A simplified flow diagram illustrating the program is provided in Fig. 1, which demonstrates that documentation occurs at each step within the program. This figure illustrates the skeleton of the program, with the details being provided in this report and customized as necessary for each DOE facility.

Fig. 1

The development of the DOE ERP parallels the preparation of the actual waste for off-site shipment. Much of the DOE ERP, such as descriptions of the DOE facility's waste characterization and certification programs and a forecast of mixed waste shipment campaigns, can be developed from template information. Other information required for the ERP, such as the characterization of the specific waste being shipped, is obtained through implementation of the Plan. The checklist of DOE Order 5820.2A exemption request instructions facilitates preparing the ERP in parallel with characterizing the waste.

The characterization program involves the following steps. These steps assume that the common elements and templates have been developed before beginning the process. The DOE ERP is prepared parallel to this process.

1. Select the category of waste stream for off-site treatment or disposal and enter it into the project database.
2. Identify key words describing the waste stream selected (e.g., chemical names, regulatory classifications, and chemical categories) that can be used to search the waste management database.
3. Query the waste management database to identify the containers of waste applicable to the chosen waste stream.
4. Enter the selected container numbers into the project database.
5. If, at any time throughout this process, containers of waste are withdrawn from consideration, document the rationale in the project database.
6. Review all available characterization information (i.e., hard copy and electronic) for the selected containers.
7. Enter the characterization information into the project database for each container.
8. Using the information available, complete the applicable TSDF WAC checklist for each container and enter the information into the project database.
9. Identify the containers that cannot conform to the TSDF's WAC and enter the reason in the project database subfield. Remove these containers from consideration for shipment.
10. Identify the analytical parameters required by the TSDF's WAC and enter them into the project database.
11. Based on the project-specific sampling plan and TSDF requirements, and following a documented sampling protocol, collect samples of waste from selected containers. Enter the sampling plan and sampling protocol

document numbers and the containers selected for sampling in the project database.
12. Maintain chain of custody for the samples by complying with a documented chain-of-custody procedure.
13. Maintain all records and logbooks for the sampling activity in the project files according to a documented records management procedure.
14. Define the analytical parameters and analytes of interest for each sample for the analytical laboratory.
15. Validate the analytical results received, completing the data validation documentation and entering the results in the project database.
16. Complete the TSDF WAC checklist based on the validated analytical results and enter the results in the project database.
17. Complete the DOE ERP.
18. Ensure that the waste is packaged according to TSDF and Department of Transportation requirements.
19. Upon obtaining the TSDF's and DOE's approval, ship the waste to the TSDF.
20. Review the project file to ensure that it is complete.

SUCCESSFUL IMPLEMENTATION OF THE PROGRAM

LANL successfully shipped 15 55-gallon drums of liquid scintillation fluid to Diversified Scientific Services, Incorporated, (DSSI) in Tennessee for treatment and disposal. Preparation of this shipment provided guidance for and insight into developing the program described in this paper. The lessons learned from this shipment campaign are also serving to enhance the productivity, efficiency, and flawlessness of the LLMW off-site shipment program.

DOE has reviewed and approved without comment the ERP for 1602 cubic feet of solvent-contaminated soil. This waste stream is being reviewed by Envirocare of Utah, and LANL expects to receive Envirocare approval. LANL is also anticipating DOE approval to ship to DSSI over 100 55-gallon drums of isopropyl alcohol waste and scintillation vial fluid waste by March, 1996. Using this program as a guide to the thought process, LANL intends to complete the disposal of the following radioactively contaminated waste streams, pending sampling, characterization, DOE approval, and acceptance at Envirocare:

- Soil with heavy metals in June, 1996
- Lead blankets in July, 1996
- Activated and inseparable wastes in August, 1996

As lessons are learned from different waste streams, the program is adapted. Throughout the process, LANL is gaining a better understanding as to how to solve problems that arise with each shipment. The resolutions to these problems are incorporated into the program. Finally, this program allows each person responsible for preparing a waste stream for off-site shipment to understand the process and ensure quality management for each shipment.

The success of this program allows LANL to expeditiously and cost-consciously ship LLMW off site and to demonstrate a reasonable and good faith effort to comply with New Mexico Compliance Order and FFCA. Because of LANL's successful implementation of this program, DOE has recognized the value added of the program and has subsequently increased funding to all expeditious shipments of LLMW. This has allowed LANL to expand the number of personnel from one person at program inception to a current number of over 10 subject matter experts who comprise the program core

competency group. This core competency group also utilizes the expertise of other LANL groups in the areas of transportation, waste profiling, sampling, document and database research, and acknowledges the efforts of DOE to ensure overall program success.

COST ANALYSIS

Although a direct analysis of cost savings resulting from the implementation of this program cannot be conducted because of the infancy of the program, indirect savings in level of effort can be seen. LANL expended 16 months of effort to prepare the soils for shipment to Envirocare. Upon implementation of this program, however, it took only nine months of effort to ship the scintillation fluids off site for disposal. As LANL continues to improve the program, the effort will become streamlined and a routine operation.

ABSTRACT

Evaluations of gas stream compositions and products of incomplete waste conversion are valuable for screening and controlling remediation processes. In this work, the effluent from a pilot scale plasma torch processing a surrogate waste has been analyzed by conventional gas analyzers, gas chromatography, GC/MS and FTIR spectroscopy. Initial studies on the use of on-line Air ICP are discussed along with development efforts for an instrument capable of quantifying

polychlorinated organics (PCB's dioxins) on-line. Results from the surrogate processing studies indicate a reduced oxygen gas stream along with the presence of NOCI. The formation of NOCI (from the HCI arising from PVC destruction and the NO generated from the plasma torch) is accompanied by the liberation of chlorine, The HCl, NOCI and CI2 represent acorrosive gas stream and attention is needed in the design of APCD systems for plasma torch units. Results from the on-line Air ICP indicated the presence of copper which was not a component of the surrogate feed and has been traced to the torch electrode. GC/MS experiments using surrogate waste spiked with hexachlorobenzene indicated a DRE of at least 99.99%. The results obtained thus far indicate the instruments employed for the measurements should be suitable for routine analysis and may find application in torch facility controls.

INTRODUCTION

Plasma torches and joule-heated melters are two technologies which have been selected for mixed waste stream remediation demonstrations by the U. S. Department of Energy. The high temperatures generated in the furnaces of these units permit the formation of a glass which is expected to contain the radioactive material along with metals from the waste. The processes realize a volume reduction and provide a means for separation and packaging of the glass.

Some of the current efforts at the Diagnostic Instrumentation and Analysis Laboratory center on the analysis and further development of plasma torch technologies. This work includes the evaluation of operational factors related to torch electrode life, the establishment of instrumentation for characterization of process parameters (gas and surface temperatures, velocities and turbulence levels), and the characterization of gas stream effluents which could include permanent, inorganic, and organic gases, trace organics (PCB's, PCDF's and PCDD's), heavy metals, and particulates. Control schemes integrating the signals from the various monitors and process instrumentation are under development. Details of the integrated plasma torch development program are presented in a companion paper submitted to this conference (1).

The work described here concerns the characterization of gas streams arising from plasma torch processing of a surrogate waste. Factors affecting torch operation including torch gas, power, and stand-off have been investigated. Measurements were performed using conventional gas analyzers, gas chromatography (GC), GC/Mass Spectroscopy (GC/MS), on-line and extractive Fourier transform infrared (FTIR) spectroscopy, and inductively coupled plasma spectroscopy (Air-ICP). The instruments provide a detailed analysis of the gas stream composition at various locations of the DIAL plasma torch facility. In turn, this information is critical for selecting the proper operating envelopes of the torch and air pollution control devices and for understanding the reactions occurring within and downstream of the primary torch furnace. The instruments described in this work, when combined in an integrated approach, represent a comprehensive means for the rapid and on-line characterization of gases, organics, polychlorinated organics and heavy metals arising from plasma torch operations.

Two major instrumental development efforts are also discussed. One concerns the use of an advanced MS/MS technique for the rapid on-line determination of target organic compounds (PCB's, PCDF's, and PCDD's) while the other method will allow for the quantification of a number of

trace metals at, or below, current regulatory levels. The advanced ICP work may also find application as an air pollution control device.

EXPERIMENTAL

All of the experiments were performed on the DIAL plasma torch facility (1). The system consists of a 250 kW plasma torch operated either with air or nitrogen as the torch gas. Powers investigated ranged from 80-190 kW. The exhaust from the torch furnace was routed to the DIAL combustion test stand facility and then to a scrubber and stack. Details of the plasma torch system are discussed in Ref. 1.

Experiments were performed with and without a surrogate mixed waste feed which contained poly(vinyl chloride), glass beads, pecan shell flour, perlite (a volcanic glass) and iron powder each at a percentage of 12.8 % by weight. Alumina, aluminum, Portland cement, activated carbon, and metal chlorides made up the balance. Percentages by weight were 19.6 for carbon, 8.8 for oxygen, 7.14 for chlorine, and 1.67 for hydrogen. Inert material comprised 63% by weight of the feed with the balance metals. Preparation of the feed as briquettes has been described (2). A number of different molecules may result from the destruction of PVC. In order to estimate destruction and removal efficiencies by GC/MS, some of the briquettes were spiked with hexachlorobenzene (HCB).

Sampling and optical penetrations are located on the torch furnace, on the transition section 8 between the furnace and the test stand, and at various locations along the test channel. All measurements were taken upstream of the APCD systems. Samples for the conventional gas analyzers were taken from a location on the transition section meters downstream of the furnace. Samples for analysis by gas chromatography were collected at the same location as that for the conventional CO2, CO, NOx, SOx and O2 measurements. The gas chromatograph was configured to utilize both FID (Flame Ionization Detection) and TCD (Thermal Conductivity Detection) capabilities through use of two ten-port gas sampling valves. Permanent gases were analyzed using a Molsieve 5A column with the TCD while the halogenated hydrocarbons were analyzed using a DB-624 column with the FID.

FTIR measurements were performed either in an emission or an absorption mode. Emission spectra were collected at a port location approximately 1 m downstream of the furnace and gas samples were routed from the facility penetration 2 m downstream of the torch. Details of the FTIR measurements have been reported previously (3).

Samples for GC/MS analysis were collected within the test stand channel (approximately 12 m from the furnace). HCB spiking levels of 10 and 25 mg were employed. Samples were collected cryogenically with collection times ranging from ten to twenty minutes. The volumetric flow rate through the sampling train was calibrated using a mass flow meter and glass wool was used to retain particulates. Samples collected throughout the series of experiments were acidic (HCl and HNO3), and varied in appearance. Sample workup involved a residue quality extraction protocol. GC/MS data were obtained on two instruments; one configured with a quadrupole ion trapsuitable for MS/MS experiments and the second, a quadrupole MS, capable of both positive and negative chemical ionization (PICI and NICI).

On-line detection of metals present in the offgas stream from the plasma torch (and most exhaust stacks) is a difficult problem using a standard argon ICP as the emission or ion source. Argon plasmas are rapidly quenched by the introduction of a molecular gas aerosol flow. The

standard sampling procedure involves filtering the gas stream, followed by dissolution of the captured metals and analysis in the laboratory. The turn-around time may be in terms of days rather than seconds.

One solution to this problem is the use of a molecular gas ICP. The principle advantage of such a system includes the ability to provide real-time sampling of an offgas stream. In addition, the increased thermal conductivity within a molecular plasma results in improved decomposition of refractory particles and increased plasma tolerance of high sample loading. AES work performed by Barnes & Meyers (1,2) in 1985 demonstrated the technique's viability (4,5). More recently, with the advent of the Clean Air Act, a need to provide an online metal emission monitor for molecular gas streams has been established. Baldwin et al. re-evaluated the air-ICP and in the process, demonstrated markedly improved detection limits (6). The elimination of the requirement for argon significantly reduces the operating costs. The disadvantages of such a system include the need for higher input powers (2.5 to 3.5 kW @ 27.12 MHz), lower excitational energies (max. ~12 eV for air as compared to 15.7 eV for argon) and the presence of a much more complex molecular spectral background.

An evaluation and optimization of the Air ICP as an emission monitor is in progress in these laboratories. This work includes optimizing the system with respect to the ICP operating parameters (input power, flowrate, sample introduction) and investigating spectral line selection, spectral interferences and matrix effects. The work is performed using an argon ICP modified to operate on air with emission detection using monochromaters, photomultiplier tubes and/or a CCD array.

The sampling of the exhaust gases by the Air-ICP is designed to occur after the HEPA filters, large particles having already been removed. During the preliminary experiments, the aerosol flow is introduced into the Air-ICP using a heated-head diaphragm pump 15 m from the torch facility. Several experiments were undertaken by sampling directly using a slipstream from the offgas with a filter being used to remove larger particles. As mentioned above, the increased thermal conductivity within a molecular plasma yields improved decomposition of refractory particles and increases the plasma tolerance for high sample loading. To take advantage of this and explore the use of the Air-ICP as a secondary combustor, the operation of the Air-ICP under direct sample loading (prior to filtering) is being evaluated.

RESULTS

Plasma torch experiments were conducted using air and nitrogen as the plasma gas. The results presented below correspond to operation of the torch with air. Sampleswere collected at intervals corresponding to the injection of briquettes or to a change in torch operating power. A comparison of gas composition as measured through gas chromatography (GC) and through gas analyzers (GAS) is presented in Fig. 1. Detailed data are given in Table I. The samples for GC and GAS analysis were obtained at the same location downstream of the plasma torch. Discrete samples for GC analysis were collected over an interval of two minutes in 1 liter Tedlar sample bags. Collection was initiated as soon as the on-line gas analyzer began registering a change in composition. For the on-line gas analyzers, the composition was obtained at 13 second intervals. The results for each gas analyzer, obtained during the collection of the discrete samples, were averaged and these values are presented for comparison with GC results. Of interest are the oxygen concentrations, which are reduced as

compared to normal air, and the levels of carbon monoxide. The lack of detectable carbon monoxide indicates that conversion of the organics in the surrogate feed are very nearly complete. The reduction in oxygen concentrations correlates to formation of CO_2, and of NO, NO_2, and other species. Agreement between the carbon dioxide results for the two analysis techniques is excellent. For oxygen, a systematic deviation between the GC and gas analyzer results is noted. This discrepancy may be a result of acid gases present in the plasma effluent which affect the performance of the oxygen gas analyzer. The presence of PVC can result in the formation of hydrogen chloride and chlorine gas, (see below) both of which are very corrosive. Quantification of these species through gas chromatography is currently under investigation.

Fig. 1

Table I

FTIR studies have been performed across the duct leaving the plasma torch furnace and in an extractive configuration with a folded path cell configured for a path length of 75 m. Figure 2 represents an absorption spectrum from the extraction measurements. In addition to CO_2, NO, NO_2, and HCl, the molecules HNO_2 and NOCl (nitrosyl chloride) were also observed. NOCl was also found in the in-situ experiments and the source of this molecule has been traced to the reaction

$$4NO + 4HCl \rightarrow 2NOCl + 2H_2O + Cl_2 + N_2$$

where the HCl is the principle transformation product from the poly(vinyl chloride) contained in the surrogate feed. The formation of NOCl is accompanied by the liberation of chlorine and further efforts in these laboratories are being directed at the fate and removal of these corrosive materials. A preliminary identification of the levels of chlorine in the plasma effluent has been conducted using color detector tubes. The presence of chlorine has implications in the use of secondary combustion. Specifically, the operation of a fuel-fired burner with an added chlorine source may lead to the formation of additional chlorinated organics.

Fig. 2

GC/MS experiments have been performed on samples collected during briquette injection and with spiked briquettes containing hexachlorobenzene. At the operating conditions tested, analysis of the raw surrogate material did not reveal the presence of polychlorinated biphenyls, polychlorinated dibenzo furans and polychlorinated dibenzodioxins. Qualitative analysis of samples collected with the spiked feed revealed that not all of the hexachlorobenzene was destroyed. Figure 3 shows a typical full scan electron ionization (EI) spectrum. The base peak at m/z 284 and the isotopic pattern associated with this peak represent six chlorine atoms, therefore characterizing the presence of HCB in the off-gas stream.

Fig. 3

The intensity of the m/z peak at 284 in the reconstructed ion chromatogram indicated a low level of HCB in the sample. This peak intensity is consistent with that of a nanogram (or less) of HCB injected on a GC column. Assuming complete quantitative trapping and extraction of the material, a destruction efficiency of at least greater than 99.99% for HCB occurs. Sampling conditions are anticipated to be less than ideal owing to the complicated sample matrix; consequently, the destruction efficiency (relative to the amounts of HCB present) could be slightly greater than that mentioned above.

In several experiments a compound was observed with spectra consistent with pentachlorinated biphenyls; however, correlation to the torch conditions proved difficult. Potential problems include those due to sampling and subsequent sample workup along with memory effects in the torch and manifold. Future work will concentrate on improving quantification, correlation of operational parameters to destruction efficiencies and sampling at different locations to determine if the distribution of analytes is consistent in the waste stream.

Over twenty years effort have been expended on optimizing the argon ICP to reach its present sensitivity. Very little of this essential work has been done on the Air-ICP. An air plasma is not only chemically reactive but the background spectrum contains complex molecular contributions absent from noble gas plasmas. This later artifact requires a careful re-evaluation of the selection criteria used to optimize the detection limits of the elements of interest. At present, research is being directed at the calibration of the instrument for use as an emission monitor of toxic metals. For example, the DIAL torch facility is processing feed that contains cesium, cadmium, lead, chromium, cerium, and nickel. The Air-ICP is being configured for the analysis using a slipstream and system optimization is in progress. Preliminary data (Fig. 4) demonstrate the presence of sodium plus copper from the torch electrode. On line analysis would then permit the assessment of electrode wear. In addition, the molecular spectra are complicated with the addition of contributions from other molecules (i.e., CN). Future work will focus on spectral line selection, calibration and improved quantification.

Fig. 4

INSTRUMENTATION DEVELOPMENT

The determination of trace organic molecules and metals is currently possible only through the extraction of a sample from the gas stream followed by analysis in the laboratory. Such information, while an average description of the process emissions at a given point in time, may not reflect rapid changes in the effluent and correlation to facility operations is delayed. Two projects are currently underway at DIAL which are anticipated to provide low limits of detection for large chlorinated organics and formetals in an on-line and rapid (<4 minutes) way.

An advanced MS/MS system is under development which should allow the quantification of large organic molecules (polychlorinated biphenyls, dioxins, etc.). The instrument is comprised of a molecular beam interface, a laser ionization source, and an orthogonal quadrupole ion trap housed in a six way cross vacuum chamber. A capillary tube and skimmer cone are mounted in a differentially pumped region and used to produce a continuous defined molecular beam. SIMION6, an electrostatic modeling program, was used to design the source region and lens stack necessary to direct ions into the orthogonal trap (7). The fourth harmonic of a Nd:YAG laser (266 nm) is used for multiphoton ionization of target compounds. The ion trap is controlled by a commercial electronics unit which also controls data acquisition. Resonant MS/MS capabilities (available in the control unit) will be used to enhance analytical specificity and sensitivity.

Additional efforts with the Air-ICP include the development of a fieldable system and application of the unit as a downstream pollution control device. A major drawback with the use of an Air-ICP for on-line monitoring of heavy metals has been the capital cost as well as the bulk

of the power supply. Air-ICP power requirements are on the order of 2.5-3.5 kW and have typically been beyond the capabilities of solid-state RF generators. DIAL has funded the development of a solid-state 3.5 kW 27.12 MHz RF generator and matching system. The unit will be rack mountable and will weigh 60 kg which is approximately 1/10 the weight of a standard generator. Air is supplied by a portable compressor thereby freeing the system from the supply requirements of the standard ICP.

As mentioned, different detection methods are also being explored. For complicated matrices it is sometimes necessary to employ high resolution monochromators of up to 1.5 meters in focal length. Ideally, for a fieldable system, the resolution of the monochromator is desired but the size is cumbersome. Baldwin has developed a fiberoptic interferometer which is expected to provide the resolution of a 1.5 m unit in a 0.5 m package (8). A protoype system is being developed and will be interfaced to the Air-ICP.

Another aspect of the Air-ICP work is the potential use of this system as a secondary combustor for the off-gas from a plasma torch. Plasma torch units typically operate at very low flow rates as compared to combustion-driven technologies. As an example, the 250 kW plasma torch used in this work normally operates in a range from 225-500 liters/min. (8-18 cfm). The addition of the large flow rates from a conventional secondary combustor may have many drawbacks including the fact that considerable amounts of additional mass are placed into the system. Reactions of the burner fuel with molecular chlorine and HCl may actually increase the chlorinated organics in the effluent An additional thermal load and added costs are also associated with using burner fuel. An air plasma has significantly increased thermal conductivity over an argon plasma. This, together with the presence of dissociated oxygen and nitrogen, makes the plasma very chemically-reactive. The ICP can rapidly destroy anyhydrocarbons without the introduction of the large quantities of additional gas and energy supplied by the propane burners. In addition, it may be possible to, by the addition of selected gases (e.g. hydrogen), control the plasma chemistry thereby reducing further the reaction end products.

CONCLUSIONS

Analysis of the effluent from a pilot-scale plasma torch processing a surrogate mixed-waste have indicated that the principle products of destruction are CO_2, NO_2, NO, and HCl. In most cases only low or trace concentrations of CO were found indicating complete conversion of the organics in the feed to CO_2. FTIR emission and absorption experiments have indicated that the NO from the plasma can react with the HCl (liberated from the PVC) to produce Nitrosyl Chloride. Although NOCl can be easily scrubbed from the gas stream the generation of Cl_2 accompanies this reaction. Problems may be encountered with downstream systems which are not designed for removal and handling of the corrosive gas stream. GC/MS experiments with added hexachlorobenzene have indicated destruction and removal efficiencies close to 99.99 %. Further studies are planned concerning various torch operating envelopes and different feed compositions and rates. Preliminary results demonstrate that the Air-ICP has an excellent future as a toxic metal emission monitor. However, it must be noted that considerable work remains in characterizing and optimizing the system. The use of the Air-ICP as a secondary combustor may have advantages other than merely reducing the thermal loading and

similar associated costs. If so, this may substantially reduce problems in downstream treatment. Further studies are planned.

