unit activity and its cost. To start the game, each stakeholder is allocated $28 million in non-negotiable million-dollar bills. Twenty-eight million dollars represents the total funding needed to complete all of the planned FY 1994 activities.

The first two blocks on the board are mandatory "stops." The first is labeled "Budget Reduction, Lose $11 Million." Each stakeholder has to place $11 million in a basket labeled "budget reductions." The second stop, "Program Operating Costs,"

reduces available funding by another $6 million. These costs are defined as employee salaries, utilities, and public participation activities. As with the "budget reductions," the "operating costs" are collected in a basket that is passed around the room. Each stakeholder is now left with $11 million and a very clear understanding of how quickly funds are reduced or spent.

"Playing" the game then focuses on setting priorities given the reduced amount of funding available. Stakeholders place their money on the game board blocks representing their "Priority" activities. The game ends after each stakeholder "purchases" their "Priority" activities. The money placed on each activity is then counted as "used" and represents a preliminary result of stakeholder priorities. Within a week of this meeting, DOE sent a return postage-paid survey to all stakeholders asking for their formal input on priority selection. DOE received 100 completed surveys.

The "Priority Game" enlivened the meeting and provided a strong visual presentation of an otherwise abstract concept. The stakeholders could clearly see the impact of supporting their particular priority in light of the priorities of others. The formal surveys were returned quickly, suggesting that interest in the topic was retained after the meeting concluded. The "Priority Game" allows stakeholders to choose activities to be conducted while becoming aware of what activities won't get done. There isn't a "winner" in the "Priority Game." The stakeholders choose from an open set of possibilities, not a DOE selected option.

The "Roadshow" Traveling Exhibit

The EM Roadshow is an exhibit display accompanied by various publications designed to communicate technical and programmatic information about the EM Program to the public. The exhibit also highlights some of the successful applications of modern cleanup technology that are being used nationwide. There are five primary goals to the Roadshow: 1) inform and educate EM Program stakeholders and the general public; 2) increase public awareness of DOE's overall environmental mission; 3) encourage and improve public participation in EM programs and decision making processes; 4) provide an opportunity for a positive interaction with a DOE/EM representative; and 5) solicit feedback on EM Program directions and public information needs.

The Roadshow has been traveling to technical conferences and workshops, educator conventions, Community Days, and other public and professional venues since 1989. In that time, DOE has reached more than one million people who have attended more than 200 events. The exhibit staff is selected from a cadre of 75 EM Federal and contractor employees, with more than 50 percent of those individuals being Federal technical staff working in the EM Program. Roadshow staff have developed and distributed more 250,000 EM Program publications since 1989. The most popular publications are a set of EM Fact Sheets, the Nuclear Age Timeline Poster and Resource Guide (which is in its fourth printing), the EM "Primer (both the standard and Student edition)," a Q&A booklet on ER activities, and a series of classroom experiments and other teaching aids.

There are two key benefits to the Roadshow activity. First, by proactively reaching out to the public and providing information that is tailored to a broad spectrum of interest and understanding levels, the Roadshow has been able to increase DOE's public credibility. There is always a technical staff person at each event, who is familiar with EM sites and activities and can discuss cleanup progress. Attendees at Roadshow events are hungry for information, and take as many publications as they can carry. Roadshow staff are consistently greeted with the comment: "We are glad to see DOE here," which indicates a positive trend in abandoning the secrecy of the past. The second benefit is the opportunity for Roadshow staff to work across EM organizational lines, meet the public, and learn firsthand the concerns of various stakeholder groups. EM technical staff and contractors have become more sensitized to the challenges of addressing public information and participation needs.

The Fernald Envoy Program

The Fernald Envoy Program was established in February of 1994 by DOE and the Fernald Environmental Restoration Management Corporation (FERMCO) to promote one-on-one communication between Fernald personnel and local community groups. More than 75 FERMCO and DOE employees have been trained as Fernald envoys. These employees serve a wide range of stakeholder groups such as adjacent property owners, business leaders, schools, environmental groups and agencies, and public officials. Envoys provide detailed information about Fernald objectives, policy, mission, roles, constraints, and requirements, and then listen to stakeholder opinions, suggestions,

values, questions, and other input about Fernald issues. The input from stakeholders is then submitted to the decision makers at the site. Relationship-building through home visits and small group meetings is the foundation of the Envoy Program.

The Envoy Program has provided employees an opportunity to develop personal, face-to-face relationships with more than 100 stakeholder groups, many of which had previously not been included in the decision making process at Fernald. Through Envoy Program tours of the site and one-on-one relationships that have been established, stakeholder trust and confidence has increased at Fernald. Stakeholders have realized that some previously held perceptions were not accurate, that a cleanup program is underway at the site, and that regulatory milestones are being accomplished. In some cases, the feedback that Envoys have received from stakeholders has changed decisions made by management. For example, the final Strategic Plan for the site was revised based upon stakeholder comments received through the Envoy Program. The personal attention Envoys have given stakeholders has helped diffuse some potential controversial situations. In fact, several stakeholders now help Fernald employees educate the public and correct misperceptions about Fernald site cleanup efforts. Based upon the success of the Fernald Envoy Program, several other ER sites are considering developing a similar program.

CONCLUSION

ER/EM public information and participation efforts exhibit many of the attributes of "Best in Class" programs, with variations across ER sites and field offices. The ER Program is thinking creatively about what, how, and when it communicates. CFAT is continuing to examine other public and private sector practices and will recommend to ER Program managers new procedures, techniques, and tools that may be adopted. The ER Program is also continuing to work closely with the EM Office of Public Accountability to develop public involvement program measures of success.

About The Authors

Bobbie Smith is the Public Participation Coordinator for the Office of Environmental Restoration. She has spent the last 16 years working for DOE, with 12 years of field experience. Helen Belencan is an environmental engineer with more than 15 years of experience in the environmental management field, including 4 years in Community and Media Relations. She left the private sector in 1993 to join the DOE's ER Program. Verna Montgomery has been a public participation consultant to the EPA and DOE for 13 years. She also served as the public outreach specialist for a United States Senator.

ABSTRACT

According to Secretary of Energy Hazel O'Leary, "Public participation must be a fundamental component of the Department's program operations, planning activities,

and decision-making." The Department of Energy's (DOE) current focus on improving the form and format for public input is clearly a step in the right direction. But simply changing the way input is gathered from the public fails to help agencies make more informed and collaborative decisions. A paradigm shift is needed to achieve the purpose and goals of DOE's public participation policy--mutual understanding and trust between the Department and the public it serves. Managers and communicators must forge mutual understanding and trust between themselves to incorporate function, as well as form and format, into the public participation equation. This paper presents three case studies that exemplify the failure to optimize stakeholder involvement and input in the Department's public participation efforts and offers observations and suggestions for a new paradigm that focuses on the internal process that creates decision outputs.

INTRODUCTION

Activities by government agencies are increasingly performed under legally mandated public oversight and involvement. Numerous programs at the Department of Energy's Idaho National Engineering Laboratory (INEL) are no exception, and managers with mostly technical backgrounds are often faced with implementing public participation efforts in the course of making technical and program decisions. Conversely, communicators with mostly social science backgrounds are responsible for gathering public input for the technically oriented decision maker's use. Involving stakeholders up front at the points where these disparate but interdependent disciplines first meet may offer the greatest opportunity for optimizing public participation programs.

For the purposes of this paper, the authors have used James L. Creighton's definition for public participation: "public participation is the process by which public concerns, needs, and values are incorporated into governmental decision making. Public participation is two-way communication, with the overall goal of better decisions, supported by the public." (1) The three case studies below are used to illustrate some problems common in public participation activities: stakeholder involvement designed to provide input early in the decision process made "useless" by circumstance or poor planning, efficiency and potential public support lost by failing to incorporate public participation early in the process, and failure to deliver on implied commitments and a public mandate.

CASE STUDY 1, WENDY GREEN: THE SITE TREATMENT PLAN FOCUS GROUP PROCESS

Compliance with the Resource Conservation and Recovery Act's (RCRA) Land Disposal Restrictions (LDR) has presented difficulties for the Department of Energy (DOE). Previously, DOE could generate and store mixed wastes (wastes that are both radioactive and hazardous) in compliance with RCRA. In May 1992, however, the Environmental Protection Agency's (EPA) national capacity variance expired, and any future generation and storage of mixed wastes by DOE would violate RCRA unless an approved treatment technology existed for such wastes.

Because no approved treatment technologies existed for most of these wastes, Congress passed the Federal Facility Compliance Act (FFC Act) in October 1992. The FFC Act waived DOE's sovereign immunity for penalties under RCRA and provided a three-year window before penalties could be assessed for storage prohibition violations. In addition, the FFC Act required each DOE site to develop a site treatment plan (STP) to identify treatment plans for mixed wastes generated or stored at the site. Additionally, the Act mandated public participation during the development of the STP; the regulator for each DOE site was given the responsibility for conducting the mandated public participation. DOE published its strategy for complying with the FFC Act in the April 6, 1993, Federal Register--including a commitment to seek its own public participation prior to the publication of the Draft STPs.

As part of that commitment to public participation, DOE's Idaho Operations Office developed a focus group process to solicit input from Idaho residents. The process was designed to build a better understanding of how Idaho residents evaluate projects proposed for the INEL. At the time, the DOE thought it would be considering multiple options for dealing with each mixed waste at the INEL and planned to use focus group input to help provide a publicly defensible set of criteria for determining which of the technical options should be proposed as elements of the STP.

In December 1993, nearly 200 people throughout the State of Idaho were invited to attend a series of two focus group meetings to be held in four regions of the State.

An open invitation was extended to include other interested parties as well. At the first meeting, a neutral process-facilitator solicited issues of concern through a "brainstorming" session, resulting in a total of 196 identified issues. Afterwards, the facilitator categorized and reformulated the list of issues, combining related issues to the extent possible to arrive at a list of 45 potential evaluation criteria. At the second session, the participants ranked the 45 evaluation criteria using two social science tools, dot polling and a simplified nominal group process. The end product of the groups' work was a set of overall rankings of evaluation criteria that the focus group participants use to evaluate proposed projects; all were presented in the final report on the focus group process. The report was sent to the focus group participants and to the DOE decision makers working on the STP. According to the overall rankings, the most important conclusion that can be made is that "Water Resources Impacts" are considered to be very important; the criterion ranked first in the five overall rankings. Four other criteria ranked in the top 10 in all rankings: Health Impacts, Air Impacts, Biological Impacts, and Accidents and Accident Impacts. The five can therefore be assumed to be very important to Idaho residents in evaluating projects proposed for the INEL.

It was planned that the criteria ranked in the report would prove useful to DOE in selecting technical options for inclusion in the INEL Draft STP when multiple options exist for treating specific mixed-waste streams. For example, if two options were considered technically feasible by DOE-ID decision makers, the one which offers more protection for water resources might be selected in response to predicted public opinion. Similarly, if the results of this study can be assumed to be representative of opinion among Idaho residents, such selections should be supported even if the non-preferred option is more costly because participants ranked water resource impacts much higher than "responsible use of tax dollars." Even when only one treatment option exists, however, the facilitator felt the results would provide insight into how a project design might be modified to meet the concerns of Idaho residents.

Unfortunately, the people responsible for selecting treatment options to be included in the INEL STP were unable to use the focus group input because, as the selection process proceeded, no real options existed. As previously stated, it was originally believed that multiple treatment options would be available for each mixed waste generated or stored at the INEL. Many of the options were eliminated on technical grounds, however, after a close reading of the LDR. As a result, there was only one option each still in consideration (after complying with the LDR) for most of the mixed wastes. The LDR treatment standards essentially left no real choices open to the DOE. The original mission of the focus group was lost, and the public input could not be used to help select treatment options.

In general, a wise strategy for public participation includes the collection of public input early enough in the decision process to be of use to decision makers. Conforming with that general principle, the schedule for conducting the focus groups was driven by a desire to gather input before DOE had gotten too far along in its decision process. The strategy backfired in this case, however, as the parameters of the decision making process were not well understood up front. The focus group component of the public participation process was selected too early in the decision making process to be designed to collect input that could be of use to those making technology selections. It should be noted that this did not result from a lack of effort--DOE fully intended to use the input to select from a range of options. Perhaps the first mistake was made by DOE-Headquarters in making the commitment to conduct public participation prior to the release of the Draft STP; the aggressive schedule did not make the effort any easier and sound public participation strategies require adequate time and budget.

Although the focus group process is discussed at length in the chapter of the STP dedicated to the public participation process, the document fails to explain why the focus groups' input could not be used in making technology selections. In addition, the Draft STP was not mailed to the focus group participants. After telling the focus group participants why their input was being sought, DOE should have (in the author's opinion) provided an explanation as to why that input could not be used as planned. Additionally, DOE should commit to using the results to modify project designs in an effort to address the concerns of Idaho residents.

DOE deserves commendation for the innovative, interactive manner in which it sought public input for the STP. Unfortunately, however, the agency did not know enough

about its internal decision making processes ahead of time to ask for input that could subsequently be used.

CASE STUDY 2, JOYCE POLE: The SNF AND INEL EIS

The Department of Energy Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs Environmental Impact Statement (SNF and INEL EIS) is as complicated as its lengthy name implies. It is both a complex-wide and a site-specific document, a first in the annals of environmental impact statements for the DOE. How this hybrid came to be is a complicated story by itself, but suffice it to say it is driven by a negotiated United States district court order that dictates its schedule; it involves the Department of Navy as a cooperating agency because the Navy and DOE jointly manage spent naval fuel; and ten different sites are considered under five management alternatives in the programmatic portion.

The EIS supports two sets of decisions and will have a preferred alternative for each of those. Volume 1 covers spent nuclear fuel management across the entire DOE complex over the next forty years until the department decides the ultimate fate of its spent nuclear fuel. Volume 2 is specific to environmental restoration and waste management at the INEL for the next decade. Several appendices provide detailed data for the main volumes to make a total draft document of more than 4,200 pages.

When the draft EIS was distributed to the public in June of 1994, it had a missing piece--no identified preferred alternatives for DOE. But there was a reason for this, and it didn't break any of the rules of the National Environmental Policy Act (NEPA) or circumvent regulations from the Council on Environmental Quality (CEQ). Preferred alternatives are to be called out in a draft environmental impact statement only if preferences exist. (CEQ does direct that the final document identify preferred alternatives.) The analysis of the environmental impacts of the five alternatives considered for spent nuclear fuel management and the four specific to the INEL Environmental Restoration and Waste Management Programs revealed no significant differences to warrant a preference based solely on environmental factors.

So DOE said it would use public input, along with technical and practical considerations of the impacts on DOE and Navy missions and projected costs for the various actions, to help derive preferred alternatives for the final EIS. The decision management process was structured to include three panels, one for each of the two volumes to develop technical criteria, and one for public issues that would provide input to the two other panels. The purpose of the public issues panel was to develop a sense of public concerns based on the 5,100 comments that had been received through the EIS comment process and then translate those concerns into useful factors for decision making. This panel's task was completely separate from the formal comment response process (prescribed by NEPA), which was focused solely on determining the adequacy of the document itself. In fact, many of the public concerns that were identified as "out of scope" in the formal comment response emerged as significant issues for the public issues panel.

A support team to the public issues panel, composed of EIS project office personnel, reviewed all 5,100 public comments and categorized them according to a pre-determined list of issues and concerns, statements of favor or disfavor for any of the alternatives, and the geographic location of the commentor. Following this, each team member independently drew up a list of what he or she thought the key public issues were. By continued refinement of the group list, the support team reached agreement on five concerns of most importance to the public.

Although specific social science methodology wasn't employed in the team's issues categorizations, that process was never intended to be--or portrayed as--a true random sampling of public opinion. Its intent was to advance an understanding of relative public sentiment rather than to attempt extrapolation of absolutes. Based on a limited review of available opinion polls related to environmental and nuclear issues, the issues panel found their roll-up of public concerns to be consistent with other published surveys.

Was the process successful? The decision panels for the programmatic and site-specific parts of the EIS did, indeed, take into serious consideration the work of the public issues panel. The concerns distilled from public opinion were folded into the two document-specific decision panels' structured and systematic process to arrive at recommendations for preferred alternatives. The public issues panel recommendations were subsequently approved by DOE high level managers who bought

into the three-part decision process and the role public opinion played in it. There is agreement among those involved that the preferred alternatives that evolved from the decision process represent the best balance of addressing public issues, DOE and Navy mission impacts, costs of implementation, and regulatory compliance. At the time of this writing, the preferred alternative recommendations were working their way to the Secretary of Energy for approval.

Will the public believe they have been heard and that what they have said has made a difference? That remains to be seen because the final document won't be available until later this spring. Also, the public's view may depend on how well DOE communicates the process that was used to reach the decision. Even more fundamental, however, is the fact that many of the public called into question the very purpose and need of the programmatic portion of the EIS. In their view, the scope of the document put the "cart before the horse". Many of the commentors wanted DOE first to identify the end of spent nuclear fuel, that is, how the department would dispose of it once and for all, before the department proposed the means for storing spent nuclear fuel until that end could be achieved. This issue was quickly identified by the public issues panel and evolved into one of the panel's decision factors.

But an EIS is not an end in itself; it's a tool to help an agency reach a decision. Public involvement has a rightful place in this decision process, too. Because NEPA and CEQ are woefully silent on this aspect of public involvement, federal agencies are left to their own devices. DOE's track record in this arena may be changing, if the decision process developed for this hybrid programmatic and site-specific environmental impact statement is used as a measure. Although DOE was treading into foreign territory without a roadmap as it developed this process, the end of the journey still represents one of DOE's best efforts yet at capturing and acting on public concerns.

CASE STUDY 3, AMY DIRKS STEVENS: THE SITE SPECIFIC PLAN

What would you do if you were producing a public communication product with a 94% positive response rating from its intended audience, which wants to see the document continued? If you were the U. S. Department of Energy, facing budget cutbacks and with no requirement to continue, you'd cancel it.

In this case, the product was a document--the annual Site-Specific Plan for the U.S. Department of Energy's Idaho National Engineering Laboratory. In late 1989, the DOE Headquarters issued the national Environmental Restoration and Waste Management Five-Year Plan, which outlined then Secretary Watkins' plans for cleaning up and managing the wastes at the Department's sites. The Five-Year Plan was updated each year to provide the public with a complex-wide progress report of the status of activities and projection for future actions and technology development.

A companion document for the public was required from each operations office to detail its site's specific Environmental Restoration and Waste Management conditions and plans. Content was both descriptive and prescriptive. Topics included an explanation of fiscal year budgetary proposals and distribution of funds by project; discussion of how the broad goals within the Five-Year Plan would be tailored and implemented at the site; an accounting for compliance with relevant laws and regulations; updates on project status and technology applications; and an overview of general site demographics (e.g., size, location, mission).

Public involvement associated with development of INEL's Site Specific Plan evolved and increased over time. The basic approach was to release a draft for public comment on the site's proposed activities for the coming year. Public meetings, surveys, and outreach office efforts were used to glean reaction and encourage face-to-face interaction on Department of Energy Idaho Operations Office plans for the Environmental Restoration and Waste Management Programs. The intent was to use public reaction to finalize the site's plans for the coming year and to better understand the concerns and level of support from its stakeholders. The final version of the Site Specific Plan reflected the effect of the public's input on the draft.

Involvement of the public changed the content, focus, and utility of the document. Comparison of the first version of the Site Specific Plan to the last issue shows visible improvements, such as a more approachable less technical format and language style; instructive graphics to enhance clarity of complex technical activities; educational sections on concepts such as radiation and toxicology; and highlights of key issues needing public evaluation, with accompanying explanations of how to take part in DOE decision processes. In the final year of production, the document was

split into two pieces: a concise summary, with a high-level overview of concepts, accomplishments, and proposed actions (8,000 copies printed) and a full plan with detailed data allowing for open scrutiny of the Environmental Restoration and Waste Management Programs (1,000 copies printed). This two-part approach satisfied both sides of a growing schism within the stakeholders' needs for and interest in salient information about the sites.

During the preparation of the Fiscal Year 1994 Draft Site Specific Plan, DOE Headquarters announced that it was considering elimination of the requirement and funding for both the overarching Five-Year Plan and the related Site Specific Plans. By production time for INEL's final version of the Fiscal Year 1994 Site Specific Plan, the document was known to be in its last required publication. However, the DOE Idaho Operations Office wondered if canceling the document would be an impediment to open communication with its stakeholders. If the Site Specific Plan was not produced, how would people get access to user-friendly, timely, and consolidated information on the site's two largest and most controversial programs? The answers to this question and others were captured through a mail-in survey form printed in the front of both the Site Specific Plan and Summary.

The response was unprecedented. The survey had the highest return rate ever received on any questionnaire or response method used in the history of INEL's public participation efforts. Intriguingly, the site's employees and contractors wanted the full document continued nearly as much as the public did. About 5% of each of the two target audiences were in favor of its cancellation. Eighty-seven percent of the employee respondents and 94% of the public (the intended primary audience) wanted the full Plan continued. It seems significant that all stakeholders in the public group responded to the question, but 8% of the employee respondents abstained from answering the query. The Summary, in its inaugural issue, received less favorable ratings, but not significantly so--84% of the public wanted it continued, as did 77% of the employees. The results were expected since the Summary had not benefitted from the evolution of several years of public input.

The survey also asked how the reader would respond to the absence of the documents. Only 3% responded that they would never even realize the full Plan was missing; 70% of both employees and public stakeholders said they would have to find the information themselves from some other source; and 19% said they would wonder what was happening at the site but not enough to do their own research (80% of these self-identified apathetics were employees, only 20% were the public). The fledgling Summary would have 14% never missing it, 53% of the respondents out on their own looking for the information (also equally split between employees and the public), and 27% wondering what was going on but not caring enough to follow up (a daunting research task for non-site workers).

Respondents were asked if they had ever sent in a DOE Idaho Operations Office comment form before. For the full Plan, 39% had not, 61% had; for the Summary, 64% had never sent in a comment, 36% had. This survey clearly brought in many fresh voices for the DOE to hear. And these new commentors wrote telling sentiments such as, "I had never been asked to comment until now." and "I never had a reason to comment before."

In spite of several years of public participation in the development of the document, which resulted in inputs to decisions on the Environmental Restoration and Waste Management Programs, and in the significant mandate evidenced in the survey results, the DOE Idaho Operations Office canceled the Site Specific Plan due to the lack of a DOE Headquarter's requirement and related funding. The public had been asked about the document's importance, but its unequivocal response was seemingly unimportant. However, the DOE Idaho Operations Office decision was in step with its guidance from the DOE Headquarters. By appearing to disregard the input it sought, the process called into question how much value the DOE had really attached to the public's contributions then and in the past.

Having invested in a comment process that yielded a 94% positive reaction, it may have been a more responsible approach for the DOE Idaho Operations Office to have at least responded to the mandate received when it asked for help in making a decision. The DOE Idaho Operations Office does take its public seriously--the fact that it asked for public input on a document that was no longer required or funded attests to that. DOE is trying to find other ways, within its financial constraints, to give stakeholders the information they have asked to receive. Stakeholder input on how to fill the information gap would contribute to the public confidence that the DOE

Idaho Operations Office still wants to share the same level of data and to solicit stakeholder input.

OBSERVATIONS AND SUGGESTIONS

The three case studies all typify DOE's growing commitment to involving the public in its activities at the INEL. While the intent of genuine stakeholder involvement appears to be present in each case study, each also illustrates that there is a missing component in the public participation equation: an awareness of function, or of how to optimize the investment in public participation efforts. The following lessons learned from the case studies offer insights into ways to improve the often uneasy alliance between the technical/managerial and communication disciplines. Although each of the points below has relevance for both communication professionals and managers within the DOE system, subheads highlight the party most likely in a position to authorize or implement, not just influence, the suggestions.

Be Careful Not to Promise More than can be Delivered

Management: The case studies show a disconnect between the Department's ultimate intention of what and how decisions will be made. Although it is impossible to exactly predict program processes and constraints, a reasonable attempt should be made to forecast how public involvement could be used. If there is no real ability or desire by staff or management to use input to cooperatively develop plans and make decisions, then the public should be told the Department is only gathering information on reactions to a proposal being made within rigid boundaries. When unforeseen changes occur that negate or effectively reduce the utility of public input already received or in progress, the Department should immediately explain the evolving situation and let people know why their input is no longer relevant or useful in the context it was solicited. An effort also should be made to capture the general value that was gained from the input or interaction (e.g., include findings in a database on general public attitudes and preferences).

Communicators: Practitioners also need to be honest with management about what can realistically be expected from communication activities. Changing the minds of individuals with strongly held opinions is unlikely. Control of the press is hardly realistic, or advisable. But what communication professionals can do is help level the playing field on which the Department's ideas are presented. Communicators can work to make accurate information easily accessible to the public and the media. Mechanisms can be offered to reduce the public's sense of alienation or exclusion (and the resulting distrust and anger) from the information exchanges and decision processes. The communication practitioner's roles are most productively and realistically those of negotiator, facilitator, and mitigator, not savior, placater, or protector. To behave otherwise is to be an acquiescent partner to a closed internal decision process.

Public Involvement Projects are Conducted in a Fluid Environment

Management: Managers must learn to live with their discomfort related to public involvement. The current trend is towards more public participation, not less. And poorly conducted public participation erodes DOE credibility. Technical managers, while unaccustomed to the highly dynamic, often uncontrollable nature of public involvement, must learn to relinquish control and let communicators do their jobs. As managers give communication practitioners the opportunity to run involvement programs using assumptions (such as "planned unknowns" and rolling schedules) and techniques (such as Communication and Stakeholder Involvement Plans) unfamiliar to those trained in more rigid technical project management, they will gain confidence in the ability of the communication staff to effectively manage their element of the project.

Communicators: A basic tenet of communication planning is to expect the unexpected. The specific tactics will often need to be responsive to the project's changing conditions (e.g., revised regulations or guidance, funding cuts, political shifts, schedule requirements). Practitioners are aided by planning allowances into their overarching strategies. Many communication professionals specialize in strategy (not just tactics) and can contribute significantly if they are allowed to stay closely apprised of the technical and management aspects of the project. They need to be alert that the planned form of the communication element does not dominate the opportunity for the internal decision process to function dynamically.

Management and Communicators Must Invest Time Initially to Fully Understand the Technical Decision Process and the Role that Public Participation will Play Within that Process

Management and Communicators: An investment of time must be made at the outset of any project requiring public participation to understand the full scope of the technical program and the communication process implications for implementing the technical program, as was evidenced in the Site Treatment Plan case study. Time must also be spent on creating a public participation process that will work for the technical basis of the project, before activities begin.
Timing has a tremendous impact on the benefits an involvement program can yield. Going out to stakeholders prematurely or with too short a time line will inherently limit the viability of the interaction. And, it may appear to outsiders as proof that involvement was not really desired since its implementation was handled poorly.
The Department must teach the public about internal decision processes.
Management and Communicators: Decision makers cannot criticize the quality and usefulness of input or involvement if it is not adequately explained what type of contributions will be welcomed by DOE's internal system and deemed to add value when decisions are contemplated. For example, in the EIS case study the public was told how to make a comment from a process and logistical perspective, but was not instructed on how to craft the comment itself. Telling the public "we want to know what you think" can be interpreted as an open invitation for those sweeping referendum-type comments on DOE policy that are generally relegated to the "out of scope" pile. What's the result? DOE complains that the public didn't provide substantive comments specific to the document while the public counters that, once again, DOE didn't listen to what they had to say. DOE owes it to stakeholders to help them understand the prescribed processes and the public's role in it. Tools for collecting consistent data from stakeholders could be considered, such as surveys of value rankings and alternative acceptance scales in addition to open-ended, non-directed comment (the latter of which is the current approach for collecting comment).
It will be to the Department's benefit in the future to explain the larger decision making system in which the Department operates (e.g., cooperating agencies, regulatory bodies, legislative directives, political expediences). If, for instance, a stakeholder wants to challenge a decision that was justified on the basis of DOE's mission or support DOE efforts to avoid funding cuts, that interested citizen needs to know alternative and perhaps more appropriate paths to register concerns or support. There is great fear associated with teaching stakeholders how to "work the system," despite the fact that many of them are more astute at it than the Department is. But not telling stakeholders only builds dissatisfaction and encourages belief that DOE must be hiding something.
The Department Should Reward Stakeholder Involvement Champions Within Decision-maker Circles
Management: Those with the authority to make decisions need also to be people who appreciate and know how to use public input to enhance internal decisions. Managing communication programs should be deemed as important as managing technical projects--because good science alone can no longer provide an adequate justification for the merit of a program. Reward structures should encourage--if not require--evidence of effective inclusion of public issues in program management.
Communicators: Practitioners need to lead this shift by providing the impetus and demonstrate the value of designing stakeholder sensitivities, ideas, and partnerships into the process.
Departmental decisions should be grounded in results from public involvement activities relying on solid social science methods.
Management: Decision makers can benefit from the use of communication objectives and criteria in grappling with decisions. In the case of a NEPA public comment process, for example, being able to state that public comments were analyzed with proven content analysis techniques could have bolstered the legitimacy of decisions. Use of sound social science methods also reduces the traditional rift between the often questioned competence and appropriateness of including communication professionals in key roles within technical projects--a situation which has often caused management to overlook the value of the communication field in arriving at well-rounded decisions.
Communicators: Public participation and associated communication specialties are theoretically grounded disciplines, not unlike the engineering and physical science professions. Too often practitioners neglect to present communication strategies and tactics with the academic and field research data to support the soundness of their

proposals. Like technical verification and validation, communication methodologies are available for the communicator's defense and offense. In the EIS case study for example, comments could have been coded using content analysis techniques from the social sciences. Surveys, such as those used in the Site Specific Plan case study, can be constructed to provide valid, reliable quantitative and qualitative findings. Preoccupation with opposition groups can be put into perspective when simple principles are foundational to strategies--e.g., persuasion efforts focused on either end of an attitude spectrum will produce negligible results.

The Department should make better use of public input across projects and programs. Management: Amongst all the projects with communication components is a cumulative wealth of untapped understanding. Absent a common mechanism for gleaning and compiling separate data sets and lessons learned on communication elements of projects, mistakes are repeated, inefficiencies continue, and individuals, instead of a central repository, retain the hard-won knowledge. It would be beneficial to develop baselines and databases, analogous to technical benchmarks and codified models, that decision makers and practitioners alike could turn to for factual evidence of public attitudes and concerns. Such efforts could provide trend analyses, historical perspectives, and inter-/intra-agency case studies for use in contemplating decision options. Field operations seem no more equipped to capture and share evolving internal knowledge about public interactions than do headquarters functions. Toll-free lines, museums, and science, visitor, and information centers have been established for the purposes of fielding questions, distributing program materials, and educating the public (such as those for the Office of Civilian Radioactive Waste Management, the Office of Environmental Management, and the Yucca Mountain Project). The DOE should consider a similar resource for internal consolidation and dissemination of communication "technical" data--if not because it will aid project management, provide consistency within the Department, and increase professional knowledge, then at least for the tremendous cost savings it could afford.

Public input on the design of the decision process should be as critical as public input on public involvement process design.

Management: The Department has made laudable advances in working together with stakeholders to develop functional mechanisms for soliciting better input into decisions. The same path should be extended into unveiling the "black box" into which the input is dumped. The perspective an outsider brings to redesign of internal systems could yield innovative, fresh approaches with the potential to satisfy more parties and conduct negotiations in parallel rather than serially. And it would go far to educate stakeholders on the facets and constraints operating in the internal system.

DOE as a federal agency has yet to truly engage stakeholders at the front end of any contemplated action so that they can help frame the process and, therefore, have some ownership for its success. If the public understands the process and believes it is credible, they may be more accepting of its outcome even if they don't particularly agree with the decision itself.

CONCLUSION

It is the authors' supposition that the Department needs to shift its emphasis on the input variable of the stakeholder involvement process and focus instead on the internal process that creates the decision outputs. Neither greater involvement from a broader array of perspectives nor increased interactive, personalized exchange will significantly advance the credibility and soundness of DOE's decisions. No level of improvement in input can substitute for the ultimate misuse or disuse of those inputs. The case studies suggest a particular set of potential options for improving the output side of the equation, as described above. These represent a small portion of the opportunities DOE has for strengthening and balancing stakeholder relations by reshaping its paradigm and looking inward for solutions.

COMMUNICATING WITH THE PUBLIC ON NUCLEAR MATERIALS DISPOSITION ISSUES

G. Bert Stevenson
Department of Energy

Patricia Wherley
Science Applications International Corporation

ABSTRACT

The storage and disposition of weapons grade fissile materials involves complex technical issues. The goal of reaching consensus on the best method or methods for storing and ultimately disposing of these materials can only be achieved after an open public discussion of all reasonable alternatives. The Department of Energy considered a number of factors in developing a program for public involvement. These factors included defining the affected public, public knowledge about the proposed action, Government decisions to be made, availability of pertinent information, current public perceptions, and responding to public input.

Based upon an analysis of these factors, three primary techniques were selected for communicating with the public. The techniques are distribution of a quarterly newsletter, establishment of an electronic bulletin board, and holding periodic conference calls and public meetings. The newsletter is designed to reach the widest segment of the public and to be meaningful regardless of the reader's level of familiarity with the project. Periodic conference calls and meetings are used to reach the public that have a real but periodic interest in the issues. The electronic bulletin board is used to communicate with a core group of stakeholders who have a continuing high interest in the total storage and disposition program.

Initial indications are that these techniques are effective in reaching a wide segment of the public on highly technical and complex questions related to weapons grade nuclear materials. The effectiveness is not the result of these being new techniques but rather using each technique, to the maximum extent possible, to provide open, on-going, two way communications.

INTRODUCTION

The storage and disposition of weapons grade fissile materials, primarily plutonium and highly enriched uranium, involves complex technical issues. There are aspects of every storage and disposition alternative that are at the frontiers of our knowledge. Therefore, the challenge for the Department of Energy is to effectively communicate important environmental impact information on the best method or methods for storing and ultimately disposing of these materials.

In January 1993, the Secretary of Energy created a project to focus on the control and disposition of these materials. Congress then authorized the creation of a Office within the Department with the responsibility for all activities relating to management, storage and disposition of fissile materials from weapons and weapons systems that are excess to the national security needs of the United States. Congress also authorized funds for the accomplishment of these responsibilities. These actions resulted in the creation of the Office of Fissile Materials Disposition.

One of the major activities being undertaken by the new office is to prepare a Programmatic Environmental Impact Statement on the Storage and Disposition of Weapons-Usable Fissile Materials as required by the National Environmental Policy Act. This act requires a certain level of public participation in the preparation of the document. However, the Secretary of Energy, recognizing the considerable benefits from full public participation, has issued policies that go well beyond the minimums of the law. The Secretary's policy defines public participation as an open, ongoing, two-way communication, both formal and informal, between the Department and those interested in or affected by its actions.

This paper presents the methods being used by the Office of Fissile Materials Disposition to communicate important information about potential environmental impacts and other technical issues in an open, ongoing and two way manner.

COMMUNICATIONS PLANNING

The first step taken by the Office was to obtain answers to several questions about the public with whom communication was needed. Then, based on those answers, a public participation plan, was developed. The questions asked were:

Who are the individuals and groups (stakeholders) that are interested in or could be affected by the proposed action?

What decisions are contemplated that would benefit from stakeholder input?

What is the stakeholder's level of knowledge about the proposed action? What additional information does the stakeholder need? What additional information do they think they need? What is the technical complexity of this information? What are the classification restraints, if any, on this information?

What is the current stakeholder perception about the proposed action? What are their primary areas of concern?

How will the Office use stakeholder input and show its response to that input?

The individuals and groups affected by the proposed action could, in the broadest sense, include every citizen of the United States because the proposed action could affect national security. In a narrower sense, the stakeholders can be divided into national and local levels of interest. At the national level, examples of stakeholders are arms control advocates, environmentalists, unions, and members of Congress. At the local level, examples of stakeholders are environmentalists, state officials, city mayors, chambers of commerce, contractors to the Department, employees, and union locals. Based upon this answer, communications have been established and maintained with a very wide spectrum of the public across the United States. The answer to this question was also used to determine the location of the PEIS scoping meetings. The meetings were held near the potentially affected sites and three regional locations.

The decisions to be made by the Department of Energy on the storage and disposition of fissile materials must be communicated to the public in a clear, concise and effective manner. Furthermore, the process for reaching these decisions must be clearly defined and allow for public participation. The decisions center around which storage and disposition alternatives will be selected for detailed technical, cost and environmental impact analysis plus which of these alternatives will finally be selected for implementation. The technical merits and costs of the alternatives, as well as their relative ability to meet the goals of United States nonproliferation policy, are being evaluated in other studies. All of these studies will be incorporated into the decision making process.

The Public Participation Program is the process by which the Department also factors diverse public values and perceptions into the decision process. For example, as part of the review of the Draft Programmatic Environmental Impact Statement, the public will have the opportunity to let the Office of Fissile Materials Disposition know whether they prefer leaving the material in its present location or whether to transport it to a new consolidated storage facility. Obviously, there are technical, economic and environmental aspects in deciding between these alternatives. But, there are also value judgements relating to whether the public would rather accept the risks associated with moving the material or those associated with leaving it in place.

The evaluation the public's existing knowledge about nuclear weapons showed that the level of knowledge varied widely among the stakeholders. On one end of the spectrum, are people who have little or no knowledge about nuclear issues and how the proposed action might affect them or the environment. This group of stakeholders is composed primarily of members of the general public. At the other end of the spectrum, are people very knowledgeable about nuclear weapons, nuclear reactors, and the proposed action. This group of stakeholders is composed of external special interest groups (arms control advocates; environmentalists) and internal special interest groups (unions, contractors, employees). Therefore, all communications need to be intelligible to the general public while not insulting the sensibilities of nuclear professionals.

The information the public needed or wanted was discovered to include some very basic information about nuclear radiation and weapons, the proposed action, how the proposed action could affect other environmental actions, public participation opportunities, and the Department's decision making process. To meet the public need for basic nuclear and process information, a series of short, one to three page, fact sheets were prepared. Each fact sheet covered one specific topic such a radiation, plutonium, uranium, and the National Environmental Policy Act. Every attempt was made to have each fact sheet easy to read by the use of high school level language and the use of simple graphics. Further, the content of each fact sheet was kept as generic as possible so that it could be used though out the life of the program.

The most technically complex information needed by the public relates to plutonium disposition. The National Academy of Sciences, at the request of the U.S. National Security Advisor, conducted a detailed study on the disposition of plutonium. The study was requested by Brent Scowcroft, the National Security Advisor to President Bush, and sponsored by the Department of Energy. The National Academy of Sciences, as a private, non-profit society of distinguished scholars, produced a report that

provided information that was helpful to both the general public as well as the nuclear professionals. In fact, the disposition recommendations made in the report were used by the Office of Fissile Materials Disposition as the starting point to develop options which would be studied in the Programmatic Environmental Impact Statement. The use of these options helped to establish the fact that the Department had not already decided on a course of action. The proposed action was, therefore, not a DAD situation, decide-announce-defend.

In order to answer the question about the public's perceptions on the storage and disposition of fissile materials, a public meeting was held before formally announcing the proposed action in the United States Federal Register. This meeting was conducted in an interactive format using small discussion groups and facilitators. The meeting format, agenda, and facilitators were used to encourage each person to actively participate. During the discussion groups, the public provided the Office of Fissile Materials Disposition information on the areas of concern to them. For example, there were differing views regarding the timing of disposition actions. Some participants wanted the Office of Fissile Materials Disposition to move as quickly as possible to preclude the potential threat of proliferation and to put the materials into a form that would prevent it from being reintroduced into the nuclear stockpile. Others wanted the Office of Fissile Materials Disposition to move slowly to ensure that potential environmental health and safety concerns would be thoroughly examined before any disposition decisions were implemented.

The discussions also focused on the methods that would be most useful in establishing open, on going and two-way communications with the public. The techniques finally selected to aid public participation in the Programmatic Environmental Impact Statement process were greatly influenced by the discussions during this meeting and comments submitted in writing as part of the participant's meeting evaluation.

The policy answer to the question about how the Office would respond to public input was easy and straight forward. All input would be documented, seriously considered and a response provided to the submitter. The process of implementing this policy was much more difficult because it involved all of the Office staff, Department personnel outside the Office, and contractors. It was decided to integrate this policy one way or another into each communication technique.

OPEN COMMUNICATIONS

One of the primary considerations in open communications was to overcome public perceptions about the Department's desire to keep information classified, the accuracy of its information, the completeness of the information and the currency of the information. This perception was significantly reduced by the Secretary of Energy's "Openness Initiative". This project resulted in thousands of documents being declassified and made available to the public. Additional classified information that would be useful to the public was identified and requests have been made to remove the classification so that the information could be included in program fact sheets, and presentations.

Open communications also require information to be accurate and honest and thus credible. Therefore, the initial information to be provided on the program was prepared and reviewed with meticulous care. It was important that the Office of Fissile Materials Dispositions's motives not be impugned by inaccurate information from the very start. Initial inaccurate or incomplete information would have made it very difficult for the public to accept the information put out at a later date. Early credibility will help the program recover from mistakes or inaccuracies that will inevitably creep into documents at one time or another.

ONGOING COMMUNICATIONS

Planning considerations lead to the realization that the public would have varying degrees of interest in the proposed actions and that this level of interest would vary during the process of preparing the Programmatic Environmental Impact Statement. Therefore, the Office's communication techniques were devised to recognize the public's level of interest and allow them to change their level of involvement in the decision making process. This approach can be explaining by using an "onion" analogy.

The outer layer of the onion consists of members of the public who are only slightly aware of or interested in this program. To establish an ongoing communication with them, a quarterly newsletter is being published and public meetings are being held

on topics of concern to the Office of Fissile Materials Disposition and the public. The newsletter is designed to provide a wide section of the public with a program overview, information on the direction, successes, failures and barriers to the program. The newsletter also provides information on opportunities for increased involvement in the program such as announcements of upcoming meetings. Newsletters can be expensive to prepare and distribute. In order to keep costs to a minimum, the newsletters have few photographs or graphics, and printed on recycled paper. Publication of the newsletter requires the development and maintenance of a mailing list. Keeping a mailing list up to date is not an insignificant cost. Our present mailing list contains over 2, 300 stakeholders. A mailing, at the present postal rate, costs over $2,000.

Another challenge to making a newsletter an effective tool is to attract and maintain reader interest on issues related to the subject of fissile materials storage and disposition. Sustaining public interest is difficult because the subject matter is technically complex, there are no dynamic actions or processes that would lend themselves to interesting visual images, and the time period for the completion of the proposed action may be decades. However, an attractive, periodic newsletter can be an effective mechanism to maintain ongoing communication with the general public. It is a comfortable, familiar format that does not require a heavy investment of an individual's time, but provides sufficient information for a reader to choose their level of involvement.

Public meetings should be designed to reach the widest cross section of the public possible. They are held to present information and discuss a topic of special concern to the public and the Department. Based upon the results of the initial meeting mentioned above, it was determined that a large segment of stakeholders support interactive format meetings. This format gave the participants a chance to ask questions and get immediate answers. It also gave the Office the chance to determine why certain issues were of concern. Interactive workshops were also used to obtain public comment about the scope of the proposed action. The public comments were summarized in a report that was made available to the public by various means including providing copies to DOE reading rooms. The Office of Fissile Material Disposition's responses to the comments have been provided to the public in a separate report. A critical element of each public meeting is the use of feedback forms and questionnaires. For example, the use of questionnaires was helpful in obtaining specific public comments on the screening criteria to be used in eliminating unreasonable storage and disposition alternatives. Approximately 15 percent of the public attending the scoping meetings completed the screening criteria questionnaires. The information obtained was analyzed and used to improve the screening process.

Public meetings are expensive and require a great deal of logistical support to make them effective. However, they are worth the expenditure of significant time and money because they are such an extremely effective means of ongoing communication. One note of caution about public meetings. Their use should be limited to those times when important information is to be discussed. Interactive public meetings require a significant commitment of time by all the participants. This commitment must be acknowledged. Meetings are more productive when substantive discussions are held, based on new or developing program information, and when it is clear how the results of the meeting will contribute to the decision making process.

The middle layer of the "onion" includes those members of the public who have a continuing interest and want to be quickly informed about program changes that affect them. To communicate with this group periodic conference calls are made with specific interest groups. The largest groups in this layer are state officials, local officials and members of the business communities near DOE sites. As stated before, these calls, for the most part, are established with different special interest groups. This has two effects. First, it allows the agenda of the call to be tailored to the needs and interests of that group and second, it keeps the number of participants to a manageable number. As a matter of policy, no one is excluded from joining us the call. For a variety of reasons, including economics, the length of each call is kept to between 30 and 45 minutes. A constraint of this technique is the inability or reluctance of some groups or individuals to spend their resources on long distance telephone charges.

In the inner layer of the "onion" are those members of the public who have an intense, almost daily interest in the program. This group of stakeholders is

primarily composed of people who are full time representatives of environmental, arms control, nuclear industry or other special interest groups. To communicate with them, an electronic bulletin board system has been established. This system allows the Office of Fissile Materials Disposition to maintain a dialogue with a core group of stakeholders on a daily basis. They can access the bulletin board in one of two ways. They can use a modem to dial into a toll free number, or through one of several methods on the Internet. The bulletin board contains five sections, four of which provide a different types of information. These sections are Announcements, Press Releases, Program Documentation, and Registration Forms. The Program Documentation section includes the fact sheets discussed above, briefing charts from public meetings, and technical reports. The fifth section is a public forum in which topics related to storage and disposition of fissile materials are debated. Users of the bulletin board can provide comments on information provided by the Office of Fissile Materials Disposition or comment on the comments made by other bulletin board users. The most significant down-side to this technique is the fact that not all members of the public have access to a computer and thus the technique does not reach everyone in this layer of the "onion".

TWO-WAY COMMUNICATIONS

Incorporated into each of the techniques listed above are very specific mechanisms for the public to provide the Office of Fissile Materials Disposition information about both the content of the program and the public participation process. Feedback forms are used to ensure two way during public meetings. Forms are prepared for all meetings. In order to maximize the use of these forms by the public, the meeting leaders and facilitators request the public participants to complete the form. The Department officials and the facilitators are also requested to stress the importance that is attached to public feedback. All completed forms are read, analyzed and appropriate changes made where possible. These changes are then communicated through each of the outreach techniques including the newsletter, the electronic bulletin board, and conference calls. The public has expressed an interest in feedback on meeting results. Therefore, attendance lists and meeting summary reports are always made available. The attendance lists provided to the public are restricted to names and organizations so that individuals do not become unwelcome targets for mailing lists of other organizations.

The method of obtaining two way communications in the newsletter is to include an explicit requests that readers write to the Office of Fissile Materials Disposition about anything in the newsletter. This section of the newsletter also requests that the reader inform the Office of Fissile Materials Disposition about changes of address, plus additions and deletions to the mailing list. Additional two-way communication mechanisms in the newsletter include "Letters to the Director" and guest articles by stakeholders.

By it's very nature, a conference call is a two way communication. It provides the Office with immediate feedback on new information from interested and active members of the public. This means of communication, more than the other two techniques allows the Office to ask "why" a comment or concern is being made. The answer to this question many times gives the opportunity to improve a response to that comment or concern. The primary two way communication mechanism in the electronic bulletin board is the Forum. The Registration Forms Section of the board can be used to request documents not available on the bulletin board because of their size or age. Users can also use the Registration Forms Section to provide comments on the program independent of the forum topic. As an indication of its commitment to two-way communication, the Office has pledged to provide an answer to questions on the bulletin board within five working days of the question being posted.

The critical part of two way communication is for the Office to react to the feedback and recommendations from the public. This may mean making immediate changes to information, and changing procedures. It also, and very importantly, means the Office must tell the public when the suggested changes are not being made and why.

CURRENT ASSESSMENT OF THESE TECHNIQUES

The Office of Fissile Materials has found that the techniques discussed in this paper have been effective in providing information to the public and obtaining feedback on that information. The communications program was instrumental in obtaining good comments and attendance at its PEIS scoping meetings. During the 12 meetings, over 1,000 individuals provided over 3,000 comments. The feedback forms

indicated that 4 out of 5 stakeholders who completed forms felt that the Department Officials had been very open to public comment The same ratio of stakeholders liked the interactive scoping meeting format instead of the traditional hearing format. The Office's communications program was also helpful in having stakeholders, for the most part, recognize the fact that plutonium has a greater potential for harming the environment and potentially affecting the health and safety of the public than highly enriched uranium. The stakeholders, again for the most part, have come to recognize that the disposition of plutonium will take longer, cost more and be technically more complex than the disposition of highly enriched uranium.
Management support for ongoing, two-way communication with the public has been a factor contributing the effectiveness of the techniques. The obvious willingness of key senior managers to engage in dialogue, even when the discussions were critical of the Department, has influenced the participants in two ways. First, more mid-level managers and technical staff have participated in the public involvement activities. As a result, the interactive and diverse communication methods listed in this paper have been successful in increasing the access of stakeholders to the technical staff and decision makers within the Department of Energy. These interactions appear to have both increased the Department's understanding of stakeholders' concerns and have increased the public's awareness and understanding of the technical, funding, and administrative constraints associated with program implementation.
However, the above techniques have not been effective in reaching the "general" public; that is the people who could be potentially affected by the proposed action but are not part of an organized special interest group. These techniques have also not been very effective in reaching and sustaining the involvement of state and local officials to the degree felt necessary.
SUMMARY
The use of newsletters, public meetings, conference calls and electronic bulletin boards systems are and will continue to give the Department of Energy ways of having an open, on-going, two way communication with the public on the storage and disposition of fissile materials. Further, we believe that communication with the public on the disposition of fissile materials, while technically complex, can be done effectively by providing information:
  on a continuing basis,
  by a number of communication techniques,
  in short, accurate, easy to read documents, and
  with easy to use feedback mechanisms.

Session 21 -- Federal Facility Compliance Act Year-2: Implementation, Status and Issues
Co-chairs: Lawrence Harmon, MACTEC;
Joseph Coleman, USDOE
21-1
DEPARTMENT OF ENERGY STRATEGY FOR MANAGING MIXED WASTE UNDER THE FEDERAL FACILITY COMPLIANCE ACT
Jill E. Lytle
James A. Turi
U.S. DOE
ABSTRACT
The Federal Facility Compliance Act (FFCAct) was enacted on October 6, 1992, amending the Solid Waste Disposal Act, which was previously amended by the Resource Conservation and Recovery Act (RCRA). The FFCAct set in place requirements for the Department of Energy (DOE) and other Federal agencies to bring their mixed (hazardous and radioactive) waste into full compliance with the requirements of RCRA and be treated in a manner similar to non-governmental operations. For DOE, this means its mixed waste treatment operations will be regulated by either the state in which the site is located or an Environmental Protection Agency (EPA) regional office. Over the past two years, the DOE, states, and EPA have developed a unique process for implementing the FFCAct.
The key feature of this process is DOE and its regulators working in an interactive, iterative fashion to meet the requirements of the FFCAct at both the local and national levels. The process is a challenging one involving 49 DOE sites and the requirement to negotiate compliance orders with the 22 affected states or EPA within

three years. The 49 DOE sites that are involved in this process are shown in Fig. 1. In order to be successful in complying with the FFCAct, the DOE needed to ensure the process met certain requirements. First, to meet the aggressive schedule required by the FFCAct, the process needed to be established quickly and needed to provide mechanisms for DOE Headquarters and its field offices to communicate and plan for meeting the FFCAct requirements. Second, the process needed to provide an opportunity for national coordination among the sites to blend the individual site treatment plans into a sensible national configuration of treatment systems to avoid redundant efforts, to provide comparable results, and to coordinate required funding and implementation schedules on a national level. And thirdly, the regulators who will approve the plans needed to be intimately involved throughout the process and the public, Indian tribes, and others needed to be provided with opportunities to participate within the process.

The DOE's interaction with the associated regulators to jointly discuss, analyze, and plan DOE's implementation is a unique aspect of the process. To accomplish this, the DOE established a cooperative agreement with the National Governors' Association (NGA) that provides for the NGA to act as coordinator and facilitator for the states, EPA, and Indian tribes throughout the development of the plans. This interaction has been advantageous to establish DOE policies and planning that are in tune with the regulators' interests. One early result of this communication was that DOE agreed to establish a "bottom-up" process, i.e., that the sites prepare their plans individually, rather than DOE Headquarters preparing a national plan that the sites must follow.

The process that emerged to meet the challenges of complying with the requirements of the FFCAct involved coordination at a number of levels, both within and external to the DOE.

INTRODUCTION

Aside from the technical challenges contained in the FFCAct, the DOE was faced with the challenge of coordinating a massive national planning effort during a time of significant change. Historically, the DOE mission of development and production of nuclear weapons in providing national security required that most operations be conducted in complete secrecy. To facilitate this high level of secrecy, the overall mission of the DOE sites were coordinated from Headquarters, but the details of the operations were conducted with a high-level autonomy at the sites. Very little information was transferred between the DOE sites with even less communication to the local stakeholders and regulators. The recent changes in the world order and the end of the cold war have resulted in a sea change to the DOE mission which have created a need to change the very culture of the institution itself. The DOE is no longer in the business of actively building nuclear weapons and supporting plutonium reprocessing operations have been shut down. Previously classified information is being released to the public and DOE is actively involved in one of the largest and most complex waste management and environmental remediation programs in the world. The program's goal is to properly manage waste produced as a result of past operations and clean up its facilities for future use. Attempts to change the culture of DOE from one of total secrecy needed to protect the national security to a more open way of doing business, with full participation of the public, stakeholders, and even within the Department has been steady, but uneven. One noteworthy success is the process that has emerged through efforts to comply with the requirements of the FFCAct. This process has laid the groundwork for a much higher degree of external communications and participation in planning a DOE program than ever before, and has resulted in the development of a cooperative working relationship with the state and EPA regulators and other stakeholders.

REQUIREMENTS OF THE FEDERAL FACILITY COMPLIANCE ACT

The FFCAct provided that federal agencies be treated as any other entity and waived the federal government's defense of sovereign immunity thereby allowing states to impose fines and penalties against federal agencies for RCRA violations. The DOE is not in compliance with the RCRA Land Disposal Restrictions (LDR) because it does not have sufficient capacity to treat its mixed radioactive and hazardous waste and is storing this waste in violation of the storage prohibition. Because of the complexity and enormity of the task of bringing almost 1,000 DOE mixed waste streams into compliance, Congress provided, in the FFCAct legislation, a three year postponement of the waiver of the defense of sovereign immunity for DOE for violations of the LDR storage prohibition if certain conditions are met. One of

these conditions is that DOE be in compliance with approved plans for developing treatment capacity and technologies for mixed waste generated or stored at the DOE sites. The FFCAct provides authorized states in which DOE sites generate and store mixed waste, or the EPA, authority to approve DOE's plans and issue orders requiring DOE to comply with those plans.

Additionally, the FFCAct required DOE to develop and provide to EPA and the affected states a comprehensive inventory of mixed waste that is generated, stored and projected to be generated by DOE over the five years following the enactment of the FFCAct. The DOE met this requirement through the publication of the Interim Mixed Waste Inventory Report in April of 1993. The DOE has since updated the original inventory and produced a new report in disk form in April of 1994 and anticipates a second update to be available in late 1995.

The most demanding requirement of the FFCAct is the development of plans to provide treatment capacity for each site at which DOE generates or stores mixed waste. The DOE utilized the Mixed Waste Inventory Report as a baseline for the development of these plans. These data have been continually updated and refined throughout the process. The DOE has adopted a "bottom-up," three-phased approach for the development of its Proposed Site Treatment Plans (Proposed Plans). The bottom-up approach requires the plans to be developed by each DOE site in consultation with other DOE sites. In the first phase, the Conceptual Site Treatment Plans were issued to the sites' regulatory agencies (State or EPA) in October of 1993. These Conceptual Plans identified for each site the broad range of options available to treat DOE's mixed waste. In the second phase, a narrow range of site preferred options were developed in coordination with the states and EPA. The Draft Site Treatment Plans were submitted in August of 1994. The third phase of the development of plans will culminate in the submittal of Proposed Plans by early April of this year.

As noted above, the Draft Site Treatment Plans presented each individual site's proposed treatment options for their mixed waste. As a result of this "bottom-up" approach, the states, EPA, and DOE recognized that the mixed waste treatment configuration that would result from implementation of the Draft Site Treatment Plans included inefficiencies and duplication in the number and type of treatment alternatives proposed. To help eliminate these redundancies and provide a bridge between the Draft and Proposed Site Treatment Plans (the second and third phases), DOE in concert with the states, EPA, and the NGA, established an Options Analysis Team (OAT). The Team analyzed accommodations necessary to blend the Draft Site Treatment Plan configuration into a sensible national configuration of treatment systems to achieve obvious efficiencies and economies over building multiple facilities at different locations to treat similar wastes. Because the strategies for the treatment of DOE's high-level waste and mixed-transuranic waste are already established, the focus of the Team's efforts was on mixed low-level waste. The states have been kept informed of these activities through the participation of NGA representatives in Team meetings. The Proposed Plans will represent a blended configuration: bounded on one side by the states' wishes for on-site treatment; and bounded on the other side by DOE's and the states recognition of the necessity to reduce inefficiencies. The process that is being used to develop these plans is shown on Fig. 2.

There is still much work to be done. The DOE will continue to work with its regulators, Indian Tribal governments, and other stakeholders in the coming months to finalize these Proposed Plans. The states or EPA, as appropriate, are on schedule for issuing compliance orders based on these plans by October 1995.