ACKNOWLEDGMENTS

ABSTRACT

Rocky Flats Environmental Technology Site and other DOE sites have large volumes of low-level mixed waste (LLMW) in powdered forms, which must be processed into stable waste forms suitable for long-term storage. Polyethylene microencapsulation, in which the waste is thoroughly mixed with molten polyethylene and extruded into containers, is the first LLMW stabilization process that can be monitored in real-time to avoid processing errors and provide regulators with proof-of-proper-processing documentation. Monitoring compatibility and the smaller, lighter, more economical, inert polyethylene waste form results in significant advantages over cementation and grout based matrices, which are prone to

chemical interaction with the waste. The monitor is a noncontact device that acquires the midinfrared spectrum of the process stream via emission spectroscopy. The stream composition is then derived from the spectrum using partial-least-squares techniques. Monitor operation is insensitive to the thickness of the process stream and to its surface morphology. The monitor has been demonstrated on polyethylene microencapsulation lines processing nitrate-salt LLMW and its surrogate, molten salt oxidation LLMW and its surrogate, and flyash. Typically, the monitor achieves a standard error of prediction of less than 1% by weight with an analysis time of less than 20 seconds.

INTRODUCTION

The DOE complex has large volumes of low-level mixed waste (LLMW) in powdered forms, such as salts and flyash, which must be converted into stable waste forms prior to long-term storage. Polyethylene microencapsulation is a waste immobilization process that produces a smaller and lighter final waste form than the cementation processes presently in use.(1, 2) Microencapsulation also avoids the chemical interactions with the waste that create cure problems for cementation.(2) Polyethylene microencapsulation is well suited for on-line monitoring that ensures the processed waste meets specifications required by regulators without experiencing costly processing errors.

The on-line monitor being developed for microencapsulation processing provides a continuous, real-time, quantitative record of the waste-loading concentration in the polyethylene matrix. This allows the process operators to better maintain the waste loading and processing conditions at optimum. They can also use the monitor analysis in developing treatment protocols for specific wastes. The immediate analysis shows the operators how the processing parameters affect the properties of the final waste form. In addition, the monitor log can assist in waste certification and act as an archival record of the waste composition. The monitor uses transient infrared spectroscopy (TIRS) to perform its analysis. TIRS is a noncontact method for acquiring the midinfrared spectrum of a moving stream of solid or viscous-liquid material. The stream composition is then derived from the spectrum using partial least squares analysis. Typically, the monitor determines the waste loading every 15 to 20 seconds with an accuracy of less than 1% by weight.

The monitor has been demonstrated on process lines encapsulating nitrate-salt LLMW and its surrogate (sodium nitrate),(1, 3, 4) flyash, and molten-salt-oxidation LLMW and its surrogate (a mixture of sodium carbonate and sodium chloride). Demonstration analyses done at Rocky Flats Environmental Technology Site on nitrate-salt LLMW and on flyash are discussed in this paper.

TIRS TECHNOLOGY

TIRS has been developed as a general molecular-analysis on-line monitor for use on process streams of solid and viscous-liquid materials. It has been demonstrated on a wide variety of moving materials, both in the laboratory (5, 6) and on process lines.(3) Figure 1 schematically shows how the TIRS monitor is set up on a waste-processing line.(4) The molten stream of polyethylene-encapsulated waste flows through the field of view of an infrared spectrometer. The molten stream, by virtue of its elevated temperature, strongly radiates in the midinfrared part of the spectrum, which the spectrometer observes. This bulk emission is a blackbody spectrum; it consists of emission at all wavelengths, and its intensity varies slowly with wavelength, following Planck's Law. This blackbody

spectrum is indicative of the temperature of the stream, but it is not useful in analyzing the stream composition. Spectroscopic analysis relies on the fact that sufficiently thin or dilute samples will absorb, emit, or reflect only those wavelengths that strongly interact with the molecules of the sample. The spectrum resulting from this interaction consists of a set of sharp features, called bands, that are characteristic of the particular molecules in the sample. The blackbody spectrum from the stream lacks these sharp features because the stream is too thick and optically opaque.

Fig. 1

The TIRS monitor avoids this blackbody problem associated with a thick, opaque process stream by focusing on only a thin surface layer of the stream. The TIRS monitor trains a small jet of room-temperature air onto the surface of the process stream as it flows through the spectrometer field of view. This cools a thin layer of the stream at its surface. This surface layer no longer emits infrared radiation strongly because of its reduced temperature, but the infrared spectrometer still observes infrared radiation from the rest of the process stream. This radiation must pass through the cooled layer to reach the spectrometer, and the cooled layer absorbs some of it. The cooled layer is sufficiently thin that it absorbs only at its characteristic bands. The spectrometer therefore observes the smooth blackbody emission spectrum of the stream bulk with the sharply structured transmission spectrum of the cooled layer superimposed on it. The process-stream analysis is based on the transmission spectrum.

For the analyses discussed here, a Bomem MB 100 FTIR spectrometer fitted with a mercury-cadmium-telluride detector was the infrared spectrometer around which the TIRS monitor was built.(3, 4) The TIRS cooling-jet nozzle was a length of 0.6 mm inner-diameter stainless-steeltubing aimed at the process stream and carrying a 1.6 L/min flow of room-temperature air. The partial least squares analysis of the data was done with Spectra Calc PLSplus (Galactic Industries).A TIRS monitor can also be used when the process stream is not at an elevated temperature. For cool process streams, a TIRS monitor uses a hot-gas jet to produce a heated, thin, surface layer.(3, 5) The structured emission from the thin layer can then be analyzed in the same manner as the structured transmission spectrum of the cooled layer produced when a cooling jet is used. Early work on applying TIRS to polyethylene encapsulation examined both cooling-jet and heating-jet versions.(3, 4) Both versions gave good quality analyses, but the cooling version is simpler and slightly more stable, so it was selected for the applications discussed here.

DATA TREATMENT

Spectra acquired by the TIRS monitor are "single beam," that is, they are the raw signal intensities observed as a function of wavenumber. Usually in spectroscopy, such single-beam spectra are "normalized" by ratioing them against a reference single-beam spectrum so as to remove any wavenumber-dependent variation in the spectrometer response. In TIRS, this normalizing also removes the Planck's Law rise and fall of signal intensity with wavenumber that is characteristic of thermal emission. Figure 2, discussed below, shows both the single-beam and normalized versions of a spectrum. The analyses discussed here are based on normalized spectra. The reference spectra used were blackbody emission spectra observed from the process stream when the TIRS cooling jet was turned off. It should be noted that the analysis can be done based on

single-beam spectra, but normalization can often result in improved accuracy.

Partial least squares is used to derive the stream composition from the spectra.(7) The partial-least-squares method calibrates the monitor by building a model from a training set of spectra. For the work reported here, the monitor acquired the training-set spectra while the waste processor is held at a series of stream compositions with other process parameters (e.g., stream temperature and flow rate) held strictly fixed. More readily applied methods of acquiring the training-set data are being developed. A prediction as to how good the resulting calibration model will be is the Standard Error of Prediction (SEP) produced by single-elimination cross validation. In a single-elimination cross validation, one of the training-set spectra is removed and a calibration is developed using only the remaining members of the set. The composition of the excluded member is then determined from this calibration. The excluded member is then put back in, a second member is taken out, a new calibration is developed, and the second member is analyzed. This process is repeated until all members of the training set have been excluded and analyzed. SEP is the root mean square of the deviations of the analyses from the known sample compositions. Once the calibration model is built, analysis of an unknown spectrum is very fast (under 1 second), so partial least squares is very compatible with real-time analysis.

DEMONSTRATION ANALYSES

Figure 2 shows spectra from demonstrations at Rocky Flats on two different processed-waste streams. The spectra in the top panel of the figure are from a molten stream of nitrate-salt LLMW in polyethylene. The two spectra labeled With Jet and Without Jet are single-beam spectra of a stream containing 55% by weight LLMW. The Without Jet spectrum is the spontaneous blackbody-like thermal emission spectrum of the stream observed with the TIRS cooling jet turned off. The With Jet spectrum is the TIRS spectrum observed by aiming the jet onto the stream. The overall rise and fall in intensity of these spectra follow Planck's Law for thermal emission, but the drop off at low wavenumbers is augmented by decreasing detector sensitivity. The sharp structure between 1300 and 1900 cm-1 are absorptions by water vapor in the air between the process stream and the spectrometer. Similarly, the features between 2300 and 2400 cm-1 and the one sharp feature at 667 cm-1 come from carbon dioxide in the air. The lower intensity of the With Jet spectrum compared to the Without Jet spectrum indicates the lower temperature of the process stream surface resulting from the cooling jet. The With Jet spectrum also has the features from the transmission spectrum of the cooled surface layer, but they are small and do not immediately catch the eye.

Fig. 2

Normalization makes the transmission features obvious by removing the Planck's Law intensity variations and the water and carbon dioxide absorptions. Division of the With Jet spectrum by the Without Jet spectrum results in the normalized 55% Waste spectrum in Fig. 2. The 35% Waste spectrum is a normalized spectrum at a different stream composition included for comparison (and offset to avoid overlap). All of the features in the normalized spectra can be assigned as absorptions by either the LLMW or the polyethylene (except for some noise above 3000 cm-1). Polyethylene produces the strong bands at 2850 and 2910 cm-1 and the moderate band at 720 cm-1, as well as other absorptions at 1300, 1360 and 1460 cm-1 that are covered up by LLMW bands (but are visible in the

spectra in the lower panel of Fig. 2). The remaining bands all arise from the LLMW. The intensities of all bands within a spectrum are dependent on noncompositional parameters such as stream temperature, but the relative sizes of the LLMW and polyethylene features indicate the stream composition. The polyethylene bands decrease relative to the LLMW bands in going from 35% to 55% waste.

The lower panel of Fig. 2 shows (offset to avoid overlap) normalized spectra of a stream of polyethylene-encapsulated flyash at the indicated compositions (% by weight flyash). All of the features in the 0% Flyash spectrum come from polyethylene, except for noise above 3000 cm-1. Flyash has a single, broad absorption between 600 and 1600 cm-1 that grows with increasing flyash concentration as the polyethylene bands shrink.

Fig. 3

Figure 3 shows the results from a single-elimination cross validation on six spectra of encapsulated nitrate-salt LLMW (including those in Fig. 2). The TIRS-predicted waste loadings are plotted against the actual waste loadings, and the linear-regression line for the points is shown. The ideal result would be a regression line that exactly bisects the plot (i.e., identical predicted and actual values). The real line comes very close to this. The SEP for the cross validation is 0.64% by weight, demonstrating an accurate TIRS analysis. Fig. 4 shows a single-elimination cross validation of 21 spectra of encapsulated flyash (including those in Fig. 2). As in Fig. 3, the TIRS predictions are plotted against the actual values (open circles) and a linear-regression line is included. The SEP is 0.84% by weight. In addition, the analyses from a set of "unknowns" not included in the cross validation are marked by triangles.

Fig. 4

CONCLUSION

The TIRS monitor provides accurate, real-time analysis of the composition of polyethylene-encapsulated waste streams. The TIRS monitor is a noncontact device that acquires the midinfrared spectrum of the moving process stream. It has been demonstrated on DOE process lines encapsulating nitrate-salt LLMW and its surrogate, molten salt oxidation LLMW and its surrogate, and flyash. On nitrate-salt LLMW and flyash, the specific demonstrations discussed in this paper, the monitor achieved a standard error of prediction of better than 1% by weight with an analysis time of less than 15 seconds.

THERMAL CHARACTERIZATION OF MIXED WASTES

Ashot Nazarian

ABSTRACT

A method for analyzing small samples of mixed wastes (MW) by a new invention known as the laser driven thermal reactor (LDTR) is presented. The processes of pyrolysis, volatilization, combustion, and thermal decomposition can be studied. The LDTR allows one to measure the kinetic parameters of these processes. Also, compositional analysis of gas phase products by gas chromatography can be realized using the LDTR. As an application of this technique, the volatilization of radionuclides, as indicated by b and g radioactivity of gaseous effluents, and residual activity of solid residues will be determined. It is also shown how a LDTR-based thermal analysis of a solid residue of MW under different heating rates will provide quantitative information about its stability and the existence of trace organics. In conclusion, it is shown that the LDTR represents a valuable test device for characterization of waste destruction processes.

INTRODUCTION

The purpose of the Laser Driven Thermal Reactor (LDTR) (1-3,7) is to measure the thermal parameters of processes for the destruction of organic and mixed wastes to enable one to develop mathematical models of the processes with numerical parameters. The models, in turn, permit one to determine optimal parameters for the thermal treatment of the wastes in large-scale systems. Because the LDTR requires only small samples (~10-3g), it is particularly useful in analyzing the thermal treatment of low level radioactive organic compounds. Further, through the measurement of the radioactivity of gaseous products and of the solid residues of the LDTR, it is possible to optimize systems for the treatment of such wastes.

A general schematic of the LDTR is given in Fig.1. Two hemispheres fabricated from copper foil form a spherical reactor, within which the waste sample, supported by a substrate, is located. The reactor is irradiated by cw YAG laser beams from two sides and is heated up rapidly to a temperature of 1000 K. The rate of heating can reach up to several

hundred degree Kelvin per second. Temperatures on the surface of the reactor vary by no more than 100 K. The sample temperature rises rapidly with increases in reactor temperature. Exothermal or endothermal processes of the sample at high temperatures lead to an additional increase or decrease of the temperature of the sample and substrate. The time dependencies of the reactor and sample temperatures permit one to determine the parameters for the thermal treatment of the sample.
Along with a determination of the thermal parameters of the process, the gaseous products are analyzed. In addition, the sample weight is determined before and after the process. All of this permits one to describe the process in the form of a mathematical model with numerical parameters.
Fig. 1
AN ILLUSTRATION OF THE LDTR METHOD
To provide an example of the determination of thermal parameters by the LDTR method, let us consider a one-stage process. The specific heat release (the energy released per unit mass of the sample), $Q = Iq(T)dt$, is the principal parameter of interest, and shall be derived. We assume that a sample is complex substance and consist of combustible (e.t. organics) and non-combustible parts. For a determination of the parameters of interest, it is necessary to analyze temperature evolution dependence of the reactor and of the sample with substrate. This method assumes that the temperatures of both the sample and substrate are the same during the process, as well as uniform throughout these substances. Therefore, this method is valid for slow processes with typical completion times exceeding 0.01 s.
Then the equation in terms of the temperature T of the sample with substrate may be expressed by the heat balance:
Eq. 1
where Tr is the reactor temperature, cp is the specific heat of the sample with substrate, m is the total mass, P(Tr) is the rate at which heat is transferred from the reactor to the sample with substrate, and R(T) is the rate of heat loss from the sample with substrate. At equilibrium, a certain sample temperature T corresponds to each reactor temperature Tr , requiring the condition,
Eq. 2
During the course of heating, the sample temperature will differ from its equilibrium temperature because of transient response to heat transport. We will give below a method for determining the equilibrium sample temperature from two measurements.
Let the reactor temperature Tr be constant, and the sample temperature be T, which will differ from its ultimate equilibrium value To. Then the process of sample temperature evolution is given by the equation:
Eq. 3
where t is the temperature dependent relaxation time to the equilibrium, which may be defined in any infinitesimal time interval as:
Eq. 4
On a basis of two measurements, for the temperatures of reactor, and for the substrate with the sample, one can determine the equilibrium temperature To and relaxation time of the system. They are given by formulas:
Eq. 5
Eq. 6

where T1 and T2 are sample temperatures for two different heating rates 1 and 2 which result in these temperatures and (dT/dt)1, (dT/dt)2 are their derivatives. Determining the parameter t allows us to analyze exothermic chemical processes. This parameter can be determined not only by the measurement of delay in the sample temperature rise during heating of a reactor, but also by another method: the sample can be heated by laser radiation separately at the constant reactor temperature, and then t is measured directly as the relaxation time of the sample temperature. The instrumentation for measuring T is shown on Fig. 1.

Thus we have the following equation for the sample temperature, derived from the Eq. 1 heat balance, with expression of R(T):

Eq. 7

Here cp', m' are the specific heat capacity and mass of the combustible part of the sample, respectively, and q is the specific heat release rate of the process. This equation allows one to determine the specific parameters of combustion on the basis of measurement of the heat release of the process. In particular, if the mass of combustible part is small compared to the sample mass m' m and it's consumed in the course of the process, we have the following set of equations which describe the heat process, from Eq. 7:

Eq. 8

Eq. 9

where Q = q(t)dt is the specific heat release of the combustibles. From this, the algorithm of the treatment of measurements follows. We then have these equations:

Eq. 10

Eq. 11

where DT = Tf -Ti, and Ti, Tf are the sample temperatures at the beginning and the end of the process, respectively. Since Dm is the change of the combustibles mass, Eq.11 permits one to determine Q, the specific heat release of the combustibles. Then from Eq. 9 one can determine m'(t), and Eq. 9 gives the value of the specific heat release rate

Eq. 12

This methodology pertains to one-stage processes. Comparing values of q(t) at different rates of heating, one can determine the validity of a model of a one-stage process in a concrete case, and also determine the accuracy of numerical experimental data.

The method has two requirements for reliability and accuracy. First, the position of the substrate inside the reactor must be the same in different experiments. Secondly, although the temperature can be varied over the reactor surface, this distribution must be the same in different heat regimes. Measurements of temperature at one point on the surface of the reactor can be sufficient to verify the second requirement, and can be used for comparison with the temperature evolution with and without a sample. The degree to which these requirements are violated determines the accuracy of the method. Note that heating of the reactor can be made not only by laser, but also by electrical heating of the reactor in the analysis of metallurgical processes. However, the laser-based method of heating offers some advantages over electrical heating, including higher heating rate, better controllability, and direct determination of heat loss.

EXAMPLES OF ANALYZED PROCESSES

Below we consider some processes which are analogous to thermal treatment of wastes and which were analyzed by the above method. Organic wastes can consist of a mixture of various organic compounds, and variations in the content of components of this mixture can require changes in the optimal parameters of the phenomenological thermal processes. Therefore, for optimization of the process of treating a given mixture, it is necessary to determine numerical parameters of the process specifically for this waste. However, the qualitative character of the process is the same for different wastes. Therefore, first let us consider the general peculiarities of the thermal treatment of wastes. There are two forms of wastes for thermal treatment. In the first case, there is inhomogeneous mixture of individual particles and, in the other case, there is liquid waste.

In the first case the total waste volume takes part in combustion, and a suitable model for this process is the combustion of a porous or powdery organic substance. Let us take activated coal as a model for this process. Different components of a waste are burned at different temperatures and the thermal process can proceed for them in different ways. Indeed, combustion of organic volatile matter (VM) which takes place at low temperatures, is accompanied by vaporization of these components. The competition of these processes is such that at high temperatures, combustion of the VM proceeds quickly, while at low temperatures they can volatize and leave the reactor without combustion. Thus the probability of combustion of volatile matter in a reactor depends on the rate of heating and the size of the combustion region. Within the framework of this method, the value of this probability can be calculated for certain parameters of the thermal reactor.

Let us consider these processes in the case of thermal treatment of an activated coal in oxygen or air, which is a model for combustion of solid organic wastes consisting of small organic particles. One can separate the combustion of a VM and of the main solid residue. This process proceeds according to this scheme (1,2):

Eq. 13

Thus a part of a coal VM can be vaporized and does not partake in the combustion process inside a coal. It becomes a factor in the heat release inside a coal and influences the temperature. Clearly, the greater the gas pressure and temperature, the more likely it is that combustion takes place inside a coal.

Let us introduce the probability Pcom that combustion of a VM proceeds inside a coal and the probability Pout of a leakage of a VM outside a coal. We have

Eq. 14a

and the ratio of these values is approximated by the Arrhenius law:

Eq. 14b

Parameters of this formula and conditions of measurement are given in Table I and this function is represented in Fig. 2 for the activated coal for two different oxygen pressures. If the oxygen pressure or the sample temperature are high enough, the chemical process goes according to the first mechanism (13). The parameters of this process - the specific chemical energy Q and the specific power of the process q(T) - are given in Table II for the combustion of an activated coal.

Fig. 2

Table I

Table II

Let us analyze the process of the combustion of a coal VM. It is described by 5 parameters that can be used if this process proceeds in a certain system. For example, if coal particles are burned out in a special energy facility, these parameters permit one to choose optimal conditions for this facility. From the data in Tables I, II, one can assume that parameters of the chemical process depend on the size of coal particles. The data show a strong dependency on the type of a coal, which can be accounted for in the estimation of optimal conditions of an energy facility. For example, if we change a type of coal in an energy reactor, the optimal conditions inside also change. Thus, it is necessary to obtain parameters of the chemical process for a given type of coal, providing an opportunity to evaluate the optimal conditions for this reactor.

The formation of gaseous components is of importance for the thermal treatment of organic compounds, both in the intermediate stage of the process, and as final oxidation products. As an example of such measurements, we can consider combustion of an activated coal in ozone, which is absorbed by coal. Accepting products of this process to be CO and CO2, assume the concentration of these compounds to be dependent only on the absorption temperature T. Figure 3 shows this dependence, obtained on the basis of chromatographic measurements (6). These data are included in the model of the process.