GROUPS ESTABLISHED BY DOE TO FACILITATE COMPLIANCE WITH THE FFCAct

To facilitate the communications that are required for DOE and the states/EPA to meet the schedules and milestones in the FFCAct, formal groups were established. Members of these groups communicate regularly through conference calls, informal discussions, and periodic workshops. The groups that have been formed by the DOE and the States/EPA are shown on Fig. 3. They include the following:

The FFCAct Task Force is a Headquarters team that includes members from various Waste Management offices who are assigned full-time to FFCAct-related activities. The mission of the Task Force is to lead, facilitate, and monitor FFCAct related efforts at the DOE Headquarters and Operation Offices, and to manage the coordination of documents for review and concurrence within DOE Headquarters. The Task Force also acts as the interface between the Operations Offices and DOE

Headquarters Offices, and others, such as the NGA, the Office of Management and Budget, the General Accounting Office, and the Congress.
The FFCAct Policy Coordination Group (PCG) is a management level Headquarters-Field team, chaired by the Task Force Director, established to provide overall coordination between DOE Headquarters and the Operations Offices, to facilitate the development of FFCAct guidance and strategies, and to resolve FFCAct implementation issues. The PCG consists of representatives from key participating DOE organizations: 1) the Headquarters FFCAct Task Force staff; 2) field Operations Office and facility staff who focus on FFCAct-related activities; and 3) other DOE Headquarters staff (in addition to the FFCAct Task Force) who focus on specific FFCAct-related issues, including representatives of Environmental Management's Office of Environmental Restoration and Office of Technology Development, the Office of Environment, Safety and Health, the Office of General Counsel, and the Office of the Chief Financial Officer. Regular communication is ensured through weekly conference calls; in addition, the PCG meets every few months among themselves and three or four times per year with the full NGA FFCAct Task Force.
The Site Treatment Plan Workgroup is a working level group established as a forum to discuss the development of each version of the Site Treatment Plans and other deliverables required by the FFCAct. This group consists of technical representatives from the sites who are responsible for the preparation of the STPs. Topics of discussion often overlap between the STP work group and the PCG; the STP workgroup discusses technical details of the Plans and FFCAct deliverables and, as needed, raises issues to the PCG for resolution.
Smaller focus groups were established to work on specific technical and policy issues identified in the process of developing the Site Treatment Plans. Each focus group developed its own procedures and processes to meet their needs in addressing their particular issue. Following are descriptions of three key groups that have been formed.
The Compliance Order Group was formed to develop guidance on compliance order administrative provisions that will implement the Site Treatment Plans, to develop sample language for large and small DOE sites, and to coordinate resolution of order-related issues. Each site is developing a negotiation strategy and draft language based on guidance provided by this group and will begin negotiations on the orders soon after submitting the Proposed Plans. In addition to Waste Management, the group's membership includes representatives from Environmental Management's Office of Environmental Activities and Office of Environmental Restoration, the Office of Environmental Compliance, the Office of Naval Reactors, the Office of General Counsel, and field representatives, usually field counsel, from the DOE Operations Offices.
The Options Analysis Team was formed to review the treatment options proposed by the sites in the Draft Plans and to blend those options into a sensible national configuration. The Team consists of technical representatives from the larger DOE sites and DOE Headquarters. The Team conducted their analysis based on the types of treatment required for the waste streams and has analyzed various treatment system configurations for cost and schedule impacts and other technical factors. They have analyzed a broad range of site treatment system configurations, including: a centralized configuration; a configuration based on the shortest possible treatment schedule; a configuration that maximizes the use of existing facilities; and others, to facilitate the development of a sensible national configuration of site waste treatment systems.
The Disposal Working Group was established to review potential sites for mixed waste disposal. Although the FFCAct does not specifically address disposal, both the DOE and the states recognize that disposal is an integral part of mixed waste management. This focus group developed a process, in consultation with the states/EPA and NGA, for evaluating options for the disposal of residuals resulting from the treatment of mixed low-level waste. The evaluation process includes only mixed low-level waste streams. DOE is relying on established processes implemented for studying, designing, constructing, and ultimately operating disposal facilities for high-level waste and mixed transuranic waste (e.g., geologic high-level waste repository and Waste Isolation Pilot Plant, respectively). The sites considered in this evaluation are the 49 sites that are currently generating or storing, or planning to generate or store mixed low-level waste in the next five years. Work has progressed steadily on the evaluation process. However, because of the complexity of

the issues and the work left to be done, proposed alternatives or final destinations for disposal of treatment residuals will not be known at the time the Proposed Plans are submitted to the states and EPA by April 1995. The interim results of this evaluation process are intended to be considered during the discussions of the Proposed Plans, both between the DOE and states and among states themselves, and to identify next steps. This process has been a vehicle for DOE and the states to discuss and to begin to resolve this important issue.

STATE TASK FORCE

The states proposed to DOE that the NGA coordinate the communications of the states that would be involved in the process of approving the Site Treatment Plans. A cooperative agreement was developed between the DOE and the NGA that established a three-year project with a total funding of approximately $2,600,000 and a first year budget of $833,000. NGA was tasked with the responsibility of coordinating the states and facilitating the exchange of information and technical, policy, and implementation issue discussions on mixed waste treatment and disposal. In addition to meeting jointly with the DOE, the arrangement also provides for the NGA and the states, EPA, and Indian Tribal government representatives to meet independently of the DOE to discuss these matters and to resolve equity issues. The NGA coordinated the formation of a State Task Force consisting of both technical and policy representative from the 22 states involved in the process. The State Task Force has established working groups to focus on public participation, technical, and legal issues. Communication between the DOE Task Force and the NGA is ensured through weekly conference calls. Meetings have been held quarterly with all of the state representatives and the PCG to keep all parties abreast of the latest developments and to resolve issues. The Options Analysis Team has provided regular briefings to the State Task Force at the quarterly meetings.

The NGA and the state representatives have been requested by the DOE to participate in some of the DOE focus group activities to ensure that their viewpoints are considered. The NGA has acted as the point-of-contact to review and provide comments on various documents and guidance for development of the Plans, and reports that are developed. This interaction with the state representatives has been advantageous to DOE in establishing policies and conducting planning that is in tune with the states' interests. This interaction has been advantageous to the states in that they have a better understanding of the Site Treatment Plan development process prior to DOE's submittals.

COORDINATION WITH OTHER ONGOING DOE ACTIVITIES

Programmatic Environmental Impact Statement Development

The Environmental Management Programmatic Environmental Impact Statement provides an analysis of the impacts of alternative strategies for conducting DOE's waste management program, including hazardous waste, high-level waste, transuranic waste, low-level waste, and mixed waste. The analysis of the mixed waste strategies is being coordinated with the discussions on, and preparation of, the Site Treatment Plans. As such, the analysis provides information on the impacts of a variety of mixed waste treatment system configurations.

Mixed Waste Technology Development Focus Area

DOE's Office of Environmental Management formulated a new approach to focus its environmental research and technology development activities on key program priorities. This approach is based on teaming the users and developers of technologies to identify, develop, and implement needed technologies. Mixed waste characterization, treatment and disposal is one of five key focus areas that have been established. The Mixed Waste Focus Area has provided key technical support to the development of the Plans in several ways: 1) reviewing, collating, and analyzing DOE complex-wide mixed waste technology needs; 2) providing direct technical assistance and recommendations to the sites to assist in the evaluation of treatment options; 3) reviewing Plans to ensure a consistent technical approach to the analysis of waste stream treatment requirements and treatment system selection throughout the DOE complex; 4) keeping the sites informed of emerging technologies being developed; and 5) aiding the Options Analysis Team by providing technical assistance and reviewing the analyses of treatment options for opportunities to optimize the treatment configuration through the application of innovative technologies. This coordination between the FFCAct process and the Mixed Waste Focus Area has provided valuable technical input to the development of the Plans and provided the Mixed Waste Focus Area hands-on understanding and knowledge of the

technology development needs, priorities, and issues facing the Waste Management program.

SUCCESSES

Since enactment of the FFCAct, the DOE has met every deadline under very aggressive schedules. Issues have been raised through early discussions with the state regulators, and changes to guidance documents and the Site Treatment Plan development process have occurred through these discussions. While there are many issues yet to be resolved, the process is on track to meet the October 1995 compliance date.

As this is an innovative process, there were concerns from everyone involved about whether it was achieving its intended goal. At the initial stages of the process, two years ago, the states requested that DOE allow the sites to develop the Site Treatment Plans themselves, with minimal guidance from DOE Headquarters. The DOE has complied with that request. Upon release of the Draft Plans, the regulators complimented DOE on the product, the process, and its adherence to the requested approach. The resulting trust and confidence in this process has allowed the process to move forward quickly and confidently.

The program is six months away from achieving compliance with the FFCAct. The Proposed Plans will be submitted to the states and EPA by early April 1995. The Proposed Plans will provide the framework for implementing the mixed waste management program for many years. Once negotiations are completed and compliance orders are in place, the DOE and states and EPA will have achieved the initial goal of the FFCAct--the creation of a blueprint for achieving compliance with RCRA. However, much remains to be done. Further discussions with Indian Tribal governments, the public, and others are needed. Moreover, DOE must seek authorization and appropriations from Congress in order to implement the compliance orders. The funding for FFCAct compliance will be a top priority for the DOE.

The success of this program is in the innovative approach that was taken to involve all affected parties throughout the planning process. The DOE has made great strides in changing its culture from one of total secrecy to protect national security, to a more open way of doing business with full participation of the public and stakeholders. The Site Treatment Plan development process is evidence of DOE's success in changing its culture.

ABSTRACT

The Site Treatment Plans (STPs) required by the Federal Facility Compliance Act (FFCAct) for all sites that generate or store mixed waste will propose the use of existing facilities with existing technologies as well as new facilities. The construction of new facilities for waste management, as well as the use of existing facilities, implies the use of a technology selection process. This paper will present an overview of the impacts of technology selection, the process and some tools, and opportunities for the implementation of emerging technologies in the waste management activity.

INTRODUCTION

Technology selection for waste treatment has an impact on many aspects of the process and politics of waste management within the Department of Energy (DOE). The selection of a particular suite of technologies as the waste management system for a facility brings into consideration, in each case, an array of factors such as cost, risk, and treatment effectiveness and others. These factors associated with a technology or treatment system are influential in a number of areas. These interaction .s are shown in Table I. There are policy issues, both budgetary and statutory, as well as political sensitivities associated with the DOE Complex-wide

treatment configuration which will be influenced by technology selection. Stakeholders and regulators have a number of demands which need to be met in the choice of waste management technologies. The results of such decision support activities as the Programmatic Environmental Impact Statement (PEIS) and the Baseline Environmental Management Report (BEMR) are strongly dependent on technology selection assumptions. The analyses carried out and recommendations carried forward in the DOE FFCAct process by the sites, the Policy Coordination Group, the FFCAct Task Force, and the Options Analysis Team (OAT) are also based on assumptions influenced by technology selection.

TABLE I

The Mixed Waste Focus Area (MWFA) of the Office of Technology Development (OTD) is responsible for overseeing the development and implementation of new mixed waste management technologies for the Office of Environmental Management. The MWFA, in order to promote consistency in the approach to technology selection, has recorded the basics of the selection process and provided tools to assist the sites. In the following discussion the technology selection process, the tools, the Technology Resource Team (TRT), and the Alternative Technology Workshop will be discussed.

DISCUSSION

The three phase process by which DOE and its sites have approached the preparation of the STPs has provided a three stage structure within which technology selection has played an important role. The evolution of the STPs from the Conceptual Site Treatment Plans (CSTPs) through the Draft Site Treatment Plans (DSTPs) to the Proposed Site Treatment Plans (PSTPs) has involved refinements of the three elements of a treatment option. The three elements of a treatment option are location, facility, and technology. As the plans have evolved, the location of future facilities has become more certain, there is more detail concerning the facility requirements, and the range of applicable technologies is better defined.

The primary driver in technology selection are the treatment requirements for each waste. The technology selection process is straightforward and involves a small number of well defined steps. For convenience wastes of like characteristics are grouped according to treatability groups. These groups take into account the waste matrix (usually the majority constituent), the radionuclide and radiological characteristics, and the Resource Conservation and Recovery Act (RCRA) regulated contaminants. Radiological characteristics such as alpha or non-alpha contamination and 'contact handled" versus 'remote handled" are important factors in assessing treatment requirements.

The treatment requirements for the RCRA regulated materials in the waste are determined by the performance requirements set forth by the Land Disposal Restrictions in RCRA. The regulated organic materials need to be destroyed and the metals need to be stabilized. The radionuclides also require stabilization. Once the treatment requirements are determined, baseline treatment technologies are matched to the treatment requirements. The waste matrix is often the dominant factor in choosing the appropriate treatment technology. Incineration, for example, is not the best way to destroy low concentrations of organic materials in an aqueous waste. Once the core treatment technology is chosen, a flowsheet can be constructed which contains the unit operations and technologies that comprise the balance of the waste management system. When the baseline flowsheet is complete, opportunities to employ innovative or emerging technologies should be evaluated and appropriate flowsheets generated for each option. If there are several options for the primary treatment technology and the balance of the flowsheet, those options should be analyzed for their comparative value using the Treatment Selection Guides.

The Treatment Selection Guides (1) were provided by DOE Headquarters as part of the guidance for the preparation of the DSTPs. The seven elements of the Treatment Selection Guides summarize the important components of several technology evaluation criteria sets that have been developed by various DOE sites in recent years. These guides supply a tool that can provide a consistent framework within which technology or treatment system options can be evaluated and compared. Once these guides were defined they were provided to the DOE sites, OTD, and to stakeholders for review and comment. The current collection of guides reflects the comments obtained during this review cycle.

The Regulatory Compliance element gives high scores to technologies that have been previously permitted. Lower scores are given to technologies that require regulatory exemptions or demonstrations of equivalency that may pose additional permitting

difficulties. Environmental Health and Safety gives high marks to processes that decrease or provide no additional risk to the workers, the public, or the environment. The recognition of Stakeholder Concerns is important to the progress of DOE's waste management program. Stakeholders may include the local public, public near the intermediate and final destinations of the waste, state and local governments, Indian tribes, Congress, the Department of Defense, and industry. Technical performance issues are evaluated under the Treatment Effectiveness element. Process properties such as volume reduction, secondary waste generation, DRE (destruction or removal efficiency), flexibility, and final waste form performance are major considerations in this category. The Implementability guide assesses the ease and likelihood of bringing a treatment technology into operation within the proposed schedule and estimated cost. Technologies that can be designed, built, demonstrated, and put into production within specified schedules while exhibiting high levels of maturity, development, availability are given high scores. Life-Cycle Cost includes the total of the direct, indirect, recurring, nonrecurring, and other related costs estimated to be incurred in the design, development, production, operation, maintenance, support, and final disposition of a major system over its anticipated useful life. Evaluation of technology transfer opportunities and the value of the technology to the commercial sector is included under the Technology Development guide.

Another tool, the Technology Catalog, initiated at Los Alamos National Laboratory, has been developed by the MWFA to assist in the technology selection process. There are several versions of the catalog. The Waste Management Automated Technology Catalog (WMATC)(2) is in a portable electronic format supported on a Macintosh PC and operates under the 4D RuntimeTM software. DOS based versions are available either through Internet access to the LANL sewer using the MOSAIC utility or a local version that uses the MOSAIC utility on a DOS based PC.

Fig. 1. is an example of the way in which this catalog is organized. In the catalog's automated version there are five flowsheets of which the Aqueous Liquids Flowsheet is one example. The WMATC's utility is based on its ability to carry out searches for technologies that match specific waste management functions such as front-end handling, pretreatment, treatment, etc. A unique feature of the WMATC is that the technologies in the database have been tied to specific unit operations in top-level flowsheets. These flowsheets are suggestive of the flowsheets developed earlier by the Mixed Waste Treatment Project during the analysis of the Complex-wide mixed low level waste treatment system requirements. Similar flowsheets have also been used in the PEIS analysis.

The graphically oriented search strategy directs the development of flow sheets by providing technology choices from the catalog for five waste matrices - organic liquids, aqueous liquids, process solids, soils, and debris. The choice of a waste matrix such as aqueous liquid from the first menu screen leads to a flow sheet with the unit operations, e.g. solids separation, neutralization, organic removal, metal removal, etc., that are necessary to treat an aqueous liquid waste. Selection of a particular unit operation in a point and click graphical display will provide a selection of technologies relevant to that unit operation. Repeating this sequence for each recommended unit operation from the start to the finish of the flowsheet will provide several technology options for each unit operation. This, in turn, will lead to several differing configurations for a treatment system. These configurations can be evaluated and compared for local and technical efficacy by using tools such as the Treatment Selection Guides.

Figure 2 shows an example of the information available for a specific unit operation selection in the aqueous flowsheet. When organic destruction is chosen for the primary treatment unit operation, four options are displayed, i.e. chemical oxidation, photolytic/radiolytic destruction, wet air oxidation, and biological. In the example given in Fig. 2. photolytic/radiolytic destruction is selected. The WMTAC technology examples that are brought in the search are shown in the figure and range from lasers and electron beams to UV oxidation techniques. The catalog has narrative descriptions which describe more fully any technology that is selected.

In addition to the tools described above the Technology Resource Team (TRT)(3) is an organization that has been supported by the MWFA. The TRT is comprised of number of experienced process engineers and technologists. The membership of the team was structured in a way that mixes technology developers l with technology users. The function of this organization has been to provide technical assistance throughout

the FFCAct process. This assistance has taken the form of technology selection and options analysis workshops at various sites, technical reviews of the CSTPs/DSTPs/PSTPs participation in OAT activities, and evaluations of the opportunities to employ emerging or innovative technologies. One of the primary responsibilities of the TRT is improving information exchange with regard to technology issues. Information concerning technology needs must be discovered and details concerning the performance characteristic of technologies must be transmitted to the users to facilitate technology selection decisions.

The most recent activity completed by the TRT was the Alternative Technologies Workshop. One of the objectives for this workshop was to take advantage of the OAT's 12/95 configuration of waste streams and facilities in a treatment technology analysis. A crosswalk of the Mixed Waste Inventory Report, Phase II waste stream data with the OAT configuration created a database. The database represents the first opportunity to view treatment facility technologies and technology requirements against the framework of detailed radionuclide/contaminant/matrix data. In the case of OAT proposed new facilities, this technology analysis provided an opportunity to identify the proposed facilities where the implementation of emerging or innovative technologies would have the greatest impact. This analysis also provided information concerning areas of the waste management process where there are additional technology development requirements. This information is intended to supply the needs of various customers. The identification of implementation opportunities should help the operations people make technology selection. The needs information will help the MWFA understand what additional technology development activities need to be considered.

Figure 3 is a summary example of a product of the workshop. The Idaho Waste Processing Facility (IWPF) is one of the proposed facilities in the current OAT configuration. The waste streams shown in Fig. 3 are a small selection of the large number of wastes targeted for the IWPF. the core technologies chosen for this facility are thermal treatment (incineration is a prime candidate) and stabilization. These are shown at the middle of the figure. Alternate technologies have been suggested. An important consideration in the ongoing negotiations with stakeholders involved in the FFCAct is the comparison of thermal and non-thermal treatment technologies. It is increasingly important to develop data for non-thermal treatment options in order to be able to defend a thermal treatment choice based on performance data. Suggestions were made by the workshop for non-thermal options including sludge Washing, direct chemical oxidation, and acid digestion. Phosphate-bonded ceramics which are being studied in a program sponsored by OTD are a new material for use in stabilization applications may be applicable to these wastes. Technology needs related to mercury recovery, stabilization, and monitoring were identified. Concerns about processing mercury contaminated wastes are not confined to waste streams directed to IWPF. These processing problems exist at other sites in the Complex such as Savannah River and Oak Ridge.

SUMMARY

We have discussed the technology selection process, tools, and other assistance that is supported by the MWFA. The MWFA has provided support to the technology .selection activities associated with DOE's response to the FFCAct. -As the STPs evolve through negotiations with the states and stakeholders additional technology selection concerns will arise as facilities are planned or modified. There are areas in which the technology selection process can be improved. Information quality and dissemination are at the heart of these needed improvements. There needs to be a more precise definition of the treatment requirements for many of the wastes. Performance data for new technologies needs to be generated and distributed to the designers and operators of facilities where implementation opportunities exist. All of the important parties including regulators, stakeholders, and technology development staff need to be involved in the early stages of the development process. The planning of demonstrations should involve the regulators and stakeholders to insure that data that are important to these groups is generated. The issues associated with technology selection will continue to influence. e the process of planning a Complex-wide treatment capability for at least a decade. The technology selection process will continue to be important to those groups and activities discussed earlier including stakeholders and regulators, decision support activities, the DOE FFCAct process, the policy. making activities, and the MWFA.

ABSTRACT

In conjunction with the development of the Site Treatment Plans (STPs), required under the Federal Facility Compliance Act (FFCAct or Act), DOE and the States affected by the Act are working closely to resolve issues associated with the disposal of treated mixed low level waste (MLLW). This paper describes the process by which DOE has responded to concerns raised by States about disposal of the MLLW treatment residuals. The continuing dialogue between DOE and the States concerning the issues surrounding disposal and how to address them has fostered a better understanding for both parties of the options for managing MLLW treatment residuals. The process for addressing disposal of MLLW treatment residuals will continue to evolve and progress as such dialogue and exchange of ideas and values continues among DOE, the States, and other stakeholders and the public.

BACKGROUND

Prior to the enactment of the Federal Facilities Compliance Act (FFCAct or Act), the DOE planning baseline for mixed low-level waste (MLLW) disposal capacity included the development of disposal facilities at the six DOE sites currently disposing of low-level waste. These sites are: Hanford Site, Savannah River Site, Oak Ridge Reservation, Idaho National Engineering Laboratory, Nevada Test Site, and Los Alamos National Laboratory. However, this complex-wide planning effort was re-directed to align with the principles set forth in the FFCAct.

The FFCAct requires the Department of Energy (DOE) to develop a plan for the treatment and storage of mixed waste for each site which currently stores or expects to generate mixed waste, called a Site Treatment Plan (STP). The law does not impose any similar requirement for the disposal of mixed wastes; however, early discussions with the States that host DOE MLLW facilities identified the need to address disposal of MLLW along with treatment addressed in the STP. Recognizing the need to address this final phase of mixed waste management to make an informed decision on treatment options, DOE agreed to work with the National Governors' Association (NGA) on issues associated with the disposal of MLLW being considered under the FFCAct. In support of this goal, DOE established a Disposal Working Group (DWG) in June 1993 to work in consultation with the States.

Rather than describing in detail the technical aspects of the evaluation process that the DOE Disposal Workgroup and States are developing, this paper focuses on the concerns and values that lead to the development of the evaluation process and the way in which DOE is addressing and incorporating these concerns into the process. (For a detailed discussion of the technical aspects of the DOE process for evaluating disposal sites, see DOE'S Planning Process for Mixed Low-Level Waste Disposal, J.T. Case, et al, and DOE's Performance Evaluation Process for Mixed Low-Level Waste Disposal, R.D. Waters, et al).

FINAL DISPOSITION OF WASTE A PRECONDITION TO STATES' AGREEMENT WITH TREATMENT PLANS

During the initial DOE-State discussions concerning compliance with the FFCAct in December, 1992, a number of States indicated that final disposition of all treated mixed waste streams would be a precondition of their agreement with any plans for the treatment of mixed waste by October, 1995. A primary concern of the States with large DOE sites having existing waste management facilities, including low-level waste disposal facilities, was that such sites and facilities would bear a greater burden due to disposal activities than those associated with treatment only. These States felt that such impacts must be considered in order to ensure that each State is doing their fair share to support the DOE waste treatment plans. While the FFCAct does not require DOE to address the disposal of mixed wastes, DOE was sensitive to

the "equity" concerns of the States regarding final disposition of treated waste. However, given the lack of existing MLLW disposal facilities and the April, 1995, schedule for submitting the Site Treatment Plans, DOE felt that completion of MLLW disposal commitments by October, 1995, was not possible without relying on existing LLW disposal facilities. Both the States and DOE agreed that an alternative approach would be preferable.

DOE responded by proposing to develop a planning process, in consultation with the States, to evaluate potential disposal sites. The DOE Disposal Work Group (DWG) and disposal evaluation process were proposed to utilize a "bottom up" approach to resolve issues associated with MLLW disposal and emphasize the incorporation of the States' values concerning disposal into the process for evaluating potential disposal sites. As such, the disposal evaluation process is an inherently iterative process that relies on continued dialogue between DOE and the States concerning issues, values, and approaches for conducting the analyses.

DOE AND THE STATES ARTICULATED THEIR BASIC VALUES FOR THE EVALUATION PROCESS

The DOE Disposal Work Group initiated the development of the disposal site evaluation process by proposing that in order for the process to be useful to all parties, the goals of the process must be reasonable and attainable. The first of these goals that DOE articulated was that final disposition could not be known by October, 1995, and therefore the evaluation process should not be structured as a site selection process. Rather, DOE proposed that the goals of the process would be to bring to light information about each of the sites being evaluated that would help the States understand the extent to which each site may have a potential to conduct disposal activities and what options may exist for ultimate disposal of a site's treated MLLW.

A second simplifying assumption that DOE proposed was that the scope of the evaluation be limited to the universe of sites subject to the FFCAct. These 49 sites in 22 States are the only DOE sites that currently store or are expected to generate mixed waste, and therefore, provide a natural universe for analysis regarding potential MLLW disposal. While other opportunities could be possible, such as pursuing disposal at non-DOE military reservations being closed under the Base Re-Alignment and Closure Act, it was felt that such alternatives were inconsistent with the goals and timeframe to which the States and DOE were working. Other principles that the DOE proposed to be incorporated into the evaluation process included:

All MLLW disposal analyses would be worked cooperatively with the States where the facilities being analyzed are located;

Discussions and working sessions would be held directly with involved States and with a consortium of States through the National Governors' Association;

Disposal alternatives considered would ensure protection of public health, worker health and safety, and the environment;

Equity among stakeholders would be sought; and

All information and decisions would be documented and made available to the public and other interested stakeholders.

The States also articulated a set of basic principles that the disposal site evaluation process needed to be founded on. First and foremost, in order to ensure the broadest possible analysis of options, the States requested that a rebuttable presumption be established that every site would be considered for disposing of their own waste on site and that existing and historical inter-site transfers of waste for disposal would not be assumed. Second, the States suggested that any reduction in the number of sites being evaluated for disposal activities would only be based on good sound technical reasons and initially the only sites that might be excluded from further evaluation would be those for which radioactive waste disposal siting criteria could not be met. Finally, the States suggested that DOE use all applicable State and local regulations and federal statutes applicable to commercial waste disposal activities, as appropriate, during each stage of the analysis.

DOE AND STATES AGREED TO REMOVE 23 SITES FROM FURTHER EVALUATION

With the basic values of the disposal site evaluation process agreed to, DOE and the States proceeded to establish the first level of analysis. DOE proposed that while the existing universe of sites being evaluated was the 49 sites subject to the Act, a number of those sites may not be able to meet basic siting criteria. At a joint meeting on March 3-4, 1994, the States proposed that DOE could conduct a screening of 49 sites to eliminate sites from further consideration that could not meet siting

criteria. The States also proposed that the only criteria that should be used at this step of the analysis would be technical criteria related to the actual performance of a site, e.g., hydrology, physical conditions, and not criteria that were merely regulatory constructs and subject to change.

DOE responded by reviewing the pertinent State and Federal statutes and regulations regarding the siting of waste treatment, storage, and disposal facilities that were proposed by the States and identified three criteria that met the States' terms. These criteria were that a MLLW disposal facility:

Must not be located within a 100-year floodplain;

Must not be located within 200 feet of an active seismic fault; and

Must have adequate clear land to support a 100 meter buffer zone around the disposal facility.

The States and DOE agreed that these three criteria would be the basis of the first step of the analysis and used as exclusionary criteria for screening sites. Utilizing these criteria, 23 sites were eliminated from consideration, leaving 26 sites remaining for further evaluation. At a joint meeting on March 30-31, 1994, DOE and the States agreed to remove those sites not meeting the screening criteria from further evaluation.

DOE AND STATES AGREED TO EVALUATE REMAINING 26 SITES BASED ON SITE-SPECIFIC FACTORS

At the joint meeting on March 30-31, 1994, DOE and the States also agreed to collect additional information on the remaining 26 sites and identify additional strengths and weaknesses of each site. The States proposed that such site-specific analysis focus on a number of factors related to each sites' ability to perform disposal activities.

DOE responded by collecting the requested information for each of the remaining 26 sites and organizing the information in easily comparable tables and fact sheets for the States to review. The criteria that the States proposed were grouped in three main classifications; Technical Considerations, Potential Receptor Considerations, and Practical Considerations. Each of the remaining 26 sites were evaluated against these consideration groupings which included criteria such as: soil stability and topography; precipitation and evapotranspiration; population; proximity to sensitive environments; land acquisition; government presence at the site; and regulatory constraints.

DOE and the States met again on July 26-27, 1994, to discuss the site-specific data on the remaining 26 sites, and to identify sites suitable for further evaluation. Sites with marginal or no potential for disposal, based on the above criteria, were recommended to be removed or postponed from further evaluation. As a result of the meeting, DOE and the States agreed to eliminate five sites from further evaluation due to their limited potential for disposal, and agreed to merge the evaluation of two other sites due to their close geographic proximity.

While not eliminated from further evaluation, DOE and the States also agreed to lower the evaluation priority of an additional four sites. Issues such as the technical capabilities of the site, the volume of mixed waste which may be generated by the sites, and the acceptability of off-site waste made disposal at these sites particularly infeasible or undesirable. DOE and the States agreed to evaluate these sites in terms of their capability to dispose of their own mixed waste on-site if no other off-site disposal options could be identified. However, these sites were not to be considered further for disposal of wastes from other sites.

As a result of this meeting, DOE and the States agreed to carry forward 16 sites for further evaluation for the potential development of MLLW disposal activities.

DOE AND THE STATES AGREED TO EVALUATE PERFORMANCE OF REMAINING 16 SITES

At the joint meeting on July 26-27, 1994, the States also requested that DOE provide even more detailed information about the actual disposal capabilities of each of the 16 sites remaining under the evaluation process. DOE responded by proposing that the remaining sites undergo a performance evaluation to assess each site's disposal potential by estimating the concentration limits of waste that may be disposed at a given site. Based on the methodology and tools used to construct radiological performance assessments, DOE constructed a generic model which could be adapted to each site's particular conditions and used to estimate radionuclide specific limits at each site.

DOE presented the performance evaluation methodology and approach to the States in August, 1994, and after addressing comments and concerns from the States, began collecting site-specific data to perform the evaluations.

DOE AND THE STATES STILL NEED TO DEVELOP NEXT STEPS IN EVALUATION PROCESS
The results of the performance evaluations, expected to be completed in May, 1995, will be reported to the States for review, comment, and discussion. Most importantly, while the States and DOE have discussed general approaches for the next steps of the disposal site evaluation process, many details remain to be developed and agreed upon. In general, the next steps will include estimating waste volumes and expected radionuclide concentrations in treated residuals, comparing these estimates to the site-specific radionuclide limits from the performance evaluations, and analyzing the trade-offs and impacts associated with alternative MLLW disposal configurations. However, the issues to be addressed and values to be incorporated in these steps of the evaluation process will require a level of dialogue among DOE, the States, and the public similar to that which occurred throughout the process to date.
CONCLUSION: THE "BOTTOM-UP" ITERATIVE DIALOGUE BETWEEN DOE AND THE STATES IS WORKING
While the FFCAct does not require that DOE address the ultimate disposal of the treated mixed waste in its plans, DOE recognized the need to work with the States to address the disposal issue. DOE engaged the affected States early in the development of the disposal site evaluation process and committed to an iterative dialogue based on eliciting the values most important to both DOE and the States in addressing the disposal issue. While it is not assured that this process will result in the establishment of waste disposal strategy for treated MLLW, both DOE and the States recognize that the disposal site evaluation process has to a large extent been successful so far. DOE believes that the successes of this process can be attributed to:

- the establishment of reasonable and attainable goals;
- Identification and incorporation into the analysis of the values most important to both DOE and the States;
- An open and flexible process based on continual and frequent dialogue; and
- Use of appropriate and relevant levels of analysis.

United States Department of Energy
K. S. Wierzbicki
D. K. Noller
Westinghouse Savannah River Company
ABSTRACT
By April 6, 1995, the U.S. Department of Energy (DOE) sites that generate and store DOE mixed waste will submit Proposed Site Treatment Plans to their states in compliance with the Federal Facility Compliance Act (FFCAct).
This paper describes the process that the Savannah River Site, a large DOE site, used to develop its Site Treatment Plan (STP). This paper also describes Savannah River's ongoing efforts to ensure that the regulator and stakeholders are fully informed and involved in the development of the STP.
INTRODUCTION
The DOE is required by Section 3021(b) of the Resource Conservation and Recovery Act (RCRA), as amended by the FFCAct, to prepare plans describing the development of treatment capacities and technologies for treating mixed waste. The Act requires STPs to be developed for each site where DOE generates or stores mixed waste. Mixed waste is defined by the FFCAct as waste containing both a hazardous waste subject to RCRA and a source, special nuclear, or byproduct material subject to the Atomic Energy Act of 1954. Upon submission of a plan to the appropriate regulatory agency, the FFCAct requires the recipient agency to solicit and consider public comments and approve, approve with modification, or disapprove the plan within six months. The agency is to consult with the U.S. Environmental Protection Agency and any state in which a facility affected by the plan is located. Upon approval of a plan, the agency shall issue an Order requiring compliance with the approved plan.
The STPs are being developed in three phases: 1) a Conceptual Site Treatment Plan (CSTP), 2) a Draft Site Treatment Plan (DSTP), and 3) a Proposed Site Treatment Plan (PSTP). The Savannah River CSTP, issued in October 1993, listed mixed waste streams

generated at Savannah River Site (SRS), and described various treatment options, including onsite treatment, offsite treatment at other DOE facilities, and vendor treatment either onsite or at the vendor's site.
For most waste streams discussed in the CSTP, the DSTP, issued in August 1994, selected a preferred treatment option. Waste streams proposed for shipment to SRS from other DOE facilities were addressed as well. The DSTP identified specific treatment facilities for treating a number of mixed wastes and, where feasible, proposed schedules for treatment or treatment technology development as required by the FFCAct. Treatment implementation schedules not identified in the DSTP will be proposed in the PSTP. If a schedule cannot be identified in the PSTP, a date for schedule development will be specified.
The PSTP will be issued by April 6, 1995. The PSTP will reflect the complex-wide needs and plans of the DOE Mixed Waste Management program. During the implementation of the PSTP, DOE will continue to evaluate and develop technologies that may offer advantages in the areas of risk, performance, and life cycle cost. These technologies will be incorporated into the STP process, as appropriate. Due to the complexity of defining a single preferred option, there may be more than one option given for some waste streams. If a waste stream is not sufficiently characterized to select a preferred option, the PSTP will propose a schedule for characterizing the waste and developing a treatment plan. In addition, if a waste stream does not have a developed technology for treatment, the PSTP will propose a strategy and a schedule for research and development of treatment technology. After the State of South Carolina accepts the SRS PSTP, it will become an approved STP and the basis for the Order.

DEVELOPMENT OF THE SITE TREATMENT PLAN

There were four basic steps in the development of the SRS STP. They included: 1) determination of the type and volume of mixed waste requiring treatment including current and five year projected volume, 2) identification of feasible options for treating the mixed wastes, 3) initial screening of feasible options to eliminate those with low technology risk and select the viable options to be further analyzed, and 4) in-depth options analysis to evaluate and score each option and selection of the best treatment option. Each of these is discussed further below.

Determination of Type and Volume of Mixed Wastes

As required by the FFCAct, SRS prepared a report providing an inventory of all mixed wastes in storage and to be generated in the next five years. This report provided a description of the type of waste, volume in storage, estimated volume expected to be generated in the next five years, the hazardous waste codes for each type of mixed waste and the RCRA Land Disposal Restrictions (LDR) treatment technology or technologies specified for the hazardous waste component of each type of mixed waste. This data was collected from the existing waste inventory records and from the SRS mixed waste generators. To facilitate analysis of the data, wastes with similar compositions were categorized into waste streams, and each stream was then assigned a unique identifying number. Annual updates to this report (referred to as the Mixed Waste Inventory Report, or MWIR) were completed by SRS to support the STP process. The updates facilitated inclusion of additional detail as each stream was analyzed by both the MWIR updates and the STP investigations. Waste stream experts evolved from this process and worked with developers of the STP to examine and select feasible, viable and preferred treatment options as discussed below.

Identification of Feasible Options

After identification of the mixed waste streams, each stream was evaluated to determine potential treatment capabilities.
A group of technical personnel familiar with the existing and planned site treatment facilities, along with personnel familiar with RCRA specified treatments, evaluated each waste stream to determine what type of treatment was required by RCRA and if an existing, modified existing, or planned onsite facility could perform that treatment. Additionally, technical personnel familiar with vendor treatment capabilities, and personnel familiar with RCRA specified treatments, evaluated each waste stream to determine if there was a vendor that could treat the waste either onsite or offsite. Lastly, the waste streams were evaluated against other known treatments available within the DOE complex to determine if the waste stream could be treated by another DOE site.
The potential treatment capabilities developed during this process were called feasible options.

Initial Screening

The first step in determining which feasible options merited further evaluation was to assess the technology risk of each of the options. The methodology used was based upon Risk Management Concepts and Guidance written by the Analytical Sciences Corporation for the Defense Systems Management College. The "risk" determined is not whether the system or process is safe but the "risk" that a process may be too new and too complex to perform as required. Some questions that were used to determine the technology risk indicator were:

Are state-of-the-art advances in technology being used in the design?
Is the equipment exposed to a harsh or unique environment?
Does the design require complex integration of control systems, or computer software?
Is the cost of recovering from system failure high?
Is the design evolving as construction is going on?
Is the design new, or an extension of a successful design?
Are standard components being used in new, non-standard ways?
Does the facility stand alone, or must it interface with other facilities or processes?

No process or facility can be simpler than its most complex part, or more mature than its newest part. Thus the technology risk assessment began with an examination of the whole process or facility to identify the part that has the most complex and the least mature technology. While the interaction of numerous parts and features may result in an overall process that is more complex and novel than its individual pieces, the identification of the crucial part is the first step in assessing the probability of a process or system failure.

Next, a magnitude was assigned to the maturity of the part, the Maturity Factor (Pm), and to the complexity of the part, the Complexity Factor (Pc). The magnitudes were assigned based on the guidance in Table I. When engineering assessment indicated the factor fell between the extremes noted, other magnitudes were assigned.

Next, a magnitude was assigned to the Consequence of Failure (Cf). Such consequences range from minor inconveniences from which recovery is quick and inexpensive, to technical catastrophes from which recovery, if possible at all, is prolonged and costly. Table II provides the guidance for assigning the magnitude.

A Cf equal to 0.7 was chosen for all assessments of the technology risk of the waste treatment options, because technical failure of a preferred treatment option was postulated to result in a costly and time-consuming redesign to develop another process to meet requirements. Until the redesign was complete and implemented, waste treatment performance would be significantly degraded.

The Maturity and Complexity Factors were then combined with the consequence factor to give the Risk Factor (RF):

First, the Maturity and Complexity Factors were averaged:

$$(Pm + Pc)/2 = Pf$$

Then, the RF was calculated:

$$RF = (Pf + Cf) - (Pf \times Cf)$$

The RF was a number between 0.19 and 0.99.

If Pf = 0.1 and Cf = 0.1, then RF = (0.1 + 0.1) - (0.1 x 0.1) = 0.19

If Pf = 0.9 and Cf = 0.9, then RF = (0.9 + 0.9) - (0.9 x 0.9) = 0.99

As can be seen from the above, the closer the RF is to 0.99 the greater the technology risk.

In the next step to screen and evaluate waste treatment options, numbers ranging from 0 to 100 were assigned to treatment option attributes, with high numbers representing more desirable features. To make technology risk assessment scores work the same way (high numbers indicating a low technology risk), the RF was converted arithmetically to a number between 0 and 100, called the Technology Success Factor (TSF). A TSF score near 100 indicates a high degree of simplicity and maturity for a treatment option.

In the initial screening of treatment options, those with TSF scores under 50 were discarded. At this time, such technologies remain unproven and would not be recommended as the preferred option in the STP. When these technologies mature, they will be reassessed for application to the site's waste treatment program.

In-Depth Options Analysis (IDOA)

After the elimination of treatment options with a low possibility for technological

success, most waste streams still had several viable treatment options. To determine the best option, all viable treatment options were subjected to an IDOA. Comparison among treatment options for a given waste stream is facilitated when each option can be assigned a number that reflects the degree to which the option satisfies a set of criteria or requirements. The method of developing a numerical ranking of treatment options is known as the IDOA model.
The IDOA process took several steps: 1) determination of the attributes by which all treatment processes would be analyzed, 2) determination of the relative importance of the attributes, 3) application of the IDOA model to each viable treatment option, and 4) determination of the Preferred Option to treat a given waste stream.
The categories and attributes analyzed were:
Process Parameters (total weight factor of 22%)
volume alteration (5%)
secondary waste generation (4%)
destruction, removal, and demobilization efficiency (2%)
flexibility (3%)
ability to be shipped (2%)
final waste form (6%)
Engineering Parameters (total weight factor of 19%)
system implementability (13%)
availability (3%)
scalability (1%)
remedial measures (1%)
schedule for treatment of waste (1%)
Personnel Parameters (total weight factor of 20%)
consequences of unmitigated accident scenarios (6%)
non-operational worker potential exposure (6%)
operational worker potential exposure (6%)
transportation potential exposure (2%)
Regulatory Parameters (total weight factor of 14%)
need for a variance (4%)
ability to obtain a permit (6%)
waste disposal (4%)
Public Acceptance (total weight factor of 9%)
public acceptance (9%)
Cost Considerations (total weight factor of 15%)
life cycle cost (14%)
funding availability (1%)
Industry Involvement (total weight factor of 1%)
market for technology (0.5%)
private sector involvement (0.5%)
"Enabling statements," clarifying the above attributes, assisted with the process experts' evaluation of treatment options.
To evaluate a viable treatment option, a team of waste treatment process experts applied the enabling statements to each option. The team assigned a number from 0 (low) to 100 (high) to each attribute. The score reflected the experts' assessment of how well the process satisfied the requirement posed by the attribute as described in the enabling statement.
For example, consider the attribute of "Secondary Waste Generation." If the process produced a small quantity, all of which could be handled by existing technologies, the enabling statement specified a "high" numerical rating (median 80). If the process produced as much as 10% additional waste that existing technologies could handle, the process was rated "medium" (median 50). If the process produced large amounts of secondary waste, or if existing technologies could not handle the secondary waste, the process rated "low" (median 20). If the experts felt a score other than the median better reflected conditions, they could assign another number, provided they gave an explanation for the variation (e.g., in the preceding case, if the process produced 20% additional secondary waste, the evaluation would include a statement such as "subtract 10 points because of additional waste generation").
For the cost attribute, a team of cost estimators determined the life cycle cost. The estimators developed:
  pre-operating cost to design and prepare initial documentation (including permits) for the facility

facility cost to build and equip a new treatment facility, or modify an existing one
operating and maintenance cost for the life of the facility
disposal cost of all final waste forms in compliance with the RCRA LDR
decontamination and decommissioning cost to return the facility to a safe and environmentally benign condition at the end of its useful life.

The process experts' evaluation resulted in a raw technical score for each attribute, and inclusion of the cost estimators' life cycle cost data resulted in a raw total score. Nevertheless, these raw scores did not reflect the relative importance of the attributes. Not applying a weighting factor to each attribute assigned the same weight to all. Therefore, each attribute received a weighting factor. The weighting factors were then reviewed and modified by independent reviewers, regulators, and a citizens' focus group. The final weight factors appear beside the attributes previously described.

Each option's weighted technical scores were summed. The total fell between 0 (least preferable) and 100 (most preferable). The sums enabled the treatment option to be ranked according to the technical weighted score. Then, the weighted life cycle cost data were added to the technical weighted score in a way that ensured that the cost of a treatment facility was equitably apportioned among the waste streams that would be processed using that facility. This resulted in a total weighted score. The IDOA model generated the technical and total weighted scores for each treatment option. These IDOA model scores were useful tools to narrow the entire population of options. The IDOA model:

ensured the same attributes were analyzed for every process or facility,
provided some guidance to help make analyses consistent among the facilities,
enhanced the engineering assessment by incorporating consistent structure and logic.

Application of the IDOA model ensured consistency and completeness in performing the in-depth analysis of the potential treatment options associated with each waste stream. The primary function of the model was to reduce the number of possible treatment options to a more manageable number for further analysis and review. The model was not developed to provide a clear preferred option (PO) winner. The application of the model results in a smaller set of POs that may have model scores within a 10 to 15% range of each other, that serve as the focus of engineering analysis. It was not expected, and in practice was not always the case, that the treatment with the best model score was the treatment option selected.

Sixteen of the waste streams also had treatment options proposed by commercial vendors. Many of these options, however, remain technologically unproven. The vendors have offered to perform studies to demonstrate that their technology can produce a waste form that will meet the LDR. Nonetheless, the technical viability of these technologies was assumed, and hypothetical vendor processes were projected, to allow application of the IDOA model for a comparison of the potential vendor processes with other treatment options.

The last step in the IDOA was to perform an engineering assessment, taking into account the score generated by the IDOA model. While application of the IDOA model analyzed the degree to which the treatment option satisfied the requirements of the prescribed attributes, engineering assessment took a broader perspective and considered other less tangible factors.

REGULATOR/STAKEHOLDER INVOLVEMENT

An aggressive program to inform the regulators and stakeholders in assessment of and selection of treatment options was implemented. Regular meetings were held with key state regulatory agency personnel to keep them informed of progress in developing the STP. Items directly affecting the selection of preferred treatment options such as assumptions, treatment selection methodology, and the IDOA, were reviewed with the agency, and their comments incorporated into the process. The agency was kept informed of the plans for treating each of the SRS mixed waste streams. The agency was also kept informed of the waste that other sites were targeting to send to the SRS for treatment, and the waste that SRS was targeting to send offsite for treatment.

Stakeholders have also been kept informed and their input obtained throughout the development of the STP. When the CSTP was issued, a fact sheet was mailed to stakeholders on the site's public involvement distribution list and a copy of the CSTP placed in the local Public Reading Room. In response to the fact sheet,

citizens volunteered to participate in a focus group to review the assumptions, treatment selection methodology, and In-depth Options Analysis Model. Comments from this group were incorporated into the process and used in the development of the DSTP.
When the DSTP was issued, copies of the DSTP and Executive Summary were placed in the local public Reading Room. The DSTP's availability and public workshops were announced through public service announcements, newspapers, television and radio advertisements and news releases, using the site's media list. SRS again issued a fact sheet summarizing the highlights of the DSTP to stakeholders on the sites public involvement list. Copies of the DSTP were also mailed to stakeholders upon request. Two public workshops were held in the local area to provide information on the treatments and facilities proposed to treat SRS mixed waste and on the wastes from other DOE sites proposed to be treated by SRS facilities. Stakeholders were invited to give comments during the workshop or provide them to SRS later. In addition, an edited videotape of the workshops was carried on cable channels in surrounding communities. During the airing of the videotape, SRS personnel were available via a toll-free number shown on the screen to answer questions about the DSTP and to solicit comments. Stakeholders attending the public workshops or calling the toll-free number during the videotape viewings were also invited to participate in focus group meetings to provide further comment on the DSTP. Although sparsely attended, some valuable input was obtained through these focus group meetings. SRS representatives also offered briefings on the highlights of the DSTP to interested community groups. Two such presentations have been provided. Both oral and written stakeholder comments gathered throughout this process have been incorporated into the development of the PSTP.
Once issued, copies of the SRS PSTP and the Executive Summary will be placed in the local Public Reading Room. The public will be made aware of the Plan's availability through public service announcements, newspapers, television and radio advertisements, and news releases, using the site's media list. A revised fact sheet will be developed and issued to stakeholders. Stakeholders will be informed that comments on the PSTP may be submitted to the state regulator.
SUMMARY
The SRS PSTP will be issued to the State of South Carolina by April 6, 1995. When issued, the PSTP will satisfy DOE's obligation under the FFCAct to develop and submit a treatment plan for SRS. Since the PSTP is intended to provide DOE's plans for achieving compliance with the LDR requirements of Section 3004(j) of RCRA at SRS, it is understood that no further civil enforcement action, administrative or judicial, will be initiated for violations of RCRA Section 3004(j) arising from storage of mixed waste covered by the approved STP for as long as DOE is in compliance with the requirements of the approved STP and its Order. This will include all mixed waste in storage at SRS and identified in the approved STP, as well as future generated mixed waste incorporated into the STP in accordance with the provisions of the STP, and any mixed waste received from offsite which is being accumulated to facilitate the treatment of such waste at SRS which is covered in another site's treatment plan approved by the appropriate regulatory agency after consultation with the State of South Carolina.

21-7
PUBLIC PARTICIPATION IN THE FEDERAL FACILITY COMPLIANCE ACT PROCESS
Martin J. Letourneau
U.S. DOE
Karen L. Martin
SAIC
ABSTRACT
The Department of Energy is continuing its efforts to open its decision making processes and to work with its state regulators, Tribal representatives, and other interested parties, or stakeholders, to resolve the issue of how to treat mixed hazardous and radioactive waste. The Federal Facility Compliance Act requires DOE to develop Site Treatment Plans that will identify, at each site, how mixed waste will be treated. Throughout the development of the Plans, DOE has worked closely with its regulators and has provided opportunities for interaction with its stakeholders. This paper discusses some of the key concepts being incorporated into the planning for stakeholder involvement and how they are working.

BACKGROUND

The Federal Facility Compliance Act (FFCAct) requires DOE to prepare plans for developing treatment capacity and technologies for any site at which DOE generates or stores mixed radioactive and hazardous waste. The plans are needed because DOE does not currently have adequate capacity for treating its mixed waste, generated by operations over the past 40 years, to standards required by the Resource Conservation and Recovery Act. The Site Treatment Plans must be submitted to the regulating state or the U.S Environmental Protection Agency (EPA) for approval. The regulatory agency will then ensure that DOE complies with the approved plan and schedules through a compliance order

DOE is developing the Site Treatment Plans in three stages: the Conceptual Plans, published in October 1993, which identify preliminary treatment options; the Draft Plans, published in August 1994, which identify the site's preferred options, and the Proposed Site Treatment Plans, due no later than April 6, 1995.

The Federal Facility Compliance Act (FFCAct) has provided an opportunity for DOE to work through an open process to develop a strategic approach to treating mixed hazardous and radioactive waste. This paper will discuss some of the keys concepts being incorporated into the planning for FFCAct stakeholder involvement and how they are working.

SUCCESSFUL INTERACTIONS TAKE TIME TO DEVELOP AND ARE BASED ON BUILDING TRUST

The Act requires DOE and its regulators, both at the State and Environmental Protection Agency, to work together in this planning process. Through this process, DOE and its regulators have developed a more cooperative working relationship and a greater understanding of the issues to be addressed in DOE's mixed waste treatment plans. At very early meetings, DOE and the state and EPA regulators agreed to use the National Governors' Association to facilitate quarterly coordination meetings between DOE and the regulators. This forum provided valuable opportunities for discussing the overall approach to developing the mixed waste treatment plans and related technical issues.

Despite the mutual goal of developing reasonable, feasible, and technically acceptable plans, DOE and the states both needed to invest time to get past the traditional regulator-to-regulatee relationship, and to begin building trust relationships. For example, in the initial meetings, DOE and the regulators were at odds regarding whether to proceed with DOE's proposed national planning effort or with the site specific planning effort proposed by the states. After significant discussion, DOE agreed to proceed with the state preferred site specific, or "bottom-up" approach. Although this approach proved to be difficult, DOE gained credibility with its regulators by agreeing to their preferred approach. When the Draft Site Treatment Plans were released, the sites recognized the inefficiencies and duplication of facilities prevalent in the plans due to use of the bottom-up approach, but supported DOE's use of that approach.

Although as a whole, DOE has focused on its FFCAct interactions on the efforts with its regulators, the DOE sites have been pursuing the philosophy of using an interactive approach with their local publics and other interested parties for some time, and have begun to see the evidence of success in their efforts. The FFCAct has been a part of the ongoing public involvement efforts at each site.

BE RESPONSIVE TO REQUESTS, BUT BE HONEST IN DEFINING LIMITATIONS

Any planning effort involving two or more parties has inherent limitations and requires mutual understanding of the issues and compromises. The keys to building successful partnerships is to listen to and understand the requests of other involved parties, to identify creative solutions, and to clearly define requests that cannot be implemented. Throughout the mixed waste treatment plan development process, DOE has shared information as it was collected and worked with the states to define the next steps in the process, but has stood firm when necessary. In fact, at several points, DOE and the States have "agreed to disagree" on issues that they were unable to resolve. In this way, the involved parties understood the issues and arguments of the other party, but the process did not stop. In most cases, disagreement was only temporary as DOE and the States identified creative approaches to work toward resolving the issues without stopping the entire process.

PUBLIC PARTICIPATION IS A PART OF EVERYONE'S JOB

In order to undertake a planning effort of this magnitude and implement the "bottom-up" approach, DOE was required to work on many facets of the mixed waste issue simultaneously. Data and technical analysis, policy evaluations, and

stakeholder involvement were ongoing at both the individual sites and DOE Headquarters. In addition to the interactions with the regulators, each DOE site was required to provide information and involvement opportunities for its local interested parties, and similar efforts were undertaken at Headquarters to reach national level interests. The consideration of effective communication and stakeholder involvement was present in the public affairs and outreach efforts and in the technical analysis. For example, initial evaluations of appropriate technologies for treating mixed waste included a consideration of stakeholder acceptability as a part of the technical criteria to be included in the evaluation. Also, development of public information was coordinated with the technical evaluation process to ensure accuracy and timeliness.

IT IS IMPORTANT TO RECOGNIZE THAT DIFFERENT LEVELS OF INVOLVEMENT MAY BE NECESSARY

Since the development of FFCAct plans is focused primarily at the individual site level, DOE has used a decentralized approach to public involvement at the site level. To ensure some consistency, each site was directed to provide a minimal level of activities, including notification and availability of the plans for review, informing the local interested parties, and providing direct interaction opportunities as appropriate.

However, DOE has recognized that it is important to provide opportunities for national level interests to be informed and involved in the FFCAct process. To address these national interests, DOE provided an information mailing to approximately 60 environmental, labor, political, and other individuals announcing the release of the Draft Site Treatment Plans. DOE held an open house prior to releasing the draft plans, in order to provide an opportunity for Washington, D.C. based interests to dialogue directly with the responsible DOE staff.

As the process of developing the plans has continued, DOE has broadened its national approach to include a national stakeholder meeting focused on identifying national issues and potential solutions. This forum provided DOE with direct feedback at the national level as the plans came together to define an emerging configuration of treatment systems.

By broadening its perspective, DOE has gained insight into the issues that are important to its stakeholders at both the local and national level. These issues are being considered in moving forward in the FFCAct process.

ACCURATE COMMUNICATION OF INFORMATION TO THE PUBLIC AFFECTS THE DOCUMENT DEVELOPMENT

The issue of treating DOE mixed waste is complex, involving 49 sites in 22 states throughout the United States and many different mixed waste with different characteristics. The analysis of how to treat these wastes involved identifying all of the types of waste, the various hazardous and radioactive characteristics of the waste, and the appropriate waste treatment based on these variables. Trying to effectively communicate the facts, the issues, and the DOE approach to resolving the issues required a focused effort to provide consistent information in various levels of detail. For example, in developing a national summary of all of the Draft Plans, DOE provided a variety of information to suit the interest level of the audience, including a one page information brief, a short fact sheet, a more detailed Executive Summary, and a document containing both a national and a summary for each site. Technical staff preparing these documents paid particular attention to trying to clearly and simply convey the information so that it would be understandable to the general public as well as the regulators.

In another effort to provide information even though it may be in draft form, each DOE site provided a brief fact sheet describing the contents of their Draft Plan and its possible treatment alternatives. These were compiled and made available to the public and Congress even before the plans had been evaluated from a national perspective. Early information of this type satisfied the level of interest at the stage of the draft plans.

Additionally, attempts were made to make information generally available and easy to obtain, with the exception of some very large documents. Documents and information were made available through the toll-free Center for Environmental Management Information (1-800-736-3282), at public reading rooms located near each site, and at an open house held to reach out to Washington, D.C. based interests.

DON'T LET AN INITIAL LACK OF INTEREST STOP YOUR EFFORTS

A crucial component of public involvement is to continue outreach and involvement opportunities throughout the process. In spite of an initially low level of interest in the topic of mixed waste treatment, DOE has continued to pursue an open process

at both the local site level and at the national level. As the FFCAct process has continued and a national configuration of treatment systems is emerging, DOE is discovering that the level of interest is increasing, and is trying to provide additional information and involvement at the sites, while pursuing avenues to provide national interaction opportunities. For example, in early December, DOE hosted a National stakeholder meeting that included members of environmental groups, labor interests, local government, American Indian tribes, and others to discuss national issues involved with the FFCAct and potential ways to resolve these issues. The forum provided DOE with insight to the issues that are important to a variety of interests, and as a result is defining further activities. Technical issues that were raised will be factored into the development of the Proposed Site Treatment Plans and the discussions with the State and EPA regulators. Through ongoing evaluation of its efforts, DOE is adjusting the public involvement opportunities to meet the level of interest and demand for information.