Fig. 3

As a model of the thermal treatment of liquid organic materials , the process of heavy fuel oil (HFO) combustion was analyzed. The first stage of this process is transformation of a liquid fuel to a gas which proceeds according to scheme:

Eq. 15

This measurement gives the specific absorption energy 0.7 0.1 kJ/g, corresponding to n = 7-10. The second stage of the combustion process leads to combustion of 30 10 % of the fuel under the conditions considered. The rate constant of the process in the temperature range750 - 1300 K and oxygen pressure range 4 - 23 kPa is approximated by the formula

Eq. 16

where q is expressed in W/g, p is the oxygen pressure in kPa and x = 1.4 0.3.

The above data demonstrate abilities of the LDTR method. Note that along with parameters of the chemical process, this method permits one to obtain thermal parameters of a sample (the heat capacity, radiative parameters) which are of interest in the calculations of the processes considered. Some examples of this capability were demonstrated in (7).

CONCLUSION

Thus the LDTR method allows one to determine parameters for the thermal treatment of any organic materials. These parameters can be used for optimization of processes involving multiple reactions of organic wastes. Moreover, if the content of organic components in a waste changes from one stage to another of an industrial process, it is useful to make such measurements prior to large-scale implementation. Because such measurements may be automated and can be interfaced with computer programs for control and optimization of these processes, this approach can lead to cleaner and more effective technologies for the thermal treatment of wastes.

ABSTRACT

Traditionally, waste minimization has been applied to process line applications, but not to clean-up operations, such as environmental restoration (ER) and decontamination and decommissioning (D&D) operations. Because the purpose of ER and D&D activities is, essentially, to generate waste, waste minimization was thought not to apply. In 1994, the U.S. Department of Energy provided limited funding to a pilot project at the Nevada Test Site to determine whether traditional waste reduction techniques, such as pollution prevention opportunity assessments, could be applied to ER and D&D projects. The purpose of the pilot was to demonstrate that there are many repeatable elements in ER and D&D activities; therefore, traditional waste reduction techniques could be applied. In addition, tools such as up-front planning, regulatory negotiations, employee awareness campaigns, and involvement of pollution prevention personnel in all phases of a project, can be used to greatly reduce the amount of secondary waste generated by ER and D&D projects. Legacy waste can also be reduced through recycling or reusing building materials, planning for waste minimization in selection of treatment and characterization technologies, and negotiating clean-up levels. The success of the program has led to additional funding to study other methods of applying waste minimization and pollution prevention to ER and

D&D projects. To date, five pollution prevention opportunity assessments have been completed for Nevada ER projects, and over 30 tons of scrap metal have been recycled from clean-up operations at the Tonopah Test Range.

INTRODUCTION

In November 1989, the Secretary of Energy established the Office of Environmental Restoration and Waste Management (EM) to improve the management of remediation, waste management, and facility decommissioning by consolidating these missions into one office. In Nevada, Environmental Restoration (ER) activities are under the auspices of the Environmental Restoration Division (ERD) and involve activities at the Nevada Test Site (NTS), Tonopah Test Range (TTR), and sites in central Nevada, Colorado, Mississippi, Alaska, and New Mexico.

The NTS is a Federally-controlled facility located 105 kilometers (65 miles) northwest of Las Vegas. The NTS occupies 3,510 square kilometers (1,350 square miles). From 1951 until 1992, the NTS has been the location for numerous above- and below-ground nuclear tests. These tests and their associated operations have contaminated certain areas of the NTS with various radioactive and hazardous materials.

The ER Project field activities at the Nevada Test Site (NTS) include decontamination and decommissioning of various facilities, and characterization of a variety of industrial sites, including ordnance detonation areas; unexploded ordnance sites; unlined surface impoundments, injection wells, and underground storage tanks; and the deep aquifer beneath the NTS.

WASTE MINIMIZATION APPLIED TO ENVIRONMENTAL RESTORATION ACTIVITIES

The pollution prevention awareness campaign, which includes an employee awareness and incentive program, has been the source of many ideas that have been incorporated into ER activities. For example, at a project which involved detonation of small cluster bombs, an employee suggested that cardboard tubing be used instead of polyvinyl chloride (PVC) pipe. The cardboard leaves behind no potentially hazardous waste residue, eliminating the need to sample for PVC degradation productions. At the clean-up of an historic landfill at the TTR, staff worked closely with recycling companies and were successful in recycling over 30 tons of scrap metal (1). Employees have also suggested rinsing and reusing plastic bottles that contain bromide standards; previously, these bottles were thrown in the trash after one use. Another employee suggestion resulted in the reuse of laboratory standards for measuring pH in the field. Other employee suggestions included using only recycled paper, establishing an office recycling program for aluminum cans and paper, and turning off lights and computers at the end of the day. These suggestions result in awards such as polo shirts and car sun shades bearing the campaign logo. Employees also participate in a variety of community outreach activities involving waste reduction such as a beach clean-up at Lake Mead, restoration of an area formerly used for desert dumping, and working with Scouts on environmental merit badge projects. While these suggestions and community outreach activities do not directly impact field activities, they help keep employees aware of the importance of resource conservation.

Waste minimization has been an integral part of the up-front planning for all ER field activities. Part of the up-front planning process includes involving waste minimization experts during development of site characterization plans and field procedures. Through the involvement of

waste minimization staff, procedures were changed so that decontamination of sampling equipment is accomplished using no regulated decontamination solvents; thereby avoiding generation of hazardous or mixed waste. The up-front planning also includes working closely with regulators to determine the proposed action and clean-up levels and regulatory strategies for managing investigation-derived waste. Future land use negotiations may lead to a lesser need for clean-up and characterization. Regulatory strategies can also be negotiated. For example, the Underground Test Area (UGTA) Subproject involves characterization of the deep aquifer beneath the NTS and produces millions of gallons of fluid in the form of groundwater and drilling fluids. At wells where radioactive contamination is not present, the fluid is managed as industrial effluent under the Nevada Water Pollution Control Act (similar to Safe Drinking Water and Clean Water Acts), which allow for discharge of the fluid into unlined infiltration areas as long as fluid quality objectives are met. If fluids do not meet fluid quality objectives, they are allowed to evaporate in lined sumps at the wellsite. The remaining uncontaminated solids are managed as industrial waste and left on site; contaminated solids are transported to an appropriate waste management facility (2).
Waste minimization is also accomplished through application of pollution prevention opportunity assessments (PPOAs). During FY 1994, the U.S. Department of Energy provided limited funding to pilot PPOAs for the Nevada ER Project. The UGTA Subproject was selected because it is a long-term project (projected to span 20 years) and has many repeatable elements. The aquifer beneath the NTS is thousands of feet deep; during drilling, millions of gallons of fluid are generated. If contaminated with radioactive or hazardous constituents, the solids must be managed as radioactive or hazardous waste. Students from the local community college were employed to form the core PPOA team, with drilling program and waste minimization staff assisting as technical experts. The PPOA investigation found a method to separate and reuse drilling additives (3).

Because of the success of the pilot PPOA program, additional funding was obtained in FY 1995 and additional college students were employed to conduct PPOAs of other ER activities, such as field sampling and decommissioning. These students are employed as part of a cooperative internship with the local university's Environmental Studies Program. Students receive classroom credit for job experience.

During 1995, five PPOAs were completed and four more are underway during 1996. These PPOAs included: four for buildings associated with decommissioning activities; one for compaction of radioactively-contaminated trash; one for life cycle costs of concrete recycling; and three for industrial sites scheduled for characterization and remediation. The PPOAs for the decommissioning activities include examining costs versus benefits of 1) recycling various building materials and appurtenances, 2) decontamination versus disposal as radioactive waste, and 3) innovative decontamination technologies. The initial PPOA conducted for a building slated for demolition resulted in segregation of building materials and chipping radioactive "hot spots" off of the concrete walls and floors. This allowed the majority of the concrete to be treated as reusable material or industrial trash rather than radioactive waste. The PPOAs for the industrial sites include examination of various characterization and remedial technologies that may reduce waste generation. For example, one PPOA examined various drilling techniques for determining the extent and magnitude of a

hydrocarbon plume. Characterization techniques examined included the cone penetrometer, the SEAMIST System, and conventional drilling. Another PPOA examined various alternatives that could be used to remediate a hydrocarbon plume, such as vapor extraction and bioremediation.

Upcoming waste minimization projects include development of a training video focusing on ER applications for waste minimization. The training video will be nationally distributed in late 1996 and will explain how waste minimization tools can be applied to ER activities. The basis for this video will be the DOE Headquarters' Guidance Document for application of pollution prevention to ER projects and information gathered from various DOE sites as to how they apply pollution prevention tools to their projects. All ER characterization and remediation plans are now required to include a PPOA as part of the plan. Waste minimization staff are part of the project team for each characterization and remediation activity and work closely with project staff to determine the amount and direction of research required to examine pollution prevention opportunities.

SUMMARY

Up-front planning is the most important tool in applying pollution prevention and waste minimization to ER activities. It is imperative that waste minimization concepts be included in site characterization plans and procedures. By including waste minimization into the early stages of a project, opportunities to prevent pollution and minimize waste can be identified and benefit the entire project. Understanding issues such as whether decontamination is cost effective for certain building materials or which treatment technologies are the most cost-effective and environmentally beneficial can help guide characterization plans and activities by ensuring that adequate data are gathered in one sampling event. Negotiating clean-up and action levels with regulators can also lead to minimized characterization and remediation, thereby reducing cost and waste. PPOAs are a viable technique for conducting cost/benefit analyses of ER activities. The PPOA technique helps ensure that decisions are thoroughly documented and can help form the groundwork for restoration technology application decisions.

Previously, pollution prevention and waste minimization techniques were not routinely applied to ER activities; the focus of ER is usually to generate waste through site clean-up. However, through activities such as the PPOAs conducted at the Nevada Test Site, pollution prevention and waste minimization are now seen as the keys to the future in reducing costs and liability for the DOE.

A RISK BASED COMPARISON OF REMEDIAL ACTION ALTERNATIVES INCLUDING WORKER RISK

A. Unione

Jason Associates Corporation

ABSTRACT

Current budget planning strategy within the Department of Energy emphasizes risk reduction potential as a basis for prioritizing expenditures within the complex. To implement such a strategy, a consistent methodology must be available for estimating health risk to workers as a result of project activity. This report provides a comprehensive methodology for considering worker risk in the evaluation of project risk reduction potential. An example comparison of alternative projects to remediate surface impoundments containing radionuclides and hazardous chemicals at the Oak Ridge National Laboratory is used to illustrate the methodology.

Results of this example evaluation clearly indicate that the choice of a preferred environmental management alternative can be affected by considering worker risk. In particular, the result of "net valuing" potentially achievable reductions in long term environmental risk against incurred worker risk tends to support a conclusion that less complex remediation alternatives have a higher net risk reduction value.

INTRODUCTION

Prioritization of Projects Using Risk Based Cost Benefit

DOE field operations are currently documenting an integrated risk based prioritization of proposed activities in support of a complex wide risk based budgeting process. The intent of the integrated risk based cost benefit process is to establish a comprehensive and consistent knowledge base of information for each activity related to environmental management in the complex. Examples of activities include a diversity of DOE expenditures such as remediation projects, waste stabilization efforts, and surveillance actions. A consistent risk based cost benefit methodology requires the capability to evaluate achievable reduction in environmental risk over time, projected cost over time of an activity, cost per unit of risk reduction, measures of the potential importance and impact of assumptions and uncertainties, and other measures which address important activity values not included in the primary cost benefit measure, such as progress toward overall cleanup goals, impact on stakeholder perceptions, and projected land use scenarios.

An infrastructure to supply these necessary elements of a cost benefit methodology addresses the intent of DOE's original Report to Congressa on risk based prioritization, yet it bespeaks a need for a technical process which goes beyond the current methodology for Risk Data Sheets.b It includes:

- an independently defined database of quantitative risk information on environmental risks and accrued worker risks,
- standardizing criteria which address inherent problems of estimating risk using documents of varying rigor and age,
- consistent assumptions and criteria for considering land use impacts,
- an independent and consistently applied set assumptions and uncertainty characterizations for risk estimates,

an independent methodology and database for estimating costs including cost of compliance, site overhead, and public perception management.

Role of Involved Worker Risk in Valuing Risk Reduction

A common source of error in establishing risk based budget priorities stems from the way in which risk reduction is estimated. For example, a common practice, in appraising the value of remediation activity, is to derive estimates of reducible environmental risk using fate and transport models with data from site characterization efforts. What is effectively assessed is an upper bound for achievable reductions in risk to the public as a result of actions which remove or immobilize radioactive and chemically hazardous materials. In other words, risk reduction potential is characterized almost entirely by the inventories at risk, the phenomenology of release, and the available pathways to man. When environmental risk projections are compared across multiple proposed projects or alternative remedies, the resulting "comparative" risk assessment, an indicator of project value and therefore priority, is based primarily on the physical characteristics of the sites and the long term hazards.

In effect, environmental risk reduction, a measure of the risk associated with "doing nothing" neglects the potential risk of "doing something", namely the risk to workers and the public as a result of an activity (or worker risk). Worker risk measures the inherent risk of implementing a project or remedy, the potential for excess cancers due to exposure due to radioactive materials and hazardous chemicals, and for fatalities due to industrial hazards.

As late as the publication of the Draft Report to Congress, estimates of worker risk were not commonly included in risk based evaluations of activities. This oversight may be a vestige of thinking which posits that there is an "implied consent" on the part of government contractor employees to accept risks over and above those involving the population as a whole, or that risks to workers are eliminated entirely through design considerations, worker protection, and operational precautions. Problems arise when these assumptions are invoked in estimating the value of remediation activity.

Involved workers (those who could be presumed to consent to excess risks) represent only a part of the population of persons potentially exposed to increased risks. Implied consent is less reasonable for collocated workers (on a site but not associated with ongoing project efforts), and is inapplicable for members of the public who might be exposed to accidents (especially where transportation is a key element of a proposed remedy).

Recent class action suits against DOE and its contractors by organizations representing employees and former employees indicate a much lower tolerance for job related risks and less of a willingness to support previous covenants regarding "accepted" on the job risks. Neighbors and the media, in general, rarely distinguish between workers at a facility and an "innocent" public.

It has been noted in the Report to Congress that worker risk can have a significant impact on the net achievable risk reduction and therefore the net value of a specific project or proposed remedy. It is well recognized that much of the contaminated land and facilities at DOE sites cannot be returned to public use without an investment in funds which is not affordable to this societyc. Worker risk is a potentially significant

impact on achievable risk reduction which must be considered in risk based budget allocations.

Attributes of a Worker Risk Evaluation Approach

Worker risk refers, specifically, to additional short term health risk posed to involved workers at a facility, collocated workers at a site, and the public by normal operations and possible operational accidents which may occur during facility construction, operation, or deconstruction. Key attributes of an effective worker risk evaluation include comprehensiveness (the capability of identifying all potential sources of risk), differentiability (the capability to prioritize hazards on the basis of potential risk significance), and quantifiability (the capability to bound the residual risk of health impacts as a function of operation scenario). Functional requirements for a consistent and comprehensive worker risk methodology include:

a comprehensive basis for identifying potentially significant accident hazards and accidental exposure scenarios for most major industrial and transportation activities involved in the management of wastes and in the remediation of contaminated sites, a capability to differentiate "residual"exposure hazards (which exist even after the implementation of administrative controls and personnel protection requirements from hazards to unaware and unprotected populations,

a quantitative basis for comparing risks of accidents and chronic exposures in DOE activities with those in other hazardous industries,

at least a qualitative basis for estimating the potential impact of additional investments in protection, training, and conduct of operations on estimated worker risks.

The effects of human exposure to ionizing radiation have been well documented in the DOE complexd. It has often been stated that our knowledge of radioactive material hazards exceeds that of most other sources of risk in the environment. Data on industrial accidents and hazardous chemicals is not as highly developed. Although industrial accident events are routinely reported, until recently it has not been feasible to estimate risks from industrial hazards and hazardous chemicals as a function of time of exposure with any degree of consistency. Recent efforts to improve the quality of available industrial risk information provide a basis for normalizing such information in worker risk evaluations.

TECHNICAL APPROACH AND ANALYSIS

Description of Site and Facilities

A set of four contaminated ponds at Oak Ridge National Laboratory contain sediments, sludges, and waters contaminated with radioactive and hazardous constituents. Although two of the impoundments are small and only lightly contaminated, two impoundments form a principal source of environmental risk at the site. One impoundment, in particular is not isolated from ground water and the continued integrity of its containment (a dike) is questionable.

Cleanup of the impoundments is a high priority commitment for the continuing cleanup program at ORNL. Since the impoundments represent the major source of contamination in that portion of the site, their cleanup would make render the local area stabilized and its facilities useful under some land use scenarios without further cleanup actions. Cleanup of the impoundments should be a part of a cost effective budget optimization strategy at ORNL.

Six alternative approaches have been developed for remediating the impoundments. Table I, taken from information in the RI/FS (1), summarizes some key attributes of each alternative. Table II summarizes, in a qualitative sense, some of the risk-based cost benefit characteristics for each alternative. Clearly, worker risk could be a key differentiator in the process of evaluating alternatives.

Table Ia

Table Ib

Table II

Scope of Worker Risk Review

The worker risk evaluation considers a full range of activities and hazards which could result in additional risk as a result of accidents and residual chronic exposures. Since persons other than workers can be impacted by risk producing events, the term worker risk is not strictly descriptive. However, it is used in here for consistency. Also, in some cases, design choices and technology to implement alternative remedial actions are not fully defined at this time. The worker risk evaluation is not intended to be a rigorous review of safety issues for each alternative. A rigorous safety assurance review consistent with DOE 5480.23 and attendant orders would be required for implementation of any of the alternatives.

The comprehensive set of activities which implement each alternative action roughly correspond to an operation which, to one extent or another, involves permanent modification of the local area. As a convenient nomenclature, therefore, the term facility describes each alternative. Total risk to workers and the public from facility operations is accrued over all phases of facility "life". For a typical DOE facility, this includes the periods of construction, operation, and deconstruction / decommissioning. For the facilities described in the six cleanup options, two separate phases of activity can be defined; 1) construction, and 2) implementation of long term monitoring and control measures.

For a worker risk evaluation it is useful to consider three sources of hazards, industrial accidents, exposure to radioactive and hazardous materials during normal operations, and exposure to radioactive or hazardous release accidents.

During the processes of facility construction and operation, personnel involved in the activities can be injured or killed in industrial accidents. Some of the activities would be typical of large civil construction efforts involving the movement of soils and rock, installing various kinds of structures and barriers, and replacement of materials. Other activities could involve pumping and treating of materials more akin to industrial or mining activities. Still other activities involve transportation of materials around the site, to adjacent government controlled areas, or to remote places.

Heavy construction activities pose risks mainly to involved workers. Pump and treat activities pose risks mainly to involved workers or collocated workers in nearby facilities. Transportation activities pose risks to involved workers (such as drivers), collocated workers within the ORNL, and the public along transportation routes.

During the processes of facility construction and operation, personnel involved in the activities will be exposed to radioactive and hazardous materials. DOE imposes a variety of radiological controls on its operations to reduce additional risks associated with exposure to

radioactive materials. These include designed in barriers, use of protective gear, and the imposition of exposure limits for personnel. DOE implements equivalent controls for hazardous materials. These controls effectively minimize the additional risk of radioactive exposure, but they do not eliminate it entirely. Expressed over a population of involved workers, exposure to radiation and hazardous materials will have the effect of increased likelihoods of cancer.

During the processes of facility construction and operation, personnel involved in the activities may be exposed to radioactive and hazardous materials as a result of radiological accidents. Examples of accidents include spills, fires, and natural catastrophes which result in failures of barriers and / or increased mobility for radioactive and hazardous materials.

Radiological health effects from accidents may result from direct exposure to gamma radiation or as a result of inhaling or ingesting various radioactive materials. Health impacts from exposure to hazardous materials can result from ingestion or inhalation. Due to the high radioactive inventories in some impoundments, it is conceivable that immediate of prompt fatal exposures could occur. However, due the lack of driving energies of release for the radioactive materials and the limited amounts of material being processed at any time provide no credible basis for early fatalities. Rather the types of exposures involved would produce an increased likelihood of cancers in an exposed population.

Accidents may be initiated by operational errors (such as operator errors), equipment failures, or natural events. A typical set of initiating events considered in SARs is shown in Table III. Due to the nature of the facilities used in the cleanup and the limited potential for operating events only a small portion of these initiating events are credible.

A subset of the six alternatives, defined in Tables I and II, are currently under active consideration for implementation and planning purposes. These alternatives 2,3, and 5 were chosen for a worker risk evaluation. Table IV provides a review of applicable sources of risk for each of the reviewed alternatives, based on descriptions of major activities associated with construction and long term monitoring of facilities defined in Ref. 1. Sources of credible risk in Table IV are reviewed with the methodology defined in the next section.

Table III

Table IV

Methodology and Analysis

This section provides methodology and analytical considerations for developing estimates of worker risk. Due to the preliminary nature of available design information on alternative cleanup facilities, the methods used are not rigorous in nature. However, methodology is sufficiently comprehensive to provide an understanding of the type of risks involved and their relative magnitude with respect to existing long term environmental risks.

Methodology and Analysis for Estimating Industrial Accident Risk

The potential for fatalities to result from industrial accidents can be evaluated using OSHA information on industrial activities similar to those defined for each of the cleanup alternatives. Activities involved in the alternative cleanup approaches include dirt and rock removal and replacement, construction of liners, caps and other structures, pumping and treating wastes, and transportation of materials. The Journal of Risk

Analysise provides an information base for evaluating industrial accidents during large scale remediation actions. The industrial accident data base includes fatality rates per hour of exposure for various types of involved worker descriptions (from OSHA sources) and estimates of the number of hours of exposure for a well defined remediation activity. Fatality rates in the industrial data review are used in this preliminary evaluation since they were reviewed for use in a similarly defined remediation effort. Exposure hours for various types of personnel were modified based on a comparison of the activities associated with each of the reviewed alternatives vs activities described for the alternatives in the industrial data review.

Estimating times of exposure based on comparisons with industrial accident data sources is given in Table V. Table V also summarizes an alternate approach to estimating exposure hours in which data used to construct initial cost estimates for each alternativef are used to define hours of exposure for various personnel types. Table V indicates that the exposure hours calculated with the different methods may differ significantly, those calculated using cost data being far more conservative.

Table V

Methodology and Analysis for Risk of Exposure to Radioactivity During Normal Operations

In a sense, DOE radiological controls and allowable doses are developed from the standpoint of restricting additional cancer risk for a population of workers to be less than one in ten thousand (1.0E-4). However, data available on the ORNL ER alternatives affords the opportunity to develop a better information source on radiological exposure, a source which can later be used for cost benefit evaluations of various enforced "burnout" levels.

For the evaluation of worker risk due normal exposure, it is assumed that workers are protected from the inhalation pathways through the use of respirators (possibly with the addition of protective clothing if particulate loadings or chemically hazardous materials are high enough to warrant it). It is also assumed that no protection against gamma radiation is afforded other than by controlling the time of exposure. A simple one dimensional exposure model assumes that:

worker doses from normal operations are a result of direct gamma radiation exposure,

most of the radioactive inventory is in currently in contaminated sediments at the bottom of the impoundments,

the major inventory of concern for direct gamma exposure is Cs137,

most of the exposure occurs during brief periods when a shallow layer of water is all that shields workers from contaminated sediments.

Table VI provides inventories of radioactive and chemically hazardous materials for each of the four impoundments. Exposure times for workers involved in less shielded activities are estimated using ORNL cost data. An estimate of the increased risk of cancer for the population of exposed personnel is estimated using commonly accepted dose conversion factors for involved workers such as ICRP (footnote e).

Table VI

Methodology and Analysis for Risk Due to Radioactive / Hazardous Chemical Release Accidents

A comprehensive systems assessment of potential radioactive release accidents was not feasible for this worker risk evaluation. Much of the

design information needed to conduct such an evaluation is not yet available, and the resulting accuracy is not needed for a preliminary comparison of alternatives. Most of the information for this worker risk evaluation has been extrapolated from reviews of safety analyses reports for similar facilities at other sites. This is not to imply that safety assurance evaluations for the impoundments need not be any more rigorous or thorough in its approach. One impoundment in particular qualifies as a Hazard Category 2 facility, and under the graded approach criteria in DOE STD 1027-93, all of the remediation alternatives would require a detailed safety assurance evaluation to meet DOE 5480.23 standards.

For facilities of the type being considered for remediation alternatives, several events can be identified which illustrate the potential for accidental exposures of involved workers, collocated workers, and the public to increased levels of radioactive or chemically hazardous materials:

a large facility fire due to an equipment failure, operational error, or other catastrophic occurrence in the system for pumping, dewatering, and treating waste slurries which results in release and dispersal of part or all of the available inventory;

a natural catastrophe such as a tornado or flood which directly affects the integrity of the SIOU and its facilities during a phase of construction when sediments can be disperse relatively easily;

an event in which long term institutional controls are ignored and a capped area or consolidation cell is penetrated.

The frequency of a major facility fire has been estimated using commercial nuclear industry and Department of Energy experience and an event sequence model for the frequency of a major release (Fig. 1). Table VII provides a summary of fire frequency data used in the evaluation of a major fire frequency. The frequency for a tornado in the local region is estimated from available weather data and an event sequence model for frequency of a major release (Fig. 2).

Fig. 1

Fig. 2

Table VII

A major flood , which overwhelms containments of the impoundments and causes a sudden release of water and sediments to local waterways is not considered part of the total risk associated with each of the projects, primarily because the vulnerability to flood induced release would exist with or without the remediation effort. However, since it is part of the spectrum of unanticipated events which can cause additional risk to the community, the frequency of a major flood induced release is estimated using an event sequence model (Fig. 3), assuming failure in a greater than 100 year flood.

The frequency of a failure of institutional controls is estimated using SAR data for a buried waste facility and an event sequence model for frequency of a major exposure to nearby personnel (Fig. 4).

Accident risk is estimated from accident frequency information using the following process:

It is assumed that the period of active construction is one year and that an accident which results in a release of nuclear material would occur during this time. The exception is an intrusion on buried waste. For intrusion on buried waste, the period in which the sediments pose a significant health hazard and the SIOU is a controlled access area, is used.

Dose to receptors is estimated using the amount of material available for release in an accident (Ia), and the fractional release of material at the point of the accident (Ra), to produce dose to an individual at the point of receptor (Di) in the algorithm

f[Ia * Ra] = Di

The functional relationship in the algorithm is estimated for the fire and tornado events using RSAC 5 to determine downwind dose at the receptor (in Rem). For the intrusion event, dose information is developed using occupational exposure information with elimination of shielding assumed.

Risk is estimated by estimating dose to an exposed population Pe from the relationship

Di * Pe = Dp

and a conversion between dose and likelihood of cancer induced fatality (5E-4 fatality / Rem for exposed members of the public, and 4E-4 for exposed workers). For the flood event, dose is inferred from No Action risk data summarized in Ref. 1, with equivalent doses estimated using dose conversion factors for public exposure.

Fig. 3

Fig. 4

Results of Worker Risk Evaluation

Results of the worker risk evaluation are developed using the information and assumptions of Section II. These results are summarized in the following sections. In order to generate a consistent comparison, the results of Ref. 1 are interpreted in a fashion which can be compared with worker risk information.

Industrial Accident Risk

Table VIII provides a summary of the risk of industrial accidents to workers, collocated workers, and the public for the three alternative remediation projects. Since vulnerability of the public is limited to conditions where offsite transportation occurs and none of the alternatives involve offsite transportation, all industrial accident risk given in Table VIII is to accrued by workers involved in the remediation efforts. Table VIII estimates are made using costing data for the ER alternatives (3) and fatality frequency data (2).

Table VIII

Risk of Occupational Radiation Exposure During Normal Operations

Risk to involved workers from occupational exposure to radiation during the construction process is estimated in Table IX. Table IX provides estimates of dose to involved workers from gamma radiation sources during periods where shielding may be minimal. These estimates utilize dose rates from one dimensional exposure models using a hypothetical worker performing tasks at the closest point to the sediment layer. These estimates also use exposure time data derived from remediation alternative cost information (3).

Table IX

Risk Due to Accidents Involving Release of Nuclear of Chemically Hazardous Materials

Risk from accidents involving a release of radioactive materials is estimated in Tables X, Xa and Xb. Table X provides a base case calculation using best information derived from all sources. Table Xa provides a sensitivity calculation appropriate for estimating the nuclear accident contribution from Alternative 2. Table Xb provides similar information for Alternatives 3 and 5. Notably, in Tables Xa and Xb, flood

caused release is not summarized as part of the accident contribution to worker risk.
Table X
Table Xa
Table Xb
Achievable and Net Risk Reduction
Table XIa summarizes in the potential reduction in risk achieved by applying the risk data in Ref. 1 to a population of persons along each of the nearby waterways. Notably, an assumption is made that a specific percent % of the population (1% in the base case) is exposed to radioactive contamination over a lifetime.
Table XIb integrates information from the worker risk evaluation with information on reducible risk in Table XIa. Results are presented as a net risk reduction which could be expected if each of the subset of Ref. 1 alternatives were selected for implementation.
Table XIa
Table XIb
Table XIc
Table XId
CONCLUSIONS AND RECOMMENDATIONS
Table XIb provides a comparison between risk estimates for worker risk and risk estimates for achievable reductions in risk, establishing a net expected risk reduction for each ER alternative. Results of the worker risk evaluation are as follows:

The sum of worker risks are small when compared with the achievable reduction in risk which can be made by implementing each of the proposed alternatives. In all cases the expected differential is an order of magnitude or more.

The net benefit associated with each of the alternatives is equal,. Thus the choice of which alternative to implement can only be made on the basis of expected cost or other factors such as uncertainty in cost, stakeholder preference, and land use issues.

Several recommendations, if implemented, would improve, validate, and extend the results of this preliminary worker risk evaluation.

Risk information from the remedial investigation should be systematically reviewed with less bounding assumptions regarding the level of risk posed by existing conditions. A systematic appraisal of populations potentially affected by leakage from existing impoundments should also be performed. The sensitivity data in Table XIc and XId indicated that a smaller estimate of population exposed to the risk of slowly leaking contamination would dramatically affect the overall value of the cleanup as well as the relative choice of alternatives.

Involved worker risk, particularly accident risk should be more systematically evaluated to assure comprehensiveness of the accident scenario identification process (This information would not be wasted since SARs and other documents using the same information base could be generated in a more cost effective manner at a later date). Also, realistic assumptions used to assess the potential for releases from energetic accidents, and the potential for populations of persons to be exposed to accidental releases. Finally, hazardous chemical releases were not estimated for this report since the makeup of impoundment inventories and postulated release scenarios did not indicate a significant potential for generating a health effect producing release. This assumption should be verified.

Net risk information compiled in this study should be integrated with cost information and other factors which could affect the overall cost benefit of each alternative using uncertainty distributions and an appropriate propagation technique.

ABSTRACT

Rocky Mountain Remediation Services, L.L.C. (RMRS), jointly formed by Morrison Knudsen Corporation and BNFL Inc., provides international experience in the nuclear, environmental, waste management, decontamination and decommissioning (D&D) , and project management industry. The company is currently the environmental restoration, waste management, and D&D subcontractor for Kaiser-Hill Company at the Rocky Flats Environmental Technology Site (RFETS). RMRS offers unique solutions and state-of-the-art technology to assist in resolving the issues that face industries today.

RMRS has been working on methods to improve cost savings recognized at RFETS, through application of unique technologies and process engineering. RMRS prepared and is implementing a strategy that focused on identifying an approach to improve cost savings in current wastewater treatment systems and to define a low-cost, safe and versatile wastewater treatment system for the future. Development of this strategy was targeted by Department of Energy (DOE) Headquarters, DOE Rocky Flats Field Office and Kaiser-Hill as a "Project Breakthrough" where old concepts were thrown out the door and the project goals and objectives were developed from the ground up. The objectives of the strategy developed in a project break through session with DOE included lower lifecycle costs, shutdown of one of two buildings at RFETS, Building 374 or Building 774, reduced government capital investment, and support of site closure program goals, identified as the site's Accelerated Site Action Plan (ASAP). The recommended option allows for removal of water treatment functions from Building 374, the existing process wastewater treatment facility. This option affords the lowest capital cost, lowest unit operating cost, lowest technical management risk, greatest support of ASAP phasing and provides the greatest flexibility for design with unforeseen future needs.

The recommended alternative provides for substantial near-term cost and technological advantages over the present operating baseline and planned capital improvement program. The total estimated capital expenditures for the recommended alternative is $6.8 million which is considerably less than the current capital funding level of approximately $65 million for

full upgrades to Building 374. In addition, the recommended alternative saves approximately $6.1 million per year in operating costs. Accelerated program implementation will produce the desired improvements as specified by the key objectives, and will release capital and operating funds for investment in the site's higher risk reduction activities, supporting ASAP programs.

RMRS and Kaiser-Hill recommended, and DOE concurred, that as a result of the project's low Net Present Value and financial and technical rate of return, the preferred recommendation be implemented through a single consolidated project. A single consolidated project will allow for direct focus across multiple functional programs (i.e., Operations, Permitting, Environmental, etc.) assuring schedule and cost compliance. RMRS also recommended that the Project Implementation Plan be prepared to support Fixed Price and Fixed Unit Price contracting terms as a means of assuring the following:

- Accelerated schedule implementation;
- Competitive project cost;
- Government/commercial risk sharing; and
- Reduced government capital investment.

BACKGROUND

RFETS is a government-owned, contractor-operated facility which is a part of the nationwide DOE nuclear weapons production complex. Prior to 1989, the primary mission of the site was the continual production of components for nuclear weapons. Production activities included metalworking, fabrication and component assembly, plutonium recovery and purification, and associated quality control functions ensuring the technical performance of the weapons' components. The plant was built in 1951 and began operations in 1952. In 1989, as a result of a changing international political climate, the decision was made by the United States government to discontinue production of components for nuclear weapons at Rocky Flats. Rocky Flats has undergone a transition from a weapons production facility to an environmental restoration and waste management site. The current mission of the site is to manage waste and material, clean up and convert RFETS to beneficial use in a manner that is safe, environmentally and socially responsible, physically secure and cost-effective.

The need for an integrated waste water management strategy was driven by the following:

- the need to reduce routine facility operating costs, to provide financing of risk reduction activities, and to provide support to site closure activities requiring accelerated waste water treatment to support deactivation and decommissioning activities over a 10-year period.
- major near-term facility improvements would be necessary to keep existing wastewater treatment facilities operational to support deactivation and decommissioning activities.
- negotiations on regulatory relief from overly restrictive stream standards and defining necessary and sufficient standards will impact the requirements for waste water treatment.
- changes in site mission from a weapons production mission to waste management, environmental clean-up and conversion to beneficial use have dramatically shifted the requirements for wastewater treatment.

PURPOSE AND OBJECTIVES

RFETS will continue to produce diverse wastewater streams as it completes its mission of environmental restoration, D&D, and waste management. This

study included the integration of previous wastewater management strategies into one overall strategy and the provision for cost-effective treatment of all wastewater to be produced at the site. Alternatives developed in the study were designed to support the ASAP site closure concept.

The primary objective of this document was to develop and document the basis of this strategy and to develop short- and long-term implementation plans. To achieve the primary objective, the following supporting objectives were identified.

The strategy must integrate multiple focused wastewater management strategies already in place or in preparation into one overall strategy.

The strategy must evaluate the routing and treatment of wastewater streams based on composition and regulatory requirements rather than the point of generation.

The strategy must ensure that adequate capacity is provided for all wastewater treatment over the foreseeable future.

The strategy will be integrated into the RFETS Water Management Plan.

The strategy must contain information on the identity and characteristics of all known wastewater sources and conveyance methods on the site. This will allow for identification of waste segregation and minimization opportunities. In addition, impacts of wastewater stream elimination on the balance of the wastewater to be treated can be evaluated.

The strategy must identify which wastewater treatment facilities currently in operation can be cost-effective components in an overall strategy.

Development of the strategy considered all current and anticipated sources of wastewater potentially requiring treatment. This included wastewater from domestic use, building process operations, facility deactivation, facility decontamination and decommissioning, and environmental restoration. Excluding domestic wastewater, the largest sources of wastewater in terms of average annual volume projected for the future include the Interceptor Trench System (ITS) (3.5 million gallons per year), the Building 566 laundry (1.3 million gallons per year), and environmental restoration activities, primarily groundwater (up to 6.5 million gallons per year). The actual volume of environmental restoration water could decrease dramatically depending upon final agreements on cleanup levels. Facility deactivation will also produce the most highly contaminated wastewater, although volumes will be low in comparison to the total of the other major sources (greater than 1 million gallons per year). Deactivation wastewater production will also peak fairly rapidly and then begin to decline, and will only be produced over the next one to five years. Characteristics and estimated volumes of future process wastewater sources are shown in Fig. 1.

Fig. 1

Development of the strategy also considered the capacities and capabilities of existing treatment facilities at Building 374, Building 774, Building 995 (the Sanitary Treatment Plant (STP)), and the Site Treatment Facility (treatment of water generated from environmental restoration activities).

ALTERNATIVES EVALUATED

Four alternatives were identified for wastewater treatment. These alternatives support achievement of the ASAP site closure goal, and include the following:

Alternative 1 - Minimum Building 374 upgrades;
Alternative 2 - Building 374 Liquid Waste Treatment Facility upgrades;
Alternative 3 - Building 374 Waste system Evaporator upgrades; and
Alternative 4 - Building 374 Elimination

These alternatives were subjected to a technical and cost effectiveness evaluation and a sensitivity analysis, and a final selection made. Alternative 4 (see schematics in Figs. 2 and 3) was selected as the recommended alternative for the following reasons:

It is the only alternative capable of supporting an early closure of Building 374 and can also support closure of building 771/774,

It has the lowest overall life cycle cost of dollars and capital cost dollars of the ten-year alternatives,

It has low risk of delay in implementation because of relatively low capital funding requirements;

It is ranked high technically due primarily to minimization of waste and overall flexibility in addressing changes in wastewater characteristics, and

It is the best alternative to support achievement of the ASAP closure goals.

Fig. 2

Fig. 3

The estimated costs of the recommended alternative is summarized below:

DOE Capital Investment $6,800,000

Average O&M Costs$8,100,000

These costs demonstrate the following savings over current operations:

The total estimated capital expenditures for the recommended alternatives is $6.8 million, which is considerably lower than the current capital funding level of approximately $65 million for full upgrades to Building 374.

The current operating budget of Building 374 is approximately $9.3 million. If operations of the Sitewide Treatment Facility and waste disposal are added, this cost increases to approximately $14.2 million. The recommended alternative saves approximately $6.1 million.

An overall life cycle cost curve for the recommended alternative is illustrated in Fig. 4.

Fig. 4

IMPLEMENTATION

Implementation of the strategy was approved by DOE in November, 1995 and alternative treatment technologies have been evaluated and a Conceptual Design Report subsequently prepared. The conceptual design includes the following features.

Building 374 will be closed in FY 97 and a new temporary treatment facility (TTF) will be designed and constructed to treat wastewater from building operations, deactivation, and decontamination and decommissioning. This facility will be located near Building 374 to take advantage of existing collection and support systems. Either leased or modular equipment will be utilized in the facility as the operational life of the facility will be less than ten years.

Regulatory relief has been sought on the existing plutonium standard for discharges from the TTF facility. This relief is based on raising the plutonium level from the current site specific standard to the Statewide plutonium standard for up to five years while tanks are drained and pipelines are flushed during initial D&D activities. Review of historic records shows that the proposed increase in stream loading would only

double the loading over levels discharged in the last five years but would not be a risk to human health or the environment. This temporary modification, currently being negotiated with the regulatory agencies would save approximately $73 million in capital and operating costs which could be redirected to higher priority risk reduction activities.

Liquids produced from deactivation activities in Building 371 will be treated for initial reduction of radionuclide and metal concentrations in the caustic waste treatment system to be installed in Building 371. Treated effluent from this process could then be treated in the Building 774 carrier precipitation process for additional radionuclide removal. The supernatant wastewater from both Buildings 371 and 774 will then be treated for further reduction of radionuclides and metals in the new temporary facility replacing Building 374.

The general approach to handling of deactivation wastewater is shown schematically on Fig. 3. Liquids produced from deactivation activities in Building 771 will be treated for initial reduction of radionuclide and metal concentrations in the oxalate precipitation process and hydroxide precipitation process located in Building 771. Additional treatment of the effluent from these processes plus other miscellaneous liquids produced in Building 771 and 774 will be treated in the carrier precipitation process in Building 774.

A temporary sludge immobilization system (TSIS) is being designed to treat sludges currently stored in Building 374 and Building 774, and for sludges produced by the Building 774 carrier precipitation process. TSIS is a mobile system that can be reassembled elsewhere on-site or offsite to treat other sludges or waste forms.

Regulatory relief on nitrate and uranium limits has been sought to allow for direct discharge of ITS wastewater. This relief is based on removing the water supply use classification from Walnut Creek but leaving the agricultural use classification, thereby allowing for compliance with nitrate standards (based on no risk to human health or the environment for nitrates) and use of statistical methods to prove that uranium levels were below background concentrations. These actions are estimated to save $20 million dollars over a ten year period. Recent meetings with regulatory agencies and Stakeholders on regulatory relief have been positive and it appears that all parties will now request the Colorado Water Quality Control Commission to revise the stream standards.

Characterization of Building 566 laundry wastewater has been conducted to verify that discharge to the STP can take place and this stream has subsequently been eliminated from Building 374.

RMRS has worked with DOE and Kaiser-Hill to obtain variances from DOE Orders and Plant Standards in the application of necessary and sufficient standards in engineering, installation and operation, thereby producing substantial capital and operating cost reduction while allowing for commercial equivalent practices.

CONTRACTING/FINANCING APPROACH

The Kaiser-Hill team has committed to performance-based contracting with an evolution toward commercialized fixed-price contracting. In addition, the ASAP necessitates a projectized approach to providing improved near-term treatment services in conjunction with lower building and routine operating costs, supporting funding of high priority risk reduction activities. As a result, RMRS looked at several options to expedite the contracting approach, including using commercialized contracting and both cost plus fixed fee and fixed unit price contracting strategies.

A typical cost plus fixed fee approach would require the government to pay for design and installation of the facility and capitalization of the equipment without an assurance that the plant would perform. In addition, the government would own the building, and with the approach proposed by ASAP, this is in contradiction to taking the site down.
The approach that RMRS proposes is a fixed price services contract, whereby RMRS provides equipment and the services associated with that equipment.

FUTURE PLANNING AND INTEGRATION

The schedule for implementation of this strategy for the recommended alternative is presented in Fig. 5.
Fig. 5

CONCLUSIONS

Kaiser-Hill and RMRS have committed to accelerated closure of RFETS buildings as a means of substantial cost savings to the government. Implementation of the Integrated Wastewater Management Strategy is in keeping with this philosophy as it allows for early closure of Building 374, thereby allowing funds to be reallocated for other site closure activities. Assuming that accelerated funding is available and a design-build approach to procurement approved, Building 374 can be closed in FY 1997. The driver for this date is the completion of the design and construction of the new facilities. Given the services contract approach, an acceleration of 12 to 24 months is anticipated./
Lessons learned from this DOE breakthrough project are applicable to other DOE and DOD facilities.
Revisiting existing baseline operations may show that substantial near-term cost savings can be realized and these funds can then be redirected for other activities. Alternate contracting strategies may also reduce required government capital investment and lead to sharing of risk between the government and contractors. There is also a need to reassess existing cleanup levels to see if there is a good risk basis for negotiating changes to standards to reduce operating costs.