EVALUATION OF THE EFFECTIVENESS OF PUBLIC INVOLVEMENT EFFORTS IS CRITICAL TO SUCCESS

This is particularly true in the case of a national program such as the FFCAct, where the majority of the involvement issues are being addressed at the site level. Preliminary evaluation of the public involvement program revealed that there were groups interested in the national perspective as well as the site perspective. To address these groups, DOE sponsored a National stakeholder meeting in December, 1994. During this meeting, the participants indicated that they did not feel their involvement opportunities had been adequate, and that additional efforts were required during the decision making process between April and October 1995. As a result, DOE is working to increase the level of involvement and to focus on national issues. One of the challenges facing DOE during this time is the need to provide public involvement while initiating a negotiation process with the regulators to define the Consent Orders that will implement the mixed waste treatment plans. Throughout its public involvement activities, DOE has found that it is vital to be open, honest, and timely in its efforts, and to keep trying different approaches. It has been particularly important to involve the public throughout the process, as the state regulators will ultimately decide how the Site Treatment Plans are implemented through Consent Orders in October 1995. The FFCAct process will continue into the future with periodic updates to the Consent Orders, and the public will continue to be involved as the plans are implemented at the site level.

Session 22 -- Management of Institutional and Industrial Radioactive Wastes

MANAGEMENT OF WASTE IN RUSSIA

Igor A. Sobolev
Serge A. Dmitriev
Alexander S. Barinov
Helen A. Turlak
Michael I. Ojovan
Scientific and Industrial Association "Radon"

ABSTRACT

A review of contemporary state is presented concerning the management of institutional and industrial radioactive wastes in the central part of Russian Federation. There are 16 specialized enterprises for management of radioactive waste of scientific and industrial centers in Russia. Almost 80% of institutional and industrial radioactive wastes from Russia are collected for treatment and disposal by Moscow Scientific and Industrial Association "Radon", which is responsible for the management of radioactive waste in the central European part of Russian Federation. SIA "Radon" provides collection of radioactive waste at enterprises -users of radioactive materials - and their transportation by means of special vehicles. After the treatment and conditioning at the Sergiev Posad division of SIA "Radon" radioactive waste is disposed into shallow ground repositories. The average volume of the waste to be treated at SIA "Radon" is 3000 m3 per year for solid waste and 350 m3 per year for liquid waste. Total radioactivity of processed waste is up to 4 PBq per year.

COLLECTION AND TRANSPORTATION

Solid and liquid radioactive wastes are collected for transportation at almost 2000

enterprises from Moscow, Moscow Region and other 9 neighboring regions in Central Russia (see Fig. 1). These enterprises use radioactive materials for scientific research, industrial and medical applications.
Transport section of SIA "Radon" deals with transportation of radioactive waste. Special vehicles are used. Solid radioactive waste is transported in vehicles OT-20 provided by transporting container with the volume of 3 m3. Liquid radioactive waste of specific activity up to 370 MBq/l is transported by vehicles OJ-2M in tight stainless steel vessels with the volume of 0,8 m3. Transportation of liquid radioactive waste with specific activity less than 1 MBq/l is performed by vehicles OJ-10 in tight stainless steel vessels with the volume of 3m3.
Transportation of high level solid radioactive waste is realized in the vehicle OT-31 with trailer-container made of stainless steel, designated for safe transportation of waste with total activity up to 150 GBq. For transportation of high level spent radiation sources shielded containers are used. They permit transportation of sealed radiation sources with the total activity up to 81 TBq.

TREATMENT

SIA "Radon" has the following basic methods for treatment of radioactive waste: incineration, compaction and water purification.

Incineration

Beginning 1983 SIA "Radon" uses two-chamber ceramic furnace for incineration of inflammable radioactive waste with specific activity up to 3.7 MBq/kg for b bearing waste. Capacity of furnace is 80 kg/h for solid waste and 65 kg/h for liquid inflammable waste. Temperature in burning zone is in the range between 800 and 1000C. Volume reduction factor of waste constitutes 50-60. Multi- step dry gas purification system, with sintered-metal filters as first main element, is used. Purification factor of the system is (1-5)104. Final product from combustion in the form of radioactive ash is included into cement matrix. Further high frequency inductive melting is provided for the ash conditioning.
Recently a new high temperature treatment method in shaft furnace was developed at SIA "Radon". It uses high efficient plasma burner, which allows slag melting directly in the bottom of the shaft and production of high stable materials for disposal (1).

Compaction

Non-inflammable solid radioactive waste is compacted in horizontal hydraulic press with the pressure up to 4,9 MPa. The waste is compacted in paper bags or inside of metallic casks. Volume reduction factor is from 2 to 10. Compacted waste is sent to the repository for the disposal of solid radioactive waste, where it is cemented.

Water Purification

For water solutions purification the system is used, which includes unit of mechanical purification on the base of cloth made of polycaproamid (SYPRON) and claydite filtering elements, electro-dialysis unit and ion-exchange purification unit with cation filters. Capacity of the system while purification of low level radioactive waste with specific activity 2 - 15 kBq/l and salt content 0,6 - 3 g/l constitutes 2,5 m3/h. Purified water is used for technical needs, related with vehicles, equipment and premises decontamination. The amount of waste arisen from the work of the system, and subjected to further conditioning is equal to 0,8 - 2,5 % of the purified water volume. Mobile module plant on the base of automobile with the capacity of 1m3/h is also used for water solution purification (2).

IMMOBILIZATION

Before disposal the radioactive waste is subjected to additional immobilisation to reduce possibilities of radionuclide migration. SIA "Radon" uses the following basic methods of radioactive waste immobilisation: cementation, bituminization, vitrification, inclusion into metal matrices.

Cementation

Low level liquid radioactive waste with specific activity up to 370 kBq/l and salt content not higher than 130 g/l is treated by cementation. Low level liquid radioactive waste is used for making cement mortar in the process of solid non inflammable waste cementation. Waste cementation is realised either directly in near-surface repositories or in metallic casks. Stationary system as well as mobile unit of high capacity on the base of automobile KRAZ-250 is used for cementation. The last unit is equipped with vacuum ejector-mixer, providing the capacity up to 20 m3 of liquid radioactive waste per hour.

Bituminization

In contrast to cementation bituminization allows to obtain hydrolytic resistant compound without growth of waste volume. Low level liquid radioactive waste bituminization is performed by the industrial system URB-8. Capacity of this system is 450 - 600 l of liquid radioactive waste per hour. Rotary film evaporator with the heat-exchange surface of 8 m2, operating at the temperature 130 - 140C, is the main part of this system. The URB-8 system provides bituminisation of low level liquid radioactive waste with salt content 300 -500 g/l. The bitumen-salt compound obtained is discharged into metal casks. It has from 40 to 50 mass% of salts, while its leaching rate is 10-4 - 10-5 g/sm2day.

Vitrification

Vitrification of intermediate and low level radioactive waste is a new perspective trend, providing the maximum waste volume reduction and maximum stable product obtaining. SIA "Radon" began experimental vitrification of radioactive waste in the early 70-th. Boron-silicate glass was selected as a matrix. Ceramic melter with direct joule heating and capacity up to 30 kg/h for glass mass was used for vitrification early. Capacity for treatment of liquid radioactive waste with salt content 200 g/l constitutes 50 kg/h. Specific glass rate is equal to 40 - 50 kg/m2 h and melting ratio 3,2 - 3,4 kWh/kg. Electrical power supply of the system-is 150 kW, temperature in melter 1250C. Many types of wastes with specific activity up to 37 MBq/l and among them wastes from atomic power stations with reactors WWR and RBMC were treated by vitrifying. Volume reduction factor in the process of vitrification is 4,2 - 4,5. Losses of radioactive Cs from the melter in the process of melting did not exceed 3,5 mass%. Leaching rate for Cs137 from final product is equal to 1,410-5 - 4,410-6 g/sm2day. Total amount of glass produced by ceramic melter constitutes more than 10 tons. This glass was disposed at the experimental site for observation and safety estimation (3).

Recently a new vitrification method was developed at SIA "Radon" (4). It is based on coreless induction melting of glass in cold crucible. Glass composite materials, which contain separately radioactive components in the form of disperse phase in the glass matrix, are considered for immobilisation of glass incompatible chemical components (such as sulphates, hard metal's oxides, etc.)

Inclusion in Metal

Being disposed in underground near-surface repositories, spent radiation sources are included into metallic matrix material. For this purpose mobile module plant assembled on the base of automobile chassis is applied. Lead or lead based alloy is used as matrix material (5).

RESEARCH PROGRAM

Research division of SIA "Radon" includes Applied Research Centre and other research departments. They provide for improving technologic processes of radioactive wastes treatment and environment remediation. Research programme includes many topics. Among them there are following items:

Improvement of technology and apparatus for vitrification of liquid radioactive waste (Tests of coreless induction melter, tests of gas purifying system, experiments with different glasses and glass composite materials, SYNROC and other ceramics, analysis of their structure and distribution of nuclides in matrix).

Development of safe disposal technology of spent radiation sources (Tests of mobile unit for spent radiation sources conditioning by using metal matrices, experiments with different metals as well as polymeric composite materials).

Long term tests of solidified radioactive waste (Tests on open testing area and tests in experimental shallow ground repositories by using real solidified waste).

Determination of economic efficiency of environment protection activities (Ecological and economical assessment of activities of radioactive waste handling enterprises in Russian Federation and development of database for financial information).

Development of solid radioactive waste treatment methods (Improvement of radioactive waste incineration technology, analysis of composition and structure of materials produced by melting ashes from incinerator, improvement of treatment technology of polymeric radioactive waste by high frequency heating, tests of shaft furnace for high temperature treatment of waste by using plasma heaters, development of gas purifying system for shaft furnace).

Development of systems of automated management of operation processes with radioactive waste (Development of database for sealed radiation sources -information system "SOURCE" - and development of an entrance radiation controlling

system for radioactive waste).
Development of treatment methods of liquid radioactive waste (Tests of mobile unit for liquid radioactive waste decontamination, investigations by using membranes and sorbents, radiation cleaning of water).
Ecological and geographical aspects of environmental protection while render harmless radioactive waste (Investigations of radiation burdens comparing with background natural reservation levels).

RADIATION MONITORING

Since 1974 SIA "Radon" carries out a complex programme of radiation monitoring of Moscow. Radio-Ecological Centre as a division of SIA "Radon" manages the activities on investigation and prognosis of radiation situation. It has a wide network, which includes more than 200 controlling surveillance elements. Meanwhile it was discovered a large number of radiation anomalies and lost spent radiation sources. In 1991 a special computer based system was introduced for the control of sealed radiation sources.

ECONOMICAL EVALUATION

Economical assessment of the efficiency of environment protection activities permits worthy decisions for selection of reliable treatment methods. Particularly for intermediate radioactive waste treatment it is important to evaluate possible treatment processes: vitrification, incineration in shaft furnace with ash melting, etc. A new method of economical assessment was developed, which take into account reliability of radionuclides retention by different matrix materials. For example, vitrification of liquid waste from nuclear power plants has an economical advantage, when specific radioactivity of waste is higher than 4 MBq/l.

MANAGEMENT AND DISPOSAL OF RADIOACTIVE WASTE FROM OUTSIDE THE NUCLEAR FUEL CYCLE

Peter W. Brennecke
Almut Hollmann
Heinz P. Berg
Bundesamt fr Strahlenschutz
Federal Republic of Germany

ABSTRACT

In the Federal Republic of Germany it is intended to dispose of all radioactive waste in deep geological formations. This includes radioactive waste originating from outside the nuclear fuel cycle. Detailed information on the various compositions of respective primary wastes, waste treatment and conditioning processes, waste forms, packagings and radionuclide inventories per waste package as well as on waste arisings have been compiled. Site-specific safety assessments covering a repository's operational and post-closure phase have been made. The results of these investigations served in particular to define the requirements to be met by the waste intended for disposal. Waste acceptance requirements have been established for the planned Konrad repository project and the Morsleben repository.

INTRODUCTION

At present, about 50 % of the radioactive waste arisings in the Federal Republic of Germany originates from outside the nuclear fuel cycle, e.g. from nuclear research establishments, other research centers, universities, industrial facilities, hospitals, pharmaceutical industry and the German Federal Armed Forces. The use of radioisotopes in these facilities results in a comparatively high volume of immobilized liquids and concentrates as well as of compressible and/or combustible

materials featuring a heterogeneous composition and a broad spectrum of radionuclides.

COMPETENCIES AND RESPONSIBILITIES

In Germany the Bundesministerium fr Umwelt, Naturschutz und Reaktorsicherheit (BMU, Federal Ministry for Environment, Nature Conservation and Nuclear Safety) is the competent authority for all aspects of spent fuel and radioactive waste management, and is the supervisory body for the licensing authorities in the federal states.

The peaceful use of nuclear energy in Germany is regulated by the Atomgesetz/Atomic Energy Law. On September 5, 1976, the Fourth Amendment to the Atomgesetz/Atomic Energy Law was enacted. It provided the legal basis for the disposal of radioactive waste. According to section 9a para. 3 of this law, the Federal Government has to establish installations for the engineered storage and disposal of radioactive waste, i.e. the disposal of radioactive waste is assigned to the Federal Government as a sovereign task. On November 1, 1989, this competency was assigned to the Bundesamt fr Strahlenschutz (BfS, Federal Agency for Radiation Protection). Accordingly, the BfS is responsible for the establishment and operation of those federal installations, acting on behalf of the Federal Government. In this respect, the BfS is supervised by the BMU.

The federal states are the licensing and supervising authorities for all nuclear installations, including the licensing of repositories, but excluding spent fuel interim storage facilities. In performing this task being legally regulated, the federal states act on behalf of the Federal Government. In addition, they have to operate collecting depots for radioactive waste originating especially from isotope application in industry, research and medicine, i.e. originating from small waste generators.

All other waste management procedures and steps, i.e. spent fuel storage, reprocessing, waste conditioning, transportation and waste interim storage are within the responsibility of the waste generators. In particular, the waste generators have to characterize and to specify their waste. They are responsible for the proper fulfillment of all conditions given within the licenses as well as of the requirements to be met when waste packages are shipped and transferred into an interim storage facility or a repository.

RADIOACTIVE WASTE FROM OUTSIDE THE NUCLEAR FUEL CYCLE

An essential prerequisite for the development of waste management and disposal strategies or the planning and construction of repositories is the provision of a realistic data base. Data on the origin, type and expected amount of radioactive waste from outside the nuclear fuel cycle are therefore necessary.

Origin and Type of Radioactive Waste

In the Federal Republic of Germany, radioactive waste from outside the nuclear fuel cycle in particular originates from

1. basic and applied investigations in the Karlsruhe and Jlich nuclear research establishments,
2. other research centers, universities, industrial facilities or medical application of radioisotopes (note: This waste is generally handed over to the collecting depots operated by the federal states), and
3. other waste generators, e.g. the German Federal Armed Forces and the pharmaceutical industry.

The term "radioactive waste" covers a wide range of various materials which are quite different according to their nature and quantity of the radioactivity associated with them. The major bulk of waste arisings comprise, among other things, the following waste types (primary waste):

Liquids, aqueous concentrates, sludges.
Scrap, filters, worn-out equipment, spent radiation sources.
Protective clothing, paper, plastics, medical waste.
Organic material, chemical residues, miscellaneous waste from laboratories.
Insulating material, debris, rubble, contaminated soil.
Indicating instruments and devices, pilot lights, compasses and sights containing luminous paints.

As the different waste types must be adequately separated to allow appropriate pretreatment and conditioning for interim storage and disposal, the development of a waste type catalogue seems to be of great advantage (1). Such a catalogue surveys the radioactive wastes from their arising to their disposal in a repository. It specifies the primary wastes, the pretreatment methods, the resulting intermediate

products, the conditioning methods and the resulting waste packages, thus describing the "flow" of radioactive waste. The waste type catalogue, therefore, forms the basis for the description and tracking of radioactive waste from the primary waste to a waste package suitable for disposal. It helps to provide the necessary transparency in waste management and, in particular, gives guidance to the waste conditioners (2).

To provide the necessary data base for disposal-related planning work comprehensive information on waste packages planned to be disposed of has been compiled by the waste generators and conditioners at the request of BfS. Details on the various compositions of primary waste, waste pretreatment and conditioning processes, waste forms and packagings, and the radionuclide inventories per waste package were listed. In addition, planning data on the expected number of waste packages per year has been gathered. According to this procedure, model data on each waste stream originating from outside the nuclear fuel cycle becomes accessible for radiological evaluation within the scope of a safety assessment.

Conditioning Techniques

Conditioning of radioactive waste includes processing and/or packing of the waste, eventually after a pretreatment or a sorting. Various strategies and techniques are applied. The selection of a conditioning process is dependent upon factors like the requirements for interim storage and disposal, acceptance of the process, and volume of the resulting waste packages. Therefore, it is not surprising that different conditioning techniques for the same type of waste may be applied. Furthermore, the necessity to minimize the volume of the conditioned waste because of in former times lacking repository capacity stimulated the development of new and advanced conditioning techniques.

Primary waste must be collected and pretreated in such a way that it is suitable for the selected conditioning process. Principal pretreatment methods are decontamination, crushing, compression, evaporation/distillation/rectification, decantation/dewatering/
filtration and incineration/pyrolysis.

Especially the incineration is attractive for all types of combustible waste. Solid or liquid waste and also alpha-bearing waste may be incinerated. The large volume reduction and, in particular, the inorganic and inert character of the intermediate product (e.g., ashes or slags) are reasons to recommend the incineration process from a repository-related point of view. Nevertheless, the off-gas treatment and the secondary waste must be taken into account.

The cementation of radioactive waste is the most well-known immobilization process being widely applied. It is used for the solidification of liquids, the embedding of solids as well as the grouting of voids in scrap, rubble or filters. Various cementation techniques are used and the equipment might be mobile or stationary. If necessary, special cement formulas and/or suitable additives are to be used. Reactions with the cement, e.g., gas generation by amphoteric metals in the ashes must be taken into account. Possible chemical reactions between the radioactive waste, the immobilization material and the packaging must be limited to permissible levels.

The high-pressure compaction with 1500 Mg to 2000 Mg compactors is an advantageous development to minimize waste amounts. Solid materials are compacted to a stable pellet. This technique is applied to, e.g., metallic materials, paper, plastic, rubble and even ashes from the incineration of organic radioactive waste. Due to possible gas generation occurring in compacted waste, a segregation before compaction is reasonable, i.e., to separate metallic and wet organic materials. Alternatively the compacted pellets may be dried.

Radioactive waste has to be packed for handling, transportation and storage. The necessary quality of a packaging is dependent on the type of waste and its radionuclide inventory. Sheet steel, reinforced concrete and cast iron are common as packaging material. Cylindrical and box-shaped packagings of different sizes and weights are being used. A standardization of the packagings has successfully been realized in order to harmonize the equipment as well as the repository-related handling and emplacement techniques.

Waste Amounts

On behalf of the Federal Ministry (BMU) the BfS carries out an annual inquiry into the amount of unconditioned and conditioned radioactive wastes generated in Germany. In the following, low and intermediate level wastes originating from outside the

nuclear fuel cycle (i.e., radioactive waste with negligible heat generation) will preferably be considered.
According to the latest inquiry (3), the total amount of unconditioned radioactive remnants and primary wastes was about 27,600 m3 on December 31, 1993. Of this, a portion of 15.5 % was produced by the nuclear research centers (4,271 m3) and 10.6 % by the collectings depots of the federal states, the pharmaceutical industry and the German Federal Armed Forces. In addition, an amount of about 200 m3 of short-lived waste was stored for decay in the collecting depots.
The total volume of conditioned radioactive waste amounted to about 63,900 m3 on December 31, 1993. Of this, waste originating outside the nuclear fuel cycle is compiled in Table I.
Based on the results of the annual waste inquiries from 1984 to 1993, a forecast of future waste arisings was carried out (3). This prognosis predicts a total amount of conditioned waste at the end of the year 2010 to about 238,900 m3. Major contributions are made by spent fuel reprocessing (73,140 m3), nuclear research centers (55,250 m3), operation of nuclear power plants (47,750 m3) as well as decommissioning and dismantling of nuclear facilities (50,000 m3). Further details are compiled in Table II.

Waste Disposal

According to the German disposal concept, all radioactive waste has to be emplaced in a repository constructed and operated in deep geological formations. As liquid and gaseous wastes are excluded from disposal in such a mine, only solid or solidified radioactive waste is accepted. In the Federal Republic of Germany, two sites are presently considered for disposal of low and intermediate level waste:
1. In the abandoned Konrad iron ore mine in Lower Saxony, it is planned to dispose of radioactive waste with negligible heat generation.
2. The emplacement of waste in the former Morsleben salt mine in Saxony-Anhalt which was operated as a repository for short-lived low and intermediate level waste with low alpha emitter concentrations has been resumed.
The planned Konrad repository is assigned to accept radioactive waste with negligible heat generation, i. e. waste packages which do not increase the host rock temperature by more than 3 K on an average. Iron ore, i. e. coral oolite, at a depth of 800 m to 1,300 m is the host rock for this repository. Waste packages will be disposed of in drifts with an excavated volume of about 1,100,000 m3 allowing an emplacement of about 650,000 m3 waste package volume. Operation of the repository is scheduled at least 40 years. A total activity in the order of 1018 Bq and an alpha emitter activity of about 1017 Bq are anticipated in this facility.
In the former German Democratic Republic an abandoned salt mine located near the village of Morsleben was reused for waste emplacement. From 1981 until 1991, radioactive waste with a total emplacement volume of approximately 14,500 m3 and about 6,700 spent sealed radiation sources were disposed of. Of this, the activity of alpha emitters amounts to 1.6 1011 Bq and that of beta/gamma emitters amounts to 4.8 1014 Bq. Subsequent to German unity the Morsleben facility has the status of a federal repository, the continuation of its former license being now limited by law until June 30, 2000. Until then, according to present planning, a radioactive waste volume of 40,000 m3 is envisaged to be disposed of. The estimated maximum activity of alpha emitters amounts to about 1013 Bq, that of beta/gamma emitters to about 1016 Bq.
Due to these planning data and marginal conditions the major bulk of low and intermediate level waste, i.e. radioactive waste with negligible heat generation, is intended to be disposed of in the planned Konrad repository. This is in particular relevant to alpha-bearing waste. The operation of the Morsleben repository will in the first instance contribute to the discharge of interim storage facilities.

WASTE ACCEPTANCE REQUIREMENTS

Pursuant to the Sicherheitskriterien fr die Endlagerung radioaktiver Abflle in einem Bergwerk/Safety Criteria for the Disposal of Radioactive Wastes in a Mine (4), the safety of a repository in the operational and post-closure phase must be proved within the scope of a site-specific safety assessment. Such an assessment comprises the undisturbed performance of the planned facility, assumed incidents, the thermal influence upon the host rock, the nuclear criticality safety and the radiological long-term effects in the post-closure phase.

Konrad and Morsleben Requirements

The results of the respective Konrad safety assessment have been converted into both

the design of the surface and underground facilities of this planned repository, and a system of waste acceptance requirements (5). They describe the general basic aspects and the general requirements to be fulfilled and then develop into more specific requirements on waste forms, packagings, radionuclide-specific activity limitations, documentation and delivery of waste packages to the repository. As the licensing procedure for the Konrad repository is still pending, the Konrad waste acceptance requirements are still in a preliminary form (2).

In analogy to the requirements derived for the Konrad repository project, corresponding requirements on the quality characteristics of a waste form, the waste containers respectively packagings of radioactive wastes, the limitations of the permissible radionuclide-specific activity concentrations, and the declaration of radionuclides have been compiled in the Morsleben waste acceptance requirements (6). The waste acceptance requirements were elaborated in such a way that a flexible system of requirements could be established, which is not only tailored to the radioactive waste presently generated but which also allows for improvements and future developments in waste conditioning techniques. Such a flexible system includes several alternatives and different options for the waste packages which ensure the required level of safety for the respective repository. The waste generators thus have the possibility of applying and fulfilling those requirements which are specifically applicable to the waste packages produced by them and to be disposed of.

Therefore, the Konrad and Morsleben waste acceptance requirements may be considered as an envelope or a frame covering all requirements to be met by the waste packages. Of course, such a flexible system of requirements may be considerably extended and more complicated but the advantages are immense if it is taken into account that a substantial modification of the waste acceptance requirements necessitates a new licensing procedure.

Acceptability of Waste Packages

In accordance with these requirements the radioactive waste originating from medical application of radioisotopes, industrial facilities or nuclear research and development laboratories was systematically checked for proper and complete evaluation. Thus, the acceptability for disposal of individual waste packages and of their annual amount was assessed. Special attention was given to the case where the activity-limiting values of the waste acceptance requirements are fully exhausted and to the necessary consequences. This assessment has shown that almost all waste packages from outside the nuclear fuel cycle can basically be disposed of in the Konrad repository (7).

Guidance for Waste Conditioning

Bearing these possibilities in mind, it is not excludable that the waste generators and conditioners will re-evaluate and optimize/rationalize present conditioning strategies and procedures. Up to now, those strategies and procedures have been determined by the available interim storage capacities, lacking repositories and the Konrad waste acceptance requirements. As a consequence, conditioning techniques are in particular aiming at volume reduction and observing the permissible activities per waste package due to the Konrad requirements. From now on, the operation of the Morsleben repository offers potential new developments or modifications of existing conditioning techniques. From a conditioner's point of view it is meaningful to analyze the Morsleben waste acceptance requirements (6) and to adopt conditioning strategies and techniques to these requirements. In addition to technical aspects, due to the Morsleben costs for disposal fixed at DM 12,500 per m3, i.e. DM 2,500 per 200 litre drum, it is henceforth possible to select appropriate conditioning procedures taking economic aspects into consideration, too. For example, as to combustible waste, it could be meaningful to use high-pressure compaction instead of incineration.

STATUS OF THE KONRAD AND MORSLEBEN REPOSITORIES

Konrad Repository Project

A final decision on the licensing procedure may possibly be expected in 1995. Thus, operation of the Konrad repository may be assumed to start towards the end of the nineties. However, the political will within the state government of Lower Saxony, i.e. the licensing authority, tries to prevent the Konrad repository project, so that the outcome of the process appears to remain open. Thus, in order to proceed, directives or instructions issued by the BMU can't be excluded.

Morsleben Repository

Since January 13, 1994 operation has smoothly been resumed. In 1994, a total waste package volume of about 1,400 m3 was disposed of. Nevertheless, due to the permissible rather low activity concentrations for U, Th, Pu and Cm difficulties concerning the emplacement of alpha-bearing waste originating from nuclear research establishments have arisen. Subject to results of additional safety assessments currently performed, final decisions on the acceptability of this waste are still to be made.

CONCLUDING REMARKS

The Konrad preliminary waste acceptance requirements are subject to the pending licensing decision. For planning and project implementation, the compulsory nature and reliability of these requirements are of great importance to the waste generators and conditioners. They have already started to adopt and to convert this guidance within their waste management system. According to a successful continuation and final realization of their efforts, the license for the Konrad repository is an important factor being a highly political and not a technical subject.

The operation of the Morsleben repository is an important step in the realization of a proper radioactive waste management system. Therefore, parallel to the Konrad work, present activities are in particular intended to increase the number of waste shipments to the repository according to the planned performance as well as to initiate further developments and improvements within the emplacement of radioactive waste in this facility.

Austin, Texas 78752

ABSTRACT

The disposal of low-level radioactive wastes for the State of Texas, as well as the proposed participating compact states of Maine and Vermont, will require the establishment of a stable classification scheme and a mutually acceptable series of waste related definitions. Additionally, the development of a precise waste acceptance criteria will be necessary for the orderly planning, development, emplacement, and closure of the proposed Texas low-level waste site. Classes

currently utilized for low-level radioactive wastes usually include: Class A, Class B, Class C, NARM, NORM, and low-level Mixed Waste. These six classes (excluding the majority of Department of Defense related wastes) originate from two basic sources or generators: utilities and nonutilities. Utility generators within the compact produce low-level wastes which are classifiable into 18 acronym categories. Non-utility generators utilize a minimum of nine basic categories which are divided into dry waste and process (wet) streams.

The proposed Texas repository currently will not accept Mixed Low-Level waste, Greater Than Class C (GTCC) waste, or Transuranic (TRU) waste (exceeding 370 Bq/g] [10 nCi/g]), thereby establishing the upper limits for disposal. At present no defined lower limit for radioactive wastes exists. This standard is essential for effective planning and the estimation of future waste streams. Its name (BRC, de minimus, Exempt) is unimportant.

Semantic problems exist. Precise definitions for such common words as processing, recycling, generation, etc. are necessary; they are not used in the same sense between utilities within the same state let alone between the states. Related waste acceptance criteria that must be addressed include: types of beneficiation of waste, validation of point of origin, consistent and easily recognizable labeling that includes an inventory, waste manifest contents, transport tracking, package standards, etc.

INTRODUCTION

In 1980 the State of Texas was required to respond to the federal mandate to establish regional low-level waste sites (Low-Level Radioactive Waste Policy Act, 42 USC 202 1b). The act required the establishment of either regional (compact) or single state (non-compact) low-level radioactive waste repositories. Six months after the passage of the act, the Texas Low-Level Radioactive Waste Disposal Authority (Authority) was established. The site selection process was initiated in February of 1983 by the Authority.

Texas was one of the states initially opting to develop its own statewide low-level radioactive waste repository (non-compact). In 1989, in response to non-compact repository problems associated with the Interstate Commerce Clause of the U.S. Constitution, the Texas legislature attached a rider to an appropriations act that directed the Authority to examine the problems and benefits of compact and non-compact status. In 1991, reports were presented and reviewed at hearings before the House Committee on Environmental Affairs and the Senate Committee on Natural Resources. These hearings resulted in the recommendation to pursue an interstate compact.

In 1993, Texas House Bill 2665 was passed which established the legislative approval for the development of the compact. In November of 1993 the legislature of Maine, on the basis of a referendum, joined the compact. The legislature of Vermont in May of 1994 became the third member of the compact. The Texas Compact will become an official entity upon its ratification by the United States Congress which is expected in 1995.

The Texas site is currently being designed as a near surface facility with engineered barriers. This option was selected over the deep geological subsurface option on the basis of simplicity of operation, flexibility, and low costs for investment and operation. This is balanced against the fact that it offers less isolation from the biosphere than the deep geological subsurface option, consumes surface land, and is more susceptible to human intrusion. Case studies of national low-level near surface and deep geological subsurface radioactive waste sites (1) lend little useful direction for the proposed semiarid Texas site.

COMPACT RESPONSIBILITY

The basic responsibility of the Authority and the Texas Compact, as well as all of the entities involved in the disposal of radioactive waste, is to ensure the protection from radiotoxicity of this and future generations by the adequate isolation of these wastes from the biosphere (2). Performance assessment is the apparent means to test the assumption of adequate isolation. It is a semi-quantitative tool that can be effectively utilized by governmental regulatory and licensing agencies.

McCombie, Papp, and Coplan (3) define performance assessment as the quantified description of the current and future behavior of a system. It is determined by the time-dependent responses of many separate, coupled and uncoupled, interdependent subsystems (e.g., duration of decreasing strength of radiation, geological setting

and events, climatological changes, engineering barrier parameters, etc.) which are fixed within a sequence of different environmental settings or scenarios. The primary purpose of the assessment is to produce a computer applicable model of the radioactive waste system.

The basic elements of the performance assessment structural database (3) include information on such parameters as: the radioactive materials present, other materials present, repository layout, materials and dimensions of engineering barriers, and site characteristics. The structural database, interacting with the chemical and physical conditions developed, form a system that must be identified and analyzed. The resulting system of interacting processes are then computer coded and converted into a mathematical model which varies with a time-dependent process. Potential environmental variations (scenarios) are then tested yielding predicted probabilities and consequences. These data are then evaluated utilizing sensitivity and uncertainty analyses to develop a justifiable level of confidence in the safety of the repository in order to meet public, regulatory, and licensing requirements. Absolute proof of the safety of any repository is not attainable nor is it required. What is always expected is a comprehensive analysis reviewed in a process of regulatory control that considers all reasonable possibilities.

The data requisites for the construction of either an adequate conceptual or utilizable mathematical model of the repository system requires an accurate, hopefully standardized, descriptions of such basic parameters as the repository engineering barriers (e.g., waste containers, backfill, etc.) as well as the more critical identification of the radioactive waste that is being disposed of in the repository. This ideal may be established by the development of adequate waste acceptance criteria, uniform terminology, and an accurate classification scheme.

LOW-LEVEL RADIOACTIVE WASTE CLASSIFICATION PROBLEMS

An example of one of the major national low-level radioactive waste classification problems is that the lower limit for radioactive wastes remains undefined. This regulatory vacuum has occurred with the loss of the Nuclear Regulatory Commission's politically incorrect BRC (below regulatory concern) designation (4).

This, in addition to other internal problems inherent in the current American approach to nuclear waste classification, would seem to indicate at least the need for revision of the system. The
adoption of a new code would seem to be an unworkable solution for a number of reasons, primarily political. It has been recommended that the appropriate governmental agencies investigate the possibility of adoption of the classification scheme developed by the International Atomic Energy Agency (I.A.E.A.) in order to exchange data globally. This concept has been discussed in detail elsewhere (5,6).

The problem of standardized low-level waste classification is pervasive throughout nuclear waste management. The widely accepted international radioactive waste classification is divided into six basic categories; they are: High-Level; Low- and Intermediate-Level (each of which is divided into a short-lived and a long-lived category); and an exemptible waste category. A contact dose rate of 2 mSv/hr (200 mrem) is generally utilized as the division between Low-Level and Intermediate-Level wastes (7)

The I.A.E.A, has been actively pursuing the development of the limits to be imposed on very low radioactivity wastes (8). They recommend that those materials which should be excluded or exempted from regulatory practice should include sources not amenable to control (e.g., cosmic rays, etc.) as well as those materials which represents so low a risk that it becomes a waste of resources to exercise control over them by the regulatory process. This philosophy yields two recommended categories: exemption and clearance. Exemption is one of the six basic I.A.E.A. categories and clearance represents a regulatory process.

Exemption includes small sources which typically are not regulated (e.g., research tracers, calibration sources, etc.). The exemption levels are determined by the International Basic Safety Standards for the protection against ionizing radiation and for the Safety of Radiation Sources (BBS). The I.A.E.A. in Safety Series no. 89 (9), concluded that for the purpose of exemption, a level of individual dose of some tens of microsieverts (a few mrems) in a year reasonably represents what is regarded as a trivial dose by competent authorities. As individuals may be exposed to radiation doses from several exempted practices, it is necessary to insure that the collective dose does not exceed the trivial dose. For this purpose the I.A.E.A. (9) suggests that individual doses be in the order of 10mSv (1 mrem) in a year for each

exempt practice.
I.A.E.A. clearance (or decontrol) includes formerly regulated radioactive materials which have been processed in such a way the materials no longer represent a radiological risk. Additionally, radioactivity lost by decay would be included in clearance process. This is an important factor in low-level waste management. Clearance would include recycled materials as well as waste materials derived from the nuclear fuel cycle and regulated facilities such as hospitals, research laboratories, industry, etc. When radioactivity reaches the level of activity or activity concentration (clearance level) regulatory control is removed, the recycled or waste material is then said to be cleared.
Low-level waste within the United States is defined as that radioactive waste which is not high-level waste, spent nuclear fuel, transuranic (TRU) waste (containing radionuclides with an atomic number exceeding 92), or other (consists primarily of uranium mill tailings) (10,11,12). This low-level system may be divided into seven basic categories; they are: Class A, Class B, Class C, greater than Class C. (GTCC), NORM, NARM, and mixed waste. Low-level mixed wastes are those wastes containing regulated hazardous chemicals in addition to radionuclides.
On national level, the Department of Energy (DOE) is currently working on an Environmental Restoration and Waste Management (EM) Programmatic Environmental Impact Statement (PEIS). The EM PEIS will be utilized in evaluating DOE radioactive wastes. Current supporting studies (13) utilizing the DOE Integrated Data Base (14) and the Waste Management Information System (WMIS) (15) recognizes six radiological categories; they are: 1) U/Th, 2) fission products, 3) induced activity, 4) tritium, 5) alpha-emitting radionuclides and 6) other wastes which are not solid or combustible. Additionally, Cooley and others (13) define ten treatability categories: they are: 1) combustible, 2) noncombustible and noncompactible, 3) noncombustible and compactible, 4) surface contaminated metal, 5) bulk-contaminated metal, 6) sludge/resin, 7) all other solid LLW, 8) aqueous, 9) organic liquid, and 10) remote handled.
Wastes may exist in conditions that can be classified as being generated, treated, stored, or disposed. These waste conditions are not only a classification problem, but also one of semantics. For clarity, they should follow the definitions used in the current DOE Integrated Data Base (16). "Generated waste" is radioactive material recently discharged from a facility production process; it has no commercial value. "Treated waste" has been chemically or physically altered to reduce its toxicity or prepare it for storage or disposal either on- or off-site. Treated waste includes volume reduction processes such as incineration and/or compaction for either storage or disposal. Cooley et al. (13) recognize eleven treatments for low-level waste; they are: incineration, solidification, vitrification, compaction, supercompaction, size reduction, decontamination, metal melting, evaporation, general aqueous treatment, and packaging. They also list ten treatments for mixed low-level waste; these are: incineration, wet-air oxidation, evaporation, solidification, thermal desorption, shredding, pelletizing, packaging, vitrification, and polymeriztion. "Stored waste" is generated waste, probably following some treatment, which is temporarily retained and monitored in a retrievable manner prior to disposal. Stored waste represents an operational convenience. It requires isolation, monitoring, and provisions for the environmental safety of the public. This category implies subsequent treatment, reprocessing, transport, or disposal of the stored waste. Its usage in low-level radioactive waste management is primarily either so short-lived radionuclides may decay to an acceptable level for clearance, or storage at a facility where waste is retained until the construction of a permanent facility (17). The interim storage problem, both on- and off-site, is being currently addressed by the NRC (personal comm., James E. Kennedy). Mixed waste will require Environmental Protection Agency (EPA) approval in addition to the NRC as it comes under the Resource Conservation and Recovery Act (RCRA). The last category, "disposed waste," refers to that waste that is in final emplacement with no plans for retrieval.
The Texas Low-Level Radioactive Waste Disposal Site currently will not accept low-level mixed waste, Greater Than Class C (GTCC) waste, or Transuranic (TRU) waste exceeding 370 Bq/g (10 nCi/g), thereby establishing the upper limits for disposal. Using the 1 mrem (10 mSv) per year as a standard, Texas has promulgated a BRC rule that allows certain radioactive materials to be deposited in a municipal landfill. Wastes meeting this standard are restricted to disposal in only the most

well-designed and operated landfills. The rule has provided an economical and safe method for the disposal of limited types of radioactive material; it could be roughly compared the IAEA's low-level, short-lived, cleared category of disposal.

PROPOSED WASTE ACCEPTANCE CRITERIA

The Authority is currently developing waste acceptance criteria, disposal container specifications, and an initial fee schedule in anticipation of a potential opening date in 1997. The disposal limit for the other compact states of Maine and Vermont will be 20% of the projected annual average of low-level waste generated in the state of Texas for the years 1995-2045. The Authority, in response to this requirement, undertook a series of studies that examine low-level waste streams and component characterization, as well as the quantities of radioactive wastes that will be generated in the states of Texas, Maine, and Vermont (18,19,20). What has emerged from these studies is that there are semantic and classification differences between the three independent low-level state regulatory bodies. The responsibility for and control of the incoming wastes lies with the host state. Authority criteria in large part parallel the I.A.E.A. generic approach (21).

The following discussion is an indication of the direction that the Texas Compact proposed waste acceptance criteria is developing. The criteria are anticipated to include specific provisions that the accepted waste must have an adequate manifest and be properly classified, document must disclose radiation quantities internally and surface dose rates externally, be in sealed and approved containers which will be placed within concrete canisters at the proposed site. Waste form must have designated stability or have been through an approved stabilization process. Free standing and noncorrosive liquids in containers shall not exceed one percent. Liquid wastes must be solidified or absorbed. If absorbed, the treated waste must have twice the necessary absorbent material present. Chelating or complexing agents should not be present. Pyrophoric waste must be treated to a level of being nonflammable. Waste delivered shall not be capable of detonation, explosive decomposition, or explosive reaction with water.

The waste shall not contain or be capable of gas generation to anyone handling the waste throughout the disposal process, except radioactive gaseous waste that is properly packaged at an absolute pressure not exceeding 1.5 atmospheres at 20oC with a total activity of less than 3.7 tetrabequerels (100 Curies).

Biological wastes must be layered with vermiculite, diatomaceous earth, or approved absorbent plus lime to reduce gas generation. The accepted ratio will be thirty parts of biological waste to one part slaked lime to ten parts absorbent. Waste containing hazardous, pathogenic, or infectious material must be treated to the maximum possible extent. Waste oil must not exceed one percent of the volume. Incineration ash and other powders must be treated so that they may not enter the air. Mixed waste shall not be accepted for disposal.

Waste will be placed in concrete canisters with maximum internal measurements of 6 ft. 8 in. vertical and 6 ft. 9 in. horizontal. This configuration accommodates a hexagonal pattern of 55 gallon drums which will be delivered on hexagonal, disposable pallets. Compliance violations of the acceptance criteria could result in several levels of fines, charges, or other actions.

TEXAS COMPACT LOW-LEVEL WASTE CLASSIFICATION

Development of a low-level radioactive waste site for the State of Texas, as well as the participating compact states of Maine and Vermont, requires a stable classification scheme for the orderly planning, development, emplacement, and closure of the Texas proposed low-level site. The Authority classifies low-level radioactive waste into six classes;: Class A, Class B, Class C, NARM, NORM, and Low-Level Mixed Waste. The proposed Texas Low-Level Radioactive Waste Disposal Site, as previously noted, will not accept mixed waste, Greater Than Class C (GTCC) waste, or Transuranic (TRU) waste exceeding 370 Bq/g (10 nCi/g), thereby establishing the upper category limits of the compact repository. The Texas BRC rule, discussed earlier, establishes the effective lower limit of disposal. These six general classes of waste, excluding Department of Defense (DoD) and Department of Energy (DOE) military wastes, originate from two basic sources or generators within the compact: utility and non-utility (18,19,20).

Operational wastes of utility generators within the compact have been divided by Shuman and others (18,19,20) into 18 common categories of low-level wastes (Table I). They define dry active waste (DAW) as consisting of both compactible (COTRASH) and noncompactible (NCTRASH) wastes which are frequently shipped together. COTRASH

normally implies material suitable for incineration while NCTRASH normally refers to metallic components and discarded equipment. High specific-activity waste (HIGHACT) is an acronym used at the Vermont Yankee Nuclear Power Station for activated stainless steel generated during replacement of recirculation piping. Non-Fuel Reactor Components (NFRCOMP) are periodically discarded components are typically composed of corrosion resistant alloys which may contain boron, cadmium, or hafnium as neutron absorbers.

Ion exchange resins (IXRESIN) are used to maintain and control water quality in reactor systems. They are typically styrene-divinyl benzene polymers. Four other recognized resin types are: (RWCUPRS) reactor water cleanup resins, (RWDMRES) radioactive waste demineralizing resins, (SSYSRES) secondary system resins, and (DECONRS) decontamination resins. Decontamination resins are used in the infrequent decontamination of primary coolant systems. All resins must be dewatered. The decontamination resins, however, may contain metallic materials from reactor grade steels in the components and cladding as well as possible high quantities of chelating agents.

Cartridge filters (FCARTRG) are typically constructed of woven or wound fabric or pleated paper supported by a stainless steel basket for the removal of suspended solids. Elements with natural fibers are subject to decomposition and oxidation through chemical attack, radiation damage and/or biological action. PROCFIL is an acronym for process filtered waste used in Texas.

Filter sludge (FSLUDGE) is waste produced by filters which include diatomaceous earth, powdered mixes of cation and anion exchange resins, and high purity cellulose filters. Three types are separately recognized; they are: (CONFDSL) condensate phase separator filter sludge, (FLDRFSL) floor drain filter sludge, and (FPFILSL) fuel pool skimmer sludges. Powered resins and cellulose sludges may produce gas. Filter sludge composed of metal oxides and dirt is referred to as crud. The classification no longer utilizes (EQDRFSL) equipment drain filter sludge and (OIL) spent oil.

Decommissioning wastes are lumped into three major waste streams by Shuman and others (18,19,20). These waste streams will require adequate classifiable acronyms in the future. Decontamination wastes are materials that are generated during reactor decommissioning operations. Neutron activated wastes consist of components that have been exposed to radiation from the reactor core. The third stream is plant dismantlement waste which is waste generated during the dismantlement of the power plant.

Non-utility generator waste (Table II) has been divided by Shuman and others (18,19,20) into nine basic categories which are divided into dry waste and process (wet) streams. The dry active waste, non-utility stream consists of five categories, three of which are utilized in utility operational wastes; these are compactible trash (COTRASH), noncompactible trash (NCTRASH), and high specific-activity waste (HIGHACT). Low specific-activity waste (LOWASTE) is an acronym used by a Vermont academic institution for a waste similar to COTRASH but with a higher density and moisture content which should probably should be placed with the process waste stream. Sealed sources (SOURCES) are low activity sealed sources used on calibration and reference standards.

Process (wet) wastes include absorbed (ABSLIQD) or bulk (BLKLIQD) liquids which may be either aqueous or organic. Biological (BIOWAST) wastes are generated primarily through medical and university research with the bulk of the material consisting of carcasses and tissues. Rare-earth processing waste (REPWAST) is material generated primarily through process metallurgy of rare-earth ores.

These subdivisions and categories also are assignable to the basic six classes. The nine categories do not necessarily cover the four remaining groups; which includes three of the six basic classes. These groups include: naturally occurring radioactive materials (NORM), naturally occurring and accelerator produced radioactive materials (NARM), mixed waste, and Process Metallurgy (Table III).

Types of beneficiation, as in the treatability of DOE wastes, (e.g., supercompaction and incineration versus untreated waste) also must be recorded. Problems that are still to be addressed include such basic items as: validation of point of origin, consistent and easily recognizable labeling that includes an inventory, waste manifest contents, transport tracking, package standards, etc.

SEMANTICS PROBLEMS

Preliminary discussions with the future participants in the compact have revealed a number of potential semantic problems. An example of this is in the description of

the waste product itself. If you use the annual projected waste as being "as generated" it means 2,290,000 cubic feet; if you use "as disposed", the volume is 384,000 cubic feet. When discussing differences between "as generated and "as disposed waste, generators within the same industry have a widely varying vocabulary. To one generator, "as generated" waste means without any treatment. To another, it means minimal treatment, or pretreatment such as 3:1 compaction. Curiously, to one generator "as disposed" meant that amount of waste that left the plant perimeter. To another, it meant the waste that was actually placed in the ground at Barnwell. To some non-utility generators "as disposed" means the waste shipped from the facility. To them, the waste is discarded - i.e., it will not return to their facility - whether it has been shipped to an intermediate processor for processing or storage, or to a disposal site for ultimate disposition.

What is required is standard, precise definitions for such very common, straightforward terms as generated, processed, produced, treated, shipped, and disposed. Equally problematic are the waste management terms (e.g., treated and untreated wastes). The reality is that the terms are not used in the same sense between operators in the same state or between the states. If this problem exists in the Texas Compact, it exists in other national compact and noncompact entities. It would seem to be the appropriate responsibility of the NRC on the national level and the I.A.E.A. on the international level to formulate such standards.

Three things remain to be resolved for the Texas Compact; they are standardized waste acceptance criteria, classification, and waste management terminology. The Texas repository is a microcosm of all low-level radioactive waste site projects. As an example, it is essential that the waste be properly packaged. Texas Class A waste containers are assumed to fail at 100 years while Class B and C waste containers are assumed to fail at 300 years (22). Knowledge of what waste is where is essential for those who will have the responsibility of monitoring the site in the future.

In order to be able to inventory disposed of waste and to know what waste is where, it is necessary that it be classified in a manner systematically rigorous enough to be useful. The six, really three (A,B,C with A being separated), major classes of low-level waste for the Texas repository would appear to be not enough while the numerous acronyms utilized may be too many.

To exemplify the problem, take the case of gas generation. We know that the processes of corrosion, microbial degradation, and radiolysis of certain wastes (e.g., resins) will generate gas (23). Additionally, Eh and pH have a profound influence on the rate of generation. The process may result in such effects as structural failure within the repository or the development of a gas-driven water flow bringing radiotoxin contaminated groundwater into the biosphere.

Participants in the Texas Compact will have to come to an agreement on the precise meaning of the words involved in low-level waste management. This problem, as stated earlier, is one that will be encountered within the other national low-level waste disposal entities. It is recommended that formalization of practical, uniform, translatable, low-level applicable acronyms be considered by the NRC, DOE, and DoD for military, utility, and nonutility generators on a national basis. The resultant data would allow comparison among current waste stream data sets and applications, enable more efficient design of repositories, maintain a national inventory, and develop future low-level waste strategies.

CONCLUSION

The purpose of classification is to reduce the number of components present within a system; conversely, it must be subdivided rigorously enough to be flexible and applicable. It is apparent that it will require the institution of negotiated parallel standards between the Texas Compact states as well as their generators. This problem is inherent in all of the national compacts and noncompact entities. The establishment of clearly defined national and/or international standard acronyms and process definitions for low-level waste is strongly recommended.

RADWASTE MANAGEMENT SYSTEM - EXPERIENCES IN OPERATING AT THE KARLSRUHE RESEARCH CENTER

Iris Hillebrand
Winfried Stegmaier
Forschungszentrum Karlsruhe GmbH

ABSTRACT

We are operating several facilities for radioactive waste treatment comprising processing of all radioactive residues arising at the Karlsruhe Research Center and at other institutions in Germany (e. g. nuclear power plants or state collection facilities) and their conditioning into waste forms amenable to repository storage. In order to be able to observe the requirements imposed by the authorities, we are making use of the KADABRA computer code as accounting and management system. KADABRA is not only a passive accounting system but it assists the users in decision making and thus exerts a direct influence on processing steps. Besides accounting, KADABRA fulfills the following tasks:

- recording the processing streams at HDB,
- monitoring observance of authorized limits,
- calculating nuclides which cannot be conveniently measured by establishing correlations,
- assisting the users in decision making regarding the number and the quality of waste packages to be produced, taking into account the transport and repository conditions,
- preparing the documents needed for repository storage,
- administrating orders from our customers,
- recording operational data for invoicing at a later date,
- writing reports for customers and authorities.

INTRODUCTION

The Central Decontamination Operations Department (HDB) is the central disposal facility for radioactive residues and wastes arising at the Karlsruhe Research Center. We are operating a number of plants for treatment and conditioning of radioactive residues, e. g. incineration plants, compacting plants, evaporator and cementing plants as well as various decontamination facilities. HDB handles all radioactive residues generated at the Karlsruhe Research Center, by institutions located there and by external institutions, i. e. either conditioned to waste forms amenable to repository storage or transferred to an interim store until repository storage or, if possible, decontaminated with a view to reusing them.

In the course of processing radioactive residues many boundary conditions must be observed, e. g. license under the Atomic Energy Act, guideline for waste control, repository conditions as well as transport regulations. In order to conform to the requirements imposed by the authorities and to verify the diverse conditions laid down in the numerous regulations, we are using the KADABRA (KArlsruher DAtenBank fr Reststoffe und Abflle) accounting and management system.

KADABRA at present comprises about 2000 individual programs and is being operated on an IBM mainframe acquired for this purpose. About 40 terminals have been installed in the operating plants proper, another 40 in offices. The users make their inputs into KADABRA in situ and almost simultaneously with physical processing of the material so that continuous documentation updated at any moment is guaranteed.

The central tasks of KADABRA, namely compliance with the obligations to report, planning of processing steps taking into account repository conditions and transport regulations, documentation of the material and activity flows as well as operational documentation, will be described and explained in more detail below.

BOUNDARY CONDITIONS

License under the Atomic Energy Act

All HDB processing plants are being operated under a license granted according to the Atomic Energy Act. The license includes general requirements concerning e. g. obligations to report as well as plant related requirements and limits. Some requirements can be observed solely by application of KADABRA. For instance, it must be known at any moment which activity inventories are contained in the respective operating buildings, broken down by nuclear fuel nuclides and other nuclides, so

that the authorized limits are not exceeded. The respective listing must be prepared every month and submitted to the supervisory authority. Considering the multitude of residues handled here, accounting satisfying the requirements above would not be manageable at all by manual entries because the residues may be transferred repeatedly every month from one store to the next or from one processing plant to the next. Other reports, e. g. listings of all residues received or residues cleared in one quarter, can be prepared as well by input of the necessary instruction to KADABRA and subsequently presented to the supervisory authority.

Guideline for Waste Control

The Federal Ministry for the Environment (BMU) issued in 1989 the "Guideline for Controlling Radioactive Wastes with Negligible Heat Evolution Not to Be Delivered to a Central State Collection Facility." In this guideline the categories of radioactive wastes have been defined as well as the responsibilities and the number of documents required when delivering, transferring and transporting radioactive wastes. Besides, the ways and means of activity assays in radioactive residues and wastes are specified and instructions given on mixing wastes from different categories of delivering institutions. Moreover, administrative details, e. g. identification of waste packages, have been fixed. The waste categories, the choice of database fields, and the whole program logic for control of materials flows in KADABRA have been laid down in this guideline and, in addition, the annual inventory and outlook reports to be submitted to the Federal Office for Radiation Protection (BfS) concerning the current waste inventory and the amounts of wastes anticipated in the year to come. The said reports are mandatory for each institution delivering radioactive wastes and can be prepared by us and many other delivering institutions only with the help of statements of account produced by KADABRA.

Repository Conditions

At present, one repository store exists in the Federal Republic of Germany for acceptance of radioactive wastes without heat evolution, namely ERAM in the Morsleben salt mine. The KONRAD iron mine near Salzgitter to be used as a repository for the same type of wastes is now at the stage of planning, but implementation can be expected for the next years. Although there are tentative ideas regarding installation of a repository for heat evolving wastes at Gorleben, its construction is very doubtful for political reasons. For the two repositories mentioned first repository conditions having legal effect exist, based on safety analyses and design basis accidents which, however, in case of the KONRAD mine are still preliminary. According to the repository conditions waste forms are classified by different waste form groups, depending on waste form quality, and the maximum activity inventories per nuclide and package are fixed. Moreover, specifications are laid down as regards the cask sizes and safety devices. These conditions must be observed in production of waste forms because otherwise transfer to the repository will not be permitted. Prior to the production of waste forms, processing is planned with KADABRA taking into account the repository conditions in order to avoid production of waste forms not capable of repository storage. After production, KADABRA verifies all limits specified for each waste form, stores them and prepares a record. If in spite of planning waste forms have been produced with excessive activity values, they must subsequently be handled separately.

Transport Regulations

Waste forms conforming to the repository conditions described above have to comply in addition with the Ordinance on Transports of Hazardous Goods on the Road and by Railway (GGVS/GGVE), respectively because transport to the repository cannot be dispensed with. These rules and regulations are verified by KADABRA as regards adherence to the limits for LSAII, LSAIII or Type A and Type B transports, respectively.

MATERIALS FLOW

Materials Receipt

In order to comply with the guideline for waste control, a number of data must be available even prior to receipt of radioactive residues. To standardize the data supplied by different delivering institutions, a residue accompanying slip has been designed which the delivering institution must fill in for each residues containing cask, normally 200-l-drums, before delivery of radioactive residues to HDB. The accompanying slip is put into KADABRA before delivery of the material to get approval for delivery, and it passes some checking routines to ensure that all information required has been entered on the slip. After delivery the accompanying

slip is input once more into the system. By redundant input and automated intercomparison of both inputs the number of input errors is minimized. By the second input the residue is simultaneously transferred into our accounting system and in this way becomes part of the quantity for which we hold a license. All residues can be identified at any moment by their unique residue slip numbers and can thus be traced. By a transfer dialog immediately following the input dialog the residue is assigned to its storage place (location or cask). In this way, the activity of the residue is added to the database-internal activity account of the respective storage facility. If, e. g., the residue causes the authorized limit for the storage facility in question to be exceeded, this is immediately displayed as a warning.

Material Processing

Residues received cannot be further processed in accounting until they have been input into KADABRA via the input dialog. Processing of the residues without prior accounting is prohibited. Processing, both in physical and in accounting terms, is done by batches. Processing batches are unambiguously identified by the facility in which they are processed, the year and the running number of the batch.

Prior to residue processing a batch must be opened in KADABRA. The residues to be processed must be posted to this batch. For proper declaration of the waste forms to be produced it is of particular importance to coprocess materials of the highest possible homogeneity in terms of nuclide vector and activity distribution because under computational aspects the material pertaining to a batch is always homogenized anyway. To allow the correct assignment of the waste forms to the delivering institution it should be endeavored to coprocess only residues delivered by one delivering institution. KADABRA assists the user by suitable checking routines. The material is retained in the batch as long as work on it is actually done. Then the intermediate or final products are taken out of the batch via separate dialogs.

Waste Form Production

In the course of residue processing either intermediate products are generated which, after decontamination, are measured for clearance or further treated in processing batches, or waste forms are generated which are amenable to repository storage. The latter result from conditioning batches, in contrast with the pretreatment batches providing only intermediate products. Regarding conditioning batches, batch planning must be performed in advance taking into account the repository conditions and the transport regulations. For this, a dialog specifically developed for that purpose is used which allows observance of the repository conditions and transport regulations to be verified very quickly. By variation of the numerous input parameters optimum use can be made of the limit authorized for each package, with the cask filled up to the maximum level and taking into account plant induced waste form qualities and operational costs. In addition, the kind of activity assignment for the waste forms is specified during batch planning (s. Chapter entitled ACTIVITIES FLOW).