GAS SAMPLING AND ANALYSIS OF 55-GALLON DRUMS CONTAINING TRANSURANIC WASTE USING COMMERCIAL VENDORS AND EXISTING TECHNOLOGY

Kenneth Guay
Carl Hess
Thomas Johnsen
Lexa McAdams
S.M. Stoller Corporation
Oak Ridge, Tennessee

Thomas Dunder
Entropy Incorporated
Research Triangle Park, North Carolina

ABSTRACT

The U.S. Department of Energy National Transuranic Program has provided funding to the Oak Ridge National Laboratory (ORNL) to use a private vendor to gas sample and analyze for hazardous constituents regulated under the Resource Conservation and Recovery Act (RCRA) and other gases in some of their existing contact-handled (CH) transuranic (TRU) waste inventory. The project is intended to demonstrate the feasibility of using private industry and existing mobile Fourier Transform Infrared

Spectroscopy technology for gas analysis. The S.M. Stoller Corporation and the Entropy Corporation have teamed together to propose the use of an existing mobile laboratory technique that is accurate, rapid and that provides the advantage of "at-line" analysis on site to the ORNL. The two companies propose to sample and analyze the headspace gas from 500 drums at ORNL that contain CH TRU waste. Currently, there is no contract awarded to the Stoller/Entropy team from ORNL to participate in this project.

INTRODUCTION

The U.S. Department of Energy (DOE) has constructed the Waste Isolation Pilot Plant (WIPP), a deep geological repository, in southeastern New Mexico as a research and development facility intended to demonstrate methods for the safe disposal of transuranic (TRU) wastes generated from defense-related programs. TRU waste is defined in DOE Order 5820.2A as ". . . waste that is contaminated with alpha-emitting transuranium radionuclides with half-lives greater than 20 years and concentrations greater than 100 nCi/gram of waste at the time of assay" (1). A transuranium radionuclide is further defined in DOE Order 5820.2A as any element having an atomic number greater than 92. TRUwastes may be classified as contact-handled (CH) or remote-handled (RH), depending on surface radiation levels. TRU waste packages having an external surface dose rate of less than 200 mrem/h are classified as CH TRU waste, while those greater than or equal to 200 mrem/h are classified as RH TRU waste. The U.S. Environmental Protection Agency (EPA) granted WIPP a conditional no-migration determination (NMD) that requires DOE to characterize nonradioactive hazardous constituents and other gases contained in TRU waste, prior to delivery to the WIPP site (2). These constituents, regulated under the Resource Conservation and Recovery Act (RCRA) codified under Part 40 of the Code of Federal Regulations Section 268 (40 CFR 268), can be characterized by obtaining a gas sample from the headspace found under the lids of 55-gal drums containing TRU waste. Adequate characterization data must be collected from all DOE sites on their TRU waste intended for disposal at WIPP.

As part of the DOE program to promote technology development, demonstration, and utilization of private industry, this project will implement existing technology used by private vendors and adapt the methodology to fit the needs of the TRU Waste Characterization Program at DOE. This project will demonstrate that a private vendor can perform gas sampling and analysis activities using Fourier Transform Infrared Spectroscopy (FTIR) as the analytical technology. Prior to demonstration of the technology, a template of documents required to perform this operation at DOE sites will be developed for the Carlbad Area Office National TRU Program (3). Objectives of the FTIR gas sampling and analysis project are as follows:

- Develop a gas sample analysis project at the Oak Ridge National Laboratory (ORNL) that would provide the National TRU Program and the TRU Waste Characterization Program with an "Eastern Site" capability to analyze gas samples in accordance with the WIPP TRU Waste Quality Assurance Program Plan (QAPP) (3);
- Obtain TRU waste characterization data for the Department of Energy Carlsbad Area Office to assist in preparation of the WIPP Compliance Package (2);
- Demonstrate rapid and cost-effective gas sampling and analysis of DOE TRU waste headspace gas using a mobile FTIR laboratory; and

Demonstrate private sector capability to support characterization of TRU waste.

FOURIER TRANSFORM INFRARED SPECTROSCOPY TECHNOLOGY

FTIR is an analytical technique used in research and analytical laboratories. In recent years, FTIR has been applied to process control, emission measurement, and gas analysis applications. Most gas molecules absorb infrared radiation in recognizable and quantifiable pattern. Therefore, it is possible to measure multiple compounds simultaneously in gas samples because of the resolution and spectral range of FTIR spectrometer systems (4).

Currently, analyses are performed by gas chromatography and gas chromatography/mass spectrometry, which require a gas sample collection device and an analytical laboratory and, consequently, delay determination of the gas concentrations. The ability to do "at-line" analysis would reduce the necessary sample handling and the cost of analysis of each gas sample.

Parallel efforts have been conducted by two entities of the U.S. government for different applications of FTIR technology. The EPA has funded research in the detection and monitoring of hazardous air pollutants (HAPs) regulated under the Title III of the 1990 Clear Air Act Amendments at stationary source emissions, and the DOE has funded research in the development and evaluation of methods for the analysis of RCRA constituents in the gaseous headspace of TRU waste drums.

Since 1989, Entropy's Research Division has been developing Extractive FTIR spectroscopy technology for Air Emissions Testing in research funded by EPA. The method involves transporting the gas sample of interest to a gas cell for analysis. Entropy has demonstrated FTIR accuracy and precision by performing EPA Method 301Validations for over 30 HAPs (4). Since 1992, Entropy has developed a library of FTIR reference spectra for over 100 HAPs, FTIR specific QA/QC procedures as detailed in the EPA-accepted FTIR Protocol Document, and a fully-equipped mobile FTIR laboratory. Field testing using a mobile FTIR laboratory to analyze various source categories of on-site emissions has been performed at numerous industrial sites since May 1992.

The NMD requires that a representative waste drum headspace gas sample be collected for analysis. The Idaho National Engineering Laboratory (INEL) has been involved in the development and evaluation of methods for the analysis of RCRA constituents in the gaseous head space of CH TRU waste drums. INEL initiated a two-phase study (5) to assess the feasibility of using FTIR for the analysis of volatile organic compounds (VOCs) in waste drum headspace in fiscal year 1993.

PROJECT ACTIVITIES

Much of the CH TRU waste stored at ORNL is suspected to contain hazardous VOCs regulated under RCRA that must be characterized through container headspace gas sampling and analysis. ORNL, however, has no capability to conduct gas sampling and analysis of TRU waste drums. The S.M. Stoller Corporation and Entropy Incorporated have teamed together to propose the use of an existing mobile laboratory technique that is accurate, rapid, and provides the advantage of real-time analysis on site to ORNL. The two companies propose to sample and analyze the headspace gas from 500 drums at ORNL that contain CH TRU waste. In the teaming agreement, Stoller will act as the primary subcontractor to ORNL, and Entropy will be a subcontractor to Stoller, when a contract is awarded by ORNL. The team, referred to as Stoller/Entropy, proposes to act as a subcontract to

Lockheed Martin Energy Systems, inc., (LMES) the prime management and operations (M&O) contractor for ORNL. LMES operates ORNL for the Department of Energy Oak Ridge Operations Office (DOE-ORO).
Entropy Incorporated was previously contracted by the EPA to provide research and development for the sampling and analysis of stack emissions. Entropy has developed quantitative gas phase FTIR techniques and has created a validated measurement method accepted by the EPA. The Stoller Corporation provides technical consultation services to DOE field offices and DOE generator/storage site M&O contractors in the area of radioactive waste management.
This project will be limited to gas sampling and analyzing for RCRA regulated constituents and other gases in relatively low-risk drums. Low-risk drums are defined as having very low surface dose rates, typically less than 50 millirem/hour, that will not require venting (because a vent filter is already installed).
Utilization of low-risk drums will eliminate the need for an explosion-proof vessel required to install a filter in unvented drums that may contain a flammable mixture of gases. The project will be conducted in three phases. Phase I will consist of the development of documentation and modification of existing equipment. Phase II will consist of transporting the FTIR laboratory to the site and conducting the gas sample and analysis activities. Phase III will consist of project closeout, writing a final report with lessons learned, and submitting a template of documents to DOE.
Strategy
DOE-ORO and LMES will oversee all activities associated with the FTIR Gas Sampling and Analysis Demonstration Project. LMES will also provide support by assisting in the site selection, participating in the Operational Readiness Process and document review activities, and retrieving TRU waste drums to provide adequate throughput during gas sampling and analysis operations. Stoller/Entropy will conduct required preparation activities, perform the gas sampling and analysis, and conclude the project in accordance with the project management plan.
Within the subcontractor teaming agreement, Stoller will prepare all required documentation necessary to gain access to ORNL. Major Stoller responsibilities will include developing all the documentation needed to satisfy environmental, safety, health, operations, quality assurance, and project management requirements and leading the performance of the Operational Readiness Process. Entropy will furnish their existing FTIR mobile gas sampling and analysis laboratory, work with Stoller to complete equipment modifications and additions, and develop maintenance plans and procedures to adapt the laboratory for TRU waste application. Entropy will also provide any technical and operations support needed to apply the FTIR technology properly.
Phase I Activities
The first task will be to complete all the documentation required to gain access to the ORNL site. Phase I will "pave the road" for other private vendors requesting to characterize or process TRU waste on DOE sites. The documents prepared will provide DOE with a "template" of typical issues and concerns at DOE operating sites. It will also cover document preparation and the steps to be followed by private vendors.
The Fiscal Year 1996 activities will include developing documentation, conducting a Operational Readiness Process, and completing the needed equipment modifications required to allow a commercial vendor access to

the ORNL site. These activities initially will involve the identification of a suitable location on the ORNL site where the sampling activities will be conducted. Site selection will be based on interviews with appropriate Waste Management and Operations personnel and the assessment of applicable information of the available sites. The site selection will then be incorporated into the gas sampling program management plan, which will provide information on the cost and schedule of the activities associated with this project.

Plans to be developed that implement specific requirements and provide guidance on the conduct of operations include a Gas Sampling and Analysis Quality Assurance Project Plan, a Health and Safety Plan, a Project Management Plan, a Waste Management Plan, and a Sampling and Analysis Plan. Standard Operating Procedures, Testing and Calibration Procedures, and Emergency Procedures will also be developed. The procedures currently used by Entropy for emissions testing will require revision to implement the requirements specified for the FTIR Headspace Method and the quality assurance/quality control specifications in the QAPP and approved by the EPA Office of Solid Waste.

Activities conducted in parallel to document development will include a Safety Evaluation that involves review of the selected facility safety documentation to determine whether an unreviewed safety question exists. In addition, the Operational Readiness Process will have to be conducted and involve Entropy, Stoller, ORNL Waste Management, and DOE Oak Ridge. Because Entropy's mobile FTIR laboratory was originally constructed to provide FTIR emissions testing at industrial facilities under an EPA protocol, some minor modifications and additions are required to allow gas sampling of TRU wastes packaged in drums. These changes are described below.

The FTIR Method Development will include the revision of existing procedures or the development of new procedures to address the requirements for calibration and performance testing. Analytical software will be obtained to ensure consistency with the INEL method used to develop an automated analysis system for headspace gases. Finally, reference spectra obtained by the INEL will be obtained and assessed for application to Entropy-owned equipment.

The modified mobile FTIR laboratory will contain all the necessary equipment for on-site measurements, including sampling and sample conditioning systems, on-board diesel electrical generators, a climate control system, an air compressor, and a purge air generator. The gas sampling equipment is mounted on an on-board table that is specially designed to dampen vibrations. The detection equipment will include an in-line FTIR spectrometer for measuring the concentration of various VOCs and a residual gas analyzer (RGA) for measuring hydrogen gas concentration. Other peripheral sampling equipment will include a vacuum pump for drawing samples, a downstream constant air monitor (CAM) for alpha radiation detection, a SUMMA canister for collecting test samples, interconnecting sample lines, and a personal computer system for data collection, analysis, and reporting.

FTIR Equipment Modification will require the purchase and installation of a low-volume FTIR gas cell. The smaller cell is required because of the smaller volumes of gases collected from a 55-gal drum as compared to emissions collected from stacks. Due to the limitations of the FTIR in identifying and quantifying homonuclear diatomic gases such as hydrogen, an RGA will have to be installed in the mobile laboratory. Data

acquisition software will also be developed to allow logging both FTIR and RGA data together.

Phase II Activities

The modified mobile FTIR laboratory will be transported to the sampling location, which has been tentatively identified as an asphalt pad just adjacent to Building 7879. To support the operation, a temporary shelter will be erected to provide a weather-protected area for temporarily staging the TRU waste drums that will be sampled. The drums will be retrieved from Building 7879 by LMES personnel and placed in the staging enclosure at the beginning of each work day. Stoller/Entropy plans to sample 12 drums per day and to maintain no additional waste in the staging area at any time. At the close of each work day, LMES will return all TRU waste drums from the staging area to their designated storage location in Building 7879.

Before beginning the gas sampling procedure, a TRU waste drum is interfaced to the glovebox to seal off the sample area and prevent the potential release of radioactive particulate to the environment. The glovebox (Fig. 1) is equipped with a sample-line penetration containing a permanently installed high-efficiency particulate air (HEPA) filter, two glove ports, a transfer port, and a separate HEPA filter vent. The sampling technician places the required tools (an adjustable wrench and new filter) inside the glovebox using the installed transfer port. The drum and glovebox assembly are positioned adjacent to the mobile FTIR laboratory and linked together with a detachable sample line. The sampling technician will gain access to the drum headspace via the carbon-composite vent filter installed in the drum lid. This is accomplished by the following activities.

A hole is drilled through the stainless steel cover of the filter using the permanently mounted drill press in the glovebox.

The sample probe (Fig. 2) is inserted through the underlying carbon-composite filter media.

A sample is subsequently drawn by vacuum into the truck-mounted FTIR equipment for real-time analysis.

Fig. 1

Fig. 2

Following sample analysis, the probe is retracted from the drum internal headspace. Then the filter is removed and replaced.

The attendant health physics technician (HPT) smears the old drum filter, drill bit, sample probe, drum lid, and wrench for possible contamination. Provided these are radiologically clean, the drum is removed from the glovebox and returned to the staging area.

In the unlikely event of contamination, sampling activities will be terminated and surveys will be conducted to determine the extent of the contamination spread. Trained personnel and procedures will be in place to take the necessary actions to mitigate this or other potential off-normal events.

A second technician will operate the FTIR sampling equipment as the sample is drawn and analyzed as described below. The FTIR and RGA sampling equipment is fully automated and operated by personal computer via a programmable controller.

The technician will purge the system using nitrogen, to ensure that no moisture or gas contaminants are present.

Prior to extracting the headspace gas sample, the technician will evacuate the sampling equipment and verify that the system is leak-tight.

The sample is then drawn into the FTIR and RGA modules and analyzed for 29 different VOCs and for hydrogen concentration.

Following the analysis, a data package is saved on computer diskette and a hard copy is printed.

Several radiological controls will be implemented during the entire TRU waste gas sampling process. These include the following:

Stoller/Entropy will verify that the inner waste contents of each drum sampled are adequately bagged and sealed by reviewing previously recorded real-time radiography videotapes.

Stoller/Entropy will use a sealed glovebox during the sampling operation and will survey all tools, filters, and other materials before they are removed from the glovebox environment.

Stoller/Entropy will install a HEPA filter at the glovebox sample inlet and will use a CAM at the outlet of the sample line to monitor for potential releases.

Stoller/Entropy will provide project funding through LMES to support full-time HPT coverage during drum retrieval and sampling activities and will ensure that all operating technicians have received LevelI Radiation Worker Training and respirator fit tests.

Stoller/Entropy will operate with ORNL-approved procedures only and will comply with all applicable site-specific radiological controls. Stoller/Entropy will also conduct an As-Low-As-Reasonably-Achievable (ALARA) Evaluation. All candidate drums will be surveyed before sampling to ensure that ALARA goals will not be exceeded and that personnel exposure to penetrating radiation will be minimized. Drums with higher surface radiation levels that might result in exposures in excess of ALARA goals will be sampled on a case-by-case basis only and special precautionary measures will be used.

Phase III Activities

The activities in this phase will include closing out the project and compiling a final report. The final report will include lessons learned and document templates. The templates will provide general guidance as to the information to be included for implementation at other DOE generator/storage sites.

CONCLUSION

In summary, funding has been provided by the DOE National TRU Program to demonstrate the feasibility of sampling and analyzing the headspace gas for RCRA-hazardous constituents and other gases from 55-gal drums containing CH TRU waste. The project utilizes an innovative approach combining the use of private vendors, mobile technology, and FTIR technology for analyzing gases regulated under RCRA. The mobile FTIR laboratory will require minimum modifications to the equipment thereby reducing costs that are associated with the purchase of a new system. The proposed project may grant the Stoller/Entropy team a subcontract with LMES to conduct the gas sample and analysis activities on 500 of the vented 55-gal drums containing CH TRU waste at ORNL by the end of fiscal year 1996.

QUANTUM-CEPTM TECHNOLOGY APPLICATION TO DOE MIXED WASTES

Claire M. Chanenchuck
Brian M. Payea
Bashar M. Zeitoon
Molten Metal Technology, Inc
51 Sawyer Road
Waltham, MA 02154

ABSTRACT

Quantum-Catalytic Extraction Processing (Quantum-CEP) uses a molten metal bath, as both a solvent and catalyst, to convert feeds to their elemental constituents, and through select reactant addition, form valuable products. Work with U.S. Department of Energy's low level radioactive and mixed waste streams has verified the ability of Quantum-CEP to dissolve the wastes and partition the radionuclide contaminants to target phases of the system and to destroy any organic contaminants in the waste, converting them to valuable synthesis gas.

M4 Environmenta, LP, a limited partnership between Lockheed Martin Corp. And Molten Metal Technology, Inc. Has built and commissioned a small-scale processing/demonstration facility in Oak Ridge, Tenn., which has begun processing DOE mixed wastes in a privatized mode. This paper, in addition to discussing the technical achievements of Quantum-CEP, reviews the design, technical capabilities, and initial processing data of this first-of-a-kind commercial facility.

INTRODUCTION

Quantum-Catalytic Extraction Processing (Quantum-CEP) uses a molten metal bath, as both a solvent and catalyst, to convert feeds to their elemental constituents, and through select reactant addition, form valuable products. Tests have been carried out to demonstrate the applicability of Quantum-CEP to the processing of the U.S. Department of Energy's low level radioactive and mixed waste streams. The three-year project has focused on contaminated scrap metal, and includes optimization for liquids, soils, sludges, combustible and inorganic debris. Specific program objectives included demonstrated recycling of ferrous and non-ferrous metals, immobilization of radionuclides, destruction of hazardous organics, recovery of volatile metals, and conceptual design of a Quantum-CEP facility for contaminated scrap metal in the DOE inventory. Experiments have verified the ability of Quantum-CEP to dissolve the wastes and partition the radionuclide contaminants to targeted phases of the system (the durable ceramic phase in the case of uranium) and to

destroy any organic contaminants in the waste, converting them to valuable synthesis gas. Using EPA Method TO-14, principal organic hazardous constituents (POHCs) were not detected to below ppb levels in the synthesis gas product corresponding to destruction removal efficiencies (DREs) 99.9999%. NOx and SOx were not detected at lower detection limits of 3 and 1 ppm respectively. Dioxins and furans were non-detectable at the targeted regulatory standard of 0.1 ng/Nm3 TEQ using a modified EPA Method 23. POHCs were non- detectable in any of the condensed phase products at several orders of magnitude below EPA land disposal restriction limits (EPA Methods 8260 and 8270). Simultaneous to this conversion efficiency, >90% of the feed was recovered as commercially-viable products as certified by the Massachusetts Department of Environmental Protection for a broad range of inorganic, organo-metallic, and chlorinated organic waste feeds. All condensed phase products were shown to pass EPA toxic characteristic leach procedure (TCLP) and synthesized glasses containing high concentrations of halogens (e.g., up to 10% Cl) surpassed high level nuclear wastes in PCT analyses. In parallel to this development effort, partitioning of multiple radionuclides has been performed with major radionuclides including 235U, 60Co, 134Cs, 136Cs, 137Cs, 65Zn, 54Mn, 51Cr, 55Fe, 59Ni, and 141Ce. For example, uranium and cerium were successfully partitioned from the metal phase to the ceramic phase to demonstrate the decontamination of scrap metal. No uranium or cerium were detected in the decontaminated metal product (lower detection limit 0.1 ppm), which had an initial contaminant concentration of >1,000 ppm. For low level wastes containing volatile radionuclides (e.g., Zn, Cs), bench scale gas phase decontamination factors (DFs) >105 were achieved (analytically limited at intermediate point in gas handling train) corresponding to commercial designs with DFs >107. Hence the efficacy of targeting a radionuclide to a desired product phase to achieve maximum volume reduction and/or recovery of valuable products has been confirmed.

M4 Environmental, LP, a limited partnership between Lockheed Martin Corp. and Molten Metal Technology, Inc. has built and commissioned a small-scale processing/demonstration facility in Oak Ridge, TN, which has begun to process DOE mixed wastes in a privatized mode. Initial target streams include sludges and gaseous diffusion plant wastes..