KADABRA automatically characterizes by data sets the intermediate and end products generated, from which data sets the respective shares of the possibly different sources of waste, customers, orders, etc. can be taken. Thus, detailed tracing back of the materials is possible. Waste forms which after such apportionment are composed of shares of several sources of waste are assigned by KADABRA to the source having the highest share because each waste form must not belong to more than one source of waste.

Disposal of Material

When residues, intermediate products or end products are disposed of, they are retired from KADABRA. The waste data sheets required for transfer into a repository are prepared and printed by KADABRA. In the dialog for disposal the date of disposal and the receiver are entered. In this way, the activity account of the last facility charged is credited.

Secondary Waste

When radioactive residues are processed quite a number of new residues are generated which, considering their histories, we do not call intermediate products but secondary waste. Secondary waste like all the other residues must be adequately identified. For this, KADABRA offers dialogs for recording of the secondary waste. The user has to enter solely information which the system cannot derive, e. g. the amount, weight, type, cask number, etc. The user can make his choice among various possibilities for automated determination of the activity inventory, e. g. by input

of the dose rate and computation using the nuclide vector averaged by us, or by input of a number of analysis or input of the gross activity and computation by means of the last completed batch or by a similar procedure.
Some secondary wastes experience shifts in the nuclide vector due to shifts in concentration in the waste, e. g. in water from cleaning of waste gas evolving in incineration furnaces: All alpha nuclides are left in the ashes, some volatile nuclides escape through the stack and others remain in the scrubbing water. This fact is taken into account by application of plant related correction factors. After a secondary waste accompanying slip has been prepared, the calculated nuclides are corrected using the appropriate correction table.
ACTIVITIES FLOW
Batch Input and Cross Contamination
When residues are assigned to a processing batch KADABRA adds up all nuclides and activities entered in the individual residue slips. In addition, KADABRA prepares, dependent on the processing facility, a residue slip for cross contamination and charges it to the batch. Cross contamination is understood to mean that contaminations from the preceding batch are still attached to plant components and spread over the materials of the new batch. Cross contamination is in most cases safety irrelevant, but on account of potential changes of the nuclide vector it is important to the waste form declaration for the repository. Cross contamination is calculated from the batch vector of the previous batch, multiplied by the contamination values to be measured or by the residues left in the casks. All batch inputs taken together make up the batch input activity. The nuclide vector so obtained is taken as the basis for producing intermediate and end products belonging to that batch.
The nuclide vector and the nuclide activities can undergo changes within a batch, e. g. by assignment of a laboratory analysis following which the analytical data are extrapolated to the batch volume by KADABRA and taken over. Not analyzed nuclides are calculated by establishing correlations, and the ratio of activity of an analyzed key nuclide to be specified to the initially declared key nuclide is used as the factor.
During waste form production the activity contained in the batch can be distributed among the waste forms in different ways:
  By residue slips
This method can be applied only if after a batch has been processed a statement can be made as to which residue is left in which waste form accommodating drum. After input of the respective residue slips per waste form drum KADABRA adds up the individual activities and so determines the gross activity of the waste forms produced. By this method, contrary to all the other methods, a residue can be followed up to the end product. The method is frequently used in compaction of residues in order to be able to identify the pellets in the product by the numbers of the residue slips.
  By relative mass
If we can assume that the processing batch is very homogeneous in terms of activity distribution, the activity contained in the batch is distributed in proportion to the mass fractions of the products. This method is mostly applied to cementing concentrates. As the material involved is an extremely homogeneous one and, in addition, the batch inventory had been determined in advance in a laboratory analysis, the declaration error is very small. The method can be applied also to nuclides hardly detectable by measurement, if determination via the dose rate must be ruled out.
  By relative dose rate
If in spite of the similarity of nuclide vectors the activity is inhomogeneously distributed, the activity contained in the batch is distributed proportional to the dose rates measured on the waste forms. This method is most frequently applied in processing solid wastes because the error in distribution by relative mass is unacceptably high on account of the inhomogeneity in activity distribution.
  By percent
This method serves less for true distribution than for providing the possibility of specifically deducting as product fractions of the batch inventory, e. g. packaging materials equivalent to 0.1% of the batch inventory, or of assigning the whole batch inventory to a waste form, e. g. 100% assignment if only one single waste form is produced.

Recalculation based on the average dose rate and the net weight

If the values declared on the residue slips prove to be not accurate enough, it is possible to recalculate the activity while retaining the nuclide vector of the batch provided that nuclides are contained in the residue which can be conveniently measured. KADABRA computes, after input of the mean dose rate, measured at 1 m distance from the drum, and of the net weight which activities correspond to that dose rate, taking into account the specified nuclide vector and the specified geometry.

Assignment of laboratory analyses

Another possibility of activity determination is the direct assignment of a product analysis. This possibility is rarely referred to in practice because the necessary laboratory analyses in most cases are directly performed with the whole material of a batch and are subsequently also directly assigned to a batch.

OPERATIONAL DOCUMENTATION

Administration of Quotations and Orders

KADABRA also administers orders placed by customers. This does not only serve the purpose of cost finding and invoicing at a later stage, but serves primarily to control the process. The orders are given unique numbers to be entered in the residue accompanying slips. In the process of receiving inspection the status of the order is queried. This ensures that we do not accept residues which are not linked to an order. During processing certain controlling fields are called from the order file, e. g. prohibition of mixing, incineration or packaging. In this way, the operating facilities are actively assisted in processing properly material received from the customers.

Cost Finding

Operational cost finding is performed in the course of processing in the facilities. For this, the processing expenditure for the respective material in the processing batch is entered in KADABRA via an expenditure dialog. After completion of batch processing the total expenditure for processing a batch is allocated in proportion to the respective amounts to the residues or intermediate products processed in the batch. The customer receives a cost breakdown by residue slips.

CONCLUDING REMARKS

KADABRA has been operated for nine years and its acceptance with the users is high. However, due to a lot of supplements and improvements, the database structures and the programs have meanwhile become too extensive and complicated. Besides, the guideline for waste control issued by the Federal Ministry for the Environment is to be replaced with the "Ordinance on the Utilization of Radioactive Residues and on the Removal and Disposal as Radioactive Wastes" (AtRAV) in which modified requirements will be laid down regarding the identification and documentation of radioactive wastes. As a fundamental revision of the present system is indispensable, the KADABRA II version is presently in the process of development and planned for being put into service in early 1996.

LOW-LEVEL RADIOACTIVE WASTE DISPOSAL: AN OVERLOOKED OPPORTUNITY FOR BENEFICIAL COOPERATION BETWEEN COMPACT STATES AND THE DEPARTMENT OF ENERGY

George R. Bierman, P.E.
Booz, Allen & Hamilton, Inc.
Germantown, Maryland

ABSTRACT

One result of the Low Level Radioactive Waste Policy Act of 1980 and the Low Level Radioactive Waste Policy Amendments Act of 1985, has been that 45 states are now members of 10 interstate compacts governing the disposal of low-level radioactive waste materials generated within their member states (excluding Federal agency wastes). Progress in acquiring disposal facilities, however, has been very slow and difficult. Many state legislatures have been unreceptive, even hostile, to the subject, as have local governments and citizens. Currently, only two states (i.e., two compacts) have operational disposal facilities. This situation gives rise to the notion that the states and Department of Energy (DOE), which cooperate not at all where waste disposal is concerned, are overlooking an outstanding opportunity to resolve several of the states' problems by reversing their course and cooperating completely in low-level radioactive waste disposal. That opportunity involves states' use of DOE facilities. Major DOE facilities are located in 14 states, five

of which are compact host states, and DOE has a major ongoing program to clean up its sites and dispose of the wastes, mostly in permanent facilities on the sites. At the same time, the low-level radioactive wastes anticipated to be generated by the states will be very small in comparison to the volume of DOE wastes, probably less then 10 percent by volume, as will the facilities needed for disposal of the states' wastes.

There appears to be little or no point in the states having to acquire property - several hundred acres each of uncontaminated property - remove it from the tax rolls, then contaminate it with waste disposal facilities, and be required to manage the property in perpetuity, with all the attendant costs, when the wastes might be disposed of at the DOE sites, which already exist and are going to be managed in perpetuity as a responsibility of the Federal government. It certainly seems that the opportunity for close cooperative actions - to do more with less - is worth investigating. The principal benefits are 1) the states would not have to remove land from productive use and from the tax rolls; 2) the states would avoid the costs of acquiring land; and 3) the costs of developing and operating disposal facilities, then perpetually maintaining the disposal facilities after closure would be avoided.

Several actions are needed to effect this proposed cooperation. Officials in the compact states need to get together with DOE representatives to discuss exactly what would be necessary in agreements and action programs. Congress and the state legislatures need to be informed of the intent to explore states/DOE cooperation, and their support requested for cooperative low-level radioactive waste disposal programs. The Federal regulators (NRC and EPA) need to be brought into the discussions in view of their regulatory responsibilities involving the states and DOE. Time is of the essence in this proposal because the states are pushing forward with their waste disposal programs, and remedial action decisions are being made for DOE sites.

BACKGROUND

At present, 45 states are members of ten (10) interstate compacts governing the disposal of low-level radioactive waste materials generated within their member states, i.e., radioactive wastes that are not generated by agencies/operations of the Federal government. The five (5) states that are not members of any compacts must "go it alone" in managing their radioactive wastes, unless they can either become compact members or arrange to use the disposal facilities of the compacts.

The compacts are an outgrowth of the Low Level Radioactive Waste Policy Act of 1980 and the Low Level Radioactive Waste Policy Amendments Act of 1985, which require that states take responsibility for disposing of their radioactive wastes. The laws also enabled and encouraged cooperative ventures among any states that could reach agreements, i.e., form compacts for this purpose, in the belief that the low-level radioactive wastes could best be managed on a regional basis. The result has been the ten compacts noted above.

Within each compact, one state has been identified as the "host" state, meaning that state would "host" the LLRW generated by all its members by constructing and operating a disposal facility for that purpose. The typical disposal facility is expected to accept the members' LLRW for a period of 20 years, after which a new host state would be selected.

STATUS

Despite the development of the compacts, the paths to achieving the desired ends - creating the necessary legislation within the states, particularly the host states, and determining precisely where within the host state the disposal facility would be located - have not been easy. In Ohio, for example, which is the host state for the Midwest Compact Commission, the enabling legislation was just introduced last November (1994), but with the knowledge that it would have to re-introduced when the new session began last month (January 1995). The legislator who introduced it in November said at the time that he was well aware that it would have to be re-introduced, but that he wanted to give his colleagues time to "gain a better understanding of a difficult issue" (1, p. 13).

Many state legislatures have proven to be unreceptive, even hostile, to the subject, as have local governments and citizens in areas identified as candidate sites. The major reasons for the resistance are the desire not to have radioactive waste disposal sites in their "neighborhoods" and, in some cases, opposition to disposal of radioactive wastes anywhere in the state.

Nationally, the result of these problems has been very slow progress, and despite

the existence of most compacts for many years, only two host states - South Carolina and Washington - have operational disposal facilities. Of the remaining host states, the earliest in the planned schedule are California and Texas, but both have suffered recent setbacks. California had expected its operations to commence in late 1994, but has encountered roadblocks in acquiring the necessary land, known as the Ward Valley site, located in San Bernardino County some 20 miles west of Needles. The land is owned by the U.S. Department of the Interior and transfer of title to California has been held up at the Federal level. No one can be certain just when the transfer will be made. Texas had anticipated starting operations late in late 1996 at a site in Hudspeth County. However, Congress was late in ratifying the Texas Compact and opponents of the facility stated that if and when the Compact is ratified, they will take their opposition to court.

Another key problem has arisen with respect to the planned Wake County disposal facility on North Carolina. This facility is planned to take over from the Barnwell site in South Carolina, which will be closed on December 31, 1995. The Wake County facility was expected to commence operations in early 1996, but has encountered difficulty in satisfying the Nuclear Regulatory Commission's licensing requirements. The result is that the license is now not expected before June 15, 1996. Even if that date is met, the facility could not begin operating until late 1997, so the Compact members are faced with a minimum 2-year delay in having a disposal facility available.

The "Barnwell problem" does not end there, however. That facility was widely used by low-level radioactive waste generators in many states outside the Southeast Compact, but was closed to outside states on July 1, 1994. With Barnwell access gone, these organizations are experiencing a squeeze in any activities that produce low-level waste, and are being forced to curtail many of those activities. Particularly affected are medical research organizations, and in such widely separated locations as California and New York, where research involving use of radionuclides is already being curtailed. These problems will only be exacerbated as delays continue.

In the remaining Compacts and states, disposal facilities are variously planned to become operational over the period of 1997-2001, but many of those plans are not at all firm. The key reasons are variously that the required legislation has not been enacted, disposal facility sites have not yet been selected, land has not been acquired, and facility designs are incomplete or non-existent. Table I indicates the currently planned schedules for commencement of disposal site operations for the various Compacts and non-Compact states (2). The primary insight to be gained from the information in Table I is that, with the exception of the Southeast and Northwest Compacts, none of the Compacts or independent states has acquired a low-level radioactive waste disposal facility. Bear in mind that the current Federal law has been in effect for 10 years.

THE OVERLOOKED OPPORTUNITY

Throughout all of this, it appears that the states, the majority of them at least, have overlooked a golden opportunity to avoid, or perhaps minimize, the difficulties. That overlooked opportunity involves the U.S. Department of Energy. The Department of Energy (DOE) has a number of large plant facilities that, over many years of operations related to weapons production, have generated large quantities of radioactive wastes that must be disposed of, and DOE has a major ongoing program to clean up these sites and dispose of the wastes. With the end of the cold war, most of those facilities have been, or soon will be, declared surplus. For this reason, not only do the wastes from earlier production operations need to be cleaned up, but the facilities themselves - vast arrays of buildings and equipment - also need to be cleaned up, in fact, eliminated. Their elimination will generate even greater quantities of waste materials to be disposed of, and the cleanup and disposal activities will be going on for many years to come. Major DOE facilities are located in 14 states, five of which are currently designated as host states (see Table II).

This situation gives rise to the notion that the states and the DOE, which currently cooperate not at all where waste disposal is concerned, are overlooking an outstanding opportunity to resolve several of the states' problems by reversing their course and cooperating completely in radioactive waste disposal. Department of Energy sites are typically very large in terms of acreage and most, if not all, of the major sites expect to have permanent waste disposal facilities located on their properties.

There appears to be little or no point in the states having to acquire property - several hundred acres each of uncontaminated property - remove it from the tax rolls, then contaminate it with waste disposal facilities, and be required to manage the property in perpetuity, when the wastes might be disposed of at the DOE sites, which are going to be managed in perpetuity as a responsibility of the Federal government. In addition, the remediation of DOE sites and management of their wastes will be taking place over a long period of time - 2019 being the nominal target date for completion of remediation - so the schedule for disposal of the states' wastes could well be dovetailed into the DOE's schedules.

A primary reason for the attractiveness of this concept of cooperation between the states and DOE is that the low-level radioactive wastes anticipated to be generated by the states will be very small in comparison to the volume of DOE wastes, probably less than 10 percent by volume, as will the facilities required for disposal of the states' wastes.

The status in the Midwest Compact offers an illustration of the proposed concept. Ohio is the host state for the Midwest Compact, whose six member states expect to generate some 1.5 million cubic feet of low level radioactive waste over a 20-year design operating life of the facility. At the same time, DOE has three Ohio sites (at Miamisburg, Portsmouth and Fernald) that have large quantities of waste for disposal. At the Fernald site, for example, one Operable Unit alone (of five Operable Units) has 50-60 times the low-level waste expected to be generated by the Midwest Compact.

While much of the waste at Fernald is planned to be disposed outside of Ohio,preliminary plans are that a substantial quantity is expected to be disposed in facilities that would be built on-site. The size and rate of construction of these facilities would not be severely impacted if the Midwest Compact's low-level wastes were to be included.* In any case, it is most unlikely that the Midwest Compact states' low-level wastes would exceed 10 percent of the DOE wastes that would be disposed of at Fernald. Other sites in the DOE complex are much larger than Fernald, and might be able to accommodate much greater quantities of civilian low-level wastes generated within the states.

Given the relative low-level radioactive waste quantities and disposal needs of the states and the Department of Energy, it certainly seems that the possibility of close cooperative actions is worth investigating. As indicated above, the benefits are numerous. The principal benefits are the following.

The states would not have to remove land from productive use and from the tax rolls;

The states would avoid the costs of acquiring land;

The costs of developing and operating disposal facilities, then perpetually maintaining the disposal facilities after closure would be avoided;

The DOE sites are already in existence and are large enough to accommodate the states' low-level radioactive wastes readily;

The DOE sites are planned to have on-site disposal facilities in any case; and

The states' low-level radioactive wastes would be managed properly and perpetually along with the DOE wastes.

Several actions are needed to bring about this proposed cooperation. The first is that responsible officials in the compact states need to get together with DOE representatives for concerted discussions to determine exactly what would be necessary in agreements and action programs. At the same time, Congress and the state legislatures need to be informed of the intent to explore the states/DOE cooperation, so that the legislators can begin to think about changes required in existing laws or what new laws might be necessary to enable and expedite the cooperative waste disposal programs. The Nuclear Regulatory Commission and Environmental Protection Agency need to be brought into the discussions in view of their responsibilities for regulating the states and DOE.

It is recognized that time is of the essence in this proposal because the states are pushing forward with their waste disposal programs, and final remedial action decisions are being made for DOE sites. In DOE's Environmental Management Program, important new emphasis has been placed on need to improve productivity - to do more with less. There is no time like the present to start the cooperative ventures.

PREPARING COMMERCIAL OFF-THE-SHELF TELEROBOTIC TECHNOLOGY FOR DOE REMEDIATION NEEDS
Eugene B. Silverman
ARD Environmental, Inc.
ABSTRACT
Over the past decade commercial nuclear power plants have turned to telerobotic technology for managing and reducing the accumulation of waste products from their plants. Additionally, this technology has been applied beyond the day-to-day housekeeping requirements to emergency response and special surveillance missions. As a result, a host of telerobotic equipment suppliers have developed specialized tools that respond to the decontamination and remediation requirements of these plants - both within the confines of the radiation protection area and around the perimeter of the plant. The theme of this paper relates to the fact that the Department of Energy (DOE) has the opportunity to tune their approach to many of their site remediation challenges by drawing from the lessons learned in the commercial application of telerobotic experiences, rather than focusing only on the conceptual ideas typical of many basic research and development efforts. This paper presents particular design features of equipment which may be applicable to DOE site remediation needs. Examples include the potential use of fuel pool decontamination equipment for reactor inspection and fuel pellet retrieval; the application of large sludge removal vacuum systems for DOE pond and basin inspection; the use of mollusk removal systems for use in site remediation; how to apply the experience of autonomous standby diesel oil tank inspection systems for DOE single wall tank inspection; and, the application of remotely controlled plant inspection systems for DOE site assessment and work monitoring. Examples of applications in the United States and overseas will be presented. The paper provides a summary of lessons learned as well as design and performance criteria relevant to particular DOE environmental restoration requirements. Particular benefits associated with the use of off-the-shelf technology for DOE applications will be highlighted.
INTRODUCTION
Over the past decade commercial nuclear power plants have turned to telerobotic technology for managing and reducing the accumulation of waste products from their plants. Additionally, this technology has been applied beyond the day-to-day housekeeping requirements to emergency response and special surveillance missions. As a result, a host of telerobotic equipment suppliers have developed specialized tools that respond to the decontamination and remediation requirements of these plants - both within the confines of the radiation protection area and around the perimeter of the plant. This paper presents a brief overview of many of the design issues and lessons learned from the application of telerobotic equipment to commercial power and process manufacturing environments which have relevance to the remediation needs of the Department of Energy (DOE).
Although there may be a need to develop comprehensive guidelines for transitioning commercial off-the-shelf technology to the needs of the DOE, this paper only summarizes some of the practical experiences gained through relevant commercial

applications. The material in this paper is primarily concerned with the use of remotely-controlled devices. The remotely-controlled component of this equipment is typically a tracked vehicle. Few examples are presented which require the manipulation of objects other than the occasional retrieval of small objects such as loose parts, fuel pellets, etc.

There are a number of valuable lessons to be learned from the application of off-the-shelf telerobotic equipment to commercial remediation needs. Over the past 14 years this author has been involved in the practical application of telerobotic technology to a variety of environmental remediation challenges. Much has been learned from these field experiences. What is clear is that it is now easier to draw on lessons from events directly experienced than from those which are conceptualized. The theme of this paper relates to the fact that the DOE has the opportunity to tune their approach to many of their site remediation challenges by drawing from the lessons learned in the commercial application of telerobotic experiences rather than focusing only on the conceptual ideas typical of many basic research and development efforts.

This paper is organized into five sections. The first section deals with some of the criteria used to evaluate the commercial resources needed to complete a job. The second section discusses specific design features which may be applicable to DOE site remediation needs. These design features are collected from projects associated with fuel pool decontamination, reactor inspections, basin/sludge and pond cleaning and inspection, tank inspection and cleaning, the removal of mollusks from intake structures and related confined spaces. The third section provides examples of commercial remediation projects in the United States and abroad. The final sections provide a summary of lessons learn in the field and a review of the overall benefits associated with the use of off-the-shelf technology for the needs of the DOE.

EVALUATION CRITERIA AND COMMERCIAL RESOURCES

The structure of a typical remediation job consists of several elements. These elements include processes which occur prior to deployment, or job planning, up to and including the post-project review.

Job Planning

Commercial site decontamination projects first specify the requirements of the project in sufficient detail to develop a Work Breakdown Structure (WBS). The WBS is the heart of the planning document which defines the structure of the project and the specific tasks, including program management functions and the evaluation criteria needed to determine both the progress of the project and the quality of the results. Each of the projects cited in this paper were initiated following the development of a WBS implemented with commercial off-the-shelf project management tools. In a similar manner, commercial software tools were used to plan each activity with regard to schedule and cost. In some cases critical paths were established. Some critical paths were based on dose thresholds and safety constraints, while others may have been based upon the availability of support equipment.

Project Operations

Project operations are usually structured into stages. Although each project has its own unique requirements, most telerobotic material removal projects share similar characteristics. The removal of material can take the form of simple vacuum procedures, or mechanical removal through the use of lifting devices or shredders. Material must be conveyed in a manner that is efficient and safe to both the removal systems and the environment. Mechanical conveying can be accomplished through the use of augers and conveyer belts or through a pumping process, as long as the proper media is available for conveying the material.

Pumping methods are well understood and there are a wide variety of systems available which can usually meet specific volume and speed criteria. Interim pre-filtration storage facilities are typically needed if the processing subsystems can not keep up with the material transfer process. Special holding tanks which can be shielded and built with secondary containments are usually found on such project sites. The filtration process is also an area that has matured to a point where there is usually a variety of options available for the process engineer. After the establishment of realistic processing goals, in terms of yield (i.e., tons per day or gallons per hour), material quality (i.e., per cent solid dry material, rad levels, chemical content), decisions can be made regarding the type of material separation approach or what stabilization technology must be used. Finally, a number

of material containment and handling options are available to meet most Federal and local requirements in this area.

Safety

OSHA has established comprehensive safety guidelines and requirements. Most projects easily incorporate these guidelines, significantly reducing safety risks. Problems can occur, however, in projects that have not been previously encountered. These projects are plagued with unusual situations, which challenge the applicability of OSHA safety standards. This is especially true for confined spaces, which is why telerobotic applications are so valuable for confined space operations.

Maintenance

Perhaps the most neglected aspect of a project is the maintenance of the equipment used to complete the project. Proper pre- and post-project maintenance of equipment ensures that the equipment is ready for the next application. Significant delays can result if equipment fails to perform during a project. Consequently, special emphasis is placed on the time and costs necessary for the refurbishment of such equipment.

Costs

A common characteristic of most well-run commercial projects is the emphasis on cost control. Each phase of the job is monitored to insure that progress can also be evaluated in terms of economics.

DESIGN FEATURES OF IMPORTANCE

After 10 years of commercial environmental remediation projects employing telerobotic devices, a significant body of knowledge has been collected relative to important design features. In all cases the major lesson learned is that the more thorough the assessment of the requirements, the fewer problems encountered in the field. Below are listed many of the critical design features and their relevance to particular job requirements:

Mobility / Traction / Drive. A number of important tradeoffs must be considered in the area of vehicle transport. They include issues related to vehicle contact pressure, vehicle size and weight (i.e., whether or not the vehicle must operate on a geothermal liner, clay, or concrete). Of equal importance is the design of track pads relative to the traction requirements established by terrain conditions. There are also tradeoffs to be made relative to the power requirements (i.e., torque) and tractive forces needed versus umbilical size and weight. The vehicle must have sufficient power to do work and pull its own weight.

Accessibility. The use of telerobotic devices usually presents challenges relative to deployment. As a result, the equipment must be shaped and sized to fit access limitations in a way that also insures proper handling. In the commercial environment there are also limitations of the number of personnel available to the site. This may be due to a number of factors which may include exposure budgets, critical paths, and cost limitations. Therefore, special emphasis must be placed on accessibility issues which clearly address these limitations.

Control and Guidance. Inherent in the use of telerobotic devices is the need to know where your equipment is in confined spaces without being there. Control and guidance devices and methods must reliably provide immediate feedback so that you can determine where you are, where you need to be, and what you have accomplished.

Viewing and Control. Remote viewing in most environments is difficult, at best. This is especially true during submerged operations. Much has been accomplished in the area of mapping systems, optical and acoustic imaging, infra-red and similar nonvisible spectrum. However, remote viewing and control creates a host of unique performance and safety issues. Vision and control requirements are unique to each project, therefore, the system design must incorporate these unique characteristics.

Performance Measurement. The future actions taken by the operator depend on the quality of information related to the material processing rate of the equipment. Although certain circumstances do not allow for the real-time assessment of progress, most remediation project schedules can only be met or adjusted through timely operator performance feedback.

Cleaning / Material Removal. For cleaning applications, the nature of the material determines the selection of the pump and pump powering approach (hydraulic, electric, pneumatic). Similarly, the characteristics of the material determine how it is removed (suction head design) and whether or not the material needs to be conditioned prior to pumping (shredding). After the best method of surface removal and pumping has been selected, the appropriate hose must be selected. Important hose

characteristics include not only size, weight and flexibility, but also design issues related to interior and exterior surface texture and hose buoyancy.
Deployment / Recovery. One of the most overlooked elements of telerobotic remediation projects is the need for appropriate equipment handling devices such as cranes, come-alongs and lifting tripods. A wide range of off-the-shelf devices are available for equipment handling and can easily be configured for different terrain conditions.
Decontamination. Standard techniques used throughout the commercial nuclear power industry and chemical industries are applicable to many of the site remediation requirements of the DOE. It is clear that, in many cases, there will be obvious limitations in the effectiveness of some of these techniques. Consequently, permanent hot storage of the equipment may be necessary. This is sometimes the case in the commercial environment and, as a result, suitable methods for the temporary storage of equipment are available. Regardless, it is important to design and fabricate equipment which can be decontaminated.
Material Compatibility. The design of telerobotic equipment must take into consideration the material in the working environment. Chemical compatibility, heat resistance, pH and the corrosiveness of waste must be addressed during each phase of the design process. Additional concerns are those of the thermal stability of the material, its radioactivity and flash points. A number of lessons have been learned as a result of the loss of steel pump impellers, the breakdown of critical neoprene seals, loss of rubber tracks and the severe pitting of aluminum structures.
Handling System. An often overlooked element of system design is the management of umbilicals. The full operational weight of the umbilical must be calculated (i.e., pressurized hydraulic lines, electrical lines, full material discharge hoses, etc.). If a method is not devised to relieve the vehicle from the stresses and drag created by the umbilical ,then the tractive forces of the vehicle must compensate for this additional burden.
Laydown Area. The design of telerobotic systems must consider the site assembly and deployment requirements. Oftentimes, machines must be dismantled and reassembled inside the work area. This is true of many tanks and sumps which were originally designed for limited access. The laydown and assembly areas must take this need into consideration. The same is true for the special handling requirements of larger machines where the laydown and preparation areas can require a significant amount of site real estate and involve a complicated arrangement of contamination control.
Personnel Entry Limitations. Although the primary objective with the use of telerobotic equipment is to remove the operator from the material hazards, there remain occasions where some degree of manned entry into the work area may be required. This still represents a critical design evaluation issue and the equipment must be designed with the appropriate man-machine tradeoffs to insure the safe operation of the system. This requirement may also include the use of appropriate oxygen sensors, LEL meters and similar remote monitoring sensors.
Support Equipment. A final critical element of the system design is the interface between the telerobotic system components and their support systems (i.e., compressors, hydraulic power units, cranes, etc.). Not only must this equipment be sized to meet the particular performance requirements of the system, it must also be incorporated safely into the job site and configured to minimize contamination, meet all site safety requirements, and be configured to maximize the use of available space.

APPLICATIONS

The previous section briefly highlighted specific telerobotic system design and project features which, through experience, have been determined to be critical to the success of a remediation job. The following paragraphs summarize various projects which are representative of typical commercial applications of telerobotic equipment. In order to provide an interesting cross section of projects, examples were included from industries other than commercial nuclear. Although many of the sites have unique remediation needs, they all have the following features in common: 1) they all require operations within or around materials which are considered hazardous; 2) the equipment used was deployed to remove the operator from the hazardous work environment; and, 3) specific production and safety goals were established.

Nuclear Plant Outage Support

A telerobotic method of cleaning a reactor vessel flange was used at a commercial

nuclear power plant in the Northeast United States during a recent outage. After fuel was replaced in the reactor, and the upper guide structure installed, divers would typically enter the cavity to perform cleaning. Due to the movement of the fuel, there can potentially be radioactive hot particles on the cavity floor creating added hazards to the diver. A telerobotic device was deployed into the cavity during and after fuel movement to remove radioactive debris and hot particles, significantly decreasing the chance that the diver would come in contact with the hot particles. Additionally, during reactor refueling, a stray bolt was found in the reactor core. The bolt was identified to have either come off of the bottom of the upper guide structure, or off of the suction deflector of one of the reactor coolant pumps. There were four reactor coolant pumps, and a study of all vibration data could not determine which pump was the source of the missing bolt. A telerobotic inspection system was deployed and sent further down the cold leg to inspect the bottom of the reactor coolant pump where the suction deflector was located. The system was able to identify the source of the missing bolt on the reactor coolant pump. Had this approach not been successful, the crews would have been forced to pull and inspect each individual pump in an effort to identify the source of the missing bolt. Use of this approach saved a potential 40 man-rem exposure.

Water Treatment Plant Cleanup

A buildup of alum sediments and water purification filtration materials such as polymer additives, carbon, and sand accumulated in the neutralization sump of a water treatment plant. The sump was 50 ft. x 50 ft. and 22 ft. deep. There were 5 support columns, spaced at 17 ft. and 11 ft., at certain intervals in the center of the sump. There were two 4 ft. x 4 ft. openings to the sump used for equipment entry. The sump pump was located on the same wall as an emergency sump, but in opposite corners. There were 2 mixers located in the central area of the sump that extended from the ceiling to within approximately 3 ft. from the floor. The accumulated sludge was 17 inches and the estimated volume of sludge was 3,052 cubic feet.

The backwash recovery sump contained an accumulation of the same sediments as those found in the neutralization sump. There was a 6 ft. slope from both sides to one corner just below the two 4 ft. x 4 ft. side-by-side manway openings. The accumulated depth was approximately 7 ft. at the deepest part. There was an estimated 4,500 cubic feet of sediments. A polyurethane liner covered the entire area of the sump.

A telerobotic cleaning and surveillance system was used to vacuum sludge materials from the sumps and transfer the material to a filter press dewatering system that was located outside the water treatment buildings. The sludge was transferred from the sump through a suction hose to the 6" diesel powered pump located outside the area, then through a transfer hose to frac tanks located near the filter press dewatering system. Water was decanted from the tanks and then concentrated materials transferred to the filter press for dewatering. The filtrate liquid from the press was returned to the sump and dried materials were deposited into roll-off containers for transport to the disposal location.

Suppression Pool Cleaning

A suppression pool of a reactor (GE Mark III Containment BWR-6 Reactor) collected debris which was contaminated from a variety of sources throughout the plant. The pool was approximately 550 square meters and contained contaminated sediment which had collected on the bottom of the pool cavity, as well as some solid debris. A telerobotic system was deployed onto the bottom of the suppression pool cavity and vacuumed sediment through a 2" neutral buoyant suction hose to a submersible pump. Waste was pumped through a 2" transfer hose into the central fuel pool demin system. This direct transfer of material to the plant's demin system eliminated the handling of highly radioactive filters. In addition, a high pressure water jet attachment was used to remove contamination which was imbedded in hard to access areas of the pool floor. This material, plus the sediment removed by the system's rotary brush attachment, was vacuumed by the vehicle as it was directed across the stainless steel floor liner.

HVAC Decontamination

A government supply facilities used an insect repellent in the early 1970s for the treatment of clothing that was being manufactured for overseas personnel. The use of this repellent resulted in the contamination of the heating and ventilation and

cooling (HVAC) system in a large manufacturing facility. The chemicals accumulated in the dust and dirt sediment that normally builds up in HVAC systems. There was a need to perform a cleaning operation on the inside of the ducts in a manner which would protect the workers and minimize the amount of hazardous waste generated from the cleaning procedure. The cleanup requirement was to achieve an atmosphere concentration of contaminated materials that was less than 10 micrograms / sq centimeter. The building had several miles of HVAC duct work of varying widths. The project required the development of an approach to the cleanup operation that would achieve the safety and waste reduction goals established by the client. A telerobotic vehicle was equipped with full pan and tilt color camera and lighting systems for viewing, navigation and recording inside the duct work. Additionally, an air sparge system that operates at 150 psi at 100 cfm and a rotating power spray head operating at approximately 3,000 psi were specially designed and fabricated for the project.

The job specification included strategic insertion of the air sparge vehicle coupled with drawing negative pressure on the system with a large hepa vac system. A thorough cleaning was accomplished that exceeded specification requirements both in terms of cleanliness and time required.

Zebra Mussel Removal

A power plant on the Great Lakes had a severe buildup of zebra mussels in the intake structures of the service water pump forebay. The forebay was an area approximately 200' x 60' and 40' deep. This project was designed to 1) demonstrate the ability to deploy and retrieve a modified a telerobotic vehicle in the inlet and screen bays; 2) remove the accumulations of zebra mussels and other pumpable material from the floor; and, 3) reduce or eliminate the need for divers, thereby reducing the overall cost and danger of removing accumulations of zebra mussels.

A telerobotic system was modified from a standard off-the-shelf system. Mounds of zebra mussels, 8 to 10 feet in height, were encountered and successfully removed. There was a large accumulation of mussels where the vehicle was introduced into the screen bay, and the vehicle was capable of working its way through the mound to the bottom, and then maneuvering to remove the remainder of the mound.

Parts Retrieval

While disassembling a service water pump during a refueling outage, extraneous materials were inadvertently introduced into the reactor coolant system. The situation was complicated by extremely high radiation levels. With use of an on-board color video system mounted on a telerobotic vehicle, all foreign material was located. Three of the five items were recovered during initial deployment activities. On-site modifications consisting of a pneumatically-controlled gripper were made which enabled the operator to remove the remaining two items that had become lodged in a small, limited access drain line. Replacement of the pump continued on schedule with significant radiation dose savings.

Basin Sludge Removal

To comply with the client's deadline to re-commission wastewater treatment fossil plant basins, 465,000 gallons of sludge had to be removed from the plant in less than three weeks. The wastewater treatment system consisted of three HDPE lined settling basins. The primary and polishing basins held 500,000 gallons each and the chemical waste treatment basin provided capacity for an additional 175,000 gallons. A telerobotic vehicle was used in conjunction with a 6" Dri-Prime centrifugal pump for removal of the material from the basins. After removal, the sludge was transferred into a 21,000 gallon tank for concentration and decant of clear water.

An off-the-shelf telerobotic system was deployed at a European nuclear generating station which had two cooling tower basins which were 284' x 408' x 16' deep. The total volume of the basins was in excess of 14 million gallons of water. Every few years there was an accumulation of sediment which included phosphates, river silt, and local ground runoff. Additionally, high levels of algae growth and other organics were measured in the basins. Sludge accumulation was approximately 1' to 3'. Polymers had been added to the basin which resulted in material compositions ranging from loose & fluffy sediment to thick / heavy jelly-like sludges. Obstructions in the basin consisted of 3 polymer additive / sparger lines running length-wise in the basin approximately 18" off bottom - supported by concrete blocks every 6'.

A standard off-the-shelf telerobotic system equipped with a 3", 300' suction hose and pan & tilt color video was used to remove the sludge material. The vehicle was

driven along the bottom, vacuuming sediments and the waste was transferred to the on-shore pump. The sediments were transferred to settling tanks, loose water was decanted off the top, chemical additives were provided and concentrated material was then pumped to a mobile filter press unit located on-site. The material was dewatered, the water was returned to the basins and the dry cake collected and disposed of at a landfill.

The submersible color pan & tilt camera was mounted on the vehicle and used for navigation of the vehicle along the bottom, observing the cleaning process, inspecting the cooling tower intake / pump pit / screens, and for post cleaning verification. Previous cleaning methods required the cooling system to be shut down and all 14 million gallons of water drained. Personnel were required to enter the basins with hoses and pumps in order to flush the sediments down a common drain which emptied into the local river. This traditional approach was a labor intensive method which was considered to be one of the high risk jobs at the plant site. Earlier records in the neighboring town suggested that there was a high correlation between the draining of the basins and the increase in toxins in the neighboring water supply. Livestock and produce were considered to be threatened by this traditional process. Use of the remote acquisition and processing approach eliminated any threat to the environment in a cost-effective and timely manner.

Chemical Plants

A buildup of carbon disulfide (CS2) contaminated sludge in a waste collection tank created an operational problem for a pharmaceutical company. The sludge was approximately three feet deep and was covered with a thick layer of brine. The sludge had to be removed without exposure to the air due to the exothermic nature of the material. Simply disturbing the material on the bottom of the containment tank by hand-raking produced dangerous off-gassing problems. These vapors are flammable and immediately dangerous to health. Conventional removal attempts, such as the use of vacuum trucks, were deemed to be both dangerous and inadequate. The combined safety hazards of the material dictated the need to minimize or eliminate the use of personnel at or near the dike.

A standard telerobotic vehicle was modified with parts that were both compatible with the sludge and intrinsically safe. The project was designed to allow the telerobotic vehicle (equipped with a hydraulically driven submersible pump) to maneuver in a set pattern around the bottom of the dike to transfer sludge to two tank trucks parked nearby on the RCRA pad. The CS2 contaminated material was successfully pumped from under a cover of brine in the dike, to a brine-covered condition in the tank trucks. The operation lasted approximately three weeks. Pumping was accomplished in stages, allowing the material to settle under the brine in the tankers, decanting excess brine, and repeating the procedure until the sludge in the dike was down to minimal levels.

Mining

A particular copper mining site had two mill water recovery sumps. Each sump was 74' in diameter and approximately 15' deep. Each sump was filled with about 5' of extremely abrasive fine powder sediment (pH 12) which, when dry, had the consistency of near solid concrete. These sumps had not been cleaned for over 20 years and, due to the critical water recovery role for the milling process, could not be taken out of service. If these sumps were taken out of service, the entire milling process would come to a stop.

To avoid a forced shut down, an off-the-shelf telerobotic system was modified by replacing particular components with materials resistant to corrosive sludge. In addition, an auger cutting head attachment was installed on the telerobotic vehicle and deployed into the sumps. The hard sediment was broken up with the auger and vacuumed out of the sump through a 4" hose to a 6" diesel pump. The materials were then returned to the plant process system through a center well. The clean-up operation was completed without impacting normal plant operations, and the water recovery pumps remained in service. Maintenance records following this cleaning operation have reported reduced maintenance costs for the water recovery pumps to be more than 70 percent.

LESSONS LEARNED

Many of the lessons learned from the commercial site remediation jobs have been summarized below. In most cases these lessons emerged from design or process problems which were unforseen even though adequate planning was thought to have been demonstrated.

Requirements. Make sure that all requirements are documented and well understood. Do not base the entire remediation operation on drawings which are not current or not representative of the actual work site. If the area is difficult to access, then the representative drawings may be less than accurate for that very reason. This is especially true for tanks and poorly maintained basins.
Traction / Power. The original power and tractive force requirements change depending on the weather and the material composition of the job site. Remotely-controlled vehicle tracks, if not configured correctly, will throw tracks and lose traction due to their deterioration.
Performance Feedback/Productivity Indicators. Without any measure of progress, there will be little sense of value. Measurements of productivity (i.e., material transfer rates, volumes, radiation levels, etc.) must be either available continuously or calculated within a reasonable period of time. Information must also be available to the operator to determine or predict hose clogging, blade loss, binding, and similar performance problems.
Reliability. Select components which are proven, especially for critical path jobs. Pilot testing, especially for one-of-a-kind designs, must be considered an essential element of the project plan. Radiation tolerance of critical components such as cameras, electronics and sensors must be determined beforehand and an operational schedule developed to prolong the useful life of these components.
Robustness. Equipment which is big and heavy is not enough. Design for robustness and incorporate forms that contribute to structural integrity without adding unnecessary weight
System Configuration. Design, fabricate and select components which must operate as an integrated system. Processing and material hauling systems must have the capacity to keep up with the material removal pumping system. This is especially true for filter press operations or decanting associated with high integrity containers.
Cost. Without cost boundaries there is reduced incentive to do the job correctly.
Safety Margin. There is safety in numbers. Design and prepare for the worst reasonable set of circumstances. Most successful commercial projects have taken this into consideration. Elegant solutions are not as important as those that meet all of the requirements at the most reasonable cost.

OFF-THE-SHELF BENEFITS

The previous discussion relative to lessons learned has been gathered directly from field experience. Many of these lessons have been incorporated into a number of telerobotic devices which are in use today. Although these designs may not address all of the specific needs of the DOE, many of their features are relevant to some of their remediation needs. Aspects of off-the-shelf benefits which deserve to be highlighted are summarized below.
Commercial field proven equipment is designed to produce results. There are strong incentives for commercial operations to develop remediation solutions that can sustain a business beyond the first project. In terms of cost, many of the commercial vendors of remediation equipment have gone through the expense of determining what works and what doesn't. Although some research and development may be necessary, these organizations have strong incentives to employ novel solutions and complete projects with limited expenditure of resources. Remediation equipment can be found successfully working in some of the most harsh environments such as the ocean, mining operations and the petro/chemical industries.
Another benefit of off-the-shelf commercial remediation equipment is its availability. Although some research and development may be necessary to modify an existing piece of equipment, there are off-the-shelf components which can be used as the basic building blocks for field systems. Another benefit of existing off-the-shelf equipment is its adaptability to a variety of remediation missions. We have found it useful to incorporate design features into certain mobile systems that would have utility in a variety of missions. The decision to use particular types of materials that are impervious to a variety of environments may justify the additional initial cost.

TWO PERSPECTIVES ON A SUCCESSFUL LAB/INDUSTRY TECHNOLOGY TRANSFER

D. W. MacArthur
Los Alamos National Laboratory
R. Ulbrich
Eberline Instrument Corporation

ABSTRACT
Technology transfer from government laboratories to private business is of increasing concern in today's marketplace. Some prospective partners (on both sides) believe that technology transfer is a relatively simple process requiring little or no extra effort from the participants. In our experience this is not true and, in fact, positive results from a collaboration are directly proportional to the effort that both parties invest in the relationship. Communication, both between prospective partners before an agreement and between partners following the agreement, is essential. Neither technology nor marketing can stand by itself; the combination of the two can produce a useful and available product. Laboratories and industries often have very different ways of looking at almost everything. Misunderstandings arising from these differences can short-circuit the transfer process or result in the production of a product that is unsalable. We will cover some of our experiences, potential problems, and our solutions.

BACKGROUND
The long-range alpha detection (LRAD) technology and several applications were developed at Los Alamos National Laboratory (LANL) with DOE support over the past four years. This technology, and the five current patents covering applications of continuous LRAD detectors, are the subject of both CRADA and licensing agreements between LANL and Eberline Instrument Corporation. Eberline is currently marketing an object monitor, the LRAD-1, based on the airflow LRAD concept discussed below. Several other LRAD applications are currently under consideration as future commercial products.

TECHNOLOGY
Sensors based on the LRAD concept (1,2) detect the ions produced by alpha particles in ambient air rather than the particles themselves. Thus, unlike traditional detection methods, LRAD-based monitors are not limited by the range of alpha particles in air. The lifetime of the ions is dominated by wall collisions so that the ions live longer in larger volumes; in a small pipe the ion lifetime (3,4) is greater than 4 s, allowing for a much longer range than the several centimeters typical of an alpha particle. The LRAD-based sensors do not require thin windows, fine wires, or specialized gases, so they are rugged, reliable, and portable. Some applications dependent on one or more of these features are discussed in Ref. 5.
The group at LANL has built two broad types of LRAD sensor. An electrostatic detector (4) uses an electric field to sweep the ions onto a detection plate. The ion current is directly proportional to the amount of contamination located under the detection plate. Electrostatic detectors are best suited for measuring contamination on relatively flat surfaces such as soil (6), concrete, floors, or liquids. In an airflow detection system (4), the ions generated inside an enclosed volume are transported by an air current produced by a fan. The air passes through a charged grid that separates the ions from the ambient air. Again, the current from this grid is proportional to the amount of contamination. Airflow detectors are suited for monitoring complex objects and tools or for contamination inside a closed volume (such as a pipe, duct, or piece of process equipment).

FIRST STEPS
Technology transfer agreements such as CRADAs work best when they are industry-driven. The researchers can (and should) develop a technology until it is interesting to industry, but trying to "sell" a technology to an industry that doesn't want it is very difficult. If there is no interest, more research is probably more useful than a hard sell.
Are the expectations and goals of the researchers and the commercial enterprise compatible? Total agreement between prospective partners is unreasonable to expect, but an understanding of these goals is important. The two partners are driven by very different desires, and each needs to understand where the other is "coming from."
A concern of the research partner is whether the company can do the job and the company's concern is whether they can match the proposed product to a real market. These concerns can be combined into the question (asked of both parties) as to whether the company will do the job. If the answer is no, then either the "job" or one partner needs to be redefined. The researchers need to realize that their definition of the "job" may not be commercially viable, and the company needs to understand that they may not be the best outlet for every technology.
The desires of the end-users for the technology need to be considered as well as

those of the prospective partners. It is possible for the researcher to know more about segments of the market than the prospective partners; in any event, it is advantageous for the researcher to understand the final market and demand to help them transfer technologies that are most appropriate.

Seeking out potential end-users/customers who are willing to take a risk on the new development is essential to the long-term success of any technologically innovative product. Their "real world" problems may not be understood or easily duplicated by either the researcher or commercial partner. Thus, the experience gained in dealing with these users is a valuable part of the commercialization process both before and after signing an agreement.

CONTINUING DIALOG

Continued communication between partners is important for continued growth of the partnership. It is very easy to "each do your own thing" without any effort to know or understand the other partner. It is important to understand what the other partner's intentions are, not just to hear the words they're speaking. In particular, researchers are often surprised at the length of time it takes to develop a new product or marketplace. Most conflicts arise from misunderstanding intentions and goals rather than intentional discord.

The common goals of both partners should be recognized and strengthened. In any partnership there are inevitable disagreements and conflicts. There are common interests between the CRADA partners (because both parties agreed to work together); emphasizing these rather than the inevitable differences makes for a productive working arrangement. We don't mean to say that there should not be differences in outlook, but it is often more profitable to work on the areas of agreement than the areas of disagreement.

Laboratory researchers and commercial enterprises each have access to information sources that are unavailable to the other. Utilizing these resources jointly gives the partnership access to users and distribution channels that would not have been available to either one individually. We have derived significant benefits from this identification of mutual points of support.

It continues to be important for both parties to communicate with potential end-users. For many emerging technologies, these initial customers are investing considerable time and expense in an unproven technology. In a very real sense, these customers are a "hidden" third partner in the agreement. The customer relationship need not be a purely sales relationship (although sales can and should take place), but rather a two-way discussion, so that the developed product(s) match a true (rather than perceived) customer need. Although this is often perceived as the responsibility of the commercial partner, continuing knowledge of the end uses for a technology can be very important for the direction of research efforts.

MARKET REALITIES

Introducing a new technology to the marketplace can take longer than anticipated. Actual demonstrations are often required to show that the technology performs as advertised. This sluggishness in acceptance can make successful transfer slower than anticipated. The researchers and commercial partners can effectively display the technology's capabilities in scientific conferences and sales demonstrations respectively.

The challenge of introducing a new technology is compounded if the appropriate market is in its infancy and also requires development. Many diverse technologies will be attempting to acquire a piece of this developing market. The fact that a technology is "new" and "innovative" does not instantly guarantee commercial success. In a developing market, the partners need to identify not only traditional competitors and competitive technologies, but other expanding innovative solutions. Effectively dealing with this infant market, and the many new technologies it creates, requires an even closer collaboration between the partners.

Some technologies (such as the LRAD) lend themselves to multiple, diverse applications. Although this may look like an ideal transfer opportunity, it can lead to a number of potential strains between the partners. Researchers, eager to develop many applications, may not understand the inevitable time lag between product development and commercial sales. On the other hand, the commercial partner may not be aware of opportunities outside of its traditional markets. Good communication between partners is also very important in a multiple application/market situation.

COMMON MISCONCEPTIONS

The newfound desire to "commercialize" technologies has led to a number of

misconceptions about the process. We have included four of the most common ones and some comments on each.

"Technology Transfer Agreements are Simple"

Two common sentiments that are quite appropriate to this issue are "nothing worth doing is simple" and "you get what you pay for." If your goal is to produce an agreement quickly, it can certainly be done, but this agreement may not have been carefully thought out by both parties. Time spent in understanding the issues before an agreement is signed is well rewarded by saving (a much larger amount of) time trying to negotiate conflicts in a working relationship.

"The CRADA is a Final Goal"

A CRADA or other document may be legally necessary to proceed with a partnership but its existence should not be perceived as a goal in itself. The goals are (for the researcher) continued funding and development of an idea and (for the commercial partner) sales of devices resulting from the partnership and market acceptance of these devices. Without these final sales, documents do not accurately reflect the success of the commercialization effort.

"We Don't Have to Communicate after the CRADA"

It is often all too easy to create an "iron curtain" between ostensible partners after an agreement is signed. A common feeling among researchers is that once a CRADA is signed, all their problems are over. Similarly, the industrial partner often feels that once they receive a basic idea, all exchange should be over. In our experience, neither feeling is true: the parties can assist each other in future development. The same characteristics that caused both parties to agree in the first place can and should be used for further benefit to the partnership.

"A CRADA is a Funding Source"

Often, a technology transfer agreement or CRADA is viewed as a funding source for an otherwise unfunded development project. Why should a researcher expect commercial support for a project that no other users or funding agencies want enough to fund? A technology that can generate interest and funding on its own can do even better with the prospect of commercial involvement, but a technology that users don't want is going to be very difficult to commercialize.

CONCLUSIONS

All of our previous discussion can be summarized by the word communication. Often the researcher, the commercial entity, and the prospective end-user are all talking at each other but not to each other. The goal of partnership agreements (for all three of the interested parties mentioned above) is successful production, distribution, and use of a product. This can only happen if each of the parties understands the needs and requirements of the others.

ACKNOWLEDGEMENT AND DISCLAIMER

A LAYERED APPROACH TO TECHNOLOGY TRANSFER OF AVIRIS BETWEEN EARTH SEARCH SCIENCES, INC. AND THE IDAHO NATIONAL ENGINEERING LABORATORY

James S. Ferguson
JoAnne E. Ferguson
John Peel, III.
Larry Vance
Lockheed Idaho Technologies Company

ABSTRACT

Earth Search Sciences, Inc. (ESSI) has been selected as a model for the layered approach to technology transfer of the Airborne Visible Infrared Imaging Spectrometer (AVIRIS) instrument and acquisition of supporting remote sensing technologies. ESSI has developed a layered approach to a costly technology development program that fully leverages diverse resources while retaining ownership, technical application and control, and management direction.

Since initial contact between ESSI and the Idaho National Engineering Laboratory (INEL) in February, 1994, at least seven proposals have been submitted in response to a variety of solicitations to commercialize, improve, and use the (AVIRIS) instrument and other remote sensing technologies. These proposals, matching ESSI's unique position with respect to agreements with the National Aeronautics and Space Administration (NASA) and the Jet Propulsion Laboratory (JPL) to utilize, miniaturize, and commercialize the AVIRIS instrument and platform, are combined with the applied engineering of the INEL. Teaming ESSI, NASA/JPL, and INEL with diverse industrial partners has strengthened the respective proposals. These efforts carefully structure the overall project plans to ensure the development, demonstration, and deployment of this concept to the national and international communities.

The objectives of these efforts include:

- developing a miniaturized commercial, real-time, cost effective version of the AVIRIS instrument
- identifying multiple uses for AVIRIS
- integrating the AVIRIS technology with other technologies
- gaining the confidence/acceptance of other government agencies and private industry in AVIRIS, and
- increasing the technology base of U.S. industry.

History

The initial contact between ESSI and INEL began in February 1994, as ESSI was involved in discussions with the Idaho Department of Commerce (IDOC). ESSI, a small business within the state, approached the IDOC with a need for assistance from a large institution with the capability to develop a miniaturized version of the AVIRIS instrument that could be deployed on a commercial airborne platform. ESSI had an agreement under the Space Act to utilize the AVIRIS instrument for mineral exploration since 1987. ESSI had been working as a research and development partner with NASA and JPL to improve the instrument, verifying and validating the results of the overflights as they were made. ESSI also concluded an agreement with NASA/JPL to re-deploy the AVIRIS from the ER-2 flight platform to NASA's C-130, fuse the AVIRIS data with that of other sensors on the C-130 platform, and to miniaturize and commercialize the instrument for use throughout the world. With an array of industrial partners in the U.S. and from other countries, ESSI assembled a world class team of potential partners who can provide unique capabilities for applications. TRW, Inc. joined the group in May 1994. In June, 1994, Tetra Tech, Inc., joined the ESSI and INEL efforts, adding their significant remote sensing and environmental reputation and expertise to the efforts. Tetra Tech is rated seventh of the top 200 small businesses in the United States by Forbes Magazine. Lockheed and several other firms followed Tetra Tech in October 1994, forming a team to use AVIRIS in Kazakhstan as a major cornerstone in the United States policy to convert defense industries to commercial entities. This has been followed by the U.S. Environmental Protection Agency participating in a demonstration of the technology for environmental assessment and monitoring of large areas in place of traditional sampling methods. U.S. commercial and agricultural industries also expressed an interest in using the same technology to assess areas prior to purchase and to monitor existing operations. Today, the education community is attracted to the field of remote sensing and is using AVIRIS as a technical cornerstone to establish an international Remote Sensing Center of Excellence accompanied by graduate degree

programs and a dedicated testing center in excess of 4,000 square miles at the University of Idaho.

Teaming

As a small, publicly-held business, ESSI has limited funds to bring to the venture which requires in excess of $10M to develop, test, and demonstrate a commercial version of the AVIRIS. Seeking funds from other partners or through joint solicitations with other federal agencies and federal entities is the primary means of securing capital. Signing Memorandums of Agreement (MOA), negotiating Cooperative Research and Development Agreements (CRADAs), and concluding Teaming Agreements with government and private industry has been the preferred route for ESSI to protect the intellectual property rights to the technology. These arrangements have increased the leveraging of funds and expanded the potential business opportunities. Business plans between team members are used to share the division of labor and profit.

PROPOSAL SOLICITATIONS

Advanced Projects Research Agency (ARPA) Technology Reinvestment Project (TRP)

This proposal was initiated to develop dual-use hyperspectral instruments for environmental, agricultural, mining, forestry and specific Department of Defense applications requiring unique signature identification. This $6M proposal involves the design and construction of a real-time, miniaturized, commercial prototype hyperspectral instrument and developing a new family of hyperspectral instruments with industrial firms, including: TRW, Inc., Earth Search Science, Inc. (ESSI), National Aeronautic and Space Administration (NASA), Jet Propulsion Laboratories (JPL), WJT Software, Integrated Spectronics PTY, CALTECH, and EG&G Idaho. A MOA between TRW, Inc, Earth Search Science, Inc., NASA/JPL, and EG&G Idaho, Inc., was concluded between the partners. Upon award, a Teaming Agreement and a Business Plan will be produced.

Rocky Flats Request for Proposals

This request resulted in another proposal entitled "Aerial Multispectral Sensor Platform for the Detection of Rocky Flats Hazardous (including Radiological) and Toxic Wastes". This $1.4M effort proposes to characterize both hazardous (including radiological) and toxic wastes surveyed from an airborne multisensor platform at hovering altitudes, mid-level altitudes (30,00 ft.), and high altitudes (>60,00 ft.). The airborne platforms will be enhanced with non-radiological sensing capability, including, but not limited to, thermal imaging to detect vegetal stress, seeps, and other hydrological features; laser induced fluorescence; and electromagnetic imaging/magnetometer/ground penetrating radar coupled to video to provide better arrays and overcome the limitations of separate sensors. Data fusion, data compression, and data management are project keystones. All data collected in the flyovers will be fused into a geographic information system (GIS) data base. These data will be used in the site-wide management information system affecting the environmental remediation of Rocky Flats Plant. A MOA was concluded between the partners. When an award is announced, a CRADA with the INEL will be executed.