TECHNOLOGY DESCRIPTION

Catalytic Extraction Processing (CEP) is a proprietary technology that allows waste materials of a wide range of chemical and physical forms to be processed leading to decontamination and resource recovery. For processing of radioactive and mixed waste streams, CEP permits both complete destruction of hazardous contaminants and controlled partitioning of radionuclides in a single step. This leads to the potential formation of one or more decontaminated product phases (fuel gas and/or metal alloys), as well as volume reduction and concentration of radionuclides in a stable condensed phase for final disposal. A typical CEP unit consists of a feed preparation system, the Catalytic Processing Unit (CPU) or the reactor holding the molten metal, followed by a gas handling and recovery train. Upon injection into the metal bath, feed materials dissociate into their elemental constituents aided by the catalytic and solvating properties of the liquid metal. Select addition of co-reactants or manipulation of operating conditions, together with the thermodynamically controlled reaction pathways, enables synthesis of products and/or partitioning of compounds into the desired phases.

The CEP process can be conceptually divided into two stages:

Catalytic dissociation and dissolution: The catalytic effect of the molten metal bath causes complex compounds in the feed to be dissociated into their elements, which readily dissolve in the metal bath. These soluble elements form dissolved intermediates.

Product synthesis/partitioning: Through the addition of select co-reactants or by controlling operating conditions, the dissolved elemental intermediates can be reacted to form desired products or made to partition to the desired phases. These reactions are driven by thermodynamic forces and solution equilibria.

The solubility of carbon in iron is key to CEP's processing of organic and organo- metallic feeds. Specifically, carbon from the dissociation of organic compounds in the feeds, readily dissolves maintaining a homogeneous reducing environment in the molten metal solvent for a large number of compounds including carbon dioxide, sulfur dioxide, water and a wide range of metal oxides. The reducing strength of dissolved carbon provides CEP the flexibility to recycle organics to synthesis gas, recover metals and inorganics such as halides, sulfur and phosphorus, and separate and concentrate transuranic compounds.

As outlined above, the molten metal bath in the CEP system ensures dissociation of the feed into 'singular' elemental intermediates. The partitioning of feed components and the synthesis of products of value is dependent on manipulating the reaction pathways of the dissolved elemental intermediates. Potential reaction pathways are controlled by reaction thermodynamics.

Metal Recovery

A significant advantage of CEP technology is its ability to recover and recycle metals from organo-metallic feeds. Consider an organo-metallic feed dissociating into its elemental constituents (e.g., C, H, M, where M is the metal) upon injection into the CEP reactor. Both the carbon and the metal will readily dissolve in the molten metal solvent. If oxygen is added as a co-reactant, two reaction pathways are possible:

$$2C + M + O_2(g) \rightarrow 2CO(g) + M \quad (1)$$

$$C + x\,M + y\,O_2(g) \rightarrow M_xO_{2y} + C \quad (2)$$

Investigation of the free energies of formation indicates which systems will proceed with formation of carbon monoxide (reaction pathway (A)) and which systems will proceed with formation of the metal oxide (reaction pathway (B)). Specifically, carbon monoxide formation is favored in systems containing metals such as nickel, cobalt and copper whose free energy of oxidation is higher than that of carbon. These metals can be recovered as alloys in the iron solvent. Metals with a free energy of oxidation lower than that of carbon (e.g., aluminum, calcium) will form oxides and partition into the ceramic phase. Certain metals can either be recovered as metal alloys or as oxides in the ceramic phase depending on the operating conditions. For example, magnesium is reduced by carbon at elevated temperatures (T1800C, P=l atm). However, at elevated pressures, magnesium oxide reduction by carbon, will not be favored.

Halogen Recovery

Under the Resource Conservation and Recovery Act (RCRA), chlorinated organic compounds of concern include the primary organic hazardous constituents (POHCs) in the waste. Carbon tetrachloride, chloroform, para-dichloro benzene, perchloroethylene, tetrachloroethane, 1,1,1-trichloroethane, trichloroethylene, methyl chloride, polyvinyl chloride

(PVC), and polychlorinated biphenyls (PCBs) and all their intermediates and derivatives are among the common organic chlorinated compounds.
CEP technology can recover and recycle halogens from halogenated organic and inorganic feed streams without the formation of undesired by-products (e.g., chlorophenols, dioxins and furans). In order to demonstrate the recovery and recycling of halides in the CEP system, consider the case of a chlorinated organic feed stream. On injection into the molten metal bath, the feed will dissociate into dissolved elemental intermediates. Chlorine can be recovered and recycled as either a metal chloride or hydrogen chloride, or as chlorine gas in the absence of hydrogen. When a ceramic layer is introduced during CEP operation, thermodynamic control predicts predominant retention of chlorine in the ceramic phase under optimized conditions.
The two reaction pathways are:
Formation of Metal Chloride: Calcium, in the form of calcium oxide, added to the molten iron bath will form calcium chloride. The effectiveness of calcium as a chloride scrubbing agent is demonstrated by the Gibbs Free Energy of formation of common chlorides as a function of temperature diagram, shown in Fig. 1. Calcium chloride is volatile under CEP operating conditions and will distribute itself in the gas product phase where it can be cooled and separated from the other gaseous components as a condensed solid. However, by manipulating the ceramic phase composition, the metal halide can be prevented from distributing into the gaseous phase.
Formation of Hydrogen Chloride: In the absence of calcium, both hydrogen chloride and ferrous chloride will be formed as the free energy of formation for both compounds is of the same order of magnitude (Fig. 1). If CEP is operated at temperatures of 1500C, the ferrous chloride will volatilize and be recovered as a condensed solid in the gaseous stream. If the CEP is operated at lower temperatures (1000C) ferrous chloride can be recovered as a liquid in the vitreous phase.
Fig. 1
Partitioning of chlorides in a metal/gas/ceramic phase system, however, must take into consideration the effects of mass transfer issues within the ceramic phase. Even though the free energy of reaction can be treated as a true measure of the driving force for the reaction, mass transfer issues can limit the extent of the reaction such that thermodynamic equilibrium is not achieved. In the case of chloride processing with a metal/CaO-Al2O3-SiO2 ceramic phase, the formation of 'CaCl2' in the ceramic phase is not only dependent on the activities of the constituents, but also influenced by ceramic phase viscosity, reaction-rate, and residence time of the gas in the ceramic phase. CaO-Al2O3-SiO2 systems are of primary interest to MMT and have been extensively studied and optimized for potential capture of chlorides as CaCl2.
The CEP flexibility in recovering halogens is a major advantage given the technical difficulties and expense associated with processing halogen-containing waste streams in typical open flame combustion processes such as incineration. Halogen containing compounds tend to suppress combustion and are often characterized as non-combustible. Therefore, incineration of these chemicals can result in incomplete combustion leading to formation of highly toxic compounds. The free radical chemistry that occurs during combustion produces radical intermediates which can react to produce dioxins and furans.
Transuranic Recovery

An important advantage of the CEP technology is that it can separate and concentrate radioactive compounds from complex contaminated feeds while also recovering and recycling the non-radioactive components of the feed. This attribute of CEP has important implications in the decontamination of radioactive sites as well as the decommissioning of nuclear weapons and the byproducts of their manufacture. This implies that radioactively-contaminated components from DOE sites can be separated, highly concentrated and immobilized in a small volume that can be safely disposed of. Furthermore, feed components such as reducible metals (e.g., nickel, chromium, manganese) can be recovered as alloys while hazardous organic components can be effectively converted to a stable final form. Table I shows that the Gibbs Free Energies of reduction by carbon of transuranic oxides are positive indicating that the reactions are not thermodynamically favored. It is this oxide stability that provides a mechanism for the partitioning of these radioactive species into the ceramic phase. Data collected from the literature demonstrates the partitioning of transuranic components from the metal to the vitreous phase. Specifically, residual concentrations ranging from 0.05 ppm to 2 ppm of such radioactive components were achieved by others using diffusion of oxidizing, vitreous-forming agents to partition the radioactive components.

Table I

Experimental Feed Conversion Demonstrations

The processing and conversion of organic, organo-metallic and inorganic compounds in mixed waste streams into stable materials has been demonstrated theoretically in the discussion above. In addition to the theoretical analysis, MMT has collected extensive experimental data in bench-scale and pilot plant units and in commercial-scale metallurgical systems. The experimental data validates the theoretical predictions and confirms CEP's capabilities to generate high quality products.

The physical chemistry of CEP, specifically, the solution equilibria and the formation of a 'singular' dissolved intermediate in the reaction pathway, ensures that complete dissociation of feed streams occurs and that product synthesis and recycling can be controlled and manipulated. Therefore, the molten metal, acting as a homogeneous catalyst and solvent with high chemical inertia, renders CEP a highly flexible and robust recycling technology.

Targeted Partitioning to Durable, Stable Form

Previously published studies have demonstrated the ability to partition radioactive components, such as uranium and plutonium, from the metal phase into a vitreous phase via melt refining. Residual concentrations ranging from 0.05 ppm to 2 ppm were achieved using diffusion of oxidizing, vitreous-forming agents to partition the radioactive components. Successful partitioning to less than 10 nCi/g levels (approximately < 0.1 ppm) has been demonstrated for uranium- and plutonium-contaminated metals. CEP offers the potential for superior performance, as the techniques involved in melt refining are completely incorporated and enhanced in CEP technology. Specifically, CEP incorporates active radionuclide partitioning through select co-reactant additions (e.g., oxygen) and enhanced mass transfer (e.g., convection), while melt refining is based upon 'passive' diffusion-based partitioning. MMT designed a series of bench-scale experiments using radioactive surrogate materials to demonstrate the oxidation and partitioning of radionuclides between the metal and vitreous phases and to identify and

optimize the effect of operating conditions on partitioning. The bench-scale experiments were followed by experiments on pilot- and demonstration-scale systems. Hafnium was selected as a radioactive surrogate due to its similarities in thermodynamic behavior (Fig. 3) and physical properties (Table II) to uranium. Zirconium, although similar to uranium in the thermodynamic properties, was not chosen as the primary surrogate material because of its significantly lower density. Following experiments with surrogates, actual radionuclides were successfully processed in CEP to confirm earlier results.

The experimental design parameters evaluated were metal system, gas environment and ceramic phase composition. Radioactive surrogate partitioning was measured using neutron activation analysis (NAA) for non-destructive trace analysis. The hafnium LDL was 0.2ppm in iron and 2ppm in nickel. X-ray fluorescence (XRF) was used for analysis of the vitreous phase composition. Metal samples were taken at different positions in the metal bath to ensure uniform decontamination. The contract objective was to demonstrate uniform metal decontamination above 98%. In addition, backscattered electron imaging and X- ray analysis were used to investigate the nature of the capture and stabilization of the radionuclide surrogate in the vitreous phase.

Fig. 2

Table II

Average decontamination of the metal samples were >99% and exceeded the contract's 98% objective in all experimental trials. The calculated decontamination factors were analytically limited with no radioactive surrogate detected in the metals. Table III summarizes the results. V1 refers to aluminosilicate vitreous compositions while V2 refers to borosilicate vitreous compositions.

Table III

Samples taken at different positions in the metal bath demonstrated uniform distribution of any trace amounts of hafnium across the metal (Fig. 3 and Fig. 5). This indicates that radioisotope transport to and incorporation in the oxide phase is very efficient under CEP operating conditions.

Fig. 3

Fig. 4

Ceramic samples were analyzed using backscatter electron imaging to identify the nature of the radionuclide capture and stabilization in the ceramic phase. This work indicated that operating conditions and vitreous phase composition can affect radionuclide capture and stabilization. Figure 6 shows the backscatter image of a vitreous sample which has separated into hafnium rich and hafnium poor regions. This is in contrast to the vitreous sample shown in Fig. 7, where hafnium is uniformly distributed. CEP conditions have been identified to achieve this desired vitreous radionuclide capture and stabilization mechanism.

Fig. 5

Fig. 6

Processing of RCRA Contaminants

CEP has been demonstrated on a range of RCRA-listed wastes as well as characteristic and RCRA-like surrogate material (Table IV) including high-molecular weight aromatics, chlorinated organics, organically-bound nitrogen species (isocyanates), plastics, and organometallics. The technology's environmental performance has been demonstrated during actual waste processing to meet and surpass current and proposed

regulatory standards. Specifically, DREs >99.9999% were achieved for principle organic hazardous constituents (POHCs). NOx and SOx were not detected in the product gases to detection limits of 3 ppm. Condensed phase non-leachable products, both ceramic and metal phases, of marketable composition were generated. Dioxins were not detected to the targeted regulatory limit of 0.1 ng 2,3,7,8 TCDD TEQ/Nm3.

Currently the effectiveness of hazardous waste treatment technologies is regulated by the EPA, by measuring the concentration of hazardous materials in the after-process wastewater and non-wastewater. All processes have to ensure that organic constituent concentrations in individual wastewater and non- wastewater streams are lower than the regulated limits set by EPA. CEP demonstrations surpass the current limits even when compared with the Best Demonstrated Available Technology (BDAT). CEP was recently approved by EPA (on October 24, 1994) as a non-combustion technical equivalent (BDAT) for eight RCRA-listed isocyanate waste codes (K027) for which incineration had previously been mandated as the commercially available BDAT technology.

The environmental performance of CEP has also been demonstrated on chlorinated waste streams, containing some of the most difficult to destroy hazardous constituents. The results of demonstration-scale processing of RCRA-listed waste F024 (chlorinated aliphatics) indicated that hazardous organic constituents in the feed were not detected in ceramic, metal and scrubber water, thereby surpassing the BDAT standards for all effluent streams (Table V). Destruction Removal Efficiency (DRE) on multiple organic hazardous constituents exceeded 99.9999%, which surpassed the current regulations mandating DREs >99.99% (Table VI). Trace constituents were not detected to the targeted regulatory limit of 0.1 ng/Nm3 TEQ.

Table IV

Table V

Table VI

CEP reaction pathways, combined with the uniform and highly reducing environment maintained over a wide range of operating conditions, preclude the formation of dioxins, furans and other undesirable by-products. Research suggests that all of the following conditions must be present to promote the formation of dioxins: excess free O2 (10-3 atm partial pressure), the presence of aromatic precursors, sufficient residence time in the temperature range around 300C (572F), and the presence of heterogeneous catalytic surfaces (e.g., particulates).iii,iv,v,vi These essential conditions for formation of dioxins are either inherently absent or can be minimized through appropriate design and operation of the CEP system.

Extremely low oxygen concentrations in the CEP off-gas will inhibit the formation of dioxins. Oxygen partial pressure is continuously monitored in the prototype demonstration unit and is not detected. Thermodynamic evaluation of CEP reaction scenarios shows that partial pressures of O2 can approach 10-15 atm.

CEP solution chemistry can ensure that all species pass through a dissolved intermediate and preclude the formation of aromatic precursors. Table IV shows that Destruction and Removal Efficiencies (DREs) are greater than 99.9999% for chlorinated plastics (PVC and polystyrene) and chlorinated solvents.

Delisting

CEP has been demonstrated on a range of RCRA-listed wastes as well as characteristic and RCRA-like surrogate material (Table IV) including high-molecular weight aromatics, chlorinated organics, organically-bound nitrogen species, plastics, and organometallics. CEP's ability to provide complete destruction of the hazardous constituents while maintaining high regulatory integrity has been proven. Due to the unique set of regulations governing the processing of RCRA-listed materials, the disposal of a stable final form containing radionuclides but not exhibiting any RCRA characteristics would benefit from delisting. Delisting would provide increased flexibility in terms of disposal destination and cost.

A delisting petition has been prepared based on experimental data generated from pilot plant and demonstration-scale testing. The delisting petition is an upfront application for a generic delisting of the ceramic phase generated from CEP systems. Five representative mixed waste streams have been selected for delisting:

- Organic sludges: e.g.,ORR MWIR 3090 (F001-F002 solvents, F006 electroplating waste); INEL ID-EGG-158:3
- Inorganic sludges: e.g., ORR MWIR 3004 (F006 electroplating waste); INEL ID- EGG-102:7 (toxic organic and metals with mercury)
- Soils and sediments: e.g., ORR MWIR 3151 (Pb, Hg); INEL ID-EGG-141:990
- Combustible debris: e.g., ORR MWIR 2028 (F003); INEL ID-EGG-114:337
- Scrap metals: e.g., INEL ID-EGG-132:20

The experimental results presented in support of the delisting petition included feed materials characterization, ceramic elemental composition, ceramic hazardous characteristics evaluation, toxicity characteristics leachability procedures (TCLP) testing, and hazardous organic constituents concentration in the ceramic phase.

For a waste to be successfully delisted, the petition must demonstrate that the waste:

- does not meet the criteria for which it was listed
- does not exhibit any hazardous waste characteristics
- does not exhibit any additional factors including additional constituents which may cause the waste to be a hazardous waste

In preparing the delisting petition, MMT has followed the requirements for delisting petitions set forth in 40 CFR 260.20 and 260.22, as well as in relevant EPA guidance (such as the guidance manual for petitions to delist hazardous waste (EPA/530-R-93-007, March 1993)). These regulations and guidance specify the administrative information, waste characterization and waste management history, process information, waste sampling and analysis information, and ground water monitoring information that must be included in the delisting petition.

ABSTRACT
Vortec has successfully completed the detail design of a high throughput glass melter for the DOE "Innovative Fossil Fuel Fired Vitrification Technology for Soil Remediation" for demonstration program.
The principal objective of the program is to demonstrate the ability of the Vortec Cyclone Melting System (CMS) to remediate DOE contaminated soils, mixed wastes and other waste forms containing RCRA hazardous materials, low levels of radionuclides, and tSCA (PCB) containing wastes. The demonstration program will verify the ability of this vitrification process to produce a chemically stable glass final waste form which passes both TCLP and PCT quality control requirements, while meeting all federal and state emission control regulations. The demonstration system is designed to process 36-72 ton/day of as-received drummed or bulk wastes.
Contruction will begin in mid 1996 with the testing to be accomplished in the first quarter of 1997. The demonstration testing will be conducted at the DOE Gaseous Diffusion Plant in Paducah, KY.
This paper presents a description of the program, equipment, and testing accomplished to date.

INTRODUCTION

The objective of this DOE demonstration program is to validate the performance and operation of the Vortec Cyclone Melting System (CMS) for processing of LLW contaminated soils found at DOE sites. This DOE vitrification demonstration project has successfully progressed through the first two phases. Phase 1 consisted of pilot scale testing with surrogate wastes and the conceptual design of a process plant operating at a generic DOE site. During Phase 2, a site specific design was developed for the processing of LLW soils contaminated with TSCA organics and RCRA metal contaminants. Phase 3 will consist of construction of a scale demonstration plant at the DOE-Paducah Gaseous Diffusion Plant located in Paducah, KY.

The overall system includes the capability to shred entire drums and drum packs containing soil, concrete, plastics and PCB's. This enhanced processing capability will substantially expand the total DOE waste remediation applications of the technology.

A total of seven soil vitrification trials of simulated waste soils containing radionuclide surrogates were conducted during Phase 2 at Vortec's pilot scale vitrification plant located at the University of Pittsburgh Advanced Research Center (UPARC) in Harmarville, PA. The sampling of the effluent and influent streams taken during the tests confirmed that virtually all of the refractory radionuclides were retained in the glass and would not leach to the environmentas confirmed by both Product Consistency Tests (PCT) and Toxicity Characteristic Leaching Procedure (TCLP) testing. The organic contaminants, anthracene, 1-2 dichlorobenzene, and naphelene, was destroyed during testing with a Destruction and Removal Efficiency (DRE) of at least 99.99%. Semi-volatile RCRA metal surrogates were captured by the Air Pollution Control (APC) system, and data on the amount and the chemical composition of the particulate were established for use in the APC system design.

PROGRAM OBJECTIVES

The principal objective of the METC/Vortec program is to demonstrate the ability of the Vortec 36-72 ton per day vitrification system to remediate DOE contaminated mixed waste and other waste forms, contaminated with

both hazardous materials and low levels of radionuclides and PCB, by producing glass which passes TCLP and PCT.

The following other objectives will be met during the program:

1. Determine the glass chemistry requirements to achieve effective vitrification of contaminated soils.
2. Determine expected feedstock particle size distribution and the glass flux requirements.
3. Determine the Destruction Removal Efficiency (DRE) for organic contaminants.
4. Establish the characterization of the off-gas so that valid designs and cost estimates can be made.
5. Establish the cost of a fully integrated waste vitrification system with a 36-72 TPD capacity .
6. Conduct start-up, shake-down, and feasibility demonstrations using the fully integrated plant.

BACKGROUND INFORMATION

The Department of Energy's goal to clean-up its nuclear complex requires the development of innovative technologies to convert soils contaminated by hazardous and/or radioactive wastes to forms which can be readily disposed in accordance with current waste disposal methods. These technologies must be able to: accomplish this task with minimum public and occupational health risks, with minimum environmental risks, and in a timely and economical manner; transform the hazardous and/or radioactive waste into a form which has long-term stability to prevent migration of RCRA metals and radionuclides; not present any major obstacles to its own safe decontamination and decommissioning; and must have long term stability.

After four years of design evolution under various DOE and EPA programs, the melter is operational at the UPARC test facility. Vortec's system has demonstrated the production of glass and the vitrification of a variety of feedstocks including EPA surrogate soils, spent pot liners (K-088) wastes, coal fired boiler ash, sewage sludge ash, auto shredder residue ash, municipal solid waste incinerator ash, metal plating sludges, fiberglass waste with organic contaminants, dusts containing heavy metals and organic materials, and electronic industry wastes.

The unique features of the CMS technology make it a particularly cost-effective process for vitrification. Benefits with respect to DOE's needs are:

1. Long-term immobilization of heavy metals, toxicinorganics, and radionuclides.
2. Effectively oxidize and destroy organic contaminants.
3. Flexibility in processing solid wastes with substantial variations of feedstock composition.
4. Ability to oxidize and vitrify waste materials introduced as slurries. Vortec has demonstrated the ability to vitrify Hanford low level tank waste simulant with a water content of approximately 70% liquid and 30% solids.
5. A sealed process which can be operated at negative pressure to prevent leakage of contaminated gases.
6. A small physical size which is transportable and modular to reduce the decommissioning and disposal costs of the process equipment.
7. Life cycle cost lower than other existing vitrification processes. In commercial applications, a 72 TPD process unit typically has total processing costs in the range of $50 - $100 per ton of material

processed. Radionuclide and PCB contamination increases the per-ton cost somewhat. Vortec estimates that the processing costs of low level waste with mixtures of TSCA or RCRA wastes at Paducah will be in the range of $50 to $200 per barrel for the Paducah drummed wastes. In comparison, of the types of wastes to be processed, other competing remediation technologies have estimated processing costs in the range of $500 to $1000 per barrel for drummed wastes.

Process Description

The primary components of the vitrification system are a counter-rotating vortex (CRV) heater and a cyclone melter. An artist's rendering of the concept is shown in Fig. 1. A unique feature of the process is the rapid suspension heating and oxidation of feedstock materials in the CRV prior to the physical and chemical melting processes which occur within the cyclone melter. The use of the Vortec CRV in conjunction with a cyclone melter distinguishes the Vortec melting technology from other types of cyclone systems. In the CMS process, granular glass-forming ingredients and other feedstocks are introduced into the top region of the CRV along with fuel and air. As a result of the intense counter-rotating vortex mixing, it is possible to achieve stable combustion in the presence of large quantities of inert particulate matter (solids-to-gas mass ratios on the order of 1:1). Both convection and radiation heat transfer mechanisms contribute to the rapid heating of the feedstock materials within the CRV. Any organic contaminants in the feedstocks are also effectively oxidized.

Fig. 1

The melted product formed in the cyclone melter, and the off-gas, exit through the cyclone melter and enter a separator-reservoir (not shown in the figure) where the liquid exits the reservoir through a bottom or side tap, and the off-gas exhausts through an air preheating and pollution control system.

The off-gas exiting the separator-reservoir is treated in an air pollution control system prior to being exhausted out the stack. As a result of the high thermal efficiency of the Vortec melter, the off-gas flow rates are relatively modest. Because the temperature and composition of the vitrified product can be closely controlled, the amount of process fuming (volatile carryover) can also be minimized.

The average gas-solids suspension temperature leaving the CRV is typically on the order of 2000F to 2700F. The process temperatures in the cyclone melter are typically in the range of 2000F to 3000F. The NOx emissions have been found to be substantially lower than those which occur in conventional cyclone systems. Excess air levels are typically in the range of 5 to 20% depending on the composition of the feedstock being processed. The pilot system has demonstrated NOx emissions of less than 4 pounds per ton of vitrified product, meeting the California emission standard for glass melting furnacescurrently the most stringent in the United States.

Heat rates demonstrated by the Vortec pilot scale facility typically ranged between 3.5 and 6 million Btu/ton at a glass production rate of 15 TPD. This heat rate is 50% to 80% lower than heat rates for conventional gas-fired glass melting at similar capacity. The savings are due to more efficient heating of the glass ingredients and lower structural heat losses. The melter can also accommodate the use of a variety of fuels, such as oil and coal-derived fuels, and even organic waste materials.

The system has demonstrated uncontrolled emissions levels of less than 0.5% of feed materials which did not contain low temperature volatiles, such as utility flyash. For materials containing heavy metals and other volatiles, such as MSWI flyash and fiberglass waste, the uncontrolled emissions levels have typically been in the range from 1% to 4%.

RESULTS

Vortec has successfully completed the verification testing and final baseline plant design required in Phase 2 of this program, and will continue the development, construction, and operation of the Demonstration Plant during Phase 3. Vortec is developing the technology to commercial readiness, and will meet all public, occupational, and environmental health and safety requirements for remediation technology. Commercial offerings of the technology, in plant sizes up to 200 TPD, have been made during the last year.

Test Program-Phase 2 Results Summary

A total of seven soil vitrification trials were conducted at Vortec's pilot plant during Phase 2 of the program. The objectives of the pilot testing were to demonstrate the effective vitrification of low level waste streams (soil) with the characteristics and compositions found at DOE-Hanford and DOE-Paducah; evaluate the melting performance with this material, that is, the feedstock composition and viscosity relationship; define the expected range of flue gas emissions; optimize the system operating parameters for the waste by determining the effect of temperature on the melting performance and on the capture rate of the surrogate contaminants in the vitrified product; and to determine the PCB destruction efficiency of the CMS.

The first set of trials used a surrogate soil composition representing the contaminated soil found at DOE's Hanford site. These tests evaluated the melting performance and expected range of flue gas emissions from the system when processing the Hanford surrogate soil feedstocks which consisted of a synthetic soil spiked with surrogate heavy metal and radionuclide contaminants. Success was measured by the ability of the melter to produce a fully-reacted vitrified product which passed both the Toxicity Characteristic Leaching Procedure (TCLP) and the Product Consistency Testing (PCT). Samples of all effluent streams were analyzed to establish the partitioning of the heavy metal and radionuclide surrogates. These tests determined the effect of temperature on the melting performance and confirmed the capture rates of the surrogate heavy metal and radionuclide contaminants in the vitrified product. Analyses of the off-gas were conducted to establish the design specification for the air pollution control system.

Five additional vitrification trials were also conducted using surrogate contaminated soil representative of the soil found at the DOE-Paducah site. The surrogate soil feedstock used consisted of a synthetic soil modeled on the data received from DOE-Paducah from their low level waste inventory. Samples of all effluent streams were analyzed to establish the partitioning of the heavy metal and radionuclide surrogates. Flue gas samples were also analyzed for PCB's.

The glass analysis was conducted on the collected samples by Corning Engineering Laboratory Services (CELS), and the TCLP testing was conducted by Blue Marsh Laboratories (BML). The TCLP analysis indicated that the TCLP extract contained very little measurable quantities of metals and in all cases were significantly below EPA TCLP limits. PCT test results indicated a Na-normalized leach rate of 0.0032 to 0.015

grams of glass/square-meter/day. The PCT specification for nuclear glasses is a Na-normalized leach rate of no greater than 1.0 grams of glass/square-meter/day. These results indicate that the glass produced is approximately 2 orders of magnitude better in retaining radionuclides than the conventional environmental assessment glasses.

The best data available from DOE-Paducah indicated that the low level waste stream (soil) contained small amounts of organic materials and small amounts of heavy metals, uranium, and plutonium. Since the worst organic material to remediate is the PCB, 1, 2 dichlorobenzene was used as an organic surrogate at a concentration approximately of 1000 PPM, a concentration well beyond what is expected in the actual low-level waste stream. Each test focused on establishing the DRE for its chemical compound. As with the tests with the Hanford soils, the DRE results were at least 99.99%.

In addition, Cerium was included at 500 PPM as a surrogate for uranium or plutonium, and the semi-volatile RCRA metals lead and cadmium were also included. Vortec has demonstrated that approximately 95% to 100% of the non-volatile RCRA metals report to the glass.

Design Program-Integrated Demonstration Plant

The major system requirements for the Demonstration Plant are as follows:

1. Targeted waste stream is 55 gallon drums of contaminated soils containing debris such as concrete, tramp metal, wood and plastics.
2. The process will be capable of processing waste containing radionuclides, TSCA, and RCRA contaminants.
3. Waste streams with up to 30% moisture at a nominal processing capacity of drummed waste of 160 drums per day.
4. The plant will be transportable and modular allowing use at multiple DOE sites and/or multiple locations at a single site.
5. The Demonstration Plant will be capable of processing a wide variety of physical and chemical waste forms throughout the DOE complex. The wastes include soils, sediments, and/or sludges contaminated with hazardous wastes and low-level radioactive wastes. Both volatile (Technetium) and nonvolatile (Uranium, Neptunium, Thorium, and Plutonium) radionuclides may be present in the soil waste stream. The eight heavy metals regulated by 40 CFR 261.24 are also present in the soil. Organic materials that can result in Hazardous Air Pollutants regulated by State of Kentucky 401 KAR 63.022 are also present in selected waste streams. Optional waste streams may include but are not limited to: personnel protective equipment (PPE), HEPA filters, treated scrubber / ESP water particulate and spent ion exchange materials.
6. The system will produce a glass frit, a chemically stable and reduced volume final waste form, that will pass the Toxicity Characteristic Leaching Procedure. The Air Pollution Control (APC) system will be required to meet DOE/EPA and the State of Kentucky standards for the removal of hazardous material and radionuclides.
7. A wastewater treatment process will remove radionuclides and other solids from process water and these solids will be recycled through the melting system.
8. The vitrified product generated will be disposed on-site or at an approved DOE site.

A system flow diagram is shown in Fig. 2, and an isometric drawing of the plant arrangement in shown in Fig. 3. The demonstration plant has been

designed as a transportable and modular system; that is, the individual, skid
Fig. 2
Fig. 3
mounted components of the process have the capability to be transported by truck, without special permits, to the site, erected, and when operation is complete, dismantled, decontaminated, loaded back onto trucks, and hauled off-site.

To demonstrate the effectiveness of the technology, 400 hours of start-up and functional testing are planned, followed by a 30-day period of nearly continuous testing. During operation, contaminated soil is transported by DOE in 55 gallon drums from the DOE-PGDP storage area to the vitrification facility. There is always at least a three day supply of the material in the storage area. Soil samples collected prior to the 30 day demonstration test will be used to determine the batch composition.

The process of vitrifying the soil begins in the Feed Preparation Subsystem. It consists of 1) transportation of drums to the drum shredder for introduction to the feed preparation system; and 2) a drying and screening operation to assure that the material has the proper moisture content and size. Upon receipt, the drums are emptied into a drum shredder using a conventional fork lift truck with standard drum holding fixture. To preclude the escape of dust particles when dumping or transporting the soil, all the conveying systems will be designed with an enclosure and operate under negative pressure. In addition, all hoppers and transfer points (dumping points) will also be enclosed and will be under negative pressure. The dust laden air from these devices will pass through a dust collector for particle removal. Solids collected in the dust collector will be transported back into the system. Discharge from the dust collector will pass through a parallel pass HEPA filter system.

The sized and dried soil is transported to a storage silo. Glass making additives are mixed with the soil. Additives (limestone and soda ash) are used to aid in glass forming, obtain the proper glass properties, or modify the temperature-viscosity curve. The blending system consists of storage silos and pneumatic feed system for the delivery of the soil and additives to a blend tank. Batch mixing precedes feeding into the Cyclone Melting System.

The CMS equipment components consist of a counter-rotating vortex (CRV) oxidizer/heater, a cyclone melter (CM), a separator/reservoir, and a recuperator heat recovery unit. The prepared feedstock is introduced into the CRV oxidizer/heater through injectors located at the top of the CRV and the glass product and the off-gases exit the CM through a tangential exit channel and enter a separator/reservoir.

The separator/reservoir separates the off-gas from the melted material and provides an interface with a vitrified product handling system. The off-gas exits through an exhaust port which is the interface for the recuperator. The recuperator utilizes the waste heat to preheat air going to the melter. Molten glass flows out the separator/reservoir to the Vitrified Product Handling System. The molten glass from the melter will be water quenched to produce a cullet approximately 1/8" in average size. The cullet will be transported by conveyor to B-25 boxes, that when full, will be moved to an area for pick-up and disposal by the DOE-Paducah.

The Air Pollution Control System (APCS) will consist of a wet electrostatic precipitator (WESP) system for particulate collection preceded by a venturi scrubber. The scrubber will remove large

particulate as well as serve the function of reducing the off-gas temperature. After removal of particles in the WESP, the temperature of the off-gas is raised in an off-gas heater prior to entering the HEPA filter for removal of fine particles. Redundant HEPA filters are used to facilitate maintenance. The off-gas exits the HEPA filters and flows to the exhaust stack. The APC system also includes a waste water treatment system to remove radionuclides from the process water used in the venturi scrubber and WESP. This system consists of a clarifier, a filter press, sand filter, ion exchange unit, and various pumps and tanks. Process water from the WESP flows through a wastewater tank, a chemical precipitation tank for chrome removal, and on to a clarifier. The solids from the clarifier, which contain some contaminants not captured in the glass, are dewatered in a filter press and are returned to the Feed Preparation System. Radionuclides are removed by first filtering the supernate water in a sand bed. The solids are removed periodically from the sand bed by back flushing with the treated water, and the backwash is reintroduced into the clarifier. Radionuclides are removed through ion exchange treatment. The treated effluent is stored in a holding tank for reuse as quench water within the quencher/venturi scrubber.

The Instrumentation and Control System consists of the sensors, electronics, instrumentation, computers, and programmable logic controllers (PLC) to control the process in real time, gather data for analysis on system and equipment performance, and monitor process off-gas. The system is capable of being shut down in emergency situations in a controlled manner using the auxiliary power unit and structured logic.

SCHEDULE

Vortec has completed Phases 1 and 2 of a three phase program to design, construct, and demonstrate the effectiveness of the CMS technology at remediating contaminated soils. The ability of the CMS to vitrify soils similar to the soil found at DOE-Paducah was demonstrated. The vitrified product passed TCLP as well as PCT for leachability of and durability. In addition, the final design of a 36-72 TPD demonstration plant to process contaminated soil is completed. Phase 3 will carry out the construction of the plant and conduct the 30 days of demonstration testing. Figure 4 represents the tentative schedule for Phase 3.

ABSTRACT

DOE Fernald is nearing completion of a project objective to treat legacy mixed waste for shipment and disposal to the Nevada Test Site (NTS). In pursuing this challenging objective, DOE-Fernald and the site cleanup contractor, Fernald Environmental Restoration Management Corporation (FERMCO), have defined the requirements and purchased the fixed-price services of a private waste treatment subcontractor. The subcontractor has mobilized and initiated stabilization of the mixed waste. The subcontractor is a team consisting of Perma-Fix Environmental Services, Inc. (Perma-Fix), and Performance Development Corporation (PDC).

The mixed waste at Fernald was generated during uranium processing operations and remedial actions at the DOE facility. This waste is classified as both low-level radioactive and hazardous, which requires treatment prior to disposal at NTS. The Mobile Mixed Waste Stabilization Project is using the Perma-Fix Process to chemically stabilize and solidify approximately 1,850 drums of waste. Chemical hazards of the targeted project waste are soluble heavy metals including lead, barium, and chromium (EPA waste codes D004 - D011).

Following processing by the Perma-Fix team, successful treatment of the waste is verified by an NTS approved laboratory using the toxicity characteristic leaching procedure (TCLP). The treated waste no longer exhibits the hazardous characteristic and will be shipped in metal boxes as solid grout monoliths to DOE's NTS Facility for disposal as low-level radioactive waste.

Under the Federal Facility Compliance Act (FFCAct), FERMCO has developed a Site Treatment Plan (STP) that specifies a preferred option for each of several mixed waste streams at Fernald. This project meets the requirements for mobile stabilization as Fernald's preferred option in the STP. By implementing the STP at the Fernald Site, FERMCO has taken the lead role in complying with the requirements of the FFCAct.

A number of lessons have been generated by this bold new approach to cleaning up DOE's waste inventories. This paper will capture many of the lessons learned on this project in promoting what we believe is a promising strategy for site clean-up that is faster, safer, and cheaper than many competing options. The key features of the project include mobile on-site treatment, fixed-price contracting, and integrated teamwork among Perma-Fix, FERMCO, and DOE FERNALD participants.

INTRODUCTION

The objective of the Mobile Mixed Waste Stabilization Project is to safely treat approximately 1850 drums of characteristic mixed low-level radioactive waste (LLRW) currently being stored at Fernald. These wastes have been characterized as containing waste constituents regulated under EPA waste codes D004 through D011. The wastes will be treated at Fernald and sent to the NTS for disposal using Best Demonstrated Available Technology (BDAT) to meet RCRA Land Disposal Restrictions (LDR) and NTS waste acceptance criteria (WAC) established under the Nevada Test Site - Defense Waste Acceptance Criteria, Certification, and Transfer Requirements (NVO-325, Rev. 1). BDAT will be accomplished using a cement based stabilization/solidification process that renders toxic heavy

metals and radionuclides insoluble by precipitation, and locks them in a grout matrix.

On-site waste treatment services are being accomplished by personnel from Perma-Fix and PDC working in conjunction with DOE Fernald and FERMCO personnel.

WASTE STREAMS

The 1850 drums of legacy mixed waste have been in storage in RCRA-permitted warehouses at Fernald. The drums of mixed waste have been grouped and categorized using Material Evaluation Form procedures developed by FERMCO. For many of the drums, Real Time Radiography (RTR) was used for identifying drum contents. This procedure uses x-ray technology to view the contents of a container, and to determine the physical properties of the waste such as presence of free liquid, particle size, and internal container capacity. The 1850 drums have been divided into six general waste categories:

1. Grit Blast residues - approx 905
2. Solidified furnace salts - approx. 145 drums
3. Sump cakes - approx. 465 drums
4. Construction rubble - approx. 40 drums
5. Miscellaneous trash - approx. 25 drums
6. Miscellaneous (1-5) additional waste - approx. 300 drums

STABILIZATION PROCESS

The waste treatment process employed in stabilizing Fernald waste is a production process based on optimal staging of incoming waste containers, screening and sorting the larger fraction, removing incompatible material, size reducing the larger fraction, and redistributing the reduced material with original container material. Treatment consists of mixing chemical reagents to precipitate soluble heavy metals, pozzolans, and fresh or contaminated water to create a slurry that is poured in metal boxes supplied by FERMCO. Figure 1 is a block flow diagram of the Mobile Mixed Waste Stabilization process. Figure 2 is a schematic illustrating how materials handling is accomplished.

STABILIZATION UNIT

The mobile treatment unit includes the following engineered facility and equipment and are depicted in Fig. 3 - Equipment Layout:

1. Incoming waste staging area
2. Deheading and inspection station
3. Screen hopper
4. Sorting table
5. Shredder
6. Mixers
7. Contaminated water holding tank
8. Liquid reagent tank
9. HEPA filtration units
10. Cement silo
11. Empty drum staging area
12. Decanting and curing area
13. Tented soaking area

Fig. 3

RESULTS

As of January 31, 1996, 905 drums of grit blast have been successfully treated and are being prepared for shipment and disposal at NTS. Another 145 drums of solidified furnace salts have been treated and are awaiting the results of confirmation sampling by TCLP. The project had planned to process an average of 35 drums per work day. To date, processing results have varied significantly, some days have included no processing due to equipment maintenance or staging efforts, and many days have seen processing rates of 50 to 65 drums. Our best efforts have sustained better than 10 drums per operating hour. The project is planned to complete processing of the contract goal inventory by March 20, 1996. Based on our results to date, this is attainable.

LESSONS LEARNED FROM THE PROJECT

The lessons learned as the result of this very successful project include the following:

On-site treatment by a private subcontractor is achievable

There are doubts within DOE and prime contractor ranks that it is possible to bring private subcontractors on site, have them live by DOE rules, work with the site labor force, manage any kind of schedule, or control costs. This project has demonstrated each of these concepts to be false. For the Mobile Mixed Waste Stabilization Project, we entered into a fixed- price contract and prepared project-specific plans acceptable to the Ohio EPA, US EPA, and DOE in less than 60 days. This documentation included a CERCLA Work Plan, Health & Safety Plan, Quality Assurance Plan, Process Control Plan, project procedures, and Processing Area drawings. After Ohio EPA and US EPA approval, Perma-Fix mobilized the processing equipment, performed pre-operational testing, and successfully responded to an independent Operational Readiness Assessment demonstrating compliance with DOE requirements. This was also done in less than 60 days. When elements of the contract were found inconsistent with a pre-existing agreement, Perma-Fix worked out arrangements to allow appropriate participation of site workers. This action enhanced site response and created a teamwork atmosphere among project workers. The project is nearing completion. Treatment and disposal costs are low compared to off-site alternatives. There have been no price increases to the subcontract. Major portions of the site's mixed waste have been treated to greatly reduce public risk prior to shipment on the open highways.

DOE site labor force can work with private contractors if concerns are considered and resolved before operations begin, and cooperatively managed during the project

After the project began, FERMCO discovered that elements of Perma-Fix's work scope conflicted with the pre-existing labor agreement. Perma-Fix renegotiated project activities with FERMCO such that Fernald Atomic Trades and Labor Council (FAT&LC) union members had an expanding role in project activities. There had been considerable concern at the beginning of the project that it would be hard to manage the schedule in this way, but all schedules have been met to date.

Technology is only as important as a good plan, competent personnel, constant communication, and cooperation

There is considerable opinion that stabilization is a low-tech technology, not robust enough to attack DOE's mixed waste problems. Our experience has demonstrated that stabilization does work on a fairly broad range of waste types, can be mobilized and employed quickly, has a great deal of operational experience, has equipment and project costs

that are much better understood, is very amenable to small batches for handling the wide variety of waste types, can be performed inside currently existing facilities, and is much less costly than many of the more exotic technologies crowding the national headlines.

One of the lessons learned on this project has been the relative importance of technology compared to other project challenges. With adequate experience and due care, making a solid that passes TCLP is not that difficult. The challenge is in planning and executing project activities with sufficient detail to satisfy project regulators. These include overviewers from: quality assurance and health & safety, FERMCO project, DOE, Ohio EPA and US EPA, and NTS. Any project that is inadequately prepared to deal with this bigger challenge runs a much higher risk of failure.

Use waste to treat waste

Stabilization requires the addition of a number of non-waste materials during treatment of the waste. These include water, pozzolans, chemicals used to precipitate contaminants, and mixing. Some waste products can be used in this process. For the Mobile Mixed Waste Stabilization Project, the water balance was managed to allow for the reuse of waste water. Additionally, we identified and were able to use surplus chemicals that were waiting for disposition on the Fernald site. These chemicals were used in waste processing for precipitating contaminants. The project also processed much of the solid waste generated during operations with the legacy waste stream. These actions support the waste minimization/ pollution preventative initiatives driven by both EPA and DOE.