Environmental Protection Agency (EPA) Environmental Technology Initiative (ETI)

This is a $700K proposal to use the Fort Hall Indian Reservation as a demonstration site to evaluate the current monitoring capabilities and development needs of hyperspectral instruments used for environmental purposes. The technology demonstration will also be used to identify the extent of recurring pollution on the reservation (nitrates, ethylene dibromide, and assorted pesticides and herbicides). Non-point-source pollution cannot be adequately addressed by traditional sampling methods. Partners include the Shoshone-Bannock Tribe, the INEL, EPA, NASA/JPL, and Earth Search Sciences, Inc. (ESSI). EPA funding is being leveraged with ESSI providing $350K. An MOA was concluded by the team to demonstrate the airborne multisensor platform and train Shoshone-Bannock Tribe personnel to use GIS to manage the reservation resources. When an award is announced, a CRADA will be executed.

EPA Requested Flyover of the San Jacinto River

In October 1994, EPA requested ESSI's assistance to use the AVIRIS to assess the environmental impact of a gasoline pipeline break in the Houston, Texas area. With demonstration of the technology for environmental purposes over large land areas, EPA has indicated that remote sensing may be substituted for traditional, expensive and time-consuming sampling procedures. This may include monitoring the environmental status of the Gulf of Mexico coast, the U.S.-Mexico border area, and other areas identified by EPA.

Retrofit of the AVIRIS to the NASA/JPL C-130 Multisensor Platform

In October 1994, ESSI obtained JPL support to retrofit the AVIRIS instrument to the NASA C-130 aircraft. This will enable the AVIRIS instrument to collect 5 by 5 meter pixel data flying at 5,000 meter AGL, a 16-fold increase in spatial resolution over the resolution available currently with the ER-2 aircraft.

International Remote Sensing Center of Excellence

The international Remote Sensing Center of Excellence's mission is to support watershed/river basin management as it affects all biota. The University of Idaho program is planned to be staffed by both university staff and remote sensing experts from industry. Idaho was selected because the state is rich in potential sensor services users and developers and offers a natural laboratory, in excess of 4,00 square miles, for sensor platform testing and evaluation. The potential client base includes agriculture, range management, fisheries, mining, forestry, wildlife management, and human engineering.

Defense Nuclear Agency Defense Industry Conversion Solicitation

This $11M proposal is to use hyperspectral and multispectral imaging to explore for minerals, perform environmental assessments, manage national industries, such as agriculture and forestry, natural resource management, and land use planning for the Republic of Kazakhstan. The teaming arrangement, which consists of Lockheed Environmental Systems and Technologies, ESSI, Tetra Tech, Inc., Ramparts Technologies, Lockheed Idaho Technologies Company, NASA/JPL, EG&G Measurements, Las Vegas, Bishop Associates, SEMTECH (Kazakhstan industry partner), and Scientech Inc., plans to begin operations in January 1995.

Latin America Initiative

Several proposals have been developed to partner with industry, universities, and State and Federal agencies to develop, package, and deliver Department of Energy and ESSI competitive advanced technology products/services. This approach provides solutions to critical environmental restoration and waste management problems while furthering national business and technology goals. The proposals include providing environmental management education and training services to build an infrastructure in Mexico and are planned for expansion to Chile and Argentina. Use of the AVIRIS and other non-intrusive remote sensing technologies provides the technical foundation for this effort.

FUTURE PLANS

Solicitation Plans

Through teaming with National Laboratories and other firms, ESSI plans to continue to respond to future solicitations. This allows them to identify possible technology applications for remote sensing which far exceed it current capability to fulfill. Current partners include several principal investigators requiring commercial support to move their remote sensing technologies from the laboratory environment to private industry and three firms based in the Washington DC area. One centers its efforts on federal government opportunities, the second focuses on international opportunities, and the third focuses on major corporations which have remote sensing requirements. Where possible, these firms are included as teaming partners in proposals. None require up front financing to obtain potential remote sensing applications. All potential partners agree to allow ESSI to establish offices with little or no overhead costs, gain access to new markets, and obtain the services of other firms' marketing capabilities of products and services.

Relocation Plans

ESSI is evaluating opportunities in relocating to southeast Idaho to more fully use national laboratory assets. National laboratories now offer a variety of services to small businesses. These range from technology transfers to CRADAs to shared use of the laboratory's staff and laboratories to being awarded contracts identified solely for small business. Ten percent of INEL's FY-95 budget is committed to small and minority businesses. With the INEL being designated as a test bed for new ways to work with industrial partners, future laboratory programs are expected to directly benefit and increase the technology base of U.S. industry. ESSI is affording itself the opportunity to participate in the INEL's innovative approaches for industry to access to national laboratory facilities and staff.

INTELLECTUAL PROPERTY PROTECTION IN US AND INTERNATIONAL ARENAS

ESSI current projects and outstanding funding proposals were reviewed by patent attorneys to determine appropriate actions to protect their intellectual property through patents, trademarks, an copyrights. Applications have been initiated to obtain patents for equipment, processes, and new applications of single and multiple

remote sensing systems. Protection of intellectual property has been included in all Memorandums of Agreement, Teaming Agreements, and proposals. Other methods are also being used, such as the CRADA which allows commercially valuable data generated to be withheld from public release for up to five years, and teaming with firms currently doing business in international arenas.

CONCLUSION

ESSI, with the assistance of national laboratories, has developed a layered approach to a costly technology development program that fully leverages the resources of others while retaining ownership, technical application and control, and management direction.

DEMONSTRATING AND IMPLEMENTING INNOVATIVE TECHNOLOGIES: CASE STUDIES FROM THE U.S. DEPARTMENT OF ENERGY OFFICE OF TECHNOLOGY DEVELOPMENT

K.J. Koegler
Bechtel Hanford, Inc.
T.M. Brouns
Pacific Northwest Laboratory
L.S. Mamiya
U.S. Department of Energy

ABSTRACT

This paper describes elements of success for the demonstration, evaluation, and transfer for deployment of innovative technologies for environmental restoration. The elements of success have been compiled from lessons learned through the U.S. Department of Energy (DOE) Office of Technology Development's Volatile Organic Compounds in Arid Soil Integrated Demonstration (VOC-Arid ID). The success of the VOC-Arid ID program was determined by the rapid development, demonstration, and transfer for deployment of technologies to operational sites that improve on safety, cost, and/or schedule of performance over baseline technologies. The VOC-Arid ID successfully fielded more than 25 innovative technology field demonstrations; several of the technologies demonstrated have been successfully transferred for deployment.

Field demonstration is a critical element in the successful transfer of innovative technologies into environmental restoration operations. The measures of success for technology demonstrations include conducting the demonstration in a safe and controlled environment and generating the appropriate information by which to evaluate the technology. However, field demonstrations alone do not guarantee successful transfer for deployment. There are many key elements throughout the development and demonstration process that have a significant impact on the success of a technology. This paper presents key elements for a successful technology demonstration and transfer for deployment identified through the experiences of the VOC-Arid ID. Also, several case studies are provided as examples.

INTRODUCTION

The Volatile Organic Compounds in Arid Soils Integrated Demonstration (VOC-Arid ID) was sponsored by the U.S. Department of Energy (DOE) Office of Technology Development. The VOC-Arid ID was one of several integrated demonstrations designed to support the demonstration of emerging environmental restoration technologies. The principal objective of the VOC-Arid ID was to identify, develop, demonstrate, and transfer for deployment new and innovative technologies for environmental restoration at arid or semiarid sites containing VOCs with or without associated contamination (e.g., radionuclides and metals). Technology demonstrations have been hosted primarily by the DOE's Hanford Site in southeastern Washington State. The DOE's Office of Environmental Management has recently reorganized its technology development efforts within the Office of Environmental Management around five "focus areas." The scope of the VOC-Arid ID, along with several other efforts, have been incorporated into the Contaminant Plume Containment and Remediation Focus Area (Plumes). The goal of this reorganization is to build upon the successes and failures of the integrated demonstrations and improve the technology development and implementation process.

TECHNOLOGY PROCESS FLOW

The movement of a technology through the VOC-Arid ID consisted of technology identification, demonstration and evaluation, and transfer for deployment. The process of identifying a technology was initiated through the preparation of a needs

statement that was distributed in a call for proposals made available by the DOE. The needs statement was developed based on input from environmental restoration operations staff and technical experts in the area of VOC monitoring, characterization, and remediation. Proposals received were processed through DOE program management and were then reviewed and evaluated by the VOC-Arid ID technical support groups. Using the technical support groups' recommendations and working to funding limitations, VOC-Arid ID management recommended technologies to be included in the program. Final decisions on technologies accepted into the program, and their funding levels, rested with DOE program management.

The demonstration process began immediately upon a technology being accepted into the VOC-Arid ID. A Demonstration Operations project engineer was assigned to guide the principal investigator for each technology through the rigors of the field demonstration and was responsible for all aspects of the demonstration. For the principal investigator's use, Demonstration Operations developed a guide for preparing demonstration documents (6). This guide defines the required documentation and delineates at what point in the process each document is due. Following each field demonstration, a series of reports were produced in evaluation of the technology.

ELEMENTS OF SUCCESS

The VOC-Arid ID has been successful in demonstrating innovative technologies and transferring those technologies for deployment. This has been due in large part to established organization, process, and interfaces. Several elements that have been identified as contributing to the program's success are described below. Woven throughout the elements for success is the consistent application of a structured process. Specific lessons learned of these elements can be seen later in the case studies.

Technology Selection

A key to the successful demonstration, evaluation, and transfer for deployment of a technology is the selection of appropriate technologies.

The VOC-Arid ID used technical support groups to provide technical review and screen technologies. The technical support groups consisted of recognized experts in the areas of environmental restoration, e.g., characterization and monitoring, drilling or access, and remediation. The technical support groups represented a cross-section of staff from DOE's operations contractors and national laboratories, universities, industry, and other Federal agencies from across the nation.

The technical support groups ensured that there was a real need for a proposed technology, and that the technical basis for the technology was sound. The technical support groups also monitored the development and demonstration of each technology to ensure that the expectations of the technology were being achieved.

Criteria, Objectives, and Parameters

Establishment of criteria by which technologies will be evaluated is a key to the successful demonstration and evaluation, and transfer for deployment of a technology.

Criteria that were established for use by the VOC-Arid ID incorporated guidance from the Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (CERCLA). These criteria were modified to incorporate input received through stakeholder involvement activities (stakeholder involvement as an element of success is discussed later). Criteria developed through this process include the following:

- Technology performance: remaining contamination
- Technology performance: process waste
- Implementability and practicality of technology
- Does the technology function as intended?
- Cost
- Time
- Worker health and safety
- Public health and safety
- Environmental impacts
- Technology reputation/familiarity to public
- Future land uses/tribal rights
- Socioeconomic impacts
- Regulatory infrastructure requirements
- Compliance with regulatory requirements
- Overall protection of human health and the environment.

Identification of appropriate demonstration objectives and the parameters to measure those objectives is a key to the successful demonstration, evaluation, and transfer for deployment of a technology.
The structured demonstration process implemented by the VOC-Arid ID ensured that appropriate information was gathered during field demonstration, e.g., information needed to evaluate the technology against the criteria. This process included identification of appropriate demonstration objectives, and appropriate parameters to be measured. Focus on the development of objectives and parameters in planning for the demonstrations prevented the gathering of inadequate information by which to evaluated the technology.
Documentation
Complete documentation is a key to the successful demonstration, evaluation, and transfer for deployment of a technology.
Documentation required from each VOC-Arid ID principal investigator before fielding a technology included a conceptual test plan with a technology profile, demonstration objectives worksheet, and environmental regulatory checklist attached. The purpose of the conceptual test plan was for the principal investigator to formulate demonstration objectives, provide information to initiate regulatory and demonstration host site compliance activities, and provide for review of plans for field activities. The technology profile was used for stakeholder involvement activities. The demonstration objectives worksheet was a tool to aid the principal investigator in formulating objectives for the field demonstration. Regulatory experts used the environmental regulatory checklist to ensure compliance with applicable regulations.
The conceptual test plan was incorporated into an integrated test plan that was the document that guided the field demonstration. The integrated test plan ensured that the demonstration was conducted in a safe and controlled manner. The integrated test plan incorporated all aspects of conduct of operations including all operating procedures necessary for the demonstration.
Following each field demonstration, a series of reports were planned. The principal investigator was responsible for producing an evaluation report of the technology demonstration. The project engineer was responsible for producing an independent evaluation of the usefulness and potential of the technology. Independent cost effectiveness and stakeholder acceptability reports were also part of the reporting process. Drawing on all of the reports listed previously, the VOC-Arid ID would produce an overall technology evaluation summary report.
Environmental Restoration Interface
Demonstration conducted through the infrastructure of an environmental restoration project, or operational platform, is another key to the successful demonstration, evaluation, and transfer for deployment of a technology.
When possible, VOC-Arid ID technology demonstrations were conducted as systems in conjunction with an operational environmental restoration project. This provided the opportunity for the comparison of innovative technologies against one another, and against baseline technologies, under real-world field conditions. Bechtel Hanford, Inc. (BHI), is the Environmental Restoration Contractor at the Hanford Site. Having the operations of the VOC-Arid ID conducted through BHI provided for the technology demonstrations to be wrapped into environmental restoration project activities. Success was found in putting the innovative technologies in the hands of the people doing the environmental restoration work. This allowed those individuals in the field to become familiar with the technology and how it could improve on the safety, cost, and/or schedule performance of baseline technologies. It also provided for input to the principal investigator on improvements that might be accomplished during the development of the innovative technology.
Emphasis on Commercialization
Emphasizing the earliest possible establishment of a tie between the technology and a commercial partner is another key to the successful demonstration, evaluation, and transfer for deployment of a technology.
At the time a technology was brought into the VOC-Arid ID, work began on commercialization. The commercialization process was managed by the principal investigator who was required to involve industry to ensure the technology would be manufactured and made commercially available. It is generally expected that technologies will be made available by commercial suppliers of goods and/or services rather than by Federal contractors, national laboratories, or universities. The goal

was to ensure industry involvement in the development and demonstration process to enhance the technology's likelihood of ultimate deployment. Identification of a commercial partner is a strong indicator of the potential of an innovative technology.

Commercialization plans and partnership plans are used by the Office of Technology Development to ensure that projects consider commercialization early in the development cycle. A commercialization plan lays out specific actions, and a general business strategy, for commercializing the technology. This plan usually sets a path toward ultimate commercialization of a technology where an industrial partner has already been identified. A partnership plan establishes a path for projects or technologies where an industrial partner is needed but not identified. This plan includes schedules and strategies for soliciting or identifying partners to support a commercialization effort.

Stakeholder Involvement

Initiating stakeholder involvement as early as possible is still another key to the successful demonstration, evaluation, and transfer for deployment of a technology. Part of the initial documentation package required by the VOC-Arid ID from the principal investigator included a technology profile. The technology profile was the basis for many of the stakeholder involvement activities conducted in support of the VOC-Arid ID. This included providing information for ProTech, a computer-based communication system designed to facilitate public understanding of innovative technologies. The ProTech audience targeted individuals and groups with a stake in a technology's deployment including, but not limited to, regulators, special interest groups, citizens in a community where an environmental technology may be used, and potential industrial codevelopers and users of a technology. The technology profile was also updated upon completion of the demonstration and used in the reporting process.

Analysis of stakeholder acceptance was conducted by a technology acceptance task team. This team used the technology profile to provide preliminary information to stakeholders on upcoming technologies, systems, and field demonstrations. Focus groups and workshops with stakeholders (e.g., regulators, interest groups, and technologists) were conducted to identify issues and concerns they may have about a technology. In addition, the technology acceptance task team conducted interviews and presentations with a variety of stakeholders with the same objective. Establishment of the VOC-Arid ID evaluation criteria were developed in part from this process.

The Plumes Focus Area has established a management approach and strong emphasis on stakeholder involvement based on the VOC-Arid ID's stakeholder process. In addition, the DOE sites, such as the Hanford Site, are developing similar stakeholder involvement processes as part of their role within the Focus Area.

TECHNOLOGIES DEMONSTRATED

Following is a list of technologies that have been demonstrated over the past several years as part of the VOC-Arid ID. These are in addition to the technologies discussed later in the case studies.

Characterization and Monitoring Technologies:
- BoreSampler
- Cross-Hole Seismic Tomography
- Portable Acoustic Wave Sensor
- Arrayed Sampler
- Colloidal Borescope
- Unsaturated Flow Apparatus
- Odyssey Sensor
- Passive Soil Gas Monitors
- Fiber Optic Sensor
- FTIR Instrument
- Prompt Fission Neutron Logging Tool

Drilling or Access Technologies:
- Cone Penetrometer
- Directional Drilling
- ResonantSonic Drilling

Remediation or Treatment Technologies:
- In-Well Vapor Stripping
- In-Situ Bioremediation

Tunable Hybrid Plasma
Passive Soil Vapor Extraction

CASE STUDIES

After completing more than 25 field demonstrations of innovative technologies for characterization, monitoring, drilling or access, and remediation, the VOC-Arid ID conducted a rigorous review of many of these demonstration projects to identify barriers to, and attributes of, successfully deployed technologies. These case studies represented both privately developed and federally developed technologies and included systems for both VOC remediation and characterization or monitoring. The following sections summarize five of these case studies and the lessons learned. Each case briefly describes the technology and a limited history of development and demonstration, along with the findings of the review.

Membrane Separation System for Treatment of VOC Off-Gases

A membrane separation system developed and supplied by Membrane Technology Research, Inc. (Menlo Park, CA), was demonstrated for concentration and removal of vapor-phase chlorinated solvents from a soil vapor extraction (SVE) system. This technology was demonstrated to assess its viability as a cost-effective alternative to granular activated carbon for treatment of SVE off-gases. Off-gas membrane systems have been used commercially in industrial solvent recycling operations, but not for soil or groundwater cleanup operations. The anticipated benefit of the technology was a lower cost separations process that produced a liquid VOC waste stream that could be more easily and inexpensively treated relative to the offsite shipment and regeneration requirements of activated carbon.

A field demonstration of a pilot membrane system was conducted in the spring and summer of 1993 at the Hanford Site, in conjunction with an ongoing CERCLA cleanup operation. Planning for the demonstration began nearly a year before the field activities through the development of a detailed test plan (3). Operations staff interested in off-gas alternatives were selected to lead the field demonstration working directly with a lead technical engineer to lease, install, and test the pilot unit. The ongoing cleanup operation allowed the membrane system to be tested without significant regulatory compliance permitting by leveraging off a previously approved system. A split stream from the SVE system was drawn into the membrane unit. Effluent from the test system was returned to the SVE system for treatment through the baseline activated carbon system, thereby reducing any potential regulatory concerns.

The membrane system demonstration successfully accomplished its objectives and provided both technical performance and cost data to support an analysis of the technology's cost benefit (4). Results indicated that the system operated well, performed at high separation efficiency, but only produced significant cost savings over the baseline at VOC concentrations above approximately 600 ppm carbon tetrachloride by volume under the conditions tested. These conditions included an assumption that the VOC from this waste site could not be recycled, therefore the cost benefit associated with this technology's usual application in solvent recovery was not possible. Although the technology was not successfully implemented following the field demonstration, the effort was considered successful because it provided valuable data to the Environmental Restoration Program. This data essentially prevented an unnecessary expenditure of capital and operating funds that may have occurred if a system was procured or leased for full-scale operations or testing based on performance of systems used in the solvent recovery area.

The following are several key attributes of this demonstration and lessons learned. Staff responsible for operations of an actual cleanup were intimately involved from the beginning in selecting, planning, and operating this technology demonstration. Test objectives and performance criteria were clearly established before the demonstration to ensure that all operations costs and technical performance issues were addressed during testing.

The operation staff's interest in demonstrating the system was enhanced by 1) the desire to consider off-gas treatment alternatives to reduce the cost of the baseline system, 2) the fact that it was a commercial technology with existing data on previous applications (i.e, track record) even though they were under different conditions, 3) the technology's attributes of being a skid-mounted, fully-engineered system with simple operational controls (i.e, could be easily integrated into existing systems), and 4) the fact that it was a commercially available system that could be purchased or leased quickly to meet immediate needs.

Halosnif Fiber Optic Spectrochemical Sensor

The Halosnif sensor was developed by researchers at Battelle Pacific Northwest Laboratory (Richland, WA) for detecting chlorine or fluorine-containing compounds in air, such as trichloroethylene or carbon tetrachloride. The sensor's attributes include a wide dynamic range of detection (e.g, 10 ppmv to 10,000 ppmv), and continuous, real-time detection. Over several years, development efforts improved the sensor's detection limit, portability, and stability. The resulting sensor system used an improved commercial power supply and could be easily set up and operated as a continuous monitor.

The sensor was demonstrated at several DOE sites, functioned well, and compared favorably against other baseline techniques for chlorinated VOC detection (7). The demonstration efforts accomplished their objectives and demonstrated the technology's performance; however, this system has yet to be successfully commercialized or implemented. Although the system has several favorable attributes, it has not satisfied the requirements of end users. Primary user needs for VOC sensing are centered around lower detection limits (e.g., 1 ppm) for health and safety monitoring, and hand-held instrumentation for field monitoring. The Halosnif system is too large and bulky for hand-held applications. The system is well suited to process monitoring; however, this is a different market and there are other commercial systems that can adequately, and more effectively meet the process monitoring and control needs.

A number of lessons were learned as this technology advanced through development and demonstration.

Commercialization, market assessment, and technology transfer are critical components of successful deployment, and must be considered very early in the development cycle. A more thorough market assessment and user survey may have identified the functional requirements of a new sensor system, and competing commercial systems that any VOC sensor would have to outperform to ensure commercial success. Commercialization plans that set a path forward and identify key decision points for a technology's development effort are critical to the process of either redirecting, redesigning, or ceasing development efforts.

Several field demonstrations were conducted over 2 years in an effort to assess the technical performance of the sensor. These tests were very successful in identifying the technical areas needing improvement. However, these test did little to define the right market, target problems, or technical attributes (i.e., size, portability, detection limit, etc.) that would ensure user needs were being met. If development objectives and criteria are adequately defined, they can be key elements in the decision process for continuing development. Commercial research and development typically assesses the business or market factors early in the development cycle. In this case, those assessments were incomplete and did not adequately identify the market for this type of sensor system.

User needs are often vague, and ill defined. This sensor system was developed based on a defined, but general need identified by environmental restoration staff. Without functional requirements, or clear performance goals associated with each need, technologies can be developed that appear to meet the requirements. Only after years of development and demonstration does the developer realize the need has either changed, or was never adequately defined.

In Situ Permeable Flow Sensor for Groundwater Flow Measurement

A groundwater flow sensor developed by researchers at DOE's Sandia National Laboratories (Albuquerque, NM) was developed and demonstrated under DOE's VOC in Non Arid Soils Integrated Demonstration (VOC Non-Arid ID) in 1993 (2). In 1994, this technology was used at DOE's Hanford Site by environmental restoration staff as part of remedial investigation efforts within the Site's 100 Area. This deployment of the in situ permeable flow sensor represented a successful technology transfer from a research and development program to a cleanup effort.

This sensor uses heating elements and temperature sensors to indirectly measure water flow, and is deployed by placement in an uncased borehole below the water table. The formation is allowed to collapse around the sensor, resulting in a system that measures flow within the natural sediments rather than within a significantly disturbed borehole or well. The goal is to achieve accurate measurement of flow that is not likely possible with conventional methods. The system can be used for aquifer characterization or monitoring before, during, or after remediation of the aquifer.

Development, demonstration, and technology transfer of the in situ permeable flow

sensor was successful for the following reasons.

The technology was demonstrated multiple times as part of the VOC-Non Arid ID and its performance thoroughly documented.

Environmental restoration staff responsible for remedial investigation/feasibility study and cleanup actions at the Hanford Site learned about this innovative sensor system through direct involvement as technical reviewers within DOE's Technology Development Program. Although information on many new technologies is disseminated through publications, conferences, and technology databases, direct, one-on-one contact between the developers or suppliers and the operations staff is critical. In addition, operations staff involvement in review and evaluation of technology demonstrations resulted in immediate, complete, and unbiased information on performance of the sensor technology.

Characterization and monitoring technologies are more easily transferred because they are generally less expensive to deploy and/or test than remediation systems. In addition, they are typically not held to the rigorous performance standards of remediation technologies (especially for screening applications), and do not usually require lengthy regulatory review or approval prior to deployment.

At the time of deployment at the Hanford Site, this sensor system was not commercially available. Therefore, deployment of the sensors was accomplished through a direct contract between the operations program and the original investigator from a DOE national laboratory. Although it is generally felt that technologies are more readily accepted if commercially available, in this case the presence of an industrial supplier was not important to the environmental restoration staff. If hardware could be procured easily and technical support obtained from the developer, a viable industrial supplier was not important. However, broad application of the technology to multiple customers would clearly require an effective commercial partner.

Six-Phase Soil Heating for Enhanced Removal of VOCs from Soils

A variety of soil heating methods are being developed and demonstrated by industry, DOE, and other Federal agencies as a means of enhancing volatilization and subsequent removal of VOCs from soils. Six-phase soil heating is an electrical resistance or "ohmic" heating method developed by researchers at Battelle Pacific Northwest Laboratory. Field testing was accomplished by the VOC-Arid and VOC-Non Arid IDs at DOE's Hanford and Savannah River Sites, respectively. The technology was tested at pilot-scale in an uncontaminated area at the Hanford Site as part of shakedown testing, and then tested at the Savannah River Site's M-Area for enhanced removal of trichloroethylene and perchloroethylene from a clay lens (1). The technique uses six electrodes in an array, with six-phase alternating current power to resistively heat soils in situ, thereby drying the soil and volatilizing contaminants. A soil vapor extraction system is used in conjunction with the heating system to recover and treat released vapors.

The demonstration was successful in heating soils to approximately 10C (50F) within a 6-m (20-ft.) dia. zone. In addition, post-test analysis of soils within the heated zone indicate that greater than 95 percent removal of contaminants was accomplished in the 2-month duration test. The demonstration resulted in increased interest from both industry and environmental restoration staff at other DOE sites. Specifically, the Environmental Restoration Program at DOE's Rocky Flats plant in Colorado requested support in remediating several operable units with VOCs and dense nonaqueous-phase liquids (DNAPLs) present in low conductivity soils. Efforts are being planned for use of soil heating at Rocky Flats. Development activities for six-phase soil heating are being finalized this year with the completion of a design tool to support deployment of the technology and commercialization.

Although deployment within the Federal and private sectors has not yet been accomplished, the outlook is very positive. Several lessons learned have resulted from this development and demonstration effort.

A well-designed, phased approach was used to develop this heating technology over approximately 4 years. Several sources of funding, primarily from DOE's Office of Environmental Management, were obtained during this time, and at times leveraged with other funding, to accomplish all of the lab-, bench-, pilot-, and field-scale tests necessary to scale-up the technology.

Commercial interest in the technology was observed early in its development cycle; however, serious interest from industry was not realized until after the Savannah River field demonstration. This is likely a result of two things. First, industrial

enthusiasm was dependent on solid evidence of the effectiveness of the technology in a field test. Until an initial contaminated site test was completed, there was little proof that the technology could be effectively used. Secondly, commercialization of the technology was not a primary focus of the funded activities. The developers focused on technical development in conjunction with the establishment of appropriate intellectual property. Identification of one or more commercial partners was somewhat delayed until intellectual property was protected, and proof of performance was obtained. Commercial interest and partnering may have been possible and beneficial earlier in the development cycle if it had been a priority. The DOE and the developers may have sacrificed some intellectual property, but the timeline for deployment may have been reduced.

SEAMIST Membrane Instrumentation and Sampling System

Science and Engineering Associates (Santa Fe, NM) developed an inflatable membrane system that is used as a continuous packer system in uncased (i.e., open) boreholes and as a platform for deploying a variety of instruments and sampling tools. The purpose of this technology is to provide for more representative sampling of soil gas, VOCs, and other soil contaminants, as well as for in situ air permeability measurements. The SEAMIST system is commercially available and is being used for site investigations and monitoring. The technology is now owned by Eastman-Cherrington Co., Albuquerque, NM.

SEAMIST was demonstrated at a variety of sites, including DOE sites such as Savannah River and Sandia National Laboratories. Environmental restoration staff at the Hanford Site became aware of the technology several years ago and purchased a system to be used in characterizing sites contaminated with VOCs (5). However, SEAMIST use at the Hanford Site was significantly different than the originally intended purpose. For example, operations staff requested a system to be used in large diameter wells, to depths of 76 m (250 ft), without predetermined sampling ports. Because of the geology at the Hanford Site, temporary casing is needed to maintain borehole stability during drilling. Open boreholes are not possible for any significant depth. Hanford Site contractors desired a system that could be deployed during drilling to collect samples at the current depth of the borehole. Therefore, a modified SEAMIST system was used where the soil vapor sampling was accomplished through a sampling line dropped down the well to depth, and the SEAMIST system was used to create a continuous packer and ensure vapor sampling occurred only from the formation adjacent to the end of the sample line.

SEAMIST is currently being used at the Hanford Site in routine characterization efforts and is gaining additional applications through continued use by environmental restoration staff. In addition, the developers are expanding applications of the technology to other contaminants and analyses.

This technology was successfully deployed at several sites and is still being used for additional applications. Several key features resulted in the successful deployment of the SEAMIST system.

Environmental restoration staff had a well-defined, immediate need (e.g., collection of representative soil gas samples during drilling) and were prepared to use their resources to find and test new approaches to sampling. Existing techniques for sampling had shown wide variability and provided inadequate results. In addition, end users gained knowledge of the details of the technology's operation, recognized applicable features, and identified features that would tailor the technology to the specific needs of the site.

End users took ownership of the modification, industrial interface, and demonstration of the technology. Direct and significant involvement from the site user resulted in a product that met the needs of the site.

The SEAMIST system was commercially available, and was supported by a company eager to modify, adapt, and redesign the system to best support the needs of the customer.

CONCLUSIONS

The ultimate goal of DOE's Technology Development Program is deployment of new technologies and technology systems that improve on safety, cost, and/or schedule of performance over baseline technologies. Field demonstrations are a critical component of successful development and deployment of environmental technologies. However, field demonstrations alone do not guarantee successful transfer for deployment. There are other key elements throughout the development and demonstration cycle for any technology or technology system that have significant

impact on the likelihood of deployment. The VOC-Arid ID established a development and demonstration process designed to enhance the likelihood of successful deployment following field demonstration. This process includes clearly defined methods for technology selection, performance evaluation involving stakeholders in the development and demonstration cycle, and commercialization. Many keys to successful technology deployment were identified in lessons learned from more than 25 field demonstrations. Also, several key attributes for successful deployment were identified through case studies. The case studies further highlight the applicability of the development and demonstration process established by the VOC-Arid ID, and identify areas where additional emphasis must be placed.

In summary, key attributes include the following:

Well-defined needs that clearly describe performance objectives and requirements for technical solutions. These needs are then used in the selection of appropriate technologies.

Well-designed development efforts with phases and tasks that identify key decision points. Clearly defined performance objectives and evaluation criteria are needed for each stage of development. A broad set of criteria is needed to ensure that as many issues can be addressed as early as possible in the development cycle. Projects unable to meet these key performance goals are redirected or terminated early, allowing more promising methods to continue toward demonstration and deployment.

Clear and complete documentation of all phases of the development, demonstration, and performance evaluation process. Thorough reporting of results with wide distribution. Effective communication of demonstration results, especially to a variety of potential end users, is critical to deployment.

When possible, conduct field demonstrations in conjunction with environmental restoration projects. This allows the opportunity for end users to become familiar with the technology and affect its development. This also provides the opportunity to view the innovative technology under field conditions along side baseline technologies.

Early efforts are needed to assess commercial markets and identify commercial partners. Industrial involvement early in the development cycle can enhance marketability, funding for development, and availability of the technology immediately after demonstration.

End user and other stakeholder involvement in the development, demonstration, and/or adaptation process for technologies and systems. This involvement includes management, oversight, and technical involvement in the development and demonstration efforts, as well as significant involvement in the development review and evaluation process.

The DOE's Office of Environmental Management has recognized the strengths and weaknesses of its past technology development and demonstration program, and has recently initiated a "New Approach" involving focus areas. This new process incorporates the key attributes identified above and in the case studies. Specifically, the focus areas are emphasizing direct user and stakeholder involvement in every facet of the development cycle, along with technology selection that is targeted more directly to complex-wide, but site-specific problems or needs. The demonstration efforts and lessons learned from the VOC-Arid ID, along with other development and demonstration efforts, have been incorporated into the Contaminant Plume Containment and Remediation Focus Area (Plumes) and are providing a building block for the New Approach.

TECHNOLOGY DEMONSTRATION PLANNING - THE KEY FOR SUCCESS IN DEMONSTRATING PRIVATE SECTOR INNOVATIVE TECHNOLOGIES AT DOE SITES

Alan R. Browne
Willkins R. Smith
Christopher O. Wyatt
Energetics, Inc.

ABSTRACT

The Department of Energy (DOE) Office of Environmental Management (EM) is actively pursuing the development of innovative technologies from the private sector to contribute to the many waste management and environmental restoration problems across the DOE complex. Before any innovative technology can be applied at a site, it must be demonstrated to both the site and the regulators that the technology will perform according to expectations. Prior to such a demonstration, there are a number of key planning steps that must be taken, including the careful identification of the most appropriate site, a commitment on the part of the site to host the demonstration, preparation of a detailed demonstration plan prior to the demonstration, clear delineation of duties and responsibilities, consideration of regulatory issues, etc.

This paper describes an approach to selecting the most appropriate site at which a private sector technology developer should demonstrate, and a discussion of the preparation of the demonstration test plan which should be prepared prior to the demonstration.

INTRODUCTION

The Department of Energy (DOE) Office of Environmental Management (EM) is actively pursuing the development of innovative technologies from the private sector to contribute to the many waste management and environmental restoration problems across the DOE complex.

Before any innovative technology can be applied at a site, it must be demonstrated to both the site and the regulators that the technology will perform according to expectations. Due to the specific nature of problems at some DOE sites, a technology that has been demonstrated at a non-DOE site usually must also be demonstrated at a DOE site before it can be accepted. Thus, the demonstration becomes the critical element in determining the success of the technology development.

Prior to such a demonstration, there are a number of key steps that must be taken, including the careful identification of the most appropriate site, a commitment on the part of the site to host the demonstration, preparation of a detailed demonstration plan prior to the demonstration, clear delineation of duties and responsibilities, consideration of regulatory issues, etc. There have been a number of technology demonstrations at DOE sites as part of the Office of Technology Development (OTD) Integrated Demonstrations and Integrated Programs. As these technologies have been developed at the sites as part of these programs, there often is an easier path to demonstration than with outside parties (including small businesses) who are often unfamiliar with the nature and culture of the DOE sites. This paper presents an approach to selecting a site for demonstration, and the elements that should be included in the demonstration test plan that must be developed prior to conduct of the demonstration.

SITE SELECTION

Demonstration site identification is a key decision in obtaining programmatic success since it impacts on all aspects of each project, it guides the planning in the initial project phase, provides a basis for Go/No-Go decisions for continuation of the project, and drives the planning for subsequent phases. Therefore, site identification, negotiation, and planning must be made as early in the project life cycle as possible.

Site identification involves the consideration, evaluation, and weighing of a

variety of issues, goals and objectives, and must be directed by appropriate and sound criteria. Seven primary criteria have been delineated for identification of a demonstration site. While all of the seven criteria are considered to be important, they are not listed in order of priority. An overriding order of priority has not been established, because the relative importance of any criterion may vary from project to project, depending on the nature of the demonstration project and/or the technology involved. Thus, prioritization of site-selection criteria will receive consideration upon initiation of the site identification process. The seven criteria are:

1. There must be a defined and documented site need for the technology.
2. The technical approach must be applicable and feasible for efficient performance at the site.
3. The regulatory status of the facility and compatibility of established regulatory schedules and constraints that apply to the site must not unreasonably limit the feasibility of a successful project demonstration.
4. Technical, scientific, commercial and operational factors that lead to the preference of a specific site by the technology development contractor must be considered.
5. The potential for the demonstration to show applicability of the technology at other sites or throughout the DOE complex must be determined, and considered.
6. The costs associated with conduct of demonstration at alternative sites must be considered in order to assure cost effectiveness. The availability and source of funding must be established.
7. The site must demonstrate its willingness, technical ability, and adequate organizational structure to support the demonstration project.

The following discussion elaborates on each of the above criteria:

CRITERION 1. There must be a defined and documented site need for the technology.

In order to support a decision to commit funding and resources to an on-site small-scale and eventual full-scale demonstration, it is necessary to establish that the basis of the proposed project will provide for resolution of an identified need. By clearly defining the needs of the end user, clear objectives and performance goals by which the success of the demonstration can be measured will be established. A major criterion must be that the technology can be applied to resolution of an identified problem. The test plan can then be developed so that the maximum probability of transferring a proven technology to a practical field application is assured.

CRITERION 2. The technical approach must be applicable and feasible for efficient performance at the site.

The technical applicability and feasibility of demonstrating the project technology at the site must be considered and verified. A technology that potentially will work very well at one site may well be a failure at another due to differences in site conditions. Differences in site conditions could include, for example, waste matrices, range of contaminants, contaminant concentrations and characteristics, geological and meteorological conditions, and clean-up levels or goals.

CRITERION 3. The regulatory status of the facility and compatibility of established regulatory schedules and constraints that apply to the site must not unreasonably limit the feasibility of a successful project demonstration.

The regulatory status of the potential site and the compatibility of the technology development project schedule with the site schedules for regulatory compliance, including characterization and remediation, must be evaluated and properly weighed in site identification decisions. The need and ability to obtain the necessary regulatory permits, whether the site is under CERCLA or RCRA, the requirements for NEPA documentation, and the requirements of a Federal Facility Compliance Agreement will all affect site identification.

CRITERION 4. Technical, scientific, commercial and operational factors that lead to the preference of a specific site by the technology development contractor must be considered.

In certain cases, a technology development contractor may have previously established a strong understanding of the requirements of a specific site remediation program and the prevailing site conditions, and may have previously structured his research and development program to address the specific concerns. This situation is particularly apparent if a contractor has been working at a site utilizing the existing state-of-the-art, and has developed more advanced concepts. A

contractor may also make the case that the conditions at the proposed site offer the greatest potential for developing a commercially viable (profitable) piece of equipment, instrument, or treatment process.

CRITERION 5. The potential for the demonstration to show applicability of the technology at other sites or throughout the DOE complex must be determined, and considered.

An important consideration in site identification is the multiple applicability of a technology to the DOE complex resulting from a demonstration at a given site. Would the demonstration results be applicable to a variety of needs at a number of sites, or would it only solve a limited or specific problem? To the extent that multiple applicability has been identified, site identification should lead to the development of a Demonstration Test Plan that will ensure the generation of adequate data to support a determination that the technology has applicability to other sites across the DOE complex, and that the results of the demonstration can be applied to other sites.

CRITERION 6. The costs associated with conduct of demonstration at alternative sites must be considered in order to assure cost effectiveness. The availability and source of funding must be established.

It is recognized that life cycle costs associated with the conduct of a demonstration may significantly differ between sites. Such differences may derive from costs for utilities, logistics, permitting, sampling and analysis, mobilization, etc. These differences may affect the cost-effectiveness of the demonstration. In addition, the site-specific demonstration costs must be evaluated in comparison with the availability of budgeted funding.

CRITERION 7. The site must demonstrate its willingness, technical ability, and adequate organizational structure to support the demonstration project.

Successful demonstration of a technology project requires active and effective support from DOE management at the facility, the Management and Operating contractor, and other support organizations. Accordingly, a particular site's technical or scientific background relative to the nature of the problem and the proposed technology application must be considered. The facility's technical and administrative resources and past experience in demonstrating projects of similar scope and complexity will be considered to be an important element in the ultimate success of the demonstration project.

SITE IDENTIFICATION PROCESS

In order to ensure that the application of new technologies will receive the acceptance and support of all affected parties, it is essential that a process of open discussion and involvement in the process is adopted. The active support of many organizations across the DOE complex facilitates and accelerates the successful demonstration of a technology development project. The comments and recommendations of all affected parties should be actively sought throughout the demonstration site identification process. Affected parties include, but may not be limited to: the technology development contractor, Environmental Restoration or Waste Management division at the DOE Operations Office, Technology Development division at the DOE Operations Office, EM-30 or EM-40, EM-50, Site M & O or ERM contractor, and Stakeholders and Regulators.

In particular, it must be recognized that the Regulators and the Stakeholders will have a significant impact on the final selection, since the ultimate use of the technology at a particular site must receive their approval. It also must be recognized that there are significant differences in the administrative approach of the different regions of the U.S. EPA, and in the states towards the adoption and implementation of innovative technologies at DOE sites.

DEMONSTRATION TEST PLAN (DTP)

Once the proposed demonstration site has been identified, the DTP is used for documenting the details of agreement by the involved parties for preparing, conducting, and reporting the results of a technology demonstration. The purpose is to ensure the effectiveness of the demonstration. The DTP should provide a means for establishing defensible data on the subject technology, thus satisfying the needs of DOE, technology developers, end users, regulators and additional stakeholders. Accordingly, the DTP should be prepared with appropriate signatory approvals prior to the onset of demonstration activities.

The DTP should be written in the context of the selected host site for the demonstration. That is, the plans for the demonstration should be integrated with

the cleanup program already underway at the site. The reason for the integration is two fold: environmental technology development projects are undertaken to help make environmental restoration programs more effective, and coordinated efforts are necessary to enhance DOE credibility.

The following are critical elements that should be included in the DTP:

1. Approval Signatures

Approval of the DTP concept is necessary to ensure that the demonstration will be conducted in a manner acceptable to all stakeholders who have a vital role. Vital roles are identified by responsibilities to conduct or support the demonstration or to pass judgement on the acceptability and/or validity of the results. Signatories include parties identified in the DTP having responsibility to perform the demonstration, having regulatory authority to accept or reject the results, or parties identified as representing concern on issues of acceptability.

The following signatories may be required to approve the DTP: the technology development contractor, the DOE host site (or other host site) representative, the DOE site contractor(s) representative, the applicable regulator(s) representative, and local or regional stakeholder(s).

2. Introduction/Project Description

This section should include a general introduction and provide a concise description of the project. This section also establishes the context of the technology to be demonstrated, including the perspectives of technical development, the ability of the technology to address DOE Focus Area needs, host site environmental and regulatory processes, and stakeholder interests. Examples of DOE EM concerns are policies, such as waste minimization, and cleanup goals for the affected sites.

This section should establish the host site background and physical setting for demonstration. The background should identify how the technology can be applied to a particular site need (i.e. Operable Unit characterization or remediation), consent order, impending Record of Decision (ROD) for remediation, or other concern which establishes a need for the subject technology. This section should also establish the site physical setting (i.e. topography, physiography, geology/hydrogeology, drainage, etc.) and, if applicable, historically establish how the site need occurred (i.e. production process, contaminant spill, etc.).

In addition to background information, the following should be included as elements of the project description for the host site: regulatory setting and special issues; the technology need with regard to DOE EM concerns; and the relationship to subsequent efforts (e.g., other phases or promotion and commercialization).

3. Technology Description

The description of the technology should address the specific EM Focus Area (i.e. Plume, Mixed Waste, etc.) addressed as well as specific technical aspects of the subject technology. This section explains the nature of the general class of technology (e.g., a type of treatment) and typical benefits (e.g. better, faster, safer or cheaper) as well as technology challenges and limitations. It describes the particular technology in general terms, then sets it apart from the general class of technology.

This section should provide a process flow diagram and narrative description, if applicable, which defines the conceptual design and indicates parameters such as influent and effluent waste streams, residuals production, major technology components/platforms, etc. which define unit operations of the technology system. This information helps to ensure that all potential impacts and support needs are identified (i.e. Health Physics) for potentially involved parties.

4. Demonstration Objectives

This section defines the objectives, their basis, and provides information on acceptability issues as well as technical issues, which were identified in the Introduction/Project Description and in the Technology Description. This section should address demonstration tasks individually and collectively and refer to the Quality Assurance Project Plan (QAPjP), if appropriate.

Additionally, the following items should be discussed: demonstration tasks, intended use of demonstration results, demonstration objectives, data quality objectives, expected results, measures of success, and criteria for evaluation.

5. Experimental Design and Procedures

The design and procedures are based on the developer's technology and the objectives of the demonstration. This section identifies the systematic aspects for the conduct of the demonstration, which will be used to develop the desired confidence in the

results. It satisfies all of the Demonstration Test Objectives and anticipates reasonable contingencies. Along with Site Preparation, Equipment, and Materials (Section 6), this section provides site-support participants adequate information to prepare for the demonstration.
This section may refer to specific appendices or documents that contain all of the details and should address, but is not limited to, the following aspects of the demonstration:
Preparation of samples (i.e. in situ, surrogate, test bed, etc.),
Definition of the volumes or amounts to be tested (influents, effluents and anticipated residuals),
Definition of test procedures and methodologies,
Definition of critical parameters and levels of testing,
Definition of demonstration limitations, and
Identification of instrumentation/controls/equipment and control strategy as well as standard operating procedures.
6. Site Preparation, Equipment, and Materials
This section describes the demonstration area at the host site, presents the details of equipment mobilization/demobilization, describes set up of the demonstration, lists the items to be used during the demonstration, and describes the immediate post-demonstration management of the equipment and site. Along with Experimental Design and Procedures (Section 5), this section provides site-support participants adequate information to prepare for the demonstration. This section should refer to Residuals Management (Section 11) and it may also refer to a Residuals Management Plan or a Demobilization Plan for the detailed information.
This section should address preparation, equipment, and materials in a comprehensive manner, including equipment lists, models and specifications. Additionally, setup prior to demonstration and demobilization procedures should be detailed.
7. Sampling and Analysis Plan
This section explains when, where, and how information will be collected (sampled or measured), including both field and laboratory procedures for sampling and analysis. Specific methods and procedures for implementing field activities should be contained in the Sampling and Analysis Plan (SAP). The SAP should include a Field Sampling Plan (FSP) that describes sampling locations, procedures and handling. The SAP should also include a QAPjP that describes sample analysis, management, custody and data validation. The SAP should be prepared in accordance with applicable local (host site), state, or regional (e.g. EPA) regulations and directives. This section should also comply with any applicable Consent Orders or Administrative Orders for the host site.
Additionally, all equipment used for measurement and sampling should be detailed in the SAP, including equipment models and operating procedures. This section should identify what quality control sampling is performed regarding each type of sample or measurement, according to the specified Data Quality Objective (DQO) level. The section refers to the FSP, the QAPjP and related standard operating procedures for detailed information.
8. Data Management
This section describes how collected (sampled or measured) data are recorded, handled, and transferred for validation and subsequent analysis and interpretation. It identifies what quality control sampling is performed regarding each type of sample or measurement, according to the specified DQO level. This section refers to the FSP and the QAPjP and related standard operating procedures for detailed information. The section needs to address data from both the field and the laboratory.
9. Data Analysis and Interpretation
This section describes how collected data are validated, interpreted, presented, and reported. It identifies what quality control sampling is performed regarding each type of sample or measurement, according to the specified DQO level. The section describes how results are assessed compared with the Demonstration Objectives. This section refers to the FSP and the QAPjP and related standard operating procedures for supplemental or detailed information. A detailed discussion of data analyses, including graphical presentation, modeling and interpretation should be provided here.
10. Health and Safety
This section addresses the health and safety of all those who might become involved

with the planned demonstration activities. Elements addressed include, but are not limited to, health physics, hazards assessment, precautions, emergency response, and training. The section refers to the Health and Safety Plan (HASP) and other standard operating procedures for supplemental or detailed information.

11. Residuals Management

This section accounts for all residuals resulting from the demonstration, including side stream effluents, unused influent waste streams (not subjected to testing), and investigation-derived waste (i.e. soil cuttings, groundwater, etc.). Non-inclusive examples are treated wastes, treatment residuals, used containers and expendable, contaminated clothing and debris, laboratory samples and sample extracts, contaminated equipment and materials. Non-inclusive examples of issues to be addressed are generated types and quantities of residuals, disposition criteria (i.e. waste manifests, waste characterization, etc.), and decontamination/demobilization. The section may refer to a supplemental Residuals Management Plan, Environmental Compliance Plan, Demobilization Plan, or other standard operating procedures for supplemental or detailed information.

12. Public Participation

This section describes the historic identification of, and interaction with, the community and other stakeholders (e.g., local citizenry, tribes, regional regulators) concerning the planned technology demonstration (e.g., site identification and evaluation process). This section shows the interaction activities that will occur during and following the demonstration. It identifies activities to achieve stakeholder consensus on the DTP, if applicable. Other topics addressed should include stakeholder identification, information releases, exchanges of ideas and information, identification of issues, and the selection of signatories to the DTP. This section may refer to a Public Participation Plan for supplemental or detailed information.

13. Reports

The reports section describes the documentation on the results of the technology demonstration, and all of the supporting records of activity and measurements. This section addresses the measures and standards developed in the Demonstration Objectives and Data Analysis and Interpretation. The discussion should identify all deliverables and their respective content and organization. This section may also refer to the QAPjP regarding records management for supplemental or detailed information. A discussion should be provided concerning the detailed presentation of capital and operating costs associated with the demonstration. Cost information will be the basis for technology economic analysis.

14. Schedules

This section provides the start and end date and dependency of each task. The period of applicability ranges from the drafting of the DTP, including a readiness review for the commencement of the demonstration, through to end of the present demonstration phase. The end of the phase is characterized by the report of the demonstration, review by those stakeholders/regulators or others who are to validate data or pass judgement on the demonstration results, and the disposition of residuals and wastes.

The section accounts for interfaces, reviews, and analytical turnarounds. It also includes reasonable slack time to preclude a miss of the project completion date. This section addresses all of the responsibilities identified under Project Organization including those associated with the Experimental Design and Procedures, SAP, HASP, Residuals Management, Community Relations, Reports, and Regulatory Compliance. This section may refer to a supplemental Readiness Review Plan for detail. The section should include a detailed Gantt Chart indicating the start date, stop date, dependencies and overall project schedule.

15. Regulatory Compliance

This section addresses regulatory compliance with respect to the overall demonstration and any applicable site cleanup process or host-site directives for the entire demonstration; prior, during and after test activities. The section particularly addresses regulatory compliance needs to be satisfied prior to the readiness review and commencement of the demonstration.

A description of how the demonstration fits into and satisfies the governing requirements of the site cleanup process (i.e. CERCLA, RCRA, etc.), including post-demonstration regulatory action on the results should be included in this section. Additionally, applicable non-environmental directives: local, state, or

federal such as security, site-access, and labor-related requirements should be discussed here.
This section should contain a discussion which accounts for conformance with other potentially applicable environmental requirements before conducting the operation, such as permits, licenses, and satisfaction of NEPA. It identifies requirements to be satisfied during the demonstration and upon cessation, such as reporting residuals to be disposed. The section may refer to a Regulatory Compliance Plan or Readiness Review Plan with supplemental or detailed information.
16. Project Organization
This section addresses management and staffing, responsibilities, support and site service requirements for the demonstration activities. It identifies roles and responsibilities of the technology development contractor, host site organizations (i.e. DOE, contractors, etc.), vendors, and regulators or stakeholders, who are expected to pass judgement on the results. It addresses all of the tasks identified under the Experimental Design and Procedures, Sampling and Analysis Plan, Health and Safety, Residuals Management, Community Relations, Reports, and Regulatory Compliance. Task managers and their responsibilities should be identified here.
17. Supplemental Material
Additional information in the form of appendices or adjunct documents and references is normally needed to provide supplemental and detailed information to complement the body of the DTP. The additional information is typically in the format of a plan or procedure. Typically the additional information necessarily conforms to a program already in place at the site where the demonstration is to occur. Typically, a particular site is selected because of involvement in an environmental restoration program (i.e. CERCLA, RCRA, etc.) with applicable Consent/Administrative Orders. The following are examples of supplemental material for a DTP:
Field Sampling Plan (FSP): (component of the SAP)
Quality Assurance Project Plan (QAPjP): (component of the SAP)
Health and Safety Plan (HASP)
Residuals Management Plan
Public Participation Plan
Readiness Review Plan
Regulatory Compliance Plan
Standard Operating Procedure(s).

Session 24 -- Geochemical Considerations in the Disposal of Radioactive and Mixed Waste

ABSTRACT
In Germany rock salt formations are envisaged as potential hosts for disposing of high level radioactive waste. One possible technique is the emplacement of vitrified HLW containers in deep boreholes, resulting in an exposure of the host rock to high doses and and temperatures. Gamma irradiation of rock salt leads via a complex reaction scheme to radiation damage with accumulation of colloidal sodium and chlorine gas in the sodium chloride lattice. The formation of the molecular irradiation products is associated with the storage of energy. Many studies have addressed this problem in the past, but in most of these studies, either the radiation-induced formation of only one of the products was determined or only rather low radiation doses have been used. In order to provide the missing data, the temperature dependence of the radiation-induced formation of colloidal sodium, molecular chlorine gas and the associated deposition of energy in rock salt was

determined between 100C and 250C. At each temperature the irradiation dose was varied between 106 and 108 Gy. After irradiation, colloidal sodium was measured via hydrogen evolution upon dissolving the salt in water. Chlorine gas was determined both in the gas phase above the salt and in the bulk. Stored energy was determined by DSC on selected halite specimen. The present study confirms the equivalence of the radiation-induced formation of the different products, i.e. colloidal sodium, molecular chlorine, and stored energy, over a substantial dose range and temperature range of interest for a repository. From the data it is concluded, that at temperatures above 150C, colloid formation starts to saturate with increasing dose. At 100C about 0.7 mol% sodium were detected for 108 Gy but no saturation was indicated. Most of the molecular chlorine after irradiation is found to be in the bulk, but chlorine evaporation from the salt increases with temperatures. The stored energy follows the trends outlined for the molecular radiation products, i.e. it increases with dose. A conversion factor of about 70 J/g per mol-% colloidal sodium in the rock salt is indicated.

INTRODUCTION

Besides Germany several other countries around the world envisage rock salt formations as potential hosts for disposing off high level radioactive waste. One possible technique is the emplacement of vitrified HLW containers in deep boreholes. Initially, this would expose the salt in the vicinity of the waste to dose rates in the order of 1000 Gy/h or less and temperatures between 150 - 200C, depending on the cooling time of the spent fuel elements. Dose rate and temperature decrease with time due to the radioactive decay of the waste. A total dose of 108 to 109 Gy will be absorbed in the salt surrounding such an emplacement borehole.

Gamma irradiation of rock salt leads via a complex reaction scheme to radiation damage with accumulation of colloidal sodium and chlorine gas in the sodium chloride lattice. The formation of the molecular irradiation products is associated with the storage of energy (1,2). In order to evaluate the long-term safety of a repository in rock salt, among other things quantitative information as to the amount of radiation damage is required.

The formation of radiation defects depends on the parameters total dose, dose rate, temperature, microstructure of the salt, and the level of impurities. This has been the subject of numerous studies in the past. In most of these studies, however, the radiation-induced formation of only one of the products was determined, one of the notable exceptions being the investigations of Jenks et al. (1975) (3), but the temperatures were below 150C. Also, in many studies only rather low radiation doses were employed at which the coagulation of molecular radiation products has just begun.

As yet no detailed data are available for the temperature dependence of the formation of radiation damage in the temperature region above 150C, which meet the following criteria: firstly, both molecular radiation products are determined chemically in the bulk of natural salt crystals, and, secondly, the stored energy is determined in the same samples. In order to provide the missing data, an experimental program was carried out.

EXPERIMENTAL METHODS

Irradiations

The irradiations were carried out in a cooling basin for spent fuel elements at the High Flux Reactor (HFR) at ECN in Petten. In order to be able to irradiate about 200 sample ampoules within two years, two special facilities were designed and built, so that the samples could be exposed between spent fuel elements which have been used in previous reactor cycles. The irradiation facility consisted of an aluminum container covered by a watertight lid with an O-ring and an aluminum sample holder housing five irradiation ampoules. The sample holder was equipped with an electrical heater and five thermocouples for measuring and controlling the temperature in the range between 80 and 250C.

Two of these irradiation containers were placed in a special fuel storage rack normally suitable for storing 42 spent fuel elements. In two positions the space for four elements has been modified for positioning the irradiation containers. A cadmium tube was utilized in order to absorb thermal neutrons. As spent fuel elements are used as irradiation source, the gamma intensity decreases and the energy spectrum changes with time. Typically, the gamma intensity of the fuel elements decreased from about 240 to 40 Gy/h within 30 days. For irradiation periods more than 28 days the fuel elements were changed every 28 days. The

radiation doses absorbed in the salt samples were individually determined in each ampoule via two different solid state dosemeters. One type of dosemeter was based on a thermoluminescence measurement of LiF while quartz powder was used in the other dosemeter, which was analysed by ESR. The dosemeters were encapsulated in small glass vials (outer diameter 8 mm, length 35 mm) and placed inside the ground salt. Both types of dosemeters were especially developed to meet the temperature and dose rate requirements of the HAW in situ irradiation.
The salt samples were irradiated in glass ampoules having a length of 250 mm and a diameter of 49,9 1 mm. These ampoules were filled with 300 grams of ground salt via a glass tube of 8 mm inner diameter. Altogether 250 ampoules were prepared. In order to remove the residual air, the ampoules were evacuated to about 1 mbar and then atmospheric pressure was re-established using either helium or a synthetic air-mixture (oxygen/nitrogen 20:80 v/v), respectively. The process was repeated three times. The ampoules were then sealed gastight by a glass blower.
Throughout this study natural rock salt from the Asse Salt Mine having a grain size of 1 to 3 mm was used . Its mineralogical composition was determined chemically and mineralogically and found to be

halite	97,5 wt.-%
anhydrite	2,0 wt.-%
polyhalite	0,45 wt.-%
total water content	0,03 wt.-%

Thus, these samples are largely representative for the envisaged repository in salt domes in Northern Germany.
Quantitative Determination of Colloidal Sodium
The amount of colloidal, metallic sodium in the crystal lattice was quantified chemically. About 10 g of salt were weighed into a teflon flask (volume about 250 ml) which was sealed with a screw cap equipped with two septa. The weighing in was carried out in a nitrogen atmosphere in a glove box in order to prevent any reaction between the metallic sodium and air humidity. Then 100 ml water were added through a septum and the salt was dissolved. The metallic sodium reacts with the water yielding hydrogen according to

$$Na_{met.} + H_2O \rightarrow Na^+ + OH^- + H_2$$

An aliquot of the gas phase in the teflon flask was withdrawn through a septum using a gastight syringe and analysed gas-chromatographically for hydrogen. For each irradiated ampoule three independent hydrogen measurements were performed. The standard deviation of these determinations was typically 10%.
The amount of colloidal sodium in irradiated salt is typically given in mol-%. It is calculated from the measured gas phase concentration of H2 as follows:
Eq. (1)
with:

mcol.sod.	yield of colloidal sodium [mol-%]
GPC	measured gas phase concentration [ml/ml]
GPV	free gas phase volume of teflon flask [ml]
mNaCl	amount of dissolved rock salt [g]
2	stoichiometry factor, since each colloidal sodium generates H2
MWNaCl	molar weight of NaCl [58,44 g/mol]
MVH2	ideal molar volume of H2 at 298,15 K [24465 ml/mol]

Quantitative Determination of the Radiolytical Chlorine
Molecular chlorine, Cl2, was determined chemically via reacting it with dilute sodium hydroxide solution and subsequent iodometric titration of the resulting hypochloride as follows:

$$Cl_2 + 2\,NaOH \rightarrow NaCl + NaOCl + H_2O$$

Hypochloride reacts with KI

$$OCl^- + 3\,I^- \rightarrow I_3^- + H_2O + Cl^-$$

and the resulting ion I3- is titrated against a redox electrode using 0.01 N sodium thiosulfate solution.

$$I_3^- + 2\,S_2O_3^{2-} \rightarrow 3\,I^- + S_4O_6^{2-}$$

The change in the redox potential is used in order to detect the equivalence point. Chlorine is volatile and may already evaporate from the salt crystal during the irradiation, thus resulting in an underdetermination, if the product was only measured in the bulk. Therefore, chlorine was quantified both in the head space of the glass ampoule and in the bulk of the salt.
As chlorine is extremely reactive, all glass surfaces which come into contact with

the gas sample were treated with hypochloride solution in order to destroy chlorine-consuming compounds (e.g. detergents). Afterwards, the flasks were rinsed thoroughly with Millipore-filtered water and dried.

Determination of Chlorine in the Gas Phase

After irradiation the ampoules were connected to a pump stand, consisting of a glass transfer tube with several connectors to which four glass bulbs, each equipped with a stop-cock and a septum, were attached. The whole system was evacuated using a membrane pump and sealed. Then the break seal at the irradiation ampoule was opened by dropping a small teflon-coated magnet on it, thus allowing the gas sample to enter the void volume. Nitrogen was added in order to adjust a final pressure of 1.5 bar. All pressures, i.e. after evacuation, after opening the irradiation ampoule, and after adding the nitrogen, were recorded for control purposes. Via the septum 5 ml of dilute sodium hydoxide solution (0,01 N) were injected into the glass bulb containing the gas sample. An aliquot of the solution was then withdrawn with a syringe and injected into the titration flask. The exact amount was determined by weighing. Afterwards 70 ml H2O, 20 ml HCl (2 mol/l) and 1 ml KI-solution (300 g/l) were added and the solution was kept dark for 5 minutes. The solution was then titrated. The mass of chlorine gas present in the head space of the irradiation ampoule is calculated as follows:

Eq. (2)

with:

mCl2(g.p.) mass of molecular chlorine in gas phase [mval/kg]
VStd consumption of standard solution [ml]
fStd titer of thiosulfate standard solution.
mNaOH amount of NaOH solution being redox titrated [g]
GPVtotal volume of gas phase in total system [ml]
GPVbulb volume of glass bulb [ml]

Determination of Chlorine in the Bulk of the Salt Crystals

The aqueous solution, that was prepared for determining the amount of colloidal sodium (see above), was also employed for measuring the amount of molecular chlorine in irradiated solid rock salt. After the hydrogen measurement between 5 to 30 ml were removed from this solution, weighed, and analysed for its hypochloride content using the same recipe as described above. The mass of molecular chlorine present in the rock salt is calculated according to:

Eq. (3)

with:

mCl2(salt) mass of chlorine in rock salt [mval/kg]
Vstd consumption of standard solution [ml]
fstd titer of thiosulfate standard solution.
mNaCl mass of dissolved rock salt [g]
msol mass of solution being redox titrated [g]

Then, the total chlorine yield in irradiated rock salt is calculated via

Eq. (4)

with:

mCl2(total) total mass of chlorine being produced upon irradiation [mol-%]

Calorimetric Measurements of the Energy Stored in Rock Salt

The determination of the energy storage in irradiated rock salt was carried out by differential scanning calorimetry (DSC) using the microcalorimeter SCERES B-900 S, that allows the application of sample masses of several hundred milligrams. Halite samples of 260 - 290 mg were weighed into small glass ampoules and heated two times from 30C to 400C at a constant heating rate of 1 K min-1. The reference ampoule contained pure sodium chloride (NaCl, suprapure) which had been heated for 3 weeks at 300C in order to recover defects in the crystalline structure. During the first heating the halite releases the stored energy and the colour of the sample changes from black to white. The second heating process is necessary in order to obtain a baseline under identical measurement conditions but without any reaction peak. In the following data evaluation the baseline (second heating curve) is subtracted from the reaction curve (first heating curve). As a result of this procedure one gets the 'true' exothermic peak without any twist in the baseline.

RESULTS

The g-radiation-induced generation of colloidal sodium depends strongly both on dose and temperature. This is shown in Fig. 1, which presents the data for irradiation

temperatures 100C, 150C, 200C, and 250C, respectively. The data points for high dose irradiations have all been set to 100 MGy. This value was estimated from recorded decay curve for the gamma intensity of the spent fuel elements, as the solid state dosemeters were not calibrated for such a high dose range at the temperatures being used. Recalibration of the solid state dosemeters is presently performed.

Significant colloid formation is observed for 100C and 150C, while only small amounts are produced at 200C and hardly any colloid formation is found for 250C. The data suggest that damage saturation occurs at the two higher temperatures. In contrast, clearly no saturation is obtained yet at 100C and 150C. As expected, the gas atmosphere during irradiation has no influence on the colloid yield. Identical results are otained both for irradiations carried out under nitrogen/oxygen (80/20 v/v) and under helium (data not shown).

At each temperature and dose, colloid formation is accompanied by the formation of equal amounts of molecular chlorine (on a molar basis). Figure 2 presents the respective data for all our irradiation experiments. The scatter at very low yields (i.e. data for low dose irradiations and/or high temperatures) is most likely due to a decrease in the measuring accuracy as the lower detection limits of the hydrogen and hypochloride detection are approached. In most cases slightly lower chlorine yields than colloid yields are obtained. The relative difference is higher at lower absolute yields. This finding is attributed to small chlorine losses during the detection procedure, which inevitably occur even though extreme care has been taken in handling and preparing the equipment used.

The relative portion of chlorine gas which is released from rock salt already during irradiation and, thus, is found in the gas phase increases with temperature. The data for high dose irradiations (duration 80 days, dose about 100 MGy) under helium are given in Table I. At temperatures of 150C and less only insignificant amounts of chlorine are released during the experiment.

The stored energy was measured in some of the samples. The available data are displayed in Fig. 3 versus the amount of colloidal sodium that was detected in these samples. Interestingly, no stored energy could be measured in samples that were irradiated at 200C (triangles in Fig. 3), even though both colloidal sodium and molecular chlorine were clearly detected.

The two lines in Fig. 3 represent conversion factors between stored energy and the amount of colloidal sodium that are published in the literature. The upper line corresponds to a conversion factor of 125 J/g stored energy per mol-% colloidal sodium in rock salt. This number was taken from Groote & Weerkamp (4). The lower line corresponds to a value of 70 J/g stored energy per mol-% colloidal sodium, that was derived by Jenks et al. (3). Clearly all our data fall close to the latter value.

Each data point in Fig. 3 represents the mean of three independent DSC-measurements. In some cases it was observed that the individual results varied considerably (up to 40%). This is likely due to the small rock salt specimens used in the DSC-measurements being different in their mineralogical composition from the bulk of the sample. If the small specimens used in the DSC-measurements contain more sulfate minerals than the bulk, a lower value for the stored energy is expected, since the radiolysis mechanism in ionic crystals depends on the charge of the ions. Currently this hypothesis is looked into experimentally.

DISCUSSION

The present study confirms conclusively that the irradiation of rock salt leads to the formation of equal amounts (on a molar basis) of the molecular products colloidal sodium and chlorine gas over a broad temperature and dose range. This is one of the few investigations, in which the various products have been determined for the same sample. Notable exceptions are the work of Jenks & Bopp (3) and of Groote & Weerkamp (4). However, in these studies the irradiation temperature was restricted to a range below 150C. In order to quantify the formation of molecular chlorine, both the amount present in the crystals and the amount released into the gas phase above the salt must be determined. This is particularly true for temperatures above 150C. A time dependence for the chlorine release is conceivable but was not investigated in the present study.

The formation of radiation defects and of molecular products in NaCl depends, in a complex manner, on the parameters dose, dose rate, and temperature. Also microstructure of the salt and the level of impurity were suggested to have an

influence. In principle, three phases can be distinguished in which the formation of defects is dependent on radiation dose. In an induction phase no significant growth of sodium colloids or other molecular irradiation products occurs. This is followed by a phase in which a more or less linear relatioship exists between defect formation and dose. Under specific conditions a saturation of defect formation occurs. When considering waste disposal it is ultimately the extent of radiation damage to the salt which is of interest. The linear phase and the possible saturation level are therefore of most significance. In the present study saturation is clearly observed at a temperature of 250C (at a very low level of damage). At 200C the start of saturation is indicated. No saturation occurs at 100C and 150C in the investigated dose range. This is in accordance with the extended Jain-Lidiard (JL) theory (5-7), which predicts that at a dose rate of 104 Gy/h damage saturation begins above 300 MGy. Unfortunately, under the boundary conditions of our experiments this dose range is only accessible using prohibitively long irradiation times. The absolute yield of radiation damage observed in our experiments is also in the expected range. At a dose of about 100 MGy, a damage level of about 0.80.1 mol-% was determined. For comparison, using the JL-theory values of 1,4 mol-% and 0,6 mol-% are estimated for dose rates of 104 Gy/h and 105 Gy/h, respectively, for that dose.

The amount of energy that is deposited in the salt due to the formation of molecular radiation products is of particular importance when the thermo-mechanical consequences of a spontaneous release of the energy is considered. Our data seem to indicate that one mol-% colloidal sodium corresponds to a stored energy of 70 J/g. This value agrees well with the one given by Jenks et al. (3). From their data Groote & Weerkamp concluded a value of 125 J/g (4). The reason for this difference is presently not clear. However, one reason may be the different type of samples used in the experiments. While natural rock salt samples were used in our experiments, Groote & Weerkamp employed melt-grown salt crystals.

WATER ROCK INTERACTIONS IN SALT FORMATIONS AND SAFETY ASPECTS OF REPOSITORIES

Herbert, H.-J.
GSF-Institut fr Tieflagerung
Braunschweig, Germany

ABSTRACT

Two very common water rock interactions in salt formations are discussed in the view of the safety considerations for underground repositories. These processes, the "Hartsalz" and "Carnallitit" dissolution were studied in two large scale in situ experiments. The results are presented and compared with the results of the geochemical modelling with the computer code EQ3/6. Geological field observations and mineral assemblages agree well with the results of the geochemical modelling employing the Pitzer formalism along with the Harvie, Mller and Weare database. The chemical compositions of the high saline solutions resulting from these processes are given along with the quantitative reactions which lead to such compositions. It is concluded that once the mechanisms of the chemical reactions are well understood it becomes possible to evaluate realistically whether such processes, when encountered in the repository, are still active or whether they are

finished. It also becomes possible to estimate the volume changes associated with the reactions and thus the impact of these reactions on the integrity and the geomechanical stability of the salt formation. The intimate knowledge of the reaction mechanisms during water rock interactions is a useful tool which helps to distinguish between geologically old and young brines, between brines from the outside or the inside of the salt formation, i.e. between hazardous and harmless brines in the repository.

BACKGROUND

In the safety assessment of a repository in salt formations - according to the German concept - the investigation of the hypothetical accident scenario of water or brine inflow is of particular significance. The water path is considered to be the most important way for the mobilization and release of radionuclides from the repository. The volume and composition of the contaminated brines is largely dependant on the accident scenario which is considered in the safety assessment. Two different accident scenarios are discussed in Germany:

- the limited scenario with a volume of maximum 1000 m3 of intruding brine
- the unlimited scenario with a brine volume equal to the volume of the repository (complete flooding)

The results of the safety assessment with these two different scenarios differ significantly. Therefore good reasons are needed for the selection of the most realistic scenario. The brine volume which has to be considered depends mainly on the origin of the brines and the access ways into the repository. Brines genetically linked to the origin of the salt formation generally have a small volume, whereas brines from the overburden have an unlimited reservoir and can completely flood the repository, provided that access ways exist. The knowledge of the origin of brines provide information on possible pathways within the salt formation and possible connections to the overburden.

Old brines formed in the geological processes which led to the formation and partial transformation of the salt formation have not only a relatively small volume but generally are trapped within the salt formation. Such brines have no connection with the overburden. They can enter the repository if they are encountered during the exploration and construction phase of the repository. But as they have no connection with the overburden their reservoir is restricted. No major brine inflow has to be expected. The practical experience made in the salt and potash mining industry shows that such brines generally dry up after a short period of inflow. If they are encountered during the operational phase of the repository they can easily be collected and removed. Once they have dried up no further brines from that reservoir must be expected. Such brines are harmless.

The situation is completely different if the intruding brines come from the overburden. Generally they don't dry up. Often they dry up in one place and reappear quickly in another place in the mine. Eventually they may completely flood the repository. Such brines are dangerous. It is essential to have tools at hand to distinguish such brines from harmless brines. Often the two different types of brines have a similar chemical composition.

This discussion shows how essential for the safety of a repository it is to collect reliable information on the origin of brines encountered during the exploration phase of the repository. In addition the discussion illustrates the limited value of the limited accident scenario in the safety assessment. It is simply not possible to demonstrate that using the limited scenario is a conservative approach.

Geomechanical processes may lead to an inflow of harmless brines with a small reservoir in the postoperational time of the repository. In this case the limited scenario would be the more realistic one. But it can not be excluded that geomechanical processes can cause the inflow of large volumes of brines from the overburden. This would require the consideration of the unlimited accident scenario. As no supervision of the repository in the postoperational time is required by the German concept such processes and the intrusion of brines would occur unnoticed. As nobody can tell in this case which kinds of brines will enter the repository the only conservative approach is the unlimited accident scenario.

In order to be able to distinguish during the operating time of a repository between hazardous brines from the overburden and harmless brines from the interior of the salt formation a thorough understanding of the geochemical reactions during water rock interactions is needed.

In the following chapters the results of two large scale in situ experiments of

relevant water rock interactions in salt formations, "Hartsalz" and Carnallitit" dissolution are discussed and compared with results of the geochemical modelling with EQ3/6, using the Pitzer-formalism (1) and the Harvie Moller, Weare database (2).

WATER ROCK INTERACTIONS IN SALT FORMATIONS

"Hartsalz" Dissolution (H_2O + sylvite + kieserite + halite + anhydrite)

"Hartsalz" is the german term for a common and valuable secondary potash formation within the Zechstein salt sequences in Northern Germany. There are different types of "Hartsalz", like kieseritic, anhydritic and langbeinitic "Hartsalz". The main components of all "Hartsalz" types are sylvite and halite. Minor components are different sulfates like kieserite, anhydrite and langbeinite which give the name of a specific "Hartsalz" type. All "Hartsalz" types were formed by the interaction of water with the primary potash formation "Carnallitite" which in turn was formed by the primary precipitation from the evaporating sea water. As the kieseritic "Hartsalz" is the most common "Hartsalz" type in the Zechstein salt formations the dissolution behaviour of this type was studied in detail.

A large scale in-situ experiment was carried out in the potash mine Hope, near Hannover in Northern Germany from 1984 to 1992. In the Hope mine "Hartsalz", consisting of 61.4% halite, 31.7% sylvite, 3.4% kieserite and 1.7% anhydrite was mined. The abandoned mine was flooded with a NaCl saturated brine. A research programme was set up to record and evaluate data on the geochemical, geomechanical and geophysical processes occurring during and after flooding. The geochemical program monitored the changes in the chemical composition of the charged NaCl solution in contact with "Hartsalz" over a period of 7 years. Preliminary results of the experimental program and of the geochemical modelling with EQ3 and EQ6 were published by (3 and 4). Later a more complete evaluation of the results and a detailed comparison between experimental data and geochemical modelling was carried out by the author. Some of the results of this work are illustrated in Fig. 1 and 2. Figure 1 shows the chemical evolution of the brine, the amount of rock affected by the dissolution process and the time needed for the solution to reach different concentrations. The symbols represent samples taken at different times from different locations in the mine, whereas the lines show the evolution as calculated with the geochemical code EQ3/6. The vertical line in Fig. 1 marked with R1 indicates the reaction step for which a quantitative reaction comprising the initial solution, the resulting solution, all reactants and all products, was calculated using the results of the geochemical modelling. The experimental results cover only a small part of the entire reaction. The line R1 in Fig. 1 corresponds to R1 in Fig. 2. The lines R1 - R7 indicate the steps for which quantitative reactions were calculated as well. As we know the composition of the initial and resulting solutions and the reactants involved in the reaction and considering the good agreement between experimental data and computer modelling at each step of the reaction, we conclude that we can extrapolate the results reliably beyond the limits of our experimental data. Figure 2 demonstrates, that during the reaction water is continuously consumed and the reaction terminates when no water is left. The water is consumed during the reaction primarily via the formation of the mineral kainite. During the reaction (R7, Fig. 2) 1 kg of water in the initial solution can theoretically affect about 90 kg of "Hartsalz". About 27 moles of sylvite, 22 moles of kieserite and 11 moles of anhydrite can be dissolved and 5.5 moles of carnallite, 5.7 moles of halite, 11 moles of kainite and 5.5 moles of polyhalite can precipitate. Between R6 and R7 the chemical composition of the solution does not change anymore. It has reached the invariant composition of an IP 21 solution in the six component system Na-K-Ca-Mg-Cl-SO_4. This solution is saturated with halite, sylvite, carnallite, kainite and polyhalite. In spite of the solution staying constant in composition between R6 and R7, the dissolution continues, as the solution is not yet saturated with kieserite and anhydrite. The dissolved amounts of $CaSO_4$ and $MgSO_4$ are consumed by the formation of new kainite. This process finally stops when no water is left. In Table I the quantitative reaction at point R6 of the entire reaction path is given.

Whereas in flooded "Hartsalz" mines the resulting solutions normally reach the composition of an IP21 solution (see final solution in the reaction R6 in Table I, b), it is very unlikely that the reaction will proceed under natural conditions to the very end (R7 in Fig. 2) where no water and no solution is left. The reaction will stop whenever one of the reactants is exhausted or has no more direct contact

with the solution. Therefore it is very important to have natural analogues, i.e. flooded potash mines, in order to be able to show which steps of the theoretical reaction can be reached under natural conditions (different mineralogical compositions of affected potash rocks, different outcrops etc.). It is equally important to have a thorough theoretical understanding of the expected reactions. Provided a good agreement between experimental results and geochemical modeling as in this example, the modelling can give a deep insight in the mechanisms of the reaction.

"Carnallitit" Dissolution (H_2O + carnallite + kieserite + halite + anhydrite)

"Carnallitite", a potash rock consisting mainly of carnallite, kieserite and halite, is very common in the Zechstein salt sequences in Northern Germany. The dissolution behavior of this salt formation, which is very different from that of "Hartsalz", has been studied in detail as well. Whereas "Hartsalz" is a secondary potash formation, "Carnallitit" was formed by the simultaneous precipitation of carnallite, kieserite and halite from the evaporating sea water. The rock "Carnallitit" can contain minor amounts of sylvite, anhydrite and clay minerals.

The dissolution of "Carnallitit" was investigated in a vertical borehole drilled into the "Carnallitit" formation in the Asse Mine, near Braunschweig. The borehole, 40 cm in diameter and 4 m deep, was filled with a NaCl saturated brine. The change of the chemical composition of the brine was measured over a period of 4.5 years. The experimental results and the results of the geochemical modelling are shown in Fig. 3 and Fig. 4. As in the "Hartsalz" experiment, a good agreement between experimental and theoretical data was obtained. In the "Carnallitit" dissolution experiment the boundary conditions were more favorable, which led to a more complete coverage of the theoretical curves with experimental data. i.e. most of the total reaction path was covered by the experiment. As we have a good agreement between the two sets of data, this experiment is even more valuable in terms of demonstrating the ability of the EQ3/6 code to reliably predict the dissolution reactions in salt formations.

For the safe disposal of hazardous wastes in salt formations it makes quite a difference if "Hartsalz" or "Carnallitit" is present in the openings of the repository. Whereas in the dissolution reaction of "Hartsalz" the initial amount of water is gradually consumed by the formation of hydrated minerals in the dissolution reaction of "Carnallite" the initial amount of water increases (compare Fig. 2 and 4). The line R4 in Fig. 3 marks the composition of an invariant solution of the six component system Na-K-Ca-Mg-Cl-SO_4 called IP19. This solution is saturated with halite, carnallite, kieserite, kainite and polyhalite. It is not yet saturated with anhydrite. The saturation with anhydrite is reached at line R5. The chemical composition of the IP19 solution and the quantitative reaction which leads to the composition of an IP19 solution (R4) is given in Table II.

Beside the differences in the dissolution behaviour of the two potash formations "Hartsalz" and "Carnallitit" there are also similarities. The resulting solutions IP 21 and IP 19 are saturated with halite, carnallite, kainite and polyhalite and have consequently very high Mg concentrations (above 100.000 mg Mg/kg H_2O).

CONCLUSIONS

By describing two relevant water rock interactions in salt formations and comparing experimental results with equilibrium calculations it was demonstrated, that we have a good understanding of these processes. The close correspondence between the calculated and experimental results of the large scale field experiments, the "Hartsalz" and "Carnallit" dissolution, indicates that the geochemical computer code EQ3/6 with the Pitzer-formalism and the Harvie, Moller, Weare database yield reliable predictions.

It can be assumed that the long term mineralogical changes establish an equilibrium between the brines and the surrounding minerals. Such equilibria can be calculated accurately for the six component system Na-K-Ca-Mg-Cl-SO_4 at 25C. In spite of the general good agreement of the results of in situ experiments and geochemical modelling, differences are noted in the sulfate saturation of these natural, young brines and the calculated compositions of these brines. In older brines the sulfate supersaturation tends to disappear. Sulfate supersaturation should not be present in very old brines, which are remnants from the long term geological processes. It is worthwhile to investigate if these differences can be used in order to distinguish reliably old from recent brine compositions. It is especially important, therefore to study not only the mineral assemblages of the long term geological processes but

also the fluid phases.
From this investigations we conclude that once the mechanisms of the chemical reactions are well understood it becomes possible to evaluate realistically whether such processes, when encountered in the repository, are still active or whether they are finished. It also becomes possible to estimate the volume changes associated with the reactions and thus the impact of these reactions on the integrity and the geomechanical stability of the salt formation. The intimate knowledge of the reaction mechanisms of the short and long term changes in the mineralogical assemblages and the associated brine chemistry is a first prerequisite for the correct evaluation of the origin of brines and essential for the correct evaluation of the hazards which brine inflows may pose for the safety of a repository in salt formations.

GEOCHEMICAL ATTENUATION: A COMPONENT OF ENGINEERING WASTE DISPOSAL CELLS
Roman S. Popielak
P.G. and Anne Lewis-Russ, Ph.D.
Titan Environmental Corporation
ABSTRACT
The primary function of waste repository sites is to isolate waste or waste-derived leachate from the underlying soil and ground water. The beneficial, attenuating properties of geologic materials have been long recognized and considered during siting of mining and radioactive waste repositories. To attain isolation of waste from the environment, engineering designs often include installation of a synthetic or natural clay bottom liner with a leachate collection system and a low-permeability cover. The engineering performance standards addressing isolation systems are mandated by regulations; however, regulations also recognize natural factors retarding or blocking the migration of contaminants away from a waste repository. In the United States, the owner of the waste repository may be exempted from stringent performance standards if the attenuating capacity of the soil present between the landfill and ground water is demonstrated. In Europe, investigation must include a study of the possible purifying power of soil and subsoil. Therefore, an efficient engineering design must take into account the natural ability of underlying soils to preclude migration of leachate components.
This paper discusses methods of identifying and quantifying geochemical barriers, both in the field and in the laboratory, and of integrating the barriers into repository engineering design. Also presented are two case studies where natural geochemical barriers were shown to mitigate the migration of heavy metals and redionuclides.
INTRODUCTION
Mining and radioactive waste, when contacted by water from precipitation, will generate mostly acidic leachate. Migration of leachate into the strata underlying waste will first contaminate the vadose zone and, if not retained in the vadose zone, will eventually contaminate the underlying ground water. Mechanisms by which percolation of leachate occur are illustrated in Fig. 1.
Engineered top covers, bottom liners, and leachate collection systems are a first line of defense against leachate migration. The second line of defense (the focus of this paper) is the geochemical barrier created by natural attenuating properties of soils underlying the repository.
The beneficial, attenuating properties of geologic materials have been long recognized and considered during siting of radioactive waste repositories. A prime

example is the ongoing investigations of Yucca Mountain, Nevada as a potential site for an underground, high-level nuclear waste repository. The presence of abundant zeolitic tuffs underlying the region was a major consideration in selection of this site for study. The zeolites are highly selective for certain cationic radionuclides and could potentially be a natural barrier to radionuclide migration (Broxton et al., 1987).

The ability of natural clay materials to retard the movement of radionuclides also has been recognized (Proust et al., 1990). The Boon clay formation in Belgium has been under consideration as a potential host formation for wastes from nuclear power production. The low permeability and high ion exchange capacity of the clay formation are considered to provide an efficient natural barrier against the release of radionuclides (Patyn et al., 1989).

Clay minerals also have been shown to attenuate heavy metals, such as cadmium, lead, and zinc (Griffin, et al, 1976). Sandstone, siltstone, and shale were found to immobilize arsenic, chromium, lead, silver, thorium, and vanadium from uranium mill tailings leachate (Serne, et al, 1983). Organic compounds are known to be attenuated by carbonaceous matter in soil (Schellenberg, et al, 1984). These and similar studies suggest the appropriateness of incorporating natural attenuation into the design of hazardous waste repositories.

Geologic materials provide natural barriers to radionuclide migration because numerous radionuclides are highly adsorptive. For example, 90Sr, 137Cs, 60Co and 226Ra are considered moderately to strongly adsorbed in most types of clayey or silty sediments (Cherry et al., 1979). Cesium-137 can be used to measure soil erosion rates because of its strong adsorption onto soil particles (Ritchie and McHenry, 1990).

Sorption ratio (Rd) values determined for geologic materials provide further evidence of their natural attenuating capacity. For example, Rd values determined in the Yucca Flat area, Nevada, indicated that the sorptive capacity of natural valley fill material could retard transport of actinide radionuclides in vadose water by two or more orders of magnitude in comparison to the movement of water (Winograd, 1981). The valley fill contained significant content of zeolitic, clayey, and other tuffaceous detritus.

Because of the importance of natural attenuation, a legal obligation to define geochemical barriers has been incorporated into environmental regulations of the United States. This regulation [40 Code of Federal Regulations (CFR) 264.301 (b)(3)] provides for an exemption from a costly liner and leachate collection system if "alternative design and operation practices, together with location characteristics, will prevent the migration of any hazardous constituents into the ground water or surface water at any future time" (emphasis added). In European Community countries, "a study of the hydrogeological conditions of the area concerned, and of the possible purifying power of the soil and subsoil," must be done (Johnson and Corcelle, 1989, p. 71).

Consideration of a geochemical barrier to leachate migration in the design of a new waste repository offers simplified and less-costly construction. Savings may exceed 30 percent of the cost of "full-scale" Resource Conservation and Recovery Act (RCRA) repositories. In the case of existing or proposed repositories, demonstrating the presence of a competent geochemical barrier may reduce efforts to obtain required permits.

RECOGNITION OF GEOCHEMICAL BARRIERS

Most soils will provide some geochemical barrier, but certain soil materials are typically much more effective. These include clays, calcareous units, iron or manganese soil coatings, and carbonaceous materials. These materials in underlying soils are the first indication of the presence of a geochemical barrier.

The geochemical reactions causing geochemical barriers are governed by the characteristics of the soil as related to the characteristics of the leachate. The change of leachate pH from acidic to neutral or alkaline due to its reaction with soils is of utmost importance in migration prevention. Also of importance are the absorptive properties of clay, especially when clay and other soil particles are coated with iron and/or manganese oxides, not an uncommon phenomenon.

Figure 2 schematically shows the various reactions as the pH of the leachate increases. The important reactions are: a) the co-precipitation of heavy metals and other ions along with iron and manganese found in the leachate; and b) adsorption of the ions on the surface of precipitated and co-precipitated oxides.

For the non-chemist, simplified definitions of co-precipitation and adsorption are as follows:

Co-precipitation involves metals becoming "entangled" in the lattice of oxides and hydroxides of iron and manganese. When the iron and manganese precipitate, other metallic elements are retained within the metal oxide and hydroxide precipitates.

Adsorption occurs when heavy metals, such as iron and manganese, precipitate and form solids with charged surfaces. Other metals are attracted to these surfaces and are held by sorption mechanisms on the surface. Henceforth, further transport of the elements ceases unless geochemical conditions are altered.

In addition to looking for the presence of calcareous, carbonaceous or clay materials, investigation of geochemical barriers should also include quantification of total organic carbon (TOC) in soils. Organic material has a large attenuating capacity for some metals.

Figure 3 is an example of the separation of leachate components as a result of a geochemical barrier. In this case, the leachate was an acidic plume from mine wastes. The leachate originally contained several metals and sulfate, but the caliche underlying the mine waste served as an effective geochemical barrier. Sulfate, which is least affected by interaction with the caliche, traveled the farthest and was located outside the hatched area shown on the figure (i.e., in "unaffected soil"). The metals in the leachate were retarded relative to the sulfate and remained within the hatched area. The confined area containing metals relative to sulfate distribution is evidence of the geochemical barrier.

QUANTIFICATION OF GEOCHEMICAL BARRIERS

Quantification of the capacity of geochemical barriers requires investigation of critical properties of the soil which typically begins with an examination of the available boring logs to obtain information on the mineralogy and content of organic matter.

Laboratory tests can provide quantitative data about geochemical barriers. Although column tests produce reliable results, the test can be time-consuming. Therefore, sequential batch tests can be used to speed the testing process by discretizing the column process into distinct sequential batches. Sequential batch tests simulate continuously-leached columns wherein successive seepage solution comes into contact with soil (Houle and Long, 1980).

A variety of information can be obtained from the sequential batch tests. For example, the weight of the constituent retained can be compared to the weight added to determine attenuating capacity (Houle and Long, 1980). Contaminant partitioning ratios between soils and water can be calculated for use in transport modeling. Also, the necessary thickness of attenuating material required to provide an adequate geochemical barrier or, conversely, the attenuation capacity of the actual material present can be calculated.

CONSIDERATION OF GEOCHEMICAL BARRIERS IN ENGINEERING OF WASTE REPOSITORIES

If quantitative analysis of a geochemical barrier demonstrates that underlying strata attenuate leachate migration, consideration of the geochemical barrier can be incorporated into the repository design. In accordance with CFR 264.301, the design requirements for the bottom liner of new repositories built in the United States after January 1992 call for construction of a two-component liner system. The upper component of the bottom liner is designed to prevent the vertical migration of hazardous constituents into the bottom liner. The lower component of the bottom liner is designed to minimize vertical migration of hazardous constituents should the upper component of the bottom liner become breached. The typical RCRA-mandated design is shown on Fig. 4, Detail A.

If the site-specific geochemical and/or hydrogeological data indicate that the native soil has sufficient capacity to attenuate migration of hazardous constituents, the lower components of the liner may be eliminated or minimized. Figure 4, Detail B, depicts the liner modified for favorable geochemical conditions. Table I shows a cost comparison for construction of a conventional bottom liner system and a modified bottom liner system for a hypothetical five-acre repository. Elimination of the lower component of the liner may result in a net capital cost reduction of about 35 percent.

CONSIDERATION OF GEOCHEMICAL ATTENUATION IN PERMITTING PROCESSES

Demonstrating the presence of a geochemical barrier can also be helpful to a regulatory process relating to assessment of liabilities from past operations or to permitting new facilities.

Case Study 1 - The operator of a large copper mine and mill in the southwestern United States had disposed of acidic copper tailings over an area of approximately 90 acres. Disposal continued for more than 100 years. The investigation to determine the impact of tailings disposal revealed the absence of metals in ground water. To ensure that metals would not contaminate the ground water in the future, the regulatory agency directed the characterization of the geochemistry of soils underneath the impoundments.

The soil samples from borings were analyzed for soil pH, acid neutralizing potential (ANP), cation exchange capacity, carbonate content (as CaCO3), and metals abundance in tailings, including cadmium, chromium, copper, iron, lead, manganese, and zinc. Background soils were found to be alkaline with high ANP. The thickness of this soil between the surface and the ground water table was 500 feet.

When calcareous soil was contacted by acidic tailings leachate, the ANP of some of the soils was compromised, yet metals were retained in soils prior to reaching the ground water. This investigation demonstrated that only five to ten percent of the geochemical barrier separating tailings from ground water had been used in the course of more than 100 years of tailings disposal. This demonstration, along with the documented absence of metals in ground water, alleviated the primary concerns of regulatory agencies in the process of site permitting.

Case Study 2 - An application of the method relying on measurement of iron and manganese coatings was used during design of a repository for flue dust from an abandoned copper smelter in the northwestern United States. Extractable iron (representing iron coatings on soil) ranged from 220 to 2,520 milligrams per kilogram of soil.

Based on expected leachate composition, arsenic was the only chemical of concern. A published study (Pierce and Moore, 1982) was used to obtain information about the attenuating capacity of iron oxide with relation to arsenic. The resulting calculation indicated that the soil had the capacity to adsorb a minimum of 160 milligrams arsenic per liter volume of soil, which was well above the expected loading. Since the repository is positioned 80 to 100 feet above the water, a breach of the geochemical barrier over the course of time is not likely.

The final decision for the flue dust disposal was to solidify the flue dust to pass the Toxicity Characteristic Leaching Procedure test. The geochemical barrier below the repository provided a redundant protection of underlying ground water.

ABSTRACT
The sorption of Cs and Cd on model soil minerals was examined by complementary analytical and experimental procedures. X-ray photoelectron spectroscopy (XPS) and nuclear magnetic resonance (NMR) spectroscopy were used to characterize the chemical and physical nature of Cs-reacted soil minerals. Cd and Cs adsorption isotherms for kaolinite were also measured at variable pH and temperature to establish likely reaction stoichiometries, while atomic force microscopy (AFM) was used to characterize the microtopography of the clay surface. XPS analyses of Cs-exchanged samples show that Cs is sorbed at mineral surfaces and at the interlayer site of smectite clays, although the spectral resolution of XPS analyses is insufficient to differentiate between basal, edge or interlayer sites. 133Cs MAS-NMR results also show that Cs is adsorbed primarily in an interlayer site of montmorillonite and on edge and basal sites for kaolinite. Cd adsorption isotherms on kaolinite were found to be additive using Al2O3+SiO2 Cd binding constants. AFM quantification of kaolinite crystallites suggest that edges comprise up to 50% of the BET surface area, and are consistent with NMR and surface charge results that Cs and Cd adsorption occur primarily at edge sites.
INTRODUCTION
Effective disposal of radioactive and mixed waste in near-surface low level radioactive waste (LLW) facilities will ultimately depend upon the geochemical interactions of dissolved aqueous waste with common oxide and silicate minerals. These minerals, which range in complexity from quartz to smectite-like clays, are found in the adjacent soils, if not in the engineered waste facility. The geochemical controls for sorption of hazardous chemical and radioactive wastes onto minerals is often governed by the structure and reactivity of those mineral surfaces (1,2). A fundamental understanding of those mineral-fluid interactions is important for proper evaluation of the waste disposal and retention scenarios, as the site licensing agency must complete a performance assessment (PA) of the proposed LLW disposal site in accordance with regulations. The key to PA is the ability to model transport and retardation of dissolved radionuclides from a LLW disposal site. Current geochemical models utilize retardation factors (KD) to handle the uncertainties involved in radionuclide transport (3,4). These models work reasonably well when the site is well characterized, but mixing of groundwater and waste leachate may produce conditions not easily modeled by the KD method. Although theoretical models exist for modeling sorption processes on minerals, experimental verification of those models lags, as does atomistic characterization of the retardation mechanism.
This study aims to examine the fundamental mechanisms and processes by which soil mineral phases absorb metal cations, specifically non-radiogenic Cs and Cd. Because sorption onto the surfaces of structurally and chemically heterogeneous soil

minerals is complex and not very well understood, we have emphasized complementary experimental and analytical studies of metal sorption using model soil minerals. Specifically, we have employed modern spectroscopic techniques, such as X-ray photoelectron spectroscopy (XPS), solid state magic-angle spinning (MAS) nuclear magnetic resonance (NMR) spectroscopy, and atomic force microscopy (AFM), to characterize surface and bulk properties of reacting soil minerals. Adsorption isotherm measurements were also done at variable pH and temperature to establish likely reaction stoichiometries and bonding enthalpies.

METHODS

Analytical and experimental studies of the cation sorption processes were performed using both natural and synthetic soil mineral samples, including quartz (SiO_2) and corundum (Al_2O_3), gibbsite ($Al(OH)_3$ from Ouro Preto, Brazil), kaolinite ($Al_2Si_2O_5(OH)_4$ from Warren Co., Georgia), and montmorillonite (Ca-interlayer clay from Apache Co., Arizona). These minerals were chosen to provide increasingly complex structures and chemical sorption sites whereby the process of metal sorption onto soil minerals might be determined. For example, quartz and corundum are simple anhydrous oxides consisting of corner-sharing Si tetrahedra or edge-sharing Al octahedra, whereas gibbsite consists of a partially-occupied Al layer which is octahedrally coordinated by hydroxyl ions. Kaolinite is a 1:1 layer type clay mineral comprised of a tetrahedral SiO_4 layer linked to an octahedral gibbsite layer (TO structure, see Fig. 1). Montmorillonite is a complex 2:1 layer type smectite clay (TOT structure), composed of an Al-deficient octahedral sheet sandwiched between two inward-pointing SiO_4 tetrahedral sheets, where interlayer cations satisfy charge balance. Characterizations of powdered minerals and reacted samples were made using standard analytical techniques (AA, DCP, EDS, ICP-MS, TEM, and XRD) in order to verify the structure of starting materials and reacted phases, and to quantify solution compositions.

After a series of Cs sorption tests, several surface-sensitive spectroscopic techniques were used to characterize the extent and site-specific control of Cs sorption onto these minerals. These techniques include X-ray photoelectron spectroscopy (XPS), which is sensitive to the near-surface (<<20) composition and chemical state of elements, and nuclear magnetic resonance (NMR) spectroscopy, which yields structural and bonding information at the molecular level. In these tests, approximately 1 g of the mineral was reacted with 100 ml of 0.1 or 0.01 M CsCl solutions in polyethylene bottles for 5 days at 25 and 50C. A shaking bath was used to maintain constant temperature and suspension of the sample. After the test, samples were separated by filtration. The XPS analyses were performed under vacuum (~ 2 x 10-9 torr) using a Perkin Elmer PHI 5400 instrument employing Mg Ka X-rays and a take-off angle of 45. Adventitious carbon (C 1s binding energy) provided an internal standard for correcting energy shifts resulting from sample charging. The 133Cs NMR spectra were collected at room temperature and at 65.5 MHZ using a spectrometer with a 11.7-T superconducting magnet. Spectra for most samples were collected at room humidity, however, a few kaolinite and montmorillonite samples were collected at 100% relative humidity (RH) in order to evaluate interlayer site occupancy and exchange. Some samples were also cooled or heated in order to evaluate thermal effects upon site occupancy. The 133Cs chemical shifts are reported in parts per million (ppm) relative to an external 0.1 M CsCl solution at room temperature. Cs and Cd adsorption onto kaolinite was measured as a function of pH at 25 and 50C. The titrant for the adsorption measurements was 0.1 M NaOH and the pH electrode was calibrated using NBS standards at the temperature of interest. Four g of kaolinite powder (BET surface area 10 m^2/g) were titrated in 50 mL of 0.1N $NaClO_4$ using a Mettler DL12 titrator. Slurries were continuously stirred and N_2 gas was pumped directly into the solution prior to and during each titration to purge CO_2. Temperature was maintained by adjustment of a hot plate and water bath in which the reaction vessel was immersed. Certified Cs and Cd AA standards were diluted to ppm levels and used as stock solutions. A 0.1 M solution of $NaClO_4$ was used as the background electrolyte in these adsorption experiments because ClO_4^- complexes with neither Cs nor Cd. Total metal concentrations in sampled solutions were measured by DCP or ICP-MS analytical methods. Cs and Cd adsorption was determined by monitoring metal concentrations as the solutions were titrated to pH ~9. The dissolved metal and pH data were regressed using FITEQL (5) to calculate best fit values of pKx and site density for Cs and Cd as a function of temperature.

Relative proportions of basal and edge surface area for untreated kaolinite were

determined using AFM techniques. Kaolinite was ultrasonically suspended in water for 1 minute. 50 mL of this solution was placed on freshly-cleaved muscovite and air-dried. Images were obtained in contact mode using a Park Scientific Instruments AutoProbe LS (5 mm scanner) and 0.6 mm thick Ultralevers (silicon cantilever and tip). Scanning speeds ranged from 0.5 to 2 Hz. Particle dimensions and step heights were measured on raw images of a few representative grains. These dimensions were used to calculate relative amounts of edge and basal surface area. Estimated errors for calculated surface areas are 10% based on an averaged 5% uncertainty in a single height or length measurement.

RESULTS

A Cs XPS signal was not observed for any of the starting materials, although several Cs peaks were observed for all reacted samples but gibbsite. EDS analyses acquired during XPS analysis indicate that powdered corundum sorbed ~0.3 mole % Cs; the kaolinite slab exhibited Cs sorption at the 1 mole % level; and powdered montmorillonite sorbed ~2 mole % Cs. Sorbed Cs concentrations were reduced by 50-75% after Ar sputtering of the near surface. Based upon these results, the relative Cs sorption capacity for these minerals is montmorillonite >> kaolinite >> corundum >> gibbsite. In addition to near-surface compositional profiles, XPS can measure shifts in the binding energy of core electrons resulting from a change in chemical environment (chemical shift). These shifts result from a change in the nearest neighbor, oxidation state or crystal structure. We did not observe a chemical shift for Cs sorbed onto montmorillonite nor kaolinite. Multiple surface or interlayer sites for Cs could not be resolved from the single peak Cs spectra observed for clay mineral samples (Fig. 2). These same samples were also characterized by 133Cs magic angle spinning (MAS)-NMR spectroscopy. There was no observed 133Cs MAS-NMR spectral signal from the corundum or gibbsite samples. The NMR spectra for the montmorillonite samples contain one broad peak at -18 to -12 ppm, whereas the kaolinite samples contain multiple peaks (Fig. 2b), including a large, relatively narrow peak at a more shielded chemical shift (-40 to -25 ppm) along with several other weak peaks. Higher concentrations of Cs in the reacting solution, as well as lower temperatures and higher humidity, resulted in less shielded chemical shifts. There was increased peak broadening for kaolinite and montmorillonite with decreasing temperature, although separate peaks were unresolved even at -80C.

Cs and Cd adsorption measurements onto a kaolinite clay substrate show that metal binding is favored at high pH, although Cd is more strongly bound to kaolinite relative to Cs (Fig. 3). Generally, association of metals with hydroxylated mineral surfaces parallels metal-hydroxyl association at high pH in aqueous solutions. The weak binding of Cs relative to Cd therefore, arises from its proportionally weaker tendency to hydroxylate. Potentiometric titrations were done on Al2O3 (6) and SiO2 (7) to resolve pH-dependent surface charge and calculate Al and Si surface site acidities. Adsorption measurements were subsequently done with Cd and regressed to calculate metal binding constants for each oxide. Potentiometric titration measurements were also made with kaolinite slurries at 25 and 50C to evaluate the pH-dependence of multi-site surface charge as a function of temperature. Proton donor-acceptor reactions were found to occur simultaneously on the Si and Al sites exposed at basal planes and edges. We found that the Si site acidity at the kaolinite-solution interface differs minimally from that of pure SiO2, whereas Al sites became appreciably more acidic with substitution into the kaolinite matrix. Increasing temperature causes both Al and Si sites to become more acidic, the Si sites more so than the Al sites. Calculated site densities increase with increasing temperature suggesting appreciable surface roughening. The combination of increasing site acidity and density points to kaolinite having a greater sorptive potential at higher temperatures.

Particles of untreated kaolinite ranges from 0.1 to 0.8 mm in diameter and 100 to 1200 in total thickness. Edge to basal surface area ratios range from 15 to 50%. Edge surface area from small steps on the surface (Fig. 1b), typically 1 to 10 unit cells high (7 to 70), increases the edge area obtained from the gross shape of the grain by a minimum of 10%. The additional contribution of step edge area depends on the number of and average height of the steps. The potentiometric titration results require a site density of 2.25 sites/nm2 to explain the amount of adsorption assuming that the entire BET surface area sorbs hydrogen or hydroxyl ions. Crystallographic site densities are estimated to be 3 to 6 sites/nm2. Therefore, if adsorption occurs only at edge sites where the density of charged sites is highest,

then a minimum of 38% of the BET surface area must be edge surface. This amount of edge surface is approximately the median of the range gleaned from limited AFM observations.

DISCUSSION

One of the primary goals of this study is to identify the specific sites for metal adsorption. Two spectroscopic techniques were employed to characterize Cs-sorbed minerals. XPS surface spectra of reacted montmorillonite samples suggests almost complete exchange of cesium for the original interlayer calcium. Mineral structures without exchangeable cation sites yielded spectra characterized by the presence of strong Cs signals, indicative of Cs sorption on mineral surfaces and along grain boundaries. The presence of single, unresolvable XPS peaks also suggests that the chemical shifts associated with Cs adsorption on edge or basal sites are not very strong. NMR spectra obtained from Cs reacted montmorillonite indicate the presence of a range of interlayer sites that are dynamically averaged at temperatures above approximately 20C. Room temperature 133Cs MAS-NMR spectra for the kaolinite samples, however, show the presence of as many as four distinct sites. The bulk of these sites are thought to be edge and basal plane sites, in addition to some smectite-like 'exchangeable layer' sites. The latter probably result from the presence of small quantities of smectite-like layers on the kaolinite crystallites. Given the sheetlike structure of kaolinite (see Fig. 1), exposed Si and Al sites at the crystal's edge would provide likely sorption sites suggested by the 133Cs NMR spectra.

We also sought to determine if soil clay KD's could be estimated from simple oxide component reactivities. Cd sorption onto kaolinite at 25C is shown in Fig. 3b as a function of pH. The line through the results was independently calculated from the Cd binding constants measured on the single oxides Al2O3 and SiO2. The quality of this fit is exciting because it suggests that metal binding on clay minerals is additive from the oxide components. Note that metal adsorption isotherms have already been measured on the most important (hydr)oxides in soils. The goodness-of-fit of the two-site model suggests that, of the four sites indicated by the NMR work, only two dominate the overall sorptive capacity of kaolinite. However, interlayer cations and multivalent cations commonly found in smectite clays will probably pose special problems when predicting additive adsorption properties for those minerals given the compositional and surface charge variability of expandable 2:1 layer clays. We are, therefore, in the process of extending our efforts to specifically account for these effects. The end result of this work will, ideally, be a methodology by which KD's can be predicted for soils.

AFM examination of the untreated kaolinite demonstrates that edges may comprise over 50% of the available sorbing surface. It is known that metal sorption onto clay surfaces is a function of the charge distribution on the surfaces as well as the absolute proportions of exposed planes of differing surface charge. Although total surface areas can be measured using routine BET methods, the best way to determine proportions of edge and basal surface is to use an imaging technique where all three dimensions can be determined on individual particles. The easiest method for doing this is AFM (8,9). Basal kaolinite surfaces often contain numerous steps of one to a few unit cells in height. AFM examination of a few kaolinite grains revealed at least a 10% increase of edge surface area from such steps beyond that estimated from average particle dimensions. Better statistical characterization of surface area proportions could affect significantly the interpretation of both NMR and experimental adsorption data.

CONCLUSION

XPS analyses of Cs-reacted soil minerals show that Cs is sorbed on the surfaces of corundum, kaolinite, and montmorillonite, but not on gibbsite. The XPS spectra suggest that Cs is sorbed on the interlayer site of montmorillonite and possibly on kaolinite, although the spectral resolution of XPS analyses is insufficient to differentiate between basal, edge or interlayer sites. 133Cs MAS- NMR results demonstrate that Cs is adsorbed in a motionally-averaged interlayer site of montmorillonite. For kaolinite, most of the adsorbed Cs is found on edge and basal sites. Measured sorption isotherms for Cd were found to be additive for simple mixed-oxide clays, suggesting a potential mechanism for predicting the sorptive capacities of other clays. A physicochemical rationale for component oxide acidity shifts in multi-oxide silicates remains an important obstacle. Quantification by AFM of edge and basal surface area for kaolinite showed that edges can comprise as much

as 50% of the total BET surface area. This is consistent with interpretation of H+/OH- adsorption occurring primarily at charged edge sites. By implication, the combined AFM and NMR results suggest that Cs and Cd adsorption also occur primarily at edge sites. These results provide a generalized and systematic method for evaluating adsorption of metals on soil minerals, and could lead to innovative techniques promoting the fixation of the metal (radionuclide) species.

ABSTRACT

The Large Block Tracer Test consists of a series of experiments to study the migration of radionuclides through fractures in rock at the scale of one meter. The separate effects being considered are sorption onto minerals within the rock matrix; diffusion of radionuclide species through the rock matrix, diffusion and hydrodynamic dispersion within the fracture; and the effect of heterogeneity in the fluid flow field (also known as macrodispersion or channeling). The rock fractures that are being used have natural fractures or artificial fractures with engineered heterogeneity. These tracer experiments will provide data with well-defined geometry and conditions for use in code validation. The experiments also provide an experimental framework to test inverse methods. Results are presented for a series of migration experiments using conservative tracers in artificial fractures with near parallel plane and near wedge-shaped fractures. The results are compared with those predicted with transport code TRACR3D (1). The fracture is treated as an equivalent porous medium with a "cubic law" permeability and a porosity that is proportional to the aperture. The results show good agreement, both between experimental results and those predicted by TRACR3D, but also between the distribution of the dye tracer in the fracture and the elution profiles. This suggests that the transport of a tracer through a fracture can be inferred from elution profiles.

INTRODUCTION

The modeling and prediction of radionuclide migration from an underground nuclear waste repository are a complex problem involving many physical and chemical processes. The coupling of these processes depend on the spatial distribution of hydrologic and chemical properties of rock. The exact details of these distributions will probably not be known. Approximations and some form of stochastic modeling will be used. The Large Block Tracer test allows the testing of sorption/retardation models in complex water flow systems. The experiments also provide an experimental framework to test inverse methods.

The primary purpose of Large Block Tracer Test is to study the effects of diffusion and adsorption on the migration of radionuclides through fractures in rock at the scale of one meter. The one meter scale is an intermediate between smaller laboratory scale experiments and the field scale. One meter scale fractures are experimentally more readily characterized because the fluid volumes are on the order of 100 milliliters rather than 100 microliters. The greater fracture volumes allows the fluid velocity to be controlled over a broader dynamic range with standard pumps. The first set of experiments (those described in this work) involves artificial fractures with simplified geometry. This was done to reduce the uncertainty in the fluid flow field (i.e., macrodispersion) so that the effects of diffusion and adsorption could be isolated.

Three different engineered fractures are being used to provide data for validation of transport models and to test inversion algorithms for inverse problems:

1. a fracture with a regular, rectangular cross section to study the effects of matrix diffusion and sorption without a need to consider channeling dispersion,
2. a fracture with grooves at 1 cm centers parallel to the flow along the fracture, to study asymptotic Fickian dispersion at low transport solution velocities, and
3. a wedge shaped fracture with the wedge dipping across the flow field. This fracture geometry has a covariance function for the permeability field that resembles the geostatistical model used by Gelhar (2) to describe stratified aquifers. The wedge shaped fracture approximates an aperture distribution where the correlation length is greater than or equal to the scale of the experiment. This situation has channeled flow and a large macrodispersivity. The results obtained with this type of fracture can therefore be used to model contaminant transport in natural fractures under field conditions.

These fracture geometries have been constructed from granite slabs and have begun to

provide experimental data. Tuff blocks have been excavated in the vicinity of Yucca Mountain and are being prepared for experimentation.
The first phase of experimentation, now completed, is intended to study only the fluid flow in the fracture. The fluid movement is studied visually using fluorescent dye. This phase tests our ability to construct idealized fracture geometries to an acceptable tolerance. Techniques were developed to determine deviations from design and compensate for the effects of those deviations.
EXPERIMENTAL
The Large Block Radionuclide Migration Facility (3) is equipped to handle blocks of rock with a maximum dimension of 1 m and is designed as an IAEA Type B laboratory. Migration experiments and post-experiment radiochemical analyses, including two-dimensional gamma scanning, alpha scanning, and autoradiography of the fracture surface can be performed in this facility.
Slabs of pink granite were obtained from the Cold Spring quarry on the south eastern flank of the Lac du Bonnet batholith near Lac du Bonnet, Manitoba, Canada. To develop the techniques required to establish uniform flow through a fracture with a regular cross section, artificial fractures were assembled from a 4 inch thick, 24 x 24 inch slab of polished pink granite and a 4 inch thick, 24 x 24 inch acrylic sheet, separated by 1/16 inch-thick strips of stainless steel. The surface of the granite slab was polished at the quarry with a mixture of iron oxides and spray painted white to increase the visibility of the colored dye in the fracture. Deviations from flatness were measured both for the acrylic sheet and granite slab. The deviations were determined using a certified, calibrated straight edge and feeler gauges.
To create uniform flow across the width of the fracture with the regular aperture, acrylic inlet and outlet plena were attached to two sides of the fracture; the other two sides were sealed with a silicone sealant (Canadian General Electric RTV-108). Porous polyethylene membranes with uniform pore size of 40 micrometers were inserted between the plena and the fracture to decrease the transmissivity between the inlet plenum and the fracture which could lead to an uneven introduction of the contaminant into the fracture. The outlet plenum was divided into eight equal sections to enable flow from each different area of the fracture to be collected into individual fractions. The parallel plane fracture was used to calibrate the flow through the fracture. Since the transmissivity through a fracture with apertures on the order of 1/16 inch is very high. slight differences in transmissivity in the fracture result in large changes in flow through the fracture. To eliminate this problem, the individual chambers of the outlet plenum were equipped with lengths of very fine bore tubing with an outside diameter of 1/16 inch. By trimming the ends of this tubing, uniform flow could be achieved across the fracture.
Distilled deionized water was used as the transport solution and was pumped through the fracture at a flow rate of 30 mL/hr, giving a residence time in the fracture with the rectangular cross section of approximately 20 hours. A 2 x 10-4 mole/L uranine concentration was used as the conservative dye. These migration experiments were performed over periods of 48 hours. Images of the dye in the fracture were obtained with a SONY Model AVC-P7 CCD video camera connected to a Data Translation Model DT 3851 frame grabber installed in a 80486 personal computer. The camera is triggered by an external trigger using a DAS-16 I/O board installed in a portable 80386 personal computer. The images are stored as .IMG files on the hard drive of the 80486 computer and enhanced with Data Translation Global Image software to produce .TIF files. Five milliliter samples of effluent from each of the eight outlets were taken by automatic fraction collectors.
RESULTS
The results described were obtained from the first set of a series of migration experiments in artificial fractures with a regular, well defined aperture width.
1. TRACR3D calculations
Forward calculations of the transport of both sorbing and nonsorbing tracers have been made using the code TRACR3D. These calculations were made to examine the effects of fracture geometry, adsorption, and sorption kinetics. The calculations have also been used to assist the design of the fracture. The porous material on the inlet and outlet of the fracture, used to make the flow field with the fracture less sensitive to small changes in pressure at the sampling locations, was included in these calculations. The code was used to predict the movement of the nonsorbing

uranine dye. The deviation from flatness was incorporated into the fracture permeability distribution.
The uranine profiles for the parallel plate fracture and for the wedge shaped fracture (shown in Fig. 1) were calculated. Sorption and matrix diffusion were set to zero because the granite face had been coated with epoxy paint The agreement between the calculatedprofiles and observed fronts is good. Only minor artifacts are evident near the boundaries of the fracture.
The wedge shaped fracture was modeled as an equivalent porous medium whose permeability is a function of the aperture (k = w2/12). The porosity of each node was proportional to the average fracture aperture (porosity = local width / maximum width). The permeability at each node is the average of the cubic law permeability for the fracture within the boundary of the node.
The target average flow velocity was 10-3 cm/s. The pressure gradient needed to provide this velocity is found by integrating the velocity across the breadth of the fracture of the fracture, i.e.,
Eq (1)
where u is the average velocity, Lx, is fracture width, Lz is the fracture length, wo is the maximum aperture, Dp is pressure difference across the fracture, and is the viscosity. From this relationship the pressure gradient needed is 0.04 millibars. This calculation shows why it is experimentally difficult to achieve a uniform flow field given small variations in permeability across the components of the inlet and outlet of these experiments.
The uranine concentrations in each of the eight outlet ports in the wedge shaped fracture were calculated using the same aperture distribution. These results are shown in Fig. 2. The earliest breakthrough is predicted in ports 3 and 4 in agreement with the concentration profiles.
Calculations have also been made for the grooved fracture for nonsorbing tracers, sorbing tracers, and high molecular weight nonsorbing tracers. The results of these calculations showed that matrix diffusion tended to reduce the effect of channeling on the tracer concentration in the fracture fluid. Sorption retarded the migration of tracer. The most significant effect of the grooved fracture was observed for the high molecular weight tracer. The effect of channeling appeared to be enhanced for high molecular weight (low diffusivity) tracers.
2. Uranine profiles
The shape of the front of the injected uranine indicated that the flow through the center of the fracture was slightly higher than at the edges. This is due to a slight concavity of the polished granite slab and the acrylic sheet. Since the linear flow velocity through the fracture varies with the square of the fracture aperture, a slight deviation from a uniform cross section is sufficient to create differences in the linear velocity through the fracture. In the case of the rectangular fracture, the aperture al the edges was 1/16 inch. Six hours after the start of the uranine injection, the leading edge of the dye had moved approximately 6 inches along the edges of the fracture, while the center of the front had moved 12 inches. This corresponds to a deviation of 1/38 inch from a perfectly flat surface. After 24 hours the dye injection was discontinued and the experiment continued with deionized water at the same flow rate. For the wedge-shaped experiment, the spacer was removed from one side of the block and the spacer on the other side was replaced by a 3/16 inch spacer. This kept the same average permeability for the fracture. The dye injection was again discontinued after 24 hours and the experiment continued with deionized water at the same flow rate. The resulting profiles are shown in Fig. 3 for 3, 6, 24, and 30 hours, respectively. The wedge shaped fracture geometry dominated the flow pattern but the effect of the cupped granite surface was still evident.
The effluent from each of the eight outlet plena was sampled using fraction collectors. The sample concentrations were analyzed using spectrophotometry. The concentrations in the eluted fractions are shown in Fig. 4. The effect of concavity of the fracture is again evident with the earliest breakthrough occurring in outlet ports 3 and 4. The breakthroughs were delayed (as expected) in the narrower part of the fracture. The dispersion (as evidenced by the lower slope of the leading edge) increased as the fracture became narrower. This is due to the greater deviation (across the portion of the fracture sampled) from the average flow in the portion of the fracture sampled.
Figure 2 Concentration in outlet plenum as a function of time and position across

fracture.
The results show good agreement, both between experimental results and those predicted by TRACR3D, but also between the distribution of the dye tracer in the fracture and the elution profiles. This suggests that the transport of a tracer through a fracture can be inferred from elution profiles.
An algorithm for inverting two dimensional integral equations has been developed. The method applied is that of Tikhonov (4) regularization. This code will be used to sharpen the images obtained by 2-D gamma scanning of radionuclide tracers retained on the surfaces of the fracture at the completion of the experiments. The code has been tested by reconstruction a regular image that had been distorted by a gaussian filter. The recovered image was sharpened considerably and was in good agreement with the initial image. This algorithm has also been incorporated into the TRACRI (5) code. TRACRI will be used to infer permeability fields from tracer experiments.
Transport of a nonsorbing tracer in the wedge shaped fracture has been calculated with TRACR3D and with one dimensional approximations. The stochastic model of Gelhar agrees very well with the TRACR3D calculation. The differences are small for nonsorbing tracers. Dispersivities inferred from migration experiments using nonsorbing tracers have been found to be too small to adequately predict the dispersion of sorbing tracers (6). Future experiments will be used to test this observation.

CONCLUSION

Construction of 1 meter scale artificial fractures from granite slabs has been completed. Calculations have been completed that predict the effects of matrix diffusion and sorption on the transport of radionuclides through the fractures. Experiments are starting to provide data for validation of the TRACR3D code.
The experiments have shown that:
1. It is experimentally difficult to engineer an ideal fracture geometry but deviations can be accounted for in the modeling.
2. Simple fractures, i.e., a wedge shaped fracture provides a realistic model of macrodispersion because the covariance function of this fracture is similar to some geostatistical models. This is validated by the excellent agreement between calculated and measured concentration profiles.
3. The fluid dynamics in these simple fracture geometries can be predicted with sufficient accuracy so that the effects of adsorption and diffusion can be studied unambiguously.
We are most interested in determining under what conditions the spatial distribution of fracture aperture and connectedness (i.e., the permeability) can be found from flux and transport measurements. This is an inverse problem and, in general, such problems cannot be solved uniquely to any arbitrary level of resolution. However, it is possible to resolve the unknown structure down to some spatial scale with an uncertainty in resolution inversely related to the scale. given sufficient observations of the system's response. In our present experimental design, with fluxes measured at eight outlet ports, the flow paths through the wedge fracture can only be coarsely estimated. This uniqueness difficulty can be alleviated by adding constraints. In this case, we have the concentration profiles of the uranine dye at each outlet port. This information can be used to reduce the magnitude of uncertainty in the fracture geometry. If we add one further constraint, that the geometry has a self-affine structure, for example, further improvement in resolution is possible. Through a sequence of simulations with our inversion model TRACRI, we show how addition of each of these data sets and constraints improves the resolution of the fracture geometry.
The results of these preliminary studies look promising for the development of a better understanding of the consequences of channeling dispersion to radionuclide migration through rock.

ABSTRACT

In assessing the performance of low-level waste disposal sites it is often found that the release of many long-lived radionuclides is controlled by solubility and interactions between the surrounding media and contaminant in solution. BLT-EC is a computational tool that directly incorporates the effects of chemistry on the release and transport from LLW disposal facilities. The capability to calculate the changes in chemistry over time due to interactions with the engineered barrier, containers, and wastes makes BLT-EC an extremely powerful tool for performing detailed calculations within the disposal region. Results from these detailed calculations can be used to support selection of parameters (solubility limits and distribution coefficients) used in performance assessments. As an illustrative example, the BLT-EC code has been applied to analyze the chemical conditions in LANL Area G pit 37. Pit 37 wastes contain a heterogeneous mix of metals, cellulosics, concrete, soils and sludges. The initial geochemical assessment focuses on estimating the range of environmental conditions that can be expected in the pit. Emphasis is placed on estimating the pH and Eh changes due to corrosion of metal components and dissolution of concrete.

INTRODUCTION

Under most shallow land disposal conditions, the ground-water pathway is the most common and important pathway for the release of radionuclides to the accessible environment. For low-level waste (LLW) disposal, release may be controlled for periods of hundreds of years by the presence of engineered barriers (disposal unit, containers, and waste form). However, at longer times and away from the engineered barriers, control of the movement of contaminants is obtained through chemical processes (sorption, precipitation, solubility, etc.).

In assessing the performance of LLW waste disposal sites it is often found that the release of many long-lived radionuclides is controlled by solubility and interactions between the surrounding media and contaminants in solution. In general, the role of chemistry is treated in an ad hoc manner by modeling porous media/contaminant interactions using an empirical parameter known as the distribution coefficient. This coefficient is the equilibrium ratio of the amount sorbed on the porous media to that in solution. For many contaminants the value of the distribution coefficient can range by several orders of magnitude depending on the chemical conditions (pH, Eh, presence of competing ions, etc.) and the properties of the sorbing media. Similarly, solubility limits are chosen from literature values or, whenever possible, from site-specific information. Again, the value for the solubility limit of a contaminant depends strongly on the existing

chemical conditions.
The chemical conditions in a disposal unit are expected to be quite different than those in the surrounding undisturbed soil. In particular, corrosion of metallic materials and leaching of cement based waste forms and engineered barriers are likely to control the pH, Eh, and local chemistry. Since radionuclide sorption and solubility properties are strongly dependent on the chemical conditions, choosing appropriate values for these properties without knowledge of disposal unit chemistry may in some cases be highly problematic.
In an attempt to provide a tool that uses a more direct approach at incorporating the effects of chemistry on the release and transport from LLW disposal facilities Brookhaven National Laboratory, BNL, has developed a coupled geochemical transport code, BLT-EC (Breach, Leach, Transport - Equilibrium Chemistry) (1). During the past several years BNL has been developing a family of computer models that predict the release and ground-water transport of radionuclides from LLW disposal facilities. These models are capable of predicting waste container degradation, waste form leaching, and radionuclide migration with retardation and first-order decay in unsaturated or saturated porous media. BLT-EC improves upon these models by including chemical processes. These chemical processes, under the assumption of chemical equilibrium, are represented by a set of nonlinear algebraic (mass action and mass balance) equations that describe how the various chemical constituents are distributed among the solid, dissolved, adsorbed, and gas phases present in the pore space. Oxidation/reduction, precipitation/dissolution, complexation, and sorption reactions may be simulated.
BLT-EC combines segments of three existing computer codes, BLT (2), HYDROGEOCHEM (3), AND MINTEQA2 (4). The container and waste-form performance models (Breach and Leach) in BLT are used to estimate the time at which release begins and the rate of release of contaminants from the waste forms. The transport model in the BLT-EC computer code is based on a modified version the hydrological transport module contained in the finite-element code HYDROGEOCHEM (3). The geochemical model used to solve the chemical equilibrium equations in BLT-EC is a modified version of the geochemical computer code MINTEQA2 (4). The fact that this geochemical computer code has a large user community was an important factor in the selection of this code for BLT-EC. In addition, the code's extensive thermodynamic data base is continually being expanded for applications in radioactive waste management.
The capability to calculate the changes in chemistry over time due to interactions with the engineered barrier, containers, and wastes makes BLT-EC a powerful tool for performing detailed calculations within the disposal region. Results from these calculations can be used to support selection of parameters (solubility limits and distribution coefficients) used in performance assessments.
The ability of BLT-EC to simulate interactions between chemical processes and transport was demonstrated on an example field-scale problem (5). In this paper, an illustrative example of the use of BLT-EC in estimating the pH and Eh conditions due to corrosion and leaching of metal and cement based materials in an existing Los Alamos National Laboratory (LANL) LLW disposal facility will be provided. Emphasis will be placed on determining the range of values that can be expected and their potential impact on the mobility of uranium.
This paper is outlined as follows. We begin by providing a description of the LANL LLW disposal facility examined in this study. A geochemical conceptual model is then presented that outlines the important chemical and transport processes likely to occur in the facility. BLT-EC is subsequently used to predict spatial and temporal variations of pH and Eh in a particular LLW disposal pit. This information is then used to assess the potential importance of in situ chemical conditions and their impact on the mobility of important radionuclides. Ultimately this information will be used to help select appropriate radionuclide distribution coefficients and solubilities for the performance assessment of the LANL LLW disposal facility.
Facility Setting and Description
The disposal facility is located at LANL's Technical Area 54 (TA-54), area G on Mesita del Buey, a mesa of the Pajarito Plateau, approximately 4 km (2.5 mi) southeast of the town of Los Alamos. Mesita del Buey is a narrow, gently sloping mesa bounded by Canada del Buey to the northeast and Pajarito Canyon to the southwest. It is at an elevation of approximately 2030 m, 30 to 40 m (98 to 130 ft) above Canada del Buey and Pajarito Canyon, and 260 m (850 ft) above the main aquifer.

LANL began disposing of LLW at TA-54, Area G in 1957. Since then 35 pits (trenches) and nearly 200 shafts have been excavated into the native Bandelier tuff and filled. Pits are used to dispose of "routine" LLW, which generally consists of refuse from laboratory processes (e.g., paper, glassware, small benchtop equipment), facility upgrades (e.g., ductwork, conduit, large machine-shop equipment), and clean-ups (e.g. building an environmental media). Routine LLW is contaminated at such low radionuclide concentrations that it poses inconsequential radiological risk during disposal operations. Shafts, on the other hand, are used to dispose of "non-routine" waste that requires special handling, containment, or disposal due to either its regulatory status or radiological characteristics.

Pit 37 is the most recently filled disposal unit at TA-54, Area G. Disposal in this pit began in 1990 and ceased in 1994. During this time, enhanced waste characterization records were maintained a result of recently implemented waste generator and disposal facility requirements. As a result, Pit 37's inventory is considered the most complete of Area G's disposal units. The material inventory includes (in descending order of volume) metals, cellulosics, concrete, soil, and sludges. A graphical representation of material volumes is shown in Table I. These waste forms are generally disposed of in plywood boxes (metals), cardboard boxes (cellulosics), bulk (soil and concrete), and metal drums (sludge). Radionuclides of concern include americium (Am), carbon (C), Cesium (Cs), cobalt (Co), neptunium (Np), Strontium (Sr), plutonium (Pu), technetium (Tc), tritium (3H), and uranium (U). In Pit 37, most of the activity is associated with U-contaminated metal (8.16 Ci) and Pu-contaminated cellulosics (4.37 Ci).

The dimensions of pit 37 are approximately 18 meters deep by 25 meters wide by 223 meters long, providing over 43000 m3 of volume. Waste was emplaced in nine layers, each approximately 1.5 meters thick, and separated by at least .3 meters of compacted crushed Bandelier tuff derived from native soils. Crushed tuff is also placed between containers as backfill, then compacted in place to minimize void space and reduce the potential for subsidence due to container failure. The resulting waste-to-backfill ratio is approximately one-to-three.

GEOCHEMICAL PROCESSES

As ground water infiltrates through disposal pit 37, its chemistry will change due to mixing with pore water and reaction with various waste form, container, contaminant, and soil constituents. The reactions that take place will modify the existing chemical form of the contaminants in the disposal facility and therefore alter their leachability and mobility. This degree of alteration will largely depend on two factors; the chemical properties of the infiltrating water and the evolution of water chemistry as the infiltrating water passes through the disposal unit. Analytical results of ground water collected at LANL's Water Canyon Gallery are provided in Table II. This native ground water is likely to be representative of recharge (noncontaminated) within pit 37. Concentrations of Cl, NO3, and PO4 are less than 1 mg/kg suggesting that anthropogenic species are not present. The presence of dissolved carbonate species may be important since they can enhance the mobility of some contaminants. For example, uranium solubility tends to be enhanced by the presence of carbonate species and the subsequent formation of Uranyl carbonate complexes, particularly if the uranium is hexavalent. These complexes are often negatively charged which tends to enhance their mobility.

Metal corrosion and leaching of cement based materials can significantly modify the chemistry of infiltrating water by generating ferrous iron and calcium hydroxide. The degree of modification in pit 37 may be substantial considering the large volumes of metal and concrete disposed (recall Table I). Corrosion of steel materials provides an appreciable source of iron to the aqueous phase which helps buffer oxidizing conditions in the region around the containers. The hydrolysis of iron also tends to decrease the pH of leachate. A simplified description of these processes is as follows (6). Assuming that the contributed iron from corrosion is FE(II), its oxidation consumes dissolved oxygen and hydrogen ions according to the following reaction:

$$Fe^{2+} + 0.25\ O_2 + H^+ \rightarrow Fe^{3+} + 0.5\ H_2O$$

The aqueous concentration of FE(III) increases as oxidation continues until saturation with respect to FE(III) oxyhydroxide is reached and precipitation occurs according to the hydrolysis reaction:

$$Fe^{3+} + 3H_2O \rightarrow Fe(OH)_3 + 3H^+$$

The result of both reactions is the net production of two moles of H+ for each mole

of Fe(II) oxidized, which tends to increase the acidity of the pit leachate. In general, several other iron redox and hydrolysis reactions will also occur but the above two reactions convey the essential point. It should be noted that corrosion products (iron oxyhydroxides) may also provide a good substrate for sorption of radionuclides.

The impact of iron corrosion on pore water acidity can be counteracted by the leaching of calcium hydroxide (Ca(OH)2), which can comprise up to 25% of the volume of cement materials (7). The generation of Ca(OH)2 helps buffer the acidic conditions by providing a source of OH- ions.

Knowledge of pH conditions in pit 37 is important because of its effect on solubility, sorption, and speciation characteristics of radionuclide species. The concentration of hydroxides, for example, directly affects the solubility of metal hydroxide and radionuclide species; as pore water becomes more acidic the concentration of the hydroxide ion decreases, causing an increase in radionuclide concentration and solubility. Moreover, a soil's capacity to adsorb contaminants is frequently influenced by pH. For example, amorphous precipitates such as iron oxyhydroxides have a zero point of charge (ZPC) of approximately 8.5 (8). At pH levels below the ZPC, the surface charge is positive. Thus, anionic complexes of U, Am, Np, Pu, and Tc will have a tendency to adsorb to a lesser extent than cationic complexes of the same elements at pH values greater that the ZPC for specific adsorbents. Cationic species of the elements of concern adsorb onto smectite and ferric oxyhydroxide to a greater extent than anionic species at pH 7 and higher. Many radionuclides are also susceptible to changes in speciation because of changes in pH. For example, many radionuclides form carbonate precipitates at higher pH levels while they do not form carbonate compounds at lower pH levels.

Redox conditions are also important in pit 37 because many hazardous and radioactive chemicals, such as the actinides, have multiple valences and are subject to redox reactions which yield species that have sharply contrasting solubility and sorption characteristics. For example, anionic complexes of U, Am, Np, Pu, and Tc tend to adsorb to a lesser extent than cationic complexes of the same elements at pH values greater that the pH ZPC for specific adsorbents. Cationic species of the elements of concern adsorb onto smectite and ferric oxyhydroxide to a greater extent than anionic species at pH 7 and higher.

Based on the above discussion, it is evident that pH and Eh conditions will control the mobilities of several key radionuclides. Moreover, these conditions are strongly dependent on the balance between the impact of infiltrating water and its constituents, acidity generated by ferrous iron oxidation reaction, and the buffering effect of cementitious materials. These processes are examined in the next section using BLT-EC.

Application of BLT-EC

Each of the package and waste materials in Pit 37 have the potential to affect the chemical environment in the disposal unit to a degree that may impact leach and/or transport rates of important radionuclides; in particular:

- Oxidized metal will alter the reduction-oxidation potential and tend to lower pH conditions.
- Cement leaching will provide a buffering effect on pH conditions.

Although chemical reactions certainly occur in the Area G disposal units, it is difficult to know whether these reactions should be considered in source term modeling. The primary objective of this work is to gain a preliminary understanding of the significance of metal waste form corrosion and cement leaching on the chemical conditions in Area G disposal units.

The potential interactions between corrosion and cement leaching in Pit 37 are examined here by considering transport with reaction in a vertical, one-dimensional column representation of the pit. This approach is based on the following simplifying assumptions:

- The metal and cement based materials are homogeneously distributed throughout the pit.
- Water infiltration through the pit is unidirectional and downward at a constant rate.
- The release of iron (Fe(II)) and calcium hydroxide (Ca(OH)2) due to corrosion and cement leaching occur at constant rates.

As noted above, the problem domain is taken to be a one-dimensional column. The ground surface is located at 0.0 meters and the downward direction is positive with

the column reaching a depth of 25 meters, 7 meters beyond the bottom of the pit. The column has a porosity of 0.5, a bulk density of 1.2 g/cc, and a dispersivity of 0.5 meters. For each simulation, the column was partitioned into fifty finite elements of size 0.5 m x 0.5 m. Simulations were conducted for 150 years using a constant time step of 0.5 years. One iteration between transport and reaction calculations was allowed.

Eleven chemical components were considered; their initial pore water concentrations (mole/l) in the column were as follows: H+ = 8.65x10-4, Ca+2=1.73x10-4, F-1=3.15x10-6, CO3-2=7.31x10-4, Mg+2=1.15x10-4, Na+1=2.13x10-4, PO4-3=7.37x10-7, SO4-2=2.97x10-5, Zn+2=7.65x10-7, Fe+2=0.0, and Fe+3=1.0x10-8. This composition is similar to the native ground water given in Table II, but with some of the lesser important constituents neglected to reduce computational effort. The partial pressure of oxygen was held fixed at a constant 0.2 atmospheres during the course of the simulations. At the top of the column (ground surface), the composition of the incoming water was set equal to the initial pore water composition. The initial pH and Eh values under these conditions are 7.6 and 770 millivolts, respectively. Finally, concrete and metal materials are assumed to be emplaced between the depths of 2.5 meters and 18 meters.

In situ degradation of metals and concrete materials are complex processes and are not well understood. These processes are strongly dependent on chemical conditions such as pH, availability of oxygen, and sulfate concentrations in addition to the degree of system drainage (9). Typical corrosion rates for steel range from as high as 7 x 10-2 cm/yr for carbon steel (9) to as low as 3 x 10-8 cm/yr for 316 stainless steel (10). Concrete degradation rates can be as high as 1 millimeter/yr (11). For the base case simulations, we selected the steel corrosion rate as 3 x 10-8 cm/yr and the concrete degradation rate as 0.01 millimeter/yr. In order to convert these rates to source terms for Fe2+ and Ca(OH)2 having units of moles per unit volume per unit time it is necessary to estimate the surface area per unit pit volume for both the metal and concrete materials. Estimates were obtained by assuming that the ratio of material surface area to the cross-sectional area of the pit is equal to the ratio of material volume to the pit volume. Surface areas for the metal and concrete were estimated to be 92 m2 and 11 m2, respectively. In addition, we assumed that the concrete materials are comprised of 25% Ca(OH)2. Based on these assumptions, the Fe2+ and Ca(OH)2 source terms are QI = 1 x 10-7 moles-Fe2+/m3-yr and Qc = 2 x 10-6 moles-Ca(OH)2/m3-yr, respectively.

A total of four simulations were performed for this study. Two simulations were performed using the source term values noted above; two additional simulations were performed using increased source term values. The four simulations are described in Table III as follows.

Simulation results for these cases showing the distribution of pH and Eh at different times are presented in Figs. 1, 2, 3, 4. As shown, Figs. 1 through 3, the pH values throughout the column initially increase and then gradually decrease with time as Fe3+ hydrolysis reactions become increasingly significant. At the lowest source term rates, only minor variations occur in the Eh and pH. Figure 1 displays this for Case 1. Case 3 with the higher flow rate is similar and not shown here. The largest variations in pH occur in cases 2 and 4, Figs. 2 and 3, the cases with the largest source terms. The pH drops below 7.0 in these two cases, with the majority of the pit being slightly acidic at 150 years in the simulation with the lower flow rate, case 2. Comparisons between cases 2 and 4 also show that an increased infiltration velocity tends to enhance the reduction in pH.

Eh values are oxidizing and range between 700 and 820 millivolts, Fig. 4. The results also indicate a linear relationship between pH and Eh; note that the pH and Eh curves for each case are inverted images of each other, compare Figs. 3 and 4. For this reason, other Eh figures are not presented here. These results are not surprising. Although Eh values were computed directly by BLT-EC during the course of solving for chemical equilibrium, their relationship with pH in this problem is determined by the redox limit of aqueous systems and is given by (12):

$$Eh = 59.2(20.78 - pH + 0.25 \log PO2)$$

The simulation results show the potential importance of metallic corrosion and cement degradation processes on solution chemistry within pit 37. Although lower bounds were used for corrosion and degradation rates, these processes still had a significant effect on the evolution of pH and (Eh) in the pit. At both flow rates, the general trend was for the pH to increase to about 8.7 during the first fifty

years and then gradually decrease over the next 100 years to values near 7.0. At higher metallic corrosion rates the reduction in pH would likely be much more substantial and the pH may fall well below 7.

Role of pH on Uranium Mobility

As noted earlier, pH can have a significant effect on the solubility and sorption characteristics of contaminants. In oxidizing environments, sorption is generally a more important control on uranium mobility than precipitation of uranium minerals (13). Hsi and Langmuir measured adsorption of uranium in well characterized systems and found that at pH values above 6, dissolved uranium species are strongly adsorbed onto amorphous ferric oxyhydroxide. This sorption behavior may be significant in pit 37 because of the large quantities of amorphous ferric oxyhydroxide precipitates likely to be present due to corrosion.

Two MINTEQA2 calculations were performed to determine the speciation of uranium for pH values of 6 (Eh = 882 mV) and 8 (Eh = 769 mV). The composition of the water corresponded to the native ground water described in Table I. The initial concentration of uranium was 10-6 moles/liter of UO2 2+. At the lower pH value approximately 90% of the uranium exists as neutral uranyl dicarbonate (UO2CO3), whereas at the higher pH approximately 90% of the uranium is predicted to exist as UO2(CO3)3-4. The neutral species will have a lower affinity for sorption than the anionic species.

Summary and Conclusions

A preliminary analysis of the influence of metallic corrosion and cement degradation on pH and Eh has been performed for the conditions found in Los Alamos National Laboratory's disposal pit 37. Two water flow rates were used for the simulations: 0.02 m/yr and 0.002 m/yr. The analysis modeled the corrosion process through a constant source term of Fe2+ and cement degradation as a constant source of Ca(OH)2. A lower bound was determined for the release rates of these contaminants. Below these release rates, substantial changes to the ambient chemical conditions will not occur. These lower bounds correspond to corrosion rates on the low end of the range of measured values for stainless steels in soil systems. Therefore, it is likely that the actual corrosion rates will be higher and metallic corrosion will play a substantial role in determining solution chemistry within the pit.

Increasing the cement degradation rates and the metallic corrosion rates by one order of magnitude above the lower bounds resulted in changes in the pH by as much as one order of magnitude. At the lower flow rate, 0.002 m/yr, changes remained localized within the waste region of the pit. At the higher flow rate, 0.02 m/yr, the incoming rain water moved the contaminants out of the pit region in sufficient quantities to alter pH several meters beneath the pit. At both flow rates, the general trend was for the pH to increase to about 8.7 after 50 years due to the dissolution of Ca(OH)2. At later times, the pH decreased due to the corrosion of Fe and the interactions with the incoming rain water. The model predicts the pH will be near 7.0 after 150 years in the pit at the low flow rate. At the high flow rate, the minimum value of pH within the trench is 6.8.

The analysis is a first step in the evaluation of the evolution of chemical conditions in Pit 37. Several refinements to the model would be necessary to better define the chemical conditions in the pit. These refinements would include:

Better characterization of the metallic components to improve the estimates of available surface area and potential corrosion rates. A more sophisticated cement degradation model to account for release of calcium silicates.

Inclusion of the chemical properties of the Bandelier tuff used as backfill

Simulation of the solubilities and sorption properties of key radionuclides as a function of the pH and Eh.

The model development and part of the model application portion of this work is sponsored under the auspices of the United States Nuclear Regulatory Commission Office of Research. The model application was sponsored, in part, by the United States Department of Energy Waste Management Program through contract with Los Alamos National Laboratory.

ABSTRACT

The contact between an obsidian flow and a steep-walled tuff canyon was examined as an analogue for a high-level waste repository. The analogue site is located in the Valles Caldera in New Mexico, where a massive obsidian flow filled a paleocanyon in the Battleship Rock Tuff. The obsidian flow provided a heat source, analogous to waste panels or an igneous intrusion in a repository, and caused evaporation and migration of water. The tuff and obsidian samples were analyzed for major and trace elements and mineralogy by INAA, XRF, X-ray diffraction, and scanning electron microscopy and electron microprobe. Samples were also analyzed for D/H and 39Ar/40Ar isotopic composition. Overall, the effects of the heating event seem to have been slight and limited to the tuff nearest the contact. There is some evidence of devitrification and migration of volatiles in the tuff within 10 m of the contact, but variations in major and trace element chemistry are small and difficult to distinguish from the natural (pre-heating) variability of the rocks.

INTRODUCTION

The U.S. Department of Energy has selected the Yucca Mountain Site (YMS), located in Nevada, as a potential repository for disposal of high-level commercial radioactive waste. Yucca Mountain is composed of rhyolite tuffs, in various states of welding and devitrification. To determine the suitability of YMS for safe storage, it is necessary to predict the chemical and physical response of the tuffs to local and site-wide heating for 10,000 years. For over a decade, scientists have used geochemical, thermal-hydrologic, and geomechanical codes to model the interaction of the tuffs, groundwater, and the radioactive waste. Most models focus on the degradation of the waste containers, dissolution of radionuclides in the waste, and the eventual diffusion, advection and sorption of the dissolved contaminants (1). However, the dissolution of the tuff minerals, and consequent reprecipitation in cooler regions, generation of halogen-rich gases, and polymorphic transitions must also be modeled, since these processes affect permeability and structural integrity of the host rocks.

Uncertainty in the models arises from the need to extrapolate from equilibrium conditions, or small-scale experiments performed on the bench top over days or months, to meter- and km-scale processes occurring in the repository over thousands of years. Radionuclide solubility and sorption calculations are based principally on equilibrium thermodynamics, and a limited number of laboratory tests to assess the rate of important reactions. The accuracy of the extrapolations can have a dramatic effect on the predicted safety of the repository. For example, some models predict that clinoptilolite, which strongly absorbs Cs and Sr, will form as the tuffs alter; other models predict the formation of less-sorptive mordenite, or even a non-sorptive feldspar-quartz assemblage from the same rocks (2,3).

One means to reduce this uncertainty is to study natural analogues -- large masses of geologic materials that were subject, over hundreds to millions of years, to processes analogous to those expected for the repository. The Valles Caldera, located in the Jemez Mountains of northern New Mexico (Fig. 1A), provides a good natural analogue for many of the processes expected at YMS. In the southwest corner of the caldera, the Banco Bonito obsidian (BBO) flow filled a steep-walled canyon cut in the Battleship Rock tuff (BRT). The obsidian, initially at temperatures in excess of 850C , heated the porous tuff in the canyon walls and vaporized much of the pore water. The goals of the Valles Natural Analogue Project were to: 1) search for evidence of chemical and mineralogic changes in the tuff -- specifically changes that occurred in response to the heating event; 2) provide a well-characterized example for testing chemical migration models; and 3) provide guidance for future analogue studies and code development.

Fig. 1. Study sites for the Valles Natural Analogue project. 1A: geologic map of Valles Caldera. 1B: vertical contact between pink-gray tuff spire (left) and blocky, blue-black obsidian (right). 1C: horizontal contact.

GEOLOGICAL BACKGROUND

The Valles Caldera formed following the eruption of the Otowi and Tshirege Members of the Bandelier Tuff, at 1.45 and 1.1 Ma (4). Subsequent to the last major eruption of the Bandelier Tuff, the caldera collapsed and a lake formed in the central depression. The Deer Canyon Rhyolite erupted in the central portion of the caldera, accompanied by landslides off the topographic rim, so that approximately 600 m of fill was deposited over the foundered cauldron floor. As lacustrine deposition waned, a resurgent dome (Redondo Peak) with 900 m of relief formed in the central portion of the caldera. From the beginning of resurgence to 540 ka, numerous rhyolite domes erupted along the ring fracture. The last volcanic activity in the region included eruption of the BRT. A deep, steep-walled canyon was eroded into the porous BRT, and the canyon was subsequently filled with 150 m of rhyolitic obsidian (the BBO flow). The ages of these units are uncertain because of ambiguities inherent in current dating methods (5); however, 40Ar/39Ar ages obtained for this study show both units are 400 to 250 ka old. After the BBO filled the ancestral canyon, the modern-day San Diego Canyon was eroded to the west, exposing much of the BRT-BBO contact. For the purposes of this study, the BRT is analogous to the tuffs at the YMS, and the BBO provides a heat source analogous to repository waste panels or a disruptive igneous intrusion. The contact region between the two units is the focus of our analyses.

SAMPLING AND METHODS

Initial samples were taken from VC-1, a vertical core hole drilled through a lobe of

the BBO. However, the VC-1 samples suffered several limitations. First of all, the core samples are small and potentially unrepresentative. More important, the BRT-BBO contact in the corehole is represented by a thick breccia zone, smearing and adding ambiguity to any observed chemical trends. Therefore, additional samples were obtained from the cliffs of the present-day San Diego Canyon, where the BRT-BBO contact is exposed in outcrop (Fig. 1B and 1C). These outcrops are near the very edge of the flow, where the flow stopped against the steep walls of the ancestral canyon; consequently the breccia zone is small to non-existent. Samples were taken from "horizontal" contacts (Fig. 1C), which provided long sampling paths, and vertical contacts (Fig. 1B) where there is little possibility of contamination by a soil layer.

Bulk chemical and mineral analyses were obtained by a variety of techniques, including: instrumental neutron activation analysis (INAA), for trace elements such as U, Th, Cs, Rb, Ba, Ta, Hf and rare earths; glass disc X-ray fluorescence (XRF) for major elements; pressed-pellet XRF for Cl and S; ion chromatography (IC) for leachable anions; fluoride ion-specific electrodes; and X-ray diffraction (XRD), electron microprobe (EMP), and scanning electron microscopy (SEM) to identify and analyze mineral phases and the abundance of glass. To test effects of heterogeneity, the tuffs were broken down into fine-grained matrix components and clasts (including xenoliths from older units), and heavy mineral separates. Differences between matrix and whole rock analyses proved to be small, and it was determined that the abundance of heavy minerals (including oxides and sphene, as well as micas, pyroxenes and amphiboles) was too small to account for significant variations in rare earth, F, and U or Th contents.

RESULTS

Figure 2 gives a sample of chemical variations observed at two outcrop sites as a function of distance from the BRT-BBO contact. Figures 2A and 2B show representative volatile contents at site 12, a vertical contact, and site 13, a "horizontal" contact (the latter has a horizontal exposure, but the BRT-BBO interface dips into the cliff face at 45). Note the large difference in the distance scale for the two sites. In all sites examined, F and Cl have an antipathetic behavior, with Cl depleted near the contact, and F enriched in the same region. Physical effects of the heating are more pronounced at site 12, where the tuff nearest the contact is deformed and obsidian clasts are oriented parallel to the contact; evidently, the contact tuffs were raised above the glass softening point (ca. 670C). At site 13, the tuffs nearest the contact have lower glass contents (are more devitrified), and are depleted in Cl and water; there is also a slight but statistically significant increase in dD near the contact. In contrast, non-volatile trace elements such as Ce, U and Ta (Fig. 2C and 2D) show little or no systematic variation. Cs may increase slightly toward the contact, but the increase corresponds to systematic changes in CaO, FeO and Na2O contents, and may reflect original variations in tuff composition. Variations of most other analytes were quite small; for example, bulk silica in the site 13 tuffs varied from 70% to 72%, with standard deviation less than 1%.

Fig. 2. Chemical variations at sites 12 and 13 as function of distance from BBO-BRT contact.

Mineralogical changes in the tuffs, as a consequence of heating, are slight. The voids of pumice shards (that comprise the tuff matrix) are lined with delicate, sub-mm lathes of albite and less abundant silica polymorphs; qualitatively, the amount of void-lining drops off with distance from the contact. Near the contacts, the matrix glass shards have partly devitrified to micro-porous, extremely fine-grained intergrowths of feldspar and silica. The Rb/Cs, a potentially sensitive indicator for clay/zeolite development, shows little variation (Fig. 2C). Neither XRD nor SEM analyses showed unambiguous development of zeolites or clays in the outcrop samples. Attempts to beneficiate fine-grained zeolites and clays, by standard settling techniques, yielded no clay or zeolite peaks in XRD spectra.

GAS TRANSPORT EXPERIMENTS

The chemical analyses above suggest we should seek mechanisms for transport and concentration of volatiles, particularly F and Cl. We developed a simple thermal model for the obsidian flow-tuff system, based on the Stefan solution (6,7), that accounted for evaporation, convection and radiation at the top of the obsidian flow, and boiling and conduction at the BRT-BBO contact. Because the tuff is very porous and has a comparatively low conductivity, temperatures well above the glass

softening point could be sustained at the contact for hundreds of years, consistent with our observations of plastic deformation in the vertical contacts. In addition, the boiling front may have been tens of m from the contact for up to a thousand years. Thus it is important to examine the behavior of the halides in steam, and determine if gaseous transport, alone or in concert with some other mechanism, could lead to the observed variations in F and Cl abundances (Fig. 2).

A simple flow-through system was constructed to measure release rates of F, Cl and metals from tuff as a function of temperature and time. Sample of crushed, washed tuff were packed between wads of silica wool in a 2.5 cm diameter, 50 cm long silica tube, and the tube was placed in a tube furnace. By means of a silica carburetor and low-volume peristaltic pump, steam was fed through the system, condensed, and collected for INAA and IC analysis (apart from Na, no trace elements were detected by INAA). Two experiments were performed; in the first, the temperature was ramped from 125 to 800C, and held at each increment for several hours; 1383 g of steam was passed through 33.2 g of tuff in 15 days. In the second, the sample was held at 400C for 54 hours; 172 g of steam was passed through 33.8 g of tuff.

Results of the two experiments are shown in Fig. 3A,B. Figure 3A gives the apparent gas/rock KD . While there is divergent behavior of Cl and F at T <600C, the apparent KD is 1 for both elements in this range, suggesting that steam-rock partitioning alone is a poor mechanism for causing the antipathetic behavior of Cl and F (Fig. 2A), and is probably inadequate to explain the F concentrations observed near the BRT-BBO contacts. However, the interaction can produce steam containing tens of ppm F, which may condense and interact with tuff elsewhere. Figure 2B, for the second experiment, shows the decrease in loss rate with time. The fitted curves assume a pure diffusion model for release of F and Cl from the glass shards, assuming the glass septa are 10 mm thick (consistent with SEM examination). The regression line for F yields an initial matrix F of 277 ppm, consistent with our chemical analyses, and a diffusion coefficient of 1.510-12 cm2/sec. The solid line fitted to the Cl data uses all points; the dashed line omits the first 3, which are potentially contaminated with the system blank. These two fits yield initial Cl of 2.7 and 4.2 ppm respectively, and diffusion coefficients of 6.310-12 and 1.610-12. The calculated initial Cl contents are clearly wrong, suggesting the control on Cl loss is not pure diffusion. However, the calculated 400C diffusion coefficients for both F and Cl are consistent with literature estimates (8,9).

Fig. 3. Results of flowing gas experiments.

CHEMICAL VARIATIONS INDUCED BY CAPILLARITY/EVAPORATION

The existence of a boiling front can create complex compositional variations in heated tuffs. Travis and Nuttall (10) calculated the distribution of SiO2 and Cl in fractured and porous tuff, as functions of time and distance from the waste canister heat source. A hot, dry zone forms immediately around the canister; the boiled water condenses several m away, yielding a concentric zone of saturation. Capillary action draws the water outward from the condensation zone; not only is the water drawn away from the heat source, out into the cooler tuff, but it is also drawn back towards the heat source. At a given time, whole rock SiO2 and Cl tend to peak on both sides of the condensation zone. On the hot side, evaporation tends to concentrate the solutions and cause SiO2 precipitation, whereas in the cool region, the inherent decrease in SiO2 solubility with decreasing temperature also causes a SiO2 buildup. These calculations suggest one should search for regions of silica and halide enrichment as proof of the capillarity/evaporation model, yet are inconsistent with the lack of significant trends in bulk silica content at the Valles analogue. However, Travis and Nutall did not consider the dissolution of other silicates, nor the possibility that the silicate deposition would be lost in the larger matrix variations.

A simple, heuristic model was developed to predict mineralogical and bulk F and SiO2 variations in the boiling region. From SEM examination of the relative volumes of voids, pumice solids, and the crystalline void fillings, we estimate an effective water/rock volume ratio ranging from 100/3.5 to 100/30 for 50% to 100% saturation. The walls of the voids and the fine-grained (0.3 mm width), high-surface-area crystallites lining the voids are assumed to be the most chemically active part of the system, and the denser clasts and glass shards (which show little sign of alteration) are assumed to be inert. We assume there is a relatively large, wet source region where water equilibrates with tuff at 100C, and this water is subsequently pulled into the boiling region by capillarity, where minerals

precipitate, existing minerals are altered by interaction with the solution, and the aqueous phase becomes enriched in components such as Na and F. The calculations were run with the react code, assuming atmospheric O2 and CO2 fugacities. In some runs precipitation of all silica polymorphs except chalcedony was suppressed to allow clinoptilolite to form, which has a dramatic effect on the sorption of Cs but very little effect on the major element chemistry of the bulk precipitates.

Figure 4A shows how the void mineralogy changes for a sample calculation, expressed as g of solids per kg of water. The relative amounts of major silicates change little, especially after about 30 pore volumes have evaporated. However, the F content of the precipitates increases steadily as fluorite precipitates. The predicted change in the bulk rock chemistry (including contributions form the inert matrix) is +0.1% for silica, and +867 ppm F after about 60 pore volumes are evaporated. The change in silica is completely insignificant compared to the 0.6% variation observed for pairs of adjacent samples taken far from the contact. However, the change in F content is several times the native F content of the tuffs, and is consistent with the F enrichment levels seen at site 12 (Fig. 2A).

Fig. 4. Mineral and chemical variations predicted for capillarity/evaporation model. Mineral abundances expressed as (g of precipitates)/(kg pore water).

Figure 4B illustrates that complex trace element variations can arise from this simple model. Translated into bulk rock concentrations, the precipitation of Na2U2O7 could elevate the bulk U content by 10 ppm in the intermediate stages of evaporation. However, as the system becomes more alkaline with increased evaporation, the U solids redissolve.

CONCLUSIONS

The BRT shows remarkably little alteration from the heating event. There is some evidence for devitrification, loss of volatiles, precipitation of albite-silica in voids, and perhaps redistribution of fluorine within 10 m of the contact. There has been little development of sorptive phases such as zeolites and clays, and there is no evidence for extensive silica remobilization in the bulk analyses. These results are consistent with a simple model for concentration of solutes and precipitation of minerals in the boiling zone.

U.S. DEPARTMENT OF ENERGY'S ENVIRONMENTAL RESTORATION RECYCLING PROGRAM

Stephen Warren
U.S. Department of Energy
Office of Environmental Restoration
Jann Buller
Booz, Allen & Hamilton Inc.

ABSTRACT

This paper outlines the U.S. Department of Energy's (DOE) proposed recycling program under the Environmental Restoration Program. The proposed "Recycle 2000" policy calls for recycling radioactively contaminated scrap metal generated by environmental restoration activities into containers for storing and disposing of wastes within the DOE complex. The paper describes the policy, DOE's approach to developing it, and the status. Supplemental information includes estimates of the supply of radioactively contaminated scrap metal and the need for waste containers, as well as brief descriptions of site-specific reuse and recycle projects.

INTRODUCTION

Millions of tons of potentially recoverable materials have accumulated over the years at U.S. Department of Energy (DOE) sites. The scrap pile continues growing as surplus DOE facilities are taken out of service through decommissioning. Surplus items in this pile include scrap metals, timber, concrete, and other structural materials that can either be reused in their present form or recycled into new products.

Some of these materials, principally high grade metals, are in demand in the marketplace. Beneficial reuse and recycle of materials that DOE no longer needs offer opportunities for responsible materials management and environmental stewardship.

REUSE AND RECYCLE PROJECTS AT DOE SITES

Many of DOE's environmental restoration site managers have recognized these opportunities. As shown in Table I (on the following page), which highlights a representative sample of site-specific reuse and recycle projects, several sites already are finding uses for materials the Department no longer wants or needs.

As the table demonstrates, these projects vary widely in purpose and scope. For example, the Savannah River site is recycling surplus heat exchangers into stainless steel containers for waste storage and disposal. The Hanford site is extracting rebar from dismantled buildings for resale and crushing concrete from these buildings for use in road construction on the reservation. Each of these sites has taken an approach to reuse or recycle suitable to its own needs. Now, DOE is looking at the prospects for reuse and recycle from a national perspective.

FOCUS OF THE NATIONAL RECYCLE PROGRAM

Many of the recoverable materials at environmental restoration sites possess significant market value, recycle potential, or both. This is particularly true for metals. Estimates of the quantity of scrap metals already available in the DOE complex vary, but the most conservative estimate puts the total on hand at approximately 150,000 tons (1). Other estimates of the current total quantity on hand range up to nearly 400,000 tons (2).

The inventory of scrap metals on hand will rise in the coming years as more decommissioning projects are started at the hundreds of facilities already identified as surplus. Estimates of scrap metals to be generated by decommissioning projects in the future are on the order of one million tons, in addition to what is now available.

THE "RECYCLE 2000" POLICY PROPOSAL

Given the quantity of metals already in the Departmental scrap pile and the expected volume to be generated by decommissioning in the future, DOE is considering setting a national policy for recycling these excess materials. This policy proposal is known as "Recycle 2000."

The Recycle 2000 policy proposal would set a goal that, by the year 2000, at least 50 percent of the waste storage or disposal containers used by DOE's Environmental Management Program would be fabricated from DOE-generated, radioactively contaminated scrap metals (RSM). The waste containers would be used only once and only within the DOE complex. If insufficient metal is available to meet the 50 percent goal, the policy would be to refrain from burying potentially recyclable steel and to use all available containers made from RSM. This proposal is

intentionally limited so as to be manageable and achievable by the year 2000.

APPROACH TO RECYCLE 2000 POLICY DEVELOPMENT

DOE decided to involve stakeholders in the formulation of the Recycle 2000 policy from the beginning, because broad-based stakeholder support will be critical to successful implementation of a recycle policy. The Recycle 2000 concept was raised first with a small group of representative stakeholders in July 1994. That group identified a broader group of stakeholders to involve in the policy development process, including local citizen groups; environmental action and public interest organizations; unions; industry; local, state, and tribal governments; federal regulatory agencies; DOE operations offices and sites, including DOE contractors; and DOE Headquarters.

DOE decided, with the encouragement of the small group of stakeholders, to involve the broader group of stakeholders in a workshop. The workshop offered an opportunity to discuss the Recycle 2000 proposal, to obtain stakeholder input on the idea, and to identify stakeholder issues and concerns.

RESULTS OF THE RECYCLE 2000 WORKSHOP

The Recycle 2000 workshop took place in early December 1994 and included representatives from 26 different organizations. The participants first had an opportunity to review and discuss relevant background information. This included research results on the supply of radioactively contaminated scrap metal and the demand for waste management containers, current disposal versus reuse/recycle practices, the scrap metal recycling industry, scrap metal reprocessing, the regulatory environmental for RSM recycling, and economic factors pertaining to RSM recycling.

Discussion of issues at the workshop centered on disposal versus recycle as RSM management options; on-site versus off-site processing and fabrication; implementation at the local versus regional versus national level and other implementation issues; waste commingling and secondary waste; RSM regulation; economics of recycle and disposal; and continued stakeholder participation in Recycle 2000 decisionmaking.

At the conclusion of the workshop, participants expressed their support for recycling RSM into waste containers, if the process is:

- Protective of public and worker health and safety
- Developed through an open, credible process
- Economic compared to other viable waste management options
- Employed for RSM unlikely to be released for unrestricted use
- Equitable for sites and states
- Scheduled according to a definite timetable
- Environmentally responsible, without compromising clean-up nor compounding existing problems
- Designed not to preclude further recycle.

Workshop participants and DOE alike agreed that more, and better, information is needed to ensure that recycling objectives and these conditions can be met.

RESOLUTION OF ISSUES FOR POLICY DEVELOPMENT

DOE has initiated a series of research and analytical efforts to address the issues discussed at the Recycle 2000 workshop and to complete the groundwork for a sound policy decision about whether or not to go forward with Recycle 2000. These efforts include an economic analysis of the Recycle 2000 proposal, analyses of technical issues associated with fabrication of RSM into other forms, the physical properties of the finished forms, and examinations of liability and regulatory constraints that may apply to recycle of RSM for DOE waste containers.

Economic Issues

The economic feasibility of the Recycle 2000 proposal depends on the answers to the following questions: What are the quantifiable costs of recycle? What are the quantifiable costs of disposal? What intangible or non-quantifiable factors need to be considered? How should these factors be weighted relative to each other and to the quantifiable costs?

To answer these questions, DOE is developing an economic model and examining available data for possible use in the model. This includes information on projected needs for waste containers, the current and future supply of scrap metals, and current and projected waste disposal costs.

DOE recently conducted a study to identify hazardous and low level radioactive waste containers used and purchased for the storage of solid, liquid, and sludge wastes

associated with operations and clean-up activities at 28 DOE sites. Table II presents the total volumetric equivalent of containers actually used each year from 1992 to 1994 and the total volumetric equivalent of containers projected for low level waste use annually during 1995 to 1997.

The economic analysis will need to link the projected demand for containers to the projected inventory of RSM to determine the prospects for achieving the goal of the proposed Recycle 2000 policy to use 50 percent or more of containers made from RSM. Several studies in recent years have examined the current scrap metal inventory and projected additions to it. Comparative analysis of these study results is complicated by differences in definitions and assumptions as well as incomplete or conflicting reports from several sites. Conservative estimates, however, put the future total for scrap metals to be decommissioned at more than one million tons (1).

Identifying the true costs of disposal also will be critical to this analysis. As reported by participants at the Recycle 2000 workshop, disposal fees at DOE facilities range from $7 to $10 per cubic foot at the Nevada Test Site to $70 per cubic foot at Hanford. Many of the workshop participants were skeptical that current disposal fees truly capture all costs associated with disposal, including future landfill management and monitoring. These costs will need to be built into the economic model for accurate comparison of relative costs for recycling and for disposal.

Technical Issues

Of particular concern are risks to workers from handling RSM, including the risks that may arise while it is processed into containers. DOE has taken a preliminary look at radionuclide partitioning during metal melt to determine contaminant fate. Recent literature on the partitioning of contaminants during melting shows the following:

- Elements remaining in the melt include Co-60, Mn-54, Ni-63, and Fe-55
- Elements that split between the melt and the slag include Ce-144
- Elements that oxidize and partition to the slag include Sr-90, U-238, U-235, and Pu-239
- Elements that vaporize and end up in the off-gas system include Cs-134, Cs-137, and Zn-65.

Once the RSM has been fabricated into waste storage or disposal containers, worker exposure risks may arise during transportation, waste loading, placement at disposal sites, or monitoring after land disposal. To address these and other potential risks, DOE plans a series of technical analyses to address the physical properties of finished containers, including grain boundaries and radiation embrittlement, and what happens between melting and final fabrication, including welding, machining, and sorting.

Liability and Regulatory Issues

Industry participants at the Recycle 2000 workshop indicated that, owing to concerns about liability, DOE would need to maintain ownership over the RSM fabricated into waste containers so that liability would remain with the Government. The Department has begun examining this issue to determine how liability concerns may affect development of the proposed policy.

At present, no regulatory standard exists for volumetrically contaminated RSM. Absent standards, DOE controls recycling and reuse on a case-by-case basis using the requirements contained in DOE Order 5400.5, "Radiation Protection of the Public and the Environment." These requirements include an appropriate evaluation under the National Environmental Policy Act (NEPA), a complete analysis of hazards and benefits of the proposed action (including addressing "as low as reasonably achievable", or ALARA, issues), and coordination of the release or reuse activity with the appropriate external regulator.

Both the U.S. Environmental Protection Agency (EPA) and the Nuclear Regulatory Commission (NRC) are contemplating regulations that address recycling radioactively contaminated materials. Both organizations are a year or more away from having draft standards available for public review. In NRC's case, the regulations, once promulgated, would apply only to NRC licensees. Restricted recycling within the DOE complex, as proposed for Recycle 2000, may not lie within EPA's purview. Regulatory parameters thus remain highly uncertain.

CONCLUSION

Stakeholders and DOE agree that recycling RSM into waste containers for use within

the DOE complex is preferable to disposal of these contaminated metals, subject to the conditions established by the stakeholders. DOE is proceeding with development of the proposed Recycle 2000 policy.
The Department expects to complete the analysis of economic, technical, and regulatory issues over the summer and to have a draft policy decision package ready for DOE management review by the end of September 1995. DOE will continue to involve stakeholders in the policy development process to ensure that their viewpoints, values, and concerns are addressed.

METAL RECYCLING TECHNOLOGY AND RELATED ISSUES IN THE UNITED STATES AND UNITED KINGDOM
Phillip Bradbury
Scott Dam
Wayne Starke
BNFL Inc.
ABSTRACT
Radioactively contaminated metallic materials comprise a large part of the potential waste products which result from nuclear facility repair, refurbishment, and decommissioning. United States Government (Departments of Energy and Defense) facilities, U.S. nuclear power plants, and other commercial nuclear fuel cycle facilities have large inventories of radioactive scrap metal which could be decontaminated and recycled into useful radioactive and non-radioactive products. Residual radioactivity and recycling criteria are needed to avoid the high cost of disposal and the waste of natural resources. The standards must be practical, measurable, and science-based. In the United Kingdom, the gaseous diffusion plant at Capenhurst has been decommissioned. A large fraction of the metallic scrap has been recycled into the metals market. Other structural materials have also been released as uncontaminated scrap. U.K. release criteria for residual radionuclide contamination have been applied to these operations. A variety of techniques were utilized to size reduce large components, to remove radioactivity, and to survey and release these materials. These methods and the application of release criteria has a direct relationship to methods which would be applicable in the U.S. and in other countries.
INTRODUCTION
This paper provides a current status of metal recycling technology and issues related to the release of recycled or decontaminated radioactive scrap metal in the US and UK. Radioactively contaminated metallic materials comprise a large part of the potential waste products which result from nuclear facility repair, refurbishment, and decommissioning. United States Government (Departments of Energy and Defense) facilities, US nuclear power plants, and other commercial nuclear fuel cycle facilities have large inventories of radioactive scrap metal which could be decontaminated and recycled into useful radioactive and non-radioactive products. Recycling this material into useful products is needed to avoid the high cost of disposal and the waste of natural resources and to reduce the impact to the environment and energy consumption for new material processing.
This paper describes the specific U.K. technology and experience in the decontamination, recycle, and release of scrap metal. It also describes the U.S. environment for metal recycle, including the volumes and levels of contamination, and the current and proposed release criteria. Comparisons are presented between the U.S. and U.K., both in technology and methodology for recycle and in regulatory criteria for residual radioactivity and material release. The paper then provides suggested approaches and criteria for U.S. recycling.
U.S. METALS PROBLEM
In the U.S. there is a large quantity of radioactive scrap metal (RSM) which could be recycled. The sources of this scrap metal are presented below along with approximate quantities of these metals.

Metal Sources

There are three main sources that represent significant quantities of metals suitable for recycle:

1. Nuclear Power Plants represent the largest current source of RSM. Nuclear power plants currently generate from regular plant overhauls radioactive scrap metal such as old heat exchangers, piping, pipe hangers, and spent fuel racks. Since this metal is not generally free-released directly by the plants to the open market, few choices exist:

a) Bury the metal at an approved low-level waste landfill, such as Barnwell, where the current cost is from $3.28/lb to $8.00/lb, depending on status as either a sited or unsited waste generator with the Southeast Compact.

b) Send the metals to a licensed radioactive scrap metal processor such as SEG or Quadrex (American Ecology).

c) Dispose directly after specific approval from the NRC (10 CFR 20.2002 -formerly 20.302). About 25 such approvals have been obtained.

The total volume of metal generated from the 109 operating nuclear power plants in 1993 has been estimated at 29 million pounds (1).

2. DOE Facilities. There currently exist stockpiles of metal at various DOE sites across the country. Significant quantities of additional metals will come from facilities as they are decommissioned and dismantled. The current estimate of the DOE facilities for all metal including that which is in stockpiles is 1.7 to 3.6 billion pounds! As facilities start to be decommissioned/dismantled and the metal is sent to be processed, the annual quantity should increase to 50-90 million pounds/year. DOE disposal costs vary from $5 to $10 per cubic foot at Nevada (not the life cycle cost) to about $50 per cubic foot per year at Idaho for low-level waste. The latter reflects the continual costs of maintenance of the disposal/storage facility.

3. Nuclear Plant Decommissioning. As power plants reach the end of their current 40 year operating licenses, they will be decommissioned. There are currently 109 nuclear power plants. The first plants to be decommissioned include Yankee Rowe, Trojan, and Shoreham. This market might be stretched if some of the plants successfully extend their NRC operating licenses beyond the 40 years of if the power plants get acceptance to put the majority of the facility into mothballs. It is currently estimated that 1.5 billion pounds of steel exist in the nuclear power plants that could be processed. The quantity of this material should start to be significant by 2003. It is estimated that the average annual flow of metal should be over 25 million pounds per year (1).

Timing

Sources of RSM are currently increasing in all three segments. The nuclear power plant RSM is expected to level off in five years and will start to decrease in the year 2003 as more plants are decommissioned, eliminating the generation of metal waste from operations. Depending on the decommissioning approach taken, plant decommissionings could be completed by 2042.

Metal from the DOE is a difficult source to predict because of the problem DOE has with free release and the fact that the Nevada Test Site is currently charging between $5 -$10/cu ft to dispose whereas the actual life cycle cost is more like $35/cu. ft. or more. Until the DOE decides on a workable free release policy (including liability issues for their management and operating contractors), the material for processing will be limited to acceptable internal end uses, such as containers, and to limited free-release from specific sites.

The third segment, RSM from the decommissioning of nuclear power plants, will be erratic in nature until about 2014. The flow of metal should continue until 2053 when the final plants will be decommissioned completely.

DOE Scrap Metal Volumes and Locations

The quantities of DOE scrap metal vary by type and location of these materials vary by site with large quantities at Oak Ridge (K-25), Paducah, Portsmouth, and Nevada (2). The specific quantities actually in inventory vary depending on which survey you believe. Total quantities in inventory are estimated from 400,000 tons to 1,800,000 tons (3).

Current U. S. Release Criteria

The Energy, Environment, and Resource Center at the University of Tennessee was directed by the DOE to research the establishment of effective environmental standards for RSM. In a draft report published in May 1993, they gave a summary of

the current status (4).
There currently are no nationally applicable standards that facilitate the treatment and recycle of RSM. Existing standards by the NRC are for surface contamination only. These are not adequate guidance in the treatment of RSM as there is currently no standard for release of volumetrically contaminated materials.
The following standards by various agencies exist:

The International Atomic Energy Agency (IAEA) - Basic Safety Standards (BSS) for specific isotopes of radioactivity follow ALARA principles. In addition, there is "The Application of Exemption Principles to the Recycle and Reuse of Materials from Nuclear Facilities" which provides safe levels for the recycle and re-use of steel, aluminum, and concrete. This set of principles includes volumetric and surface contamination levels, but is based on an individual dosage of one mrem per year, which is below what is considered practical and achievable on an economic basis.

The International Commission of Radiological Protection (ICRP) - original advocates of ALARA.

The Environmental Protection Agency (EPA) has developed standards for the safe levels of radioactivity, as they apply to drinking water, and air quality. There are also some recent guidelines pertaining to the treatment of soils and debris which might have a bearing on RSM.

The Nuclear Regulatory Commission (NRC) developed the Regulatory Guide 1.86 in 1974. This guide deals with surface contaminated materials that are nonactivated. It is this guideline that the nuclear waste processors have used in their licensed approval to free release metals from nuclear power plants. The values are in DPM/100cm2. The Energy Act of 1992 was to encourage the NRC to initiate the Enhanced Proposed Rule (EPR), an effort to establish cleanup standards for the decommissioning of nuclear power plants. This effort could result in changes or at least clarifications in how RSM is to be processed and released for unrestricted release. So far, this effort is only for decommissioning release standards for facilities.

DOE Order 5400.5 is, in part, based on NRC Regulatory Guide 1.86, and deals only with surface contamination. Unfortunately, a few years ago the director of DOE's Office of ERWM issued a memo stopping all release of DOE metals for recycle, which was done in response to a specific incident. Even though this specific problem has been corrected, some of the sites are hesitant to resort back to Order 5400.5. The only exception is Fernald, which has been sending steel to service vendors to be made into shield blocks and for decon and free release. Fernald plans to place a contract for the decontamination and release or fabrication into boxes of over 700 tons of mild steel from Building 7 (5).

U.K. EXPERIENCE IN METAL RECYCLE

Capenhurst Diffusion Plant Decommissioning

The Capenhurst Diffusion Plant was built in the early 1950's, at which time it was the largest industrial building in Europe under a single roof, measuring 1,000 yards in length and 160 yards in width. It was originally built to produce highly enriched uranium for military purposes, but this came to an end in the early 1960's when it was converted and extended for low enriched uranium production for civil use. After a further twenty years of life, the plant was shut down in 1982. By this time centrifuge enrichment plants were built and operating at Capenhurst and the diffusion plant was no longer economical. Since that time a program of decommissioning and dismantling has been in progress with an process plant material having been recycled or put in the appropriate form for disposal. Part of the building has already been demolished and a new centrifuge plant constructed on the same land. The remainder will remain in tact so long as there is economic use for it.
Post operational work to empty and cleanup the plant was carried out to leave as little residual contamination as possible by the use of a fluorinating agent to convert solid deposits to volatile fluorides which were pumped away. Further cleanup operations were carried out on the static plant to locate and deal with any significant buildup of solid or gaseous pockets of contamination remaining within the 4,800 process stages and 1,200 miles of interconnecting pipework.
A safe system of working was then established for the dismantling of the plant, which included survey measurements throughout the plant to ascertain what amounts of activity were left which would have to be dealt with at the decontamination and disposal stages. The initial phase of dismantling involved the cutout, removal, and

storage of large numbers of components, including compressors, coolers, valves, large diameter pipework, and the large process stage units.
Since 1984, up to 6,500 tons of major plant components have been successfully stored outdoors, including 850 tons of steel stage units (6). The 18,000 tons of structural steel have been dismantled and disposed of as clean scrap. Process pipework and the large process stage units have been cut up into lengths and sections suitable for the decontamination process. A variety of methods have been employed in cutting up the process plant. These include both hot and cold cutting, automated wherever feasible. Robotic-controlled plasma cutting has been employed to volume reduce a total of 5,300 tons of large aluminum stage units. Steel shells have been separated from a further 1,000 tons of stage units using remotely-controlled oxyacetylene methods. Both processes have been carried out in specially developed ventilated enclosures. Most of cold cutting was done by automated metal cutting techniques (including band sawing).

Decontamination Technology

Chemical treatment for the removal of uranium and uranium breakdown products is a well established process and significant quantities of aluminum and steel have been cleaned and recycled to the metals market. However, a large section of the plant had been exposed to reactor recycled feed material and contaminated with Np-237 and Tc-99, the latter being particularly difficult to remove. One disposal option was land burial at Drigg (near BNFL's reprocessing plant at Sellafield), the only currently available low-level waste site in the U.K. The large volumes of material involved (some tens of thousands of cubic meters), equivalent to several years of remaining Drigg lifetime, made this option unacceptable. Furthermore, costs would have been very high. It was decided to develop a procedure for effective decontamination to very low, deminimis levels at which it could be sold as uncontaminated scrap metal. An extensive laboratory and pilot plant investigation was successfully carried out and a full scale decontamination plant has been built and is in operation. Over 9,000 tons of aluminum and steel has been decontaminated to date and recycled to the scrap metal market. The flowsheet design for the plant was based on the plant discharges having a negligibly small impact on the environment and on the U.K. statutory regulations for recycling scrap metals to the open market. The process is one of successive stages of decontamination in process liquors which are subsequently treated by ion exchange methods. This results in the activity being transferred to relatively small and manageable volumes of solid and liquid residues and low activity solid and liquid wastes.

U. K. Scrap Metal Release Criteria

Criteria for free release of scrap metal was established for the U.K. based on the U.K. Radioactive Substances Act, 1960 and revised 1988 (7). Specifically, all radionuclides (total alpha, beta and gamma) must be less than 0.4 Bq/gm (0.011 nCi/gm). There is an exemption for naturally-occurring uranium (alpha) of less than 11.1 Bq/gm (0.3 nCi/gm).

Results from the Capenhurst Metal Recycle Program

In summary, the major achievements to date are as follows:

Over 99.5% of the decommissioning materials (160,000 tons) was recycled as clean material.

Disassembled a complete diffusion plant comprising 4,800 process stage units, 1,200 miles of pipework, and associated plant items, including 3,500 tons of electric motors.

Management and control of the outdoor storage of 6,500 tons of contaminated plant components for periods of time up to nine years.

Developed hands-on and remotely-controlled systems for volume reducing 8,000 tons aluminum, 23,000 tons steel, 70 tons copper, 300 tons aluminum bronze, 200 tons cupro-nickel, and 320 tons of nickel.

Since 1983, over 5,000 tons of aluminum (including 950 tons from the highly enriched section of the plant) have been prepared, decontaminated, and sold for recycle into the metals market. Some 23,000 tons of steel (including 1,100 tons from the highly enriched section) have been prepared and sold directly to the metals market as "clean" scrap, without the need for full decontamination.

The 3,500 tons of contaminated electric drive motors (including 800 tons from the highly enriched section of the plant) have been successfully treated and sold for recycle in the metals market.

Developed a process for separation of contaminated aluminum heat exchange sheaths

from cupro-nickel liner cooling tubes.

Ancillary buildings, including 11 large cooling towers (13,000 tons), pump houses, electrical substation, and part of the main diffusion plant building were completely raised to the ground producing 46,000 tons of concrete rubble for off-site disposal.

Five bays of the plant have been demolished to greenfield status. The recovered site (of approximately six acres) was made available for the construction of a new centrifuge enrichment building.

The 850 tons of low-level contaminated waste have been dispatched to the U.K. radwaste disposal site at Drigg, operated by BNFL.

Over 88,000 cubic yards of material was able to be disposed of by recycling or free release thus avoiding disposal as radioactive waste. At $2000 per cubic yard ($74 per cubic foot, much less than U.S. commercial rates), this resulted in a savings of over $180 million. Additional savings came from not having to use radioactive materials rules for much of the dismantling activity and not having to package and transport materials as radioactive. This savings is more than the cost of the actual decommissioning activity.

U.S. / U.K. REGULATORY COMPARISON

The rules and regulations under which the nuclear industry operates in the U.K. have both similarities and differences with the rules and regulations in the U.S. One area of significant difference is that in the U.K. the same agencies regulate both radioactive and hazardous wastes. This eliminates areas of conflict of jurisdiction such as occurs in the U.S. with the handling of mixed wastes. In the U.K. there is no classification such as mixed waste. Also in the U.K., the nuclear waste category called intermediate-level waste is between low-level waste and high-level waste. This intermediate-level waste is currently being cement grouted and stored for the eventual long-term burial in an underground repository.

There are also some differences in the definition of requirements and their application. In general, the U.S. requirements are prescriptive and extremely detailed, while in the U.K. the onus is placed on the owner of the waste to provide detailed protective criteria to the satisfaction of the regulator. In some cases, these risk-based criteria are more extensive than equivalent U.S. legal requirements.

Quantitative criteria for nuclear protection, upon which requirements in the two nations are based, are the same. They are the International Committee on Radiological Protection (ICRP) and the International Atomic Energy Agency (IAEA). However, these organizations' guidance and rules are applied differently. In the U.S. isotopic discharges are regulated by concentration at the source, while a U.K. site is limited to an annual total discharge quantity. In the U.K. deminimis levels of radioactivity are defined which allow innovative clean-up and recycling of materials; while in the U.S., deminimis is effectively limited to that which can be shown to result in a dose to an individual of less than 0.02 mSv/hr. Reference 7 lists the discharge limits by radionuclide for gases and liquids in the U.K. and the U.S.

On the environmental side, the U.K. has certain environmental release regulations based on the use of surrounding arable lands for food production and water for drinking and fishing. Since the U.K. has a relatively small land mass, it is more densely populated and farmed than the U.S. This makes the environmental requirements more stringent, but reasonably based on real risk rather than concepts in which no risk is acceptable.

PROPOSED U.S. REGULATORY CHANGES AND COMMENTS/SUGGESTIONS

The EPA and the NRC are currently in the process of rulemaking actions to set radiological standards for decommissioning. The EPA is also performing risk and economic evaluations in preparation for developing standards for surface and volumetric contamination release standards for recycled materials. Currently, the EPA appears not to be considering free release for DOE scrap metal, but only restricted release (8). Standards for free release are necessary to fully implement a scrap metal recycle policy.

Practical standards are needed for recycling and decommissioning. To promote their use, these standards must be useable and understandable. A separate set of criteria which is for "restricted use" should be developed and allowed which will permit a decommissioning to restrict the use of the facility/site without having to maintain an active license for the site. For example, rules should allow the use of a former nuclear facility for an industrial plant, with certain obvious restrictions.

Material recycling and free release standards are needed for volumetric contamination in addition to surface contamination. Much of the DOE scrap metal has been volumetrically contaminated. These standards must also be measurable with current technology cost-effectively. Where possible, the regulatory agencies should establish release numbers which are directly measurable; e.g. nCi/gm or DPM/100cm2. This approach is preferable than requiring each radioactive material user to develop their own release numbers from site specific analyses for exposure to the public. The experience of others should be utilized in developing these limits, especially current scrap metal recycle facilities and decommissioned facilities. Finally, the standards must be based on a body of recognized and authoritative, scientific evidence and knowledge, such as that published by NCRP and ICRP, and not on an arbitrary assumption of what may be acceptable to some interest groups.

DERIVED BENEFITS

This paper has discussed the waste forms that are generated in the U.K., how they are handled and the specific handling of radioactive scrap metal at Capenhurst. Next, a discussion was presented on the regulatory requirements in the U.K. and how they are similar and different from the U.S.

Now that these subjects have been discussed, it is appropriate to tie them together in a discussion of benefits the U.S. may derive from the U.K.'s nuclear industry experience with scrap metal recycle and waste management.

First of all, the U.K. is actively collecting, treating, and at least properly storing for disposal all of its nuclear waste as it is being generated. In the U.S. this is not the case, especially in the DOE communities. For the U.S. to get to this practice they need to expedite the collective process of standardizing the discharge limits for all nuclear waste materials as their release is related to the public health and the protection of the environment. Risk-based analysis can result in risk-based criteria that can be restrictive relative to the personal exposure and not on the absolute values.

Secondly, the U.K. has been able to actively recycle significant quantities of metal back into society. The DOE is currently stalled with this effort because of their policies on release of DOE metals. Huge quantities of metals are not being processed and recycled. In the U.K. the Capenhurst facility has been able to generate jobs for the nuclear industry and reduce the cost of D&D by recycling while protecting the public and the environment.

Thirdly, in the U.K. land is at a premium and the country cannot afford to contaminate and not clean up for reuse the land and facilities that have ceased their intended operation. Capenhurst is a very small site and is surrounded by communities. Similarly, Sellafield is located on only 700 acres and also has close neighbors. By comparison, the Savannah River site is on 192,000 acres of land with its closest communities about 20 miles away. Therefore, in the U.K. at the Sellafield Complex, when a new facility is to built, it is designed with a specific life expectancy. It is also designed to be more easily decommissioned and dismantled at the end of its useful life. When a new facility is to be built, an old facility must be dismantled completely; including any soil and ground preparation. The cost to do the eventual D&D is factored into the facility as a life cycle cost and is accrued over the life of the facility so that when the facility ceases to operate, there are sufficient funds available to perform the proper D&D.

Lastly, in the U.K. there is an integrated effort to treat the public and the environment in a proper perspective. Rules and regulations are designed along the principles recommended by the ICRP. These basic principles are:

Any practice involving radiation exposure must be justified in relation to its benefits.

Any necessary exposures must be kept as low as reasonably achievable, economic and social factors being taken into account.

Radiation doses must not exceed recommended dose levels.

In addition to the U.K. experience there are benefits derived from U.S. recycling and decommissioning experience. The cost savings of having rules that can be complied with is true not only for the owner, but also for the public. We have numerous occurrences in the U.S. of companies which declared bankruptcy, forcing the public to pay for the cost of cleanup whether it was low-level radioactive, or high-level waste. Having reasonable rules will also avoid and/or reduce dismantling, packaging, transportation and land disposal; increasing the safety to the public and to the workers.

There are additional benefits to recycling which should be considered. Most of these benefits are true whether we are talking about radioactive scrap metal or domestic scrap, such as aluminum soft drink cans. These benefits include the overall economic benefit, reduced energy consumption, and minimizing the environmental impact of new mining and material processing.

CONCLUSIONS AND RECOMMENDATIONS

Recycling is an important part of the overall safe management of radioactive materials. Reasonable standards for material recycle and free release, including radiological standards for decommissioning, will assist in compliance and will be an overall benefit to the public, workers, and industry. It is also the best use of our natural resources. Specific volumetric and surface contamination standards for recycle and decommissioning should be established such that they are practical, definitive, measurable with current technologies cost-effectively, and are based on good science.

THE STAINLESS STEEL BENEFICIAL REUSE INTEGRATED DEMONSTRATION

W. L. Boettinger
R. N. Lutz
Savannah River Site

ABSTRACT

In 1992 there was a desire to determine the ultimate disposition of 68 Process Water Heat Exchangers at the Savannah River Site (SRS). Each Heat Exchanger weighs about 100 tons. Since the Heat Exchangers are radioactively contaminated they could be classified as radioactive waste and disposed through shallow land burial on site. The cost for such a disposal would exceed $10 million. The Heat Exchanger material being over 95% 304 stainless steel would represent a commodity value of several million dollars on the commercial scrap market. Unfortunately, the metal is volumetrically contaminated, a situation for which there is no "de minimis free release" level, thereby preventing recycle of the metal into the commercial market place. However, the metal could be recycled back to the DOE in a "controlled release" manner. The radioactive scrap metal (RSM) could be reprocessed into new reusable products which are returned to the DOE for use within the DOE Complex. The new products would not be used within the public arena.
In 1994 the DOE Office of Technology Development initiated a demonstration to recycle contaminated stainless steel by melting 60 tons of RSM and refabricating it into containers (55 gallon drums and 100 cubic feet boxes) that could be used for long term, temporary storage. The Demonstration covers the entire recycle chain from the accumulation of the feed stock (through the disassembly of excess components) to

the receipt and utilization of the final products. The disposition of waste generated during the recycling process is also a part of the Demonstration. The actual melting of the radioactive scrap metal and the fabrication of the final products is accomplished through subcontracts with private industry. The Demonstration is a precursor to the establishment of regional stainless steel recycle facilities at or near major DOE sites. Radioactivity levels of the RSM to be shipped have been provided to the melt/fabrication subcontractors for their utilization in obtaining regulatory permit modifications.

Delivery of final products is schedule for 1995 and 1996. The activity level of the RSM to be supplied to industry has been determined to be less than one curie in total. The average specific activity level of the Cobalt-60 which will be volumetrically imbedded in the final products has been estimated to be of the order of 117 pico curies per gram (4.31 becquerels per gram). This level is expected to cause no difficulty in the utilization of the drums and boxes as containers of other waste forms.

THE INTEGRATED DEMONSTRATION

The Savannah River Site (SRS) has a large amount of radioactive scrap metal (RSM) which includes approximately 6800 tons contained in the form of excess heat exchangers. These heat exchangers have reached the end of their productive life and are normally declared Low Level Radioactive Waste. As such the heat exchangers would normally be disposed by burial at SRS at a cost of over $10 million. If however, the metal could be melted and refabricated into items such as waste containers, the material would be beneficially reused, eliminating the need to add an equivalent amount of clean metal to the contamination stream. In effect a potential liability would be changed into an asset. Figure 1 displays the concept.

To demonstrate the feasibility of this concept, the DOE (Office of Technology Development) is funding an Integrated Demonstration at SRS, in which a small amount of stainless steel RSM (60 tons) is to be melted, and refabricated into drums (55 gallons each) and boxes (100 cubic feet each). The melting and refabricating will be accomplished by private industry. The products will be sent to SRS for use. The secondary waste stream, consisting primarily of a small volume of clippings and possibly slag, will be returned to SRS for disposal as LLW. A total of approximately 485 drums and 85 boxes are expected to be produced. Delivery is scheduled for the 1995 - 1996 time frame.

The two private industrial companies participating in this Integrated Demonstration are:

1. Carolina Metals Inc. of Barnwell SC (a subsidiary of Nuclear Metals Inc.), and
2. Manufacturing Sciences Corp. of Oak Ridge TN.

The finished products to be produced by the private industrial participants are identified in Table I.

The numbers of boxes and drums to be fabricated are approximate since the actual values will depend on the efficiency of the (yet to be implemented) manufacturing processes.

EXPOSURE TO THE FINISHED PRODUCT

An important part of the Integrated Demonstration is to establish that the fabricated products will be sufficiently low in activity so as to allow worker proximity.

The total activity contained in the 60 tons of RSM to be sent to the melters is less than one curie. Most of the activity, being tritium, will off-gas. Of specific interest is the amount of cobalt-60 which will be volumetrically distributed in the remelted steel. This isotope will dominate the exposure from the fabricated boxes and drums. Samples taken from the 60 tons of RSM indicate the total cobalt-60 activity is of the order of 0.00636 Ci. If homogeneously distributed in the refabricated products, the concentration will be of the order of 117 pico curies per gram (4.33 Becquerels per gram).

A spectrum of RSM taken from different components will be used as feed metal. Table II groups the specific RSM selected and the cobalt-60 activity associated with each Group.

The melters, of course, will not homogeneously mix all of the recycled RSM to make each Heat at an activity of 117 pCi/g. Each Heat will be different. Figure 2 was generated assuming two ton Heats, starting with the highest activity feed RSM and proceeding to the lowest activity feed RSM. The 60 tons results in a total of 30 Heats.

It is important to know the exposure one might receive from the fabricated boxes and drums. One Heat of 2 tons will result in approximately four boxes or forty drums. Figure 3 depicts the geometry of the calculation of the maximum exposure dose rate to an individual at 100 centimeters from two boxes or eight drums fabricated out of the highest activity Heat (511 pCi/g).
Under this calculated maximum exposure a worker continuously standing in the vicinity of the products would receive a maximum of 0.39 mrem per hour (or 3420 mrem per year). A worker spending 40 hours a week for 50 weeks a year at the position depicted would receive a yearly dose of 780 mrem per year (which represents about 15% of the 5000 mrem per year dose set by the Nuclear Regulatory Commission for occupational workers). It is important to realize that these are calculated values which represent a conservative approximation of reality. The melt activity will most likely result in a mix of the various groupings in a manner which best suits the requirement to melt the actual geometry of the RSM at hand. This will cause the maximum exposure to be less than calculated. In reality it should be difficult to detect any radiation beyond background in the vicinity of the products. Table III identifies the calculated exposures at 100 centimeters for the various Heats shown in Fig. 2.

ESTABLISHMENT OF A VIABLE STAINLESS STEEL RSM INDUSTRY

To assure the commercialization of this Beneficial Reuse Industry will require a commitment to procure sufficient quantities of product over a multi-year period. The DOE has a need for large numbers of waste containers. A commitment by the DOE to buy product would allow industry to obtain financing for production equipment. Because it will also benefit the commercial nuclear industry, this activity is expected to survive on its own once it is up and running. Figure 4 depicts the steps required to establish a viable industry.
The stainless steel RSM recycle industrialization program (see Fig. 4) has essentially three phases: 1) The first phase is this Integrated Demonstration or Convergence Phase in which Government, industry, and other stakeholders converge on the best relationship for manufacturing products; 2) The second or Commitment Phase will require private industry to invest to produce products, most economically, for a government supported market. A partnership of government and industry during this Phase may be necessary; 3) The third or Completion Phase will be a self sustaining RSM recycle industry operating without the need for explicit government support. Regional RSM recycle centers on or close to a number of the DOE Sites may eventually exist.

PROGRAM BENEFITS

The recycle of any quantity of RSM eliminates the need to obtain an equivalent amount of new metal which would itself become contaminated. Also the cost of and need for burial space for the recycled RSM is avoided. If the program is successful, potential environmental liabilities can be turned into assets. Resources will be conserved and waste minimized.

APPLYING COMMERCIAL RECYCLING PRACTICES TO DEPARTMENT OF ENERGY SCRAP METALS

Dr. Anthony Kluk
US Department of Energy
J. Wynn Phillips
Analytical Services, Inc.
Michael Neal
Belfort Engineering & Environmental Services, Inc.

ABSTRACT

This paper reviews the process by which commercial generators of radioactively contaminated scrap metal transfer such material to commercial recyclers and assesses whether the same process is applicable to radioactively contaminated scrap metal originating from DOE sites. Three issues that currently prevent DOE sites from using recycling as an alternative to long-term storage or disposal of surface contaminated metals are also reviewed. The issues are:

- Moratorium on transportation of radioactive materials off-site;
- Materials shipped off-site must have "no added radioactivity"; and
- DOE radionuclides cannot be sent to commercial sites for burial.*

There are significant quantities (thousands of tons) of scrap metal already accumulated at DOE sites, with larger quantities projected to be available for

recycling from decontamination and decommissioning surplus buildings from the nuclear weapons complex. While commercial utilities and other NRC-licensed facilities have been recycling scrap metal, including copper, admiralty brass, stainless and carbon steel, and aluminum, for as many as ten years, DOE has done little to reduce the burden of either storing these materials or disposing of them as radioactively contaminated wastes.

This paper reviews the process by which commercial companies utilize vendor services for the decontamination and recycling of contaminated scrap materials. The approach DOE would use for this same process, to recycle with subsequent free release or to accomplish waste minimization, is also examined.

COMMERCIAL RECYCLING PRACTICES

Presently there are two methods by which NRC licensees may have metals containing radioactive surface contamination decontaminated for recycling. They are:

Contracting with a firm that brings specialized equipment on-site and decontaminates the material to the free release standards published in NRC Regulatory Guide 1.86.

Packaging the material in accordance with DOT and NRC regulations, and shipping it to an NRC-licensed recycler.

This report focuses on the issues relating to transportation, shared liability and transfer of title, which do not need to be addressed for materials decontaminated on-site, but are important when transferring materials to an off-site recycling facility. Both decontaminated materials and the waste products generated by on-site decontamination techniques are handled by the site licensee in the same fashion as any other on-site generated materials.

In either case, if the state in which the work is being performed is an NRC agreement state, the state may have instituted release limits that are more stringent than those found in Regulatory Guide 1.86. Regardless of the release limits, if the material is not suitable for decontamination, or if the cost of decontamination is not economical, other options such as incineration, size reduction, or super-compaction are available to substantially reduce the cost of disposal.

Recycling companies require that the licensee provide a general description of the material and its history in addition to more specific information, such as physical dimensions, weight, volume, and materials of construction (with drawings if applicable). A radiological characterization is also needed, including an isotopic analysis with activation and fission products and transuranics in abundances down to 1% or less. For undetected radionuclides the lower limits of detection must be listed unless it is known they are not present, in which case they can be identified as "not present."

When a licensee decides to ship contaminated metals to a recycling center, they normally issue a request for proposal. The nature of the contract will be dictated by whether the licensee intends to make a one-time shipment or multiple shipments. For multiple shipments, where specifics of each shipment may not be known in advance, the proposal may contain a pricing sheet.

When the contract provides for multiple shipments, the licensee may ship materials to the recycling company any time sufficient material is accumulated. The licensee may utilize a trucking company with which they have a contract for transportation services or request the recycling company to transport the material if transportation is included as part of that contract. The shipping manifest, which lists the material, its composition, radionuclides and their concentrations, also acts as a basis for the billing. The transportation cost is based on shipping distance per shipment, not weight, making it desirable for the licensee to ship as much material per shipment as possible without exceeding normal shipping weights.

If the licensee arranges for transportation, shipments may be sent at the licensee's convenience. However, the licensee must notify the recycling company of the shipment's arrival, usually 24 to 48 hours in advance. If the recycling company handles the transportation arrangements, they will inform their staff of a shipment's expected arrival.

Commercial recycling currently is limited to metals. SEG will accept virtually any ferrous and non-ferrous metal in any physical configuration which meets their Waste Acceptance Criteria (WAC) for radiological (<1,000 mR/hr on contact) and hazardous characteristics (trace only, no constituents regulated under the Resource Conservation and Recovery Act [RCRA]); however, attempts are made to limit aluminum,

galvanized metals and lead content. Surface contaminated metals accepted by SEG for decontamination for free release include ferrous and stainless steel, lead, tin, copper, aluminum, brass, and bronze, as well as refractory metals - including zirconium, tungsten, tantalum, and molybdenum - which have melting points above 3,000F. The latter four metals are accepted for surface decontamination only because their melting points are higher than the maximum temperature attainable in the SEG melter. Quadrex will accept many of the same materials, but notes that they will not accept RCRA heavy metals, toxic metals, activated metals or pyrophoric metals for decontamination.

Under special arrangement with DOE, SEG produces shield blocks for resale back to DOE. Metals are utilized which cannot be decontaminated for free release; these include stainless steel, carbon steel, iron, nickel, chromium and ferrous alloys with melting points at or below 3,000F. Small quantities of copper, aluminum, brass, bronze and stellite are acceptable as long as they do not exceed 1% by weight of the total mass. A premium is charged for materials with surface contact dose rates above 200 mrem/hour because additional shielding is required. Materials that require transportation in shipping casks are not accepted.

A recycler may want to inspect a shipment before it is sent. For a new customer or one with a one-time only contract for unusual materials, the recycler would inspect the materials prior to shipment. If, however, the customer has a long-standing general services contract and has previously shipped materials to the recycling center without incident, pre-shipment inspections are not necessary. In either case, only materials that comply with the recycling center's WAC may be shipped.

Recycling companies do not maintain detailed records on the physical form of recycled materials, but estimates of quantities are available. SEG estimates that, over the past ten years, they have decontaminated approximately 7,200 ft3 of lead weighing over 487,000 pounds, more than 75,000 ft3 of brass condenser tubing weighing more than 3 million pounds, and approximately 50 million pounds of other metals. Of this, 16 million pounds were fabricated into shield blocks for DOE, with 90% of the remaining 34 million pounds sold to the commercial scrap metals market. In the past ten years, Quadrex has accepted roughly 95 million pounds of metal, of which they have recycled (free released) about 81 million pounds or about 85% of the materials accepted. For both SEG and Quadrex, materials that could not be decontaminated effectively (or that ended up as slag in the SEG melters) were disposed of as low-level radioactive waste with ownership still vested in the generator.

Selection of a decontamination method by the recycler depends upon the composition and physical shape of the material or item to be cleaned and on the nature of the contamination. Surface contamination is considered either smearable or fixed. Smearable contamination can be removed by smearing, or wiping, the surface with a cloth. Removal can be enhanced by using several chemicals ranging from commercially available bathroom cleaners to proprietary chemicals.

Fixed contamination can be removed by either chemical or physical means. Chemical methods include acid etching, electropolishing, and complex, multi-reagent processes, some of which contain chelants. The use of multi-reagent processes containing chelants should be minimized; wastes containing these chemicals require special treatment to meet disposal criteria. Quadrex limits the use of electropolishing because of the large volume of contaminated phosphoric acid generated as a secondary waste; this material also requires special treatment.

Physical techniques usually involve impingement of the contaminated surface with particles, commonly referred to as blasting. Steel shot, solid carbon dioxide pellets, abrasive grit, ice crystals, sponge balls and high-pressure water have all been used successfully for various applications. Because of the potential for creating airborne contamination during blasting, these operations are restricted to being performed inside containment booths or glove boxes. Also, because of the need to minimize secondary waste volumes, materials like sand are rarely used. Tumbling, in large tumblers similar to those used for polishing gem stones, is used to clean scaffolding clamps.

The success of decontamination methods is highly dependent on geometric and surface features. In addition to porous materials, which are difficult to decontaminate because of the migration of contamination into the surface, materials with complex features, crevices and other inaccessible surfaces cannot be decontaminated by mechanical cleaning techniques. If such areas can be cleaned but not surveyed, the

material cannot be released for recycling.
Companies that provide on-site decontamination services have developed special equipment that vacuums up grit and dust, eliminating most, if not all, airborne contamination.
Standards used to determine when materials have been adequately decontaminated for free release are incorporated into a facility's license conditions. Facilities licensed directly by the NRC must satisfy NRC Regulatory Guide 1.86. If a facility is licensed by an "agreement state," the agreement state has the right to establish standards more restrictive than those established by the NRC. In specific cases, higher limits than specified in Regulatory Guide 1.86 can be approved in response to a petition for a license amendment incorporating appropriate risk analysis and exposure pathway modeling. In such cases, the agreement state may permit unrestricted release or restrict the use of the material to be recycled. Such restricted use normally is specified in the application.
Recycling companies use state-of-the-art radiation detection equipment, including large area-flow proportional detectors, GM detectors, plastic scintillation detectors, or intrinsic germanium detectors to adequately verify decontamination. In addition to their fixed contamination monitoring program, the SEG Unconditional Release Program includes requirements for taking smears of items to be released to determine the levels of removable contamination.
Both the SEG and Quadrex facilities are licensed by the State of Tennessee, which is an NRC agreement state. License reporting requirements under Title 10 CFR Part 20 (10 CFR Part 20) only apply to the secondary wastes generated by these facilities. These facilities are not required to report to the NRC on the quantities of materials decontaminated. Materials decontaminated at an originator's facility by an on-site services contractor are not reported under 10 CFR Part 20 since they are not part of a reportable waste stream; only secondary waste shipped off-site would be reported.
Facility inspections are performed by the State of Tennessee. Both routine and non-routine inspections may be performed from once a year to four times a year to confirm adherence to the facility license requirements. The principal concern is the nature of the activities conducted rather than the quantity of materials being handled. The NRC may participate as an observer on some inspections.
Title to recyclable materials resides with the licensee having most recent control over the material. Thus, for material shipped to a recycler by a carrier not owned by the recycler, the originator of the material holds title while it is in transit. The recycler takes title when it is determined that the material meets the recycler's WAC. This can occur at the originator's site if the carrier is owned by the recycler or at the recycler's site when the material is accepted. Material not accepted by the recycler, because it fails to meet applicable WAC or due to a Department of Transportation (DOT) violation, is returned to the originating facility at the originator's expense.
The recycler holds title of material decontaminated to release levels specified in the recycler's permit until the material is purchased and removed by a scrap dealer or other recipient.
The licensee with title to the material is responsible for compliance with applicable NRC and DOT regulations regarding storing, manifesting, labeling, packaging, and transporting the material.
Title to radionuclides removed from the material in the decontamination process is dependent upon the traceability of the radionuclides in the waste streams. Waste traceable to a specific originator after the decontamination process is considered distinguishable. Title to such waste remains with the originator until it is accepted for disposal at a licensed low-level waste burial site. Wastes generated during the decontamination process which cannot be linked to specific originators are deemed indistinguishable. Title to indistinguishable waste lies with the recycler until it is accepted by a licensed low-level waste disposal site.
An example of distinguishable waste is incinerator hearth ash. Material being fed into the incinerator can be temporarily stopped without an incinerator shutdown. The corresponding interruptions in the discharge of hearth ash can be used to determine the source of incineration ash.
Indistinguishable waste is best exemplified by bag house ash. It is not feasible to clean or remove the ash from off-gas system filters after materials from a particular originator are incinerated. Ash in these filters will generally contain

radioactivity from incineration of material from several licensees. Thus, radionuclides cannot be associated with specific originators.
Liability for problems that may occur during the transport of contaminated material to a recycler's facility is shared by those entities involved in the transportation process. Who arranges for and who provides the transportation will determine with whom liability is shared, be it the originator, the shipper or the recycler. Each of these entities is covered by insurance under the Price Anderson Act through American Nuclear Insurers.
Liability for alleged harm from the recycling of contaminated material can lie with every entity associated with moving the materials to the consumer. The originator of the material, the recycler, the transporter, the scrap dealer, and the eventual fabricator can be named as possible defendants in a law suit raised by the consumer. Each of these entities can also sue any predecessor(s) associated with the material. The basis of these legal claims would be that harm was done to one entity through the negligent activity of another. The alleged harm could be personal injury or equipment damage. Two things must be proven for the claim to succeed: that harm was done, and the material which was recycled was the cause of the injury.
Under the present standards associated with the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), originators may also be liable for their distinguishable and indistinguishable wastes after disposal at a licensed burial site. Originator liability for damages caused by the site and costs of remediating it are covered by the site's perpetual care fund. However, if site remediation costs and damages exceed the fund, it is feasible, under CERCLA, that all generators of wastes found at the site could be liable for their distinguishable wastes. Moreover, under CERCLA's present joint and several liability structure, the portion of remediation costs attributable to indistinguishable wastes would be shared among identified generators.
The terms contained in a recycler's permits can have a regulatory impact upon originators by prescribing the flow of materials from originators to recyclers. The primary terms of a recycler's permit are the standards identified for the free release of materials. Until NRC free release standards are established, permits adopt the guidelines of NRC Regulatory Guide 1.86 plus ALARA (As Low As Reasonably Achievable) as the release standard. The guidelines in Regulatory Guide 1.86 plus ALARA take on the force of law by incorporation into a recycler's operating permits.

Release limits, established in a recycler's permit, are important in the recycling process because they will likely determine the cost effectiveness of recycling materials. Materials will not be recycled if the cost of decontaminating them to the established release limits is greater than the cost of disposal.
Recyclers' permits may also contain conditions which specify their amount of storage space for contaminated materials, the radionuclide inventory they may carry, and the amount of time they can hold materials before processing. These terms will have implications for the volumes and types of materials originators may wish to recycle and the recycling schedule for the materials.
APPLYING COMMERCIAL PRACTICES TO DOE SCRAP METAL
No restrictions exist to prevent DOE from recycling surface contaminated materials. The same companies involved in decontaminating radioactively contaminated materials from commercial companies are more than willing to perform similar service for government facilities.
To a limited extent, recycling has been performed at the Fernald Environmental Management Project (FEMP) by the Fernald Environmental Restoration Management Corporation (FERMCO). This initial recycling project (1) was a competitive procurement won by SEG with Quadrex as a subcontractor. Under this procurement, SEG segregated the scrap metal piles at FEMP into carbon steel and non-carbon steel piles. The carbon steel materials were size-reduced (i.e., cut up into small enough pieces to fit into sea-land containers) on-site and packaged for shipment to SEG's facility in Oak Ridge, Tennessee. The non-carbon steel metals were also size-reduced and packaged for transportation, but shipped to the Quadrex facility, also located in Oak Ridge.
The carbon steel taken to SEG was melted in a furnace at 2,800F. The slag produced during melting contained approximately 90 percent of the radionuclide contamination, with the remaining 10 percent evenly distributed throughout the metal. While melting results in a significant decontamination of the metal, it cannot be released for

commercial use because there is no Federal regulatory standard which addresses volumetric contamination. SEG cast the steel into shield blocks for use by DOE under controlled conditions. If clean, virgin metal were used as shield blocks it would eventually become radioactive by activation. Therefore, recycling contaminated material eliminates the contamination of new, uncontaminated material.
The non-carbon steel, i.e., stainless steel and aluminum, was shipped to Quadrex, where it was decontaminated to the free release standards contained in their license. The method used was a series of proprietary chemical baths, after which the materials were surveyed and released to a local scrap metal dealer.
Both SEG and Quadrex created secondary wastes that required disposition. SEG generated both distinguishable and indistinguishable waste. The distinguishable waste was in the form of slag from the melter. As a distinguishable waste attributed to the Fernald scrap metal, ownership, or title, was still vested in DOE. This material was packaged and shipped by SEG to the Nevada Test Site as DOE waste. Other waste generated at SEG included dust collector wastes, dry active wastes (DAW), trash, wipes, rags, and booties; contamination of these materials could not be specifically attributed to the Fernald scrap metal. Being indistinguishable in their origin, these wastes were considered to be SEG wastes under SEG's Tennessee radioactive materials license. These wastes were solidified and buried at the commercial low-level waste disposal facility in Barnwell, South Carolina.
The secondary waste generated by Quadrex consisted of sludge resulting from the treatment of the decontamination solutions. As with DAW, contamination in the sludge could not be specifically attributed to the Fernald scrap metal processing and was therefore considered to be Quadrex-generated waste. This waste was disposed at the Barnwell facility after solidification with cement in 55-gallon drums.
With the success of the Fernald recycling program, an obvious question emerges: "Why aren't we doing more of this?" Several reasons have been identified, including the following:
People do not know where to start, what information is needed, or whom to contact.
DOE has a ban on the off-site shipment of radioactive materials.
DOE has a ban on the transfer of materials with "added radioactivity" to non-DOE facilities.
DOE cannot send radioactive materials to a commercial recycling facility because waste would be disposed of at a commercial burial site.
As shown by the Fernald experience, these issues do not prevent DOE from utilizing private contractors for decontaminating radioactively contaminated scrap metal for free release into the private metals market. The following discussion focuses on apparent misconceptions surrounding various DOE Orders and directives so that their true value can be understood, that is, laying a solid technical foundation by which these materials can be reused in general commerce without any hazard or adverse impact on the public.
1. Determine if the material being considered for recycling is appropriate. The flow chart in Fig. 1 is intended to assist in this decision process.
2. Assemble needed information on physical, chemical and radioactive properties of the scrap material. In addition to specific parameters previously discussed, further requirements can be identified by contacting recycling companies, including the following.
Quadrex, Oak Ridge, TN.
Scientific Ecology Group, Oak Ridge, TN.
Alaron Corporation, Beaver Falls, PA.
Bartlett Services, Inc., Plymouth, MA.
The assumption that off-site shipment of radioactive materials is prohibited is incorrect. The Environmental Management (EM) program has implemented a ban, or more precisely a moratorium, on the transportation of certain materials to facilities not licensed to handle radioactive materials. Those materials include the following:
radioactively contaminated materials which can only be shipped to a licensed facility under any circumstances, and,
material which is not known to possess any radioactive contamination but originates in areas where radioactive contamination is known to exist, such as a Radioactive Materials Management Area specified by DOE, is commonly referred to as "suspect material."
This transportation moratorium does not affect shipments of contaminated or suspect materials to a licensed recycler if the material being shipped complies with a

facility's WAC. In some cases, materials may not be contaminated above trace quantities.
The "no added radioactivity" statement is not contained in any DOE regulation or DOE Order. The term comes from the April 1993 draft of the Performance Objective for Certification of Non-Radioactive Hazardous Waste, which states that the performance objective is:
"To assure that hazardous/toxic wastes shipped from DOE facilities to commercial treatment, storage or disposal facilities have no bulk or volume radioactive contamination added as a result of DOE operations and are in compliance with DOE Order 5400.5 criteria for surface contamination unless the receiving facility is specifically licensed to manage radioactive waste."
This statement confirms the fact that current DOE regulations and Orders do permit the transportation of surface contaminated materials to licensed recycling companies for decontamination and subsequent free release. Similarly, DOE may release the material under DOE Order 5400.5 after verifying that the surface contamination limits have been met. This applies whether decontamination is performed on-site by a DOE contractor or a sub-contractor.
Any waste material with radionuclides distinguishable as originating with DOE would continue to be DOE's responsibility and either returned to DOE for disposal or sent directly to a DOE disposal facility as DOE waste. Secondary wastes that are indistinguishable as to their origin are considered to originate at the recycling facility and would be disposed of at a commercial facility.
As previously discussed, title to the contaminated material is vested in the organization under whose license the material is being controlled at any given time during the decontamination process. Radionuclides, however, if distinguishable, remain the responsibility of DOE as originator.
To avoid co-mingling of indistinguishable waste in the form of incinerator ash from the bag house filters, one commercial recycling company is constructing a low-level waste incinerator that will burn only DOE waste. Dedicating facilities to decontaminate government material may be a useful approach at several DOE sites.
DOE requires that the shipper and the recycling facility assume all liability for problems that may arise during transport to the recycling facility. Shippers and recycling companies do not like this arrangement; still, it has become accepted. Should a problem arise during transport, such as an accident resulting in contamination, DOE would respond as required by internal regulations.
"Suspect material" or "suspect contamination" is material which is suspected of being contaminated but has not been verified by any analytical method as being either contaminated or uncontaminated. At a 1992 meeting on the Waste Shipment Moratorium, a DOE representative noted "that a previous review of compliance with 5400.5 guidelines revealed that very few sites were capable of demonstrating compliance." (2) While DOE sites have the necessary equipment to characterize materials for compliance with DOT transportation regulations, it appears that some sites may lack equipment with the added sensitivity to demonstrate compliance with DOE Order 5400.5. Under these circumstances, materials could be shipped to a recycler for examination. Materials that are above the limits of either DOE Order 5400.5 or NRC Regulatory Guide 1.86 could be shipped back to DOE for disposal; materials with contamination levels below these limits could be recycled without further decontamination.
At Fernald, the cost associated with the recycling of this material - $4,755,920 - was 18 percent higher than the estimated costs of packaging, transporting and burying the same material at Nevada Test Site (NTS) - $4,021,440, based on a disposal cost of $10 per ft3 (1). However, taking into account the value of the recycled metal (an average of $800 per ton), the cost of the recycling process is reduced to $3,030,430, roughly 25 percent less than disposal. Even without the credit for the value of the recycled metal, recycling becomes cost effective when disposal costs are based on full life cycle costs, which is not the case at NTS. EPA (3) has estimated that a burial cost of $15 per ft3 at NTS is the breakeven cost for recycling. In addition to reduced cost, there are other benefits to be gained from recycling these types of materials. Issues that commonly affect waste disposal operations - for example, liability, site closure, and long-term controls - are substantially reduced.
Any distinguishable secondary waste is the originator's responsibility; disposal costs associated with these secondary wastes must be considered in a cost analysis.

By selling the cleaned scrap metal, the recycling company offsets disposal costs associated with indistinguishable secondary wastes.

CONCLUSIONS

There are no present DOE regulations, policies or procedures that prohibit DOE facilities from contracting with commercial recycling companies for services to transport, decontaminate and recycle surface contaminated materials. If detailed characterization of the material at the DOE sites is not practical, then general information, including suspected radionuclides and contact dose rates, can be used to ship materials to a recycling facility as "suspect material" for final determination by the recycler. The originating DOE facility will also have to make arrangements to receive shipments of distinguishable secondary wastes generated by the recycler for appropriate disposition.

DEVELOPMENT OF MAJOR PROCESS IMPROVEMENTS FOR DECONTAMINATION OF LARGE, COMPLEX, HIGHLY RADIOACTIVE MIXED WASTE ITEMS AT THE HANFORD SITE T PLANT

W. L. Johnson
Parsons Engineering Science, Inc.
R. L. Veilleux
Westinghouse Hanford Company
Richland, Washington

ABSTRACT

As part of the decontamination/treatment mission at the Hanford Site, Westinghouse Hanford Company, under contract to the U.S. Department of Energy, conducts decontamination activities at the T Plant complex. Currently, the 221-T canyon High-Level Waste Decontamination Facility and the 2706-T Low-Level Waste Decontamination Facility capabilities are limited because upgrades are needed. Major process improvements must be developed to decontaminate large, complex, highly radioactive mixed-waste items. At the T Plant complex, an engineering team process was used to project possible solid mixed-waste feed streams and develop a preconceptual system to decontaminate and treat the waste. Treatment objectives and benefits were identified. Selected technologies were reviewed and improvements required to implement a preconceptual system at T Plant were considered. Decontamination facility alternatives were discussed in conjunction with ongoing and future decontamination activities at the Hanford Site, including efforts to enhance overall decontamination operations and capabilities.

INTRODUCTION

The Hanford Site (currently owned by the U.S. Department of Energy) was acquired by the Federal Government in 1943 to house facilities for the World War II production of plutonium. For more than 20 years, the facilities were dedicated primarily to plutonium production and management of the associated wastes. In later years, programs were diversified to include advanced reactor research and development of renewable energy technologies. In recent years, the mission has changed from production of special nuclear materials to primarily waste management and environmental restoration. Westinghouse Hanford Company is the current Management and Operations Contractor for the Hanford Site, which comprises approximately 1,450 km2 of semiarid land located in south-central Washington State.

T Plant, located in the 200 West Area of the Hanford Site, was constructed from 1943 to 1944 as a wartime plutonium separations facility. It began chemical processing using the bismuth phosphate process in 1944 and operated under that mission until August 1956. In 1957, T Plant was converted into a decontamination and waste management facility and continues in this mission today. The T Plant canyon is a reinforced concrete structure 259 m (850 ft) long by 22.5 m (74 ft) high by 20.7 m (68 ft) wide. The canyon building contains 40 cells, each of which has a 1.8-m- (6-ft-) thick concrete cover block with 78.7-cm- (31-in.-) high protruding cover

bails. Decontamination operations occur above these cells on the canyon deck. The T Plant canyon is currently conducting only limited decontamination activities because upgrades are necessary before items can be accepted that have detectable alpha contamination or dose rates that exceed 100 mrem/hr on contact.
T Plant complex support facilities include the 221-T canyon, 2706-T Low-Level Waste Decontamination Facility, 214-T Storage Facility, 271-T Office Facility, 211-T Chemical Storage Facility, and mobile offices and change rooms. Figure 1 shows the T Plant complex layout and a cross-sectional view of the 221-T canyon.
The 2706-T facility, constructed in 1960 and upgraded in 1994, provides decontamination services for large transportable equipment having low levels of radioactive and hazardous contamination. The facility is used to decontaminate railroad equipment, plant process equipment, vehicles, and tools. The facility is equipped with a bridge crane, work pits for cleaning rail and highway rolling stock, steam cleaners, ice blasters, and various tanks. The facility cannot routinely accept items with detectable alpha contamination or items with dose rates exceeding 100 mRem/hour on contact.

WASTE STREAM EVALUATION

A waste stream analysis was performed to identify all potential feed streams to a centralized decontamination facility (1). It was estimated that over 350,000 m3 of contaminated equipment waste could potentially be generated over the next 30 years. This estimate included over 1,800 pieces of long-length equipment from tank farms (equipment items requiring size reduction for disposal in a standard burial box), a substantial mixed waste portion of the waste stream (over 35 percent of the total waste stream), and significant transuranic contaminated material.
To date at the Hanford Site, the mission to decontaminate and treat large complex equipment items and components that are currently installed in high-level nuclear waste storage tanks has received the greatest attention. These components (e.g., pumps, instrument trees, and air lances) can be up to 21.3 m (70 ft) long, 167.6 cm (66 in.) in diameter, and weigh over 70 tons when installed in the shielded transfer containers. These items are highly radioactive (up to 66 Rem/hour on contact) and are also designated as radioactive mixed waste because of the presence of a variety of chemical contaminants.
Uncertainties of the projected waste stream have a significant effect on the development of a long-term decontamination/treatment strategy and the development of a definitive processing approach. Further analysis of the preliminary waste stream projection indicates that a large portion of the contaminated equipment may never be removed from existing facilities and will either remain in place in a stabilized manner or be decontaminated/treated in the field. Recent studies indicate that only 200 pieces of long-length contaminated equipment will be retrieved over the next 10 to 15 years instead of the 1,000 pieces originally projected.
If a substantial feed stream develops, a centralized decontamination facility will likely be required. However, if the key generators at the Hanford Site perform their own decontamination and treatment in the field or obtain acceptance from the regulators to stabilize contaminated equipment in place, capital funding for a new treatment facility may not be warranted.

DECONTAMINATION/TREATMENT OBJECTIVES

Decontamination/treatment of surface-contaminated equipment as an alternative to reduce solid waste volumes and storage requirements has been deemed an option which should be evaluated further.
The benefits directly associated with the decontamination/treatment of the equipment can be summarized as follows:

- Significantly reduces radioactive mixed waste volumes and costs associated with packaging and subsequent disposal (Low-level disposal over radioactive mixed waste disposal is more economical by an approximate factor of three) (2).
- Provides a means for disposal of land-disposal-restricted hazardous waste (defined in 40 CFR 268 (3) and WAC 173-303-140 (4)), which requires treatment before disposal, mandated by the Resource Conservation and Recovery Act (RCRA) of 1976 (5).
- Contributes to waste minimization, conserves natural resources, and reduces personnel radiation exposure
- Reduces the cost for direct replacement of failed equipment
- Reduces the area required to store contaminated equipment.

By achieving these objectives, considerable cost savings can be realized through the reduction of waste volumes, mobility, and toxicity. Also, the possibility of reuse

or recycling can minimize waste storage and disposal costs. Figure 2 illustrates the desired end states of the material following decontamination/treatment.

TECHNOLOGY/PROCESS EQUIPMENT SELECTION

Team Engineering Approach

Central to developing major process improvements at T Plant is the process for selecting decontamination technologies and process equipment. To tackle this effort, T Plant personnel used a team engineering approach to define and evaluate waste and equipment treatment, handling, and volume reduction technologies and processes. This team, known as the T Plant Treatment and Disposal Evaluation (TRADE) team, was tasked with identifying technologies that could be implemented to support the waste and equipment decontamination mission. Also, the team was to identify the most viable technologies and the processes for application of those technologies.

To accomplish the process development objectives, the TRADE team formed several focus groups to examine containment systems, handling technologies, size-reduction technologies, treatment technologies, existing plant systems and capabilities, and waste stream identification and characterization methods. Throughout this process, the TRADE team followed the general methodology outlined below:

Review existing plant capabilities to determine what is usable, acceptable, and viable or could be made so through improvements (e.g., retrofit or operational changes)

Establish contact with industry experts, manufacturers, and suppliers to obtain information on existing and new technology developments and processes.

Evaluate data in a team format to determine the most viable treatment/process options and the best methods for incorporating the options into plant functions in a manner consistent with "debris" rules and accepted by cognizant regulatory authorities.

Provide recommendations for option selections to management and develop conceptual engineering information for implementation of the selected options.

Decontamination/Treatment Process Development

The team engineering efforts of T Plant's TRADE team resulted in the development of a process flow referred to as the primary decontamination module/secondary decontamination module (PDM/SDM). The PDM/SDM process flow will provide sufficient throughput capability to meet the expected contaminated equipment generation rates over the next 10 to 15 years. The concept includes two decontamination modules. In the first module, size reduction and chemical decontamination to reduce radiation levels will be performed. In the second module, abrasive cleaning and waste packaging will be performed to meet RCRA hazardous debris rule requirements. It is intended for the PDM/SDM process to be primarily remote-handled; however, waste packaging operations and material handling between the PDM and the SDM can include some contact-handled activities. A process flow schematic is provided as Fig. 3. Conceptual layouts for the PDM/SDM are shown in Fig. 4.

The following is a brief description of the PDM/SDM process:

Upon transfer into the facility, the equipment item will be remotely removed from the container using manipulators and an overhead crane. The container will be decontaminated using a water spray or by steam cleaning in the 2706-T facility. These decontamination methods will be adequate because the containers are expected to have only slight amounts of smearable contamination.

The equipment item will be transferred by conveyor to a mechanical cutting apparatus for size reduction. Size reduction will accomplish two objectives, 1) long-length items can be reduced to lengths that can be packaged in standard burial boxes, and 2) equipment can be cut and separated into portions having different levels of contamination. A typical tank farm pump can provide an example of the advantage associated with portioning contaminated items before decontamination/treatment. Highly contaminated portions of the pump that have been submerged in the tank waste could be cut and separated from less contaminated portions of the pump exposed only to the airspace between the surface of the waste and the tank dome. Another advantage would be the capability for separation of mixed waste parts of a piece of equipment from parts designated as low-level waste.

Following size reduction, The equipment pieces will be decontaminated using chemical dip tanks. Current chelating, oxidizing, and acid/base chemical technologies provide excellent radionuclide removal efficiencies. Three dip tanks will be used, each with its own rinse tank. Secondary containment will be provided for each of the dip and rinse tanks. A filtration and treatment system, an integral

part of this equipment, will provide treated recycled chemical fluids to the process.

The chemically treated equipment pieces will be moved into the secondary decontamination module where abrasive cleaning will be performed by carbon dioxide pellet blasting. This activity will remove most of the surface and embedded contamination and will also be very effective on hazardous waste such as lead-based paint. The CO2 pellet blasting operation will be performed in a self-contained module to ensure independent ventilation from the high rate of off-gas generation.

An inspection will be performed at an inspection station following abrasive cleaning and before final waste packaging. This inspection station satisfies the RCRA hazardous debris rule requirement for visual inspection. Equipment pieces with remaining radionuclide or hazardous waste contamination in excess of allowable quantities will receive repeated treatment (by chemical and/or abrasive methods) until they are deemed acceptable at the inspection station.

After passing inspection, the waste pieces will be moved to the waste packaging station. The waste packaging station includes a grout/stabilization station to meet RCRA requirements, a burial box packer, and a drum/drum overpack packing station. These various packaging stations provide flexibility for compliance with final waste disposal packaging requirements.

Facility Upgrades

To accomplish decontamination of large, complex, highly radioactive mixed waste items at T Plant in a manner compliant with all Federal and State environmental and safety standards, major process improvements to T Plant are required. These upgrades were identified after a thorough review of T Plant's viability to perform a long-term decontamination mission. These improvements include upgrading the electrical, ventilation, and liquid storage and handling systems at T Plant; upgrading a variety of other systems; and installing the new processing modules.

Alternative Evaluations

Alternatives to the installation of new decontamination/treatment process modules in the 221-T canyon are being considered. One alternative is installing the process modules in a annex to the 2706-T facility. Another alternative is performing treatment/stabilization activities in the field. The process of developing new decontamination/treatment capabilities at the Hanford Site is in its infancy and will be an evolutionary process driven by the cleanup mission and regulatory requirements.

CONCLUSIONS AND FUTURE ACTIVITIES

The evaluation and understanding of potential solid waste feed streams and the processes necessary to treat and decontaminate these streams is an ongoing, iterative process at the Hanford Site. Each step in the engineering process brings forth additional information and knowledge in the processing of unique waste types. Several decontamination facility alternatives have been developed and evaluated. These alternatives considered a full range of possibilities from no action through development of full-scale facilities.

Based on the analysis of data accumulated and the evaluation of alternatives, there is not sufficient justification to proceed with a centralized high-activity decontamination facility.

Long-length highly contaminated equipment from the waste tanks may not be a viable near-term waste stream; treatment in the field is currently being evaluated.

The waste streams are highly uncertain and will be formally evaluated in detail in the next six months.

The capital costs are relatively high.

If the treatment of long-length contaminated equipment in the field does not prove to be viable or acceptable, or if another waste stream is identified with a high degree of certainty, the use of a small annexed facility should be pursued in conjunction with the low-level decontamination capabilities at the 2706-T facility. It is vital that the low-level decontamination activities at the 2706-T facility continue and be enhanced as new or emerging technologies are identified. Any upgrades needed to maintain 2706-T should be pursued. In addition, efforts should continue in treating and disposing of the equipment and material already in the 221-T canyon and using the 221-T canyon for limited decontamination operations. The facilities and personnel associated with the 2706-T facility and the 221-T canyon can provide critical support in the areas of low-level decontamination, repackaging, and technology development. If the decision is made to decontaminate/treat material