Limit government liability with low cost commercially available equipment

One of the major risks of treating mixed waste, on site or off site, is the potential for the processing equipment to become contaminated, and failure to decontaminate causing the government to become the owner of some used contaminated equipment. This situation can and has happened many times. The lowest-risk way of limiting government liability is for contractors to propose and use as much simple, inexpensive, and commercially available equipment as possible, considering the minimum volume of equipment subject to waste disposal. Also design of equipment must address decontamination ability.

Small batch capability provides control features not available in continuous feed processes and is better suited to the many "cats and dogs" that exist in legacy wastes

Most of the money and the press in waste treatment has been spent on concepts using continuous processing equipment designed for the enormous volume of mixed waste to be treated. The problem with most large processes is that they generally work best on homogeneous and/or well characterized material. Much of the waste that has been identified at different DOE sites is far from homogeneous. Waste stream characteristics are rarely known well enough for continuous flow processes to respond to variations in the waste. Expensive automated systems can seldom manage highly variable waste streams, as well as trained and experienced operators can manage them. Stabilization is one of the few existing technologies offering the needed body of experience. When continuous processes are forced to deal with such varied material, it is often necessary to resort to batching. The equipment is usually not designed for batch operation. Batching in processes designed for continuous flow is achievable, but quite expensive compared to simpler options.

Small business can do the job

Another myth often believed by people in this business is that only major corporations are viable to attempt this type of project. The false impressions include having a larger talent pool to draw upon, deeper pockets if there is a problem, a more relevant experience base, an ability to impress the regulators and a skeptical public, and a better capability to deal with problems. The Mobile Mixed Waste Stabilization Project has employed the services of Perma-Fix and PDC, both small businesses. They have performed well. There have been many challenges for both companies on a number of occasions. Their senior managements have participated fully. Basically there is a lot more at stake with these two small businesses than there would have been with large businesses and the net effect has been an extremely responsive project organization. Our aggressive schedule would not likely have been met except for this level of attention.

On-site CERCLA treatment can be faster, safer, and cheaper than off-site RCRA Treatment, Storage, and Disposal (TSD) Facilities

Many DOE sites have concluded that the only viable alternative is to send mixed waste off site to RCRA TSD facilities that also have NRC licenses. The problem has been that this includes a very small group of companies, with technologies having narrow application, difficult prerequisites, and considerable expense. Off-site treatment generally requires repackaging into DOT approved containers. Repackaging can be very expensive. Handling and monitoring of waste prior to disposal is also a major operating cost. The Fernald Mobile Mixed Waste Stabilization Project has been performed as a CERCLA removal action, allowing on-site treatment with mobile equipment without either a RCRA part B permit or a Radioactive Material license. While the project was authorized by the Ohio EPA and the US EPA under CERCLA, the project Work Plan addressed all substantive requirements of a RCRA part B permit and was actually reviewed by the RCRA group within Ohio EPA and US EPA. This efficiency has allowed schedules to be moved forward and permitting expense to be avoided. The greatest enhancement is the ability to stabilize waste at the source, greatly reducing health & safety risk prior to shipment on the open highways. This type of project also allows much greater control of the treatment process which is appropriate considering generator liability. On-site treatment also allows better response to dealing with any abnormal situations related to characterization, fitness for treatment, container degradation and identity, and sampling. By estimate, the life-cycle cost of this project, compared to known off-site possibilities, is much less.

Demonstrate subcontractor ability to comply with DOE requirements with an Operational Readiness Assessment

One of the challenges of the Mobile Mixed Waste Stabilization Project has been addressing the impression that private treatment companies will not be able to work under DOE rules. For this project, we demonstrated compliance with DOE requirements by subjecting the project to an independent Operational Readiness Assessment (ORA). These ORAs are by nature quite a challenge for participants on all sides of the assessment, but acceptable findings and a recommendation to proceed do much to bolster DOE confidence that contractors can perform safely as advertised.

Develop planning documents to level 5 detail to avoid regulatory delays

The Mobile Mixed Waste Stabilization Project is pursuing an aggressive schedule and has relied on prompt attention by regulating bodies on

several occasions. One of our approaches to minimizing review cycles and potential delays has been to provide extraordinary detail about our plans for the project, right up front, to Ohio EPA and US EPA to minimize their asking for more detail later. Initially, we developed a work breakdown structure expanded down to level 5 activities. We then defined our plan of action and schedule down to this level. The challenge in doing this was keeping our aggressive schedule while developing this level of detail.

The contract was issued to Perma-Fix on May 30, 1995. The contract schedule called for delivery of planning deliverables to FERMCO by July 5, 1995. In the following 3 weeks, as a result of teamwork between Perma-Fix, FERMCO, and DOE, the project submitted a Work Plan to Ohio EPA and US EPA. This plan was conditionally approved without revision on September 28, 1995.

DOE and FERMCO have spent a great deal of energy in keeping Ohio EPA and US EPA abreast of upcoming activities, and they have been characteristically prompt in approving clean-up and removal actions.

Prepare good waste characterization including ample sampling, traceable documentation, and real time radiography to get good fixed-price quotations and regulatory buy-in to proposed plans

DOE has been working on an initiative to increase fixed-price contracting in an effort to improve cost performance on the nations tax base. The problem is getting fixed-price quotations for waste treatment services on the basis of process knowledge accrued under the security of the cold war. Proceeding on the basis of this approach is fairly unrealistic. Equally important is securing regulatory buy-in to planned activities rooted in a firm knowledge about the contaminants of concern. Extensive characterization is required providing significant tangible evidence of the nature and extent of contaminants in the waste stream. The approach we took on the Mobile Mixed Waste Stabilization Project was to perform ample confirmatory sampling compared to process knowledge, prepare RTR films on a large population of the waste drums considered, and prepare a strategy for waste grouping that is traceable to container ID, sampling data, RTR, and process knowledge data.

Rumors of waste swell related to solidification have been greatly exaggerated

There is information that suggests that waste swell due to the addition of pozzolans to hazardous, mixed, and radioactive waste streams can be as much as 100% to 200%. These figures, as assumptions, have been used to estimate the disposed life-cycle cost of stabilization to be greater than other more complex technologies. Our experience on the Mobile Mixed Waste Stabilization Project has demonstrated waste swell less than 15% as a result of existing void space and overpacks in the incoming waste drums. There are situations that would result in waste swell in multiples of original volume, but our project results challenge some life-cycle cost claims that are being made. A key consideration is the compressive strength desired. Producing a low strength grout minimizes volumetric swell due to added reagents.

Carefully select Source Evaluation Board (SEB) to level playing field for proposals

Evaluation criteria are usually established by the SEB to provide equal evaluation for all proposers. However, there is still a normal bias for the known, the big, and the powerful. This is perfectly logical in the sense that if they are big and powerful they must be doing things right,

have a talented work force, and have faced and solved many problems. However, in an attempt to support small business participation, DOE has set goals for subcontracting with small business. This suggests SEB's need to be equipped with more knowledge about proposers than is available in the Wall Street Journal and special interest trade publications. Major corporations were included in an unrestricted competition for this important project. However, a small business was selected and has performed quite well.

Evaluate subcontractor ability to decontaminate and remove equipment at contract completion

In general, the extent of the government's liability for a project such as the Mobile Mixed Waste Stabilization Project is the price of services, plus the fair market value of contaminated equipment. This cost is perhaps complicated by the disposal cost of equipment as radioactive or mixed waste. With this in mind there are a few things that contractors can do that can have the enhancing effect of limiting the government's risk. These are keeping the treatment scheme no more complicated than necessary, using as much simple and commercially available equipment as possible, keeping any disposal volume as small as possible, bolstering your proposal with a plan for decontamination, and generally describing corporate plans for released equipment after project completion.

Have DOE's contractor provide HEPA ventilation meeting subcontractors needs because of DOE safety rules.

There are a number of practices and validation tests used on DOE sites that are not generally available to the private sector. For the Mobile Mixed Waste Stabilization Project, we intended for the selected subcontractor to size and provide HEPA ventilation adequate for the project. After the units were purchased, delivered, and ductwork installation was underway, we discovered that site practice required di-octyl-phthalate (DOP) testing by DOE in Oak Ridge for each filter element used. Given the schedule constraints we faced, this was not possible. The site had a number of surplus HEPA filtration units with in-stock filters which met the requirements. In the end, FERMCO provided the needed HEPA units meeting subcontractor requirements. Given site rules for monitoring, filter change, sampling, record keeping, and filter testing, it makes more sense for DOE's contractor to support this requirement rather than passing it on to subcontractors.

Consider weight, handling, and disposal criteria of the disposal facility in selection of waste containers

For the Mobile Mixed Waste Stabilization Project, FERMCO selected and purchased white metal boxes. These boxes are roughly half as high as conventional B-25 boxes, are made with an integral skid for fork truck handling, and are designed for maximum load-bearing requirements based on an empty container. These containers weigh approximately 6000 pounds when filled with the solid waste form. These features have been chosen to satisfy the waste acceptance criteria of the NTS.

Integrating participation of subcontractors in weekly project meetings with site interface groups

Early after award of the project subcontract, Perma-fix began attending the weekly project meetings. The result was that much planning and other project information was made available to site groups earlier, and by the time equipment started showing up, Perma-fix was well integrated into the site team and could address and resolve issues with the site groups

involved. Meeting the project's schedule would not have been possible otherwise.

Select a subcontractor who demonstrates an ability to live and operate within DOE's "culture"

When the SEB evaluated submitted bids for the Mobile Mixed Waste Stabilization Project, most of the bidders could demonstrate that they had stabilized hazardous or radioactive waste. What became impressive to the SEB were proposals that demonstrated they understood and could operate within DOE's culture of security, site access, directives, standards, guides, and procedures. Perma-Fix demonstrated this capability by partnering the project with PDC, a company having extensive experience in DOE culture. PDC has a very strong and successful background working with contractors in support of DOE initiatives. Perma-Fix and PDC composed a project team that identified needed project positions and personnel from both companies. The proposed project team had demonstrated qualifications and experience to perform project functions on a DOE site.

Integrate the disposal site early in the process identifying their needs and implementing systems to meet them (i.e., a Process Control Plan, Nuclear Quality Assurance Program, ample documentation, and traceability)

Mixed waste treatment has a limited purpose unless there is a subsequent strategy to dispose of the treated waste. For DOE waste, there is not a less expensive option than acceptable disposal at the Nevada Test Site. NTS was developed and operated to handle radioactive waste, not mixed waste. A fairly new version of the NTS Waste Acceptance Criteria (NVO-325 Rev. 1) allows disposal of mixed waste where the hazardous characteristic has been removed. Until now, this feature has not been extensively used and operating practices at NTS are still in the developmental phase.

The key to paving the way for NTS acceptance of Fernald mixed waste has been to develop a site program for characterizing, identifying, containerizing, confirmation sampling, documenting and transporting waste products acceptable to NTS. For FERMCO's subcontractor, Perma-Fix, this included preparation of a Process Control Plan, demonstration of a Nuclear Quality Assurance Program, and a project-specific Sampling Plan responsive to FERMCO's agreement with NTS.

In conjunction with the Mobile Mixed Waste Stabilization Project, FERMCO has focused on keeping NTS abreast of project plans, conducted Fernald site visits for NTS participants, worked through closure of NTS audit findings, and supported NTS inquiries for mixed waste treatment. These actions have paved the way for disposal of the projects treated mixed waste at the NTS facility.

Keep in close contact with regulators (i.e., DOE, Ohio EPA, US EPA, and NTS)

None of the responsive behavior that has been demonstrated by DOE, Ohio EPA, US EPA, and NTS would have been possible without an informational network that allowed these participants to keep up with project plans and schedules. Having information available and flowing has contributed to creating team work among DOE, FERMCO, Perma-Fix, Ohio EPA, US EPA, and NTS participants.

Plan for a realistic schedule considering the limitations of the site infrastructure

Contractors might make big claims about how much waste per unit time they have processed on superfund sites, but none of that really matters for a DOE on-site treatment. Many site groups interface with project

activities, and sooner or later site infrastructure is going to limit processing capability. For this project, the Request for Proposal defined what the desired daily processing rate would be. Even so, several proposals were submitted on the basis of much greater processing ability.

Temper the zeal to mix waste streams to minimize volume with the need to have traceability of the waste and accountability of Special Nuclear Material (SNM)

DOE Orders require FERMCO to retain accountability of SNM on site. For the Mobile Mixed Waste Stabilization Project accountability, this has meant that we devise a scheme to track isotopic balances of SNM in project waste streams prior to, during, and after processing by Perma-Fix. This need has driven the procedural systems developed for the project, and information taken and managed at various stages during treatment operations.

The complexity of this task caused us to carefully define and understand the waste contents programed for different treatment episodes. We also decided not to mix some waste streams that could have further minimized the final disposed volume.

Start with the easier material first

The waste streams in the Fernald Mobile Mixed Waste Stabilization Project had considerable variation. Some were expected to be more difficult to successfully stabilize than others. There was a strong temptation to require the processing of the most-difficult-to-treat waste stream first to allow the maximum of time for the toughest challenge. We wisely chose however, to start with the waste stream expected to provide the minimum challenge for treatment. This allowed the best possible set of conditions for the project team to get: 1) all equipment functioning properly, 2) all organizational and process interfaces defined, 3) all project procedures improved, 4) operating data, 5) on-line air monitoring established, and 6) personal protective equipment evaluated.

Closely work the interface with the Federal Facility Compliance Act

In the early project planning stage, there was a concerted effort to identify and recognize the participants and stakeholders in the project under the Fernald Federal Facilities Agreement. The master plan for the project was established recognizing the interfaces and coordination necessary to satisfy site needs and commitments. The pre-planning and close coordination of project services with site commitments proved very effective in minimizing stops and starts and promoting project integration and efficiency.

CONCLUSION

We believe that the Fernald Mixed Waste Stabilization Project demonstrates that technically challenging mixed waste treatment projects can be successfully performed on DOE sites, within the DOE culture, by small business commercial waste treatment contractors. To be successful, the small business team must combine extensive waste treatment knowledge and experience with DOE site know-how. The successful small business team must be willing to adapt to the formalized operational environment of a DOE site, while the site prime contractor and DOE site office must recognize and capitalize on the innovative approaches from the commercial sector.

This project has shown that stabilization/solidification processes have many performance advantages over competing technologies when dealing with waste streams having highly variable chemical and physical properties, such as DOE site legacy mixed wastes. This project has provided evidence

that waste volume increases commonly attributed to cement-based waste stabilization processes are greatly exaggerated. Waste management planning decisions based on assumptions of 100 to 200 percent swell should be critically reviewed. DOE may be able to greatly reduce final treatment costs and speed up legacy waste treatment and disposal schedules by taking advantage of this inexpensive and proven technology. For highly variable wastes, the judgment of properly trained, supervised, and experienced operators can be a better recipe for success than multi-million dollar automated machines.

ABSTRACT

A mobile waste characterization systems analysis was performed by the Carlsbad Area Office National Transuranic Program, Department of Energy (DOE). The analysis identified and evaluated mobile system parameters required for input to a National TRU Waste System Model-a computer simulation specifically designed to evaluate options related to the characterization and transportation the of transuranic (TRU) waste from generator site locations throughout the DOE complex to final disposal at the Waste Isolation Pilot Plant (WIPP). Numerical estimates of these parameters were obtained from a sampling of mobile waste characterization systems currently available for lease or purchase within the DOE complex and the private sector. The analysis addressed the utility and feasibility of mobile systems to characterize contact-handled (CH) and remote-handled (RH) TRU waste stored in a variety of containers including drums and boxes. Two baseline mobile system configurations were identified as necessary and sufficient to address the transportation and disposal of CH-TRU waste. Preliminary results obtained from a spreadsheet analysis indicated cost savings could be realized when these baseline mobile systems are used in conjunction with fixed waste characterization facilities.

INTRODUCTION

Evolving regulatory requirements, a shrinking budget, and a desire to accelerate schedules have resulted in the DOE's examination of alternative resources to supplement its current waste characterization capabilities. The utilization of mobile and/or portable waste characterization systems is one of these alternatives. Mobile systems are self contained and self sufficient units capable of independent field

operation. Portable systems require the host site to provide some support functions consisting of containment facilities and/or utilities. Mobile/portable systems offer the option of providing supplemental assistance to major sites having limited fixed system capability and/or major support as in the case of small quantity sites (SQSs) having little or no waste characterization capability. When compared to fixed systems, mobile/portable systems offer several advantages including their mobility (ideally suited for field operations at major sites and/or transportation to numerous small quantity sites), modular design (capable of being easily reconfigured to address changing conditions and requirements), reduced capital costs (suitable for facilitating small business privatization of services), and reduced time between placement of a purchase order and system delivery.

WASTE CHARACTERIZATION METHODOLOGIES

The methodologies approved by the TRU Waste Characterization Quality Assurance Program Plan (QAPP) to address the requirements for disposal at the WIPP include:

- Nondestructive assay (NDA)
- Nondestructive examination (NDE)
- Headspace gas sampling and analysis
- Visual Examination
- Homogeneous waste sampling and analysis

A subset of these methodologies is considered necessary and sufficient to address the waste characterization requirements for transportation between generator/storage sites. This subset consists of:

- NDA
- NDE
- Headspace gas sampling and analysis.

WASTE CHARACTERIZATION SYSTEMS

For purposes of configuring the smallest core assembly of mobile waste characterization systems, the three methodologies identified above as necessary and sufficient for meeting the requirements for transportation are the preferred candidates. This core assembly of three mobile systems is referred to in the systems analysis as the baseline transportation configuration (BTC) or baseline transportation fleet. The larger core assembly of mobile waste characterization systems, which includes the necessary and sufficient characterization methodologies for purposes of disposal, includes all five of the methodologies listed above. This core assembly of five mobile systems is referred to in the systems analysis as the baseline disposal configuration (BDC) or baseline disposal fleet.

In recognition of the variability of the waste matrices and the variety of packaging types (drums, boxes) used to contain TRU waste, several additional systems have been identified to support the baseline transportation and disposal waste characterization core assemblies. These supporting or secondary systems provide the following functions:

- Drum venting and filter insertion
- TRUPACT-II loading/unloading
- Data integration and compression
- Box repackaging
- Size reduction (compaction, shredding)

To illustrate the flexibility in tailoring an assembly of mobile systems to address a specific problem, consider the example where a SQS desires to dispose of its CH-TRU waste contained in non-vented 55-gallon drums. Assuming all elements of its certification program have been approved,

the preferred mobile waste characterization system configuration in this case would consist of the BDC in addition to a drum venting and filter insertion system plus the TRUPACT-II mobile loading unit-a minimum of seven trailers to facilitate transport and disposal of the waste at the WIPP. (Note: The TRUPACT-II is a TRU waste shipping package.) If instead, it was deemed necessary to ship the waste to a major site for purposes of treating the waste to meet the WIPP waste acceptance criteria (WAC), the preferred waste characterization configuration would consist of the BTC in addition to the two ancillary systems used in the preceding scenario - a minimum of five trailers to facilitate transport to a site other than the WIPP.

Fixed System Capabilities

Information pertaining to the generator/storage sites and their waste characterization resources was obtained from several draft documents including the CH-TRU Waste Management Data Packages (August 1995), the CH-TRU Waste Characterization System Analysis (August 1995), and the RH-TRU Waste Facility Characterization Capability Assessment (August 1995). This data provides a compendium of information for each CH-TRU and RH-TRU waste management activity at the generator/storage sites.

A review of the above listed resources shows that only three sites currently possess the entire suite of five methodologies to characterize CH-TRU waste contained in 55-gallon drums. These sites include the Idaho National Engineering Laboratory (INEL), the Los Alamos National Laboratory (LANL), and the Rocky Flats Environmental Technology Site (RFETS). From a DOE complex wide standpoint, there is presently a limited capacity to perform waste characterization to ensure a sufficient quantity of certified CH-TRU waste will be staged and ready for disposal upon the opening of the WIPP in 1998.

Analysis of the collected data shows that no site within the DOE complex is presently capable of characterizing (using all five methodologies) CH-TRU waste contained in boxes. This result prompts the question of whether it is more efficient and effective to repackage all the boxed waste into drums or build the prerequisite fixed and/or mobile box waste characterization systems. Data analysis also discloses skid-mounted waste characterization systems, designed especially for operation within hot cells, offers an option for using portable systems to complement the existing and planned RH-TRU waste characterization capabilities site wide. Lastly, preliminary data received from a survey of SQSs indicate little or no capability to characterize waste for either transportation or disposal purposes.

Prompted in part by the gaps in the generator sites' capabilities to characterize waste for purposes of transportation and disposal, a need to evaluate alternatives for ensuring a sufficient flow of certifiable waste to the WIPP for disposal in the near term became apparent. As will be shown, the use of mobile waste characterization systems capable of addressing CH-TRU waste contained in 55-gallon drums offers the most cost-effective and time-efficient methods for characterizing the waste at the generator/storage sites in the near term.

Mobile System Capabilities (CH-TRU Waste)

The mobile system parameters required for input to the National TRU Waste System Model include the following quantities:

- Fielding time
- Throughput
- Capital cost

Operating cost
Maintenance cost
Set-up/breakdown time
Life cycle

Numerical estimates of these parameters were obtained from both the commercial and government sectors via a survey. The accompanying Table summarizes the results of that survey. Except for mobile box repackaging systems, all 13 of the mobile systems identified in the Table are available for purchase and/or lease and are capable of addressing the characterization of CH-TRU waste contained in 55-gallon drums.

In some instances the numbers obtained from the survey participants represent best estimates. Those mobile system parameters having the greatest variability relative to fixed system parameters include fielding times and capital costs. The following points of clarification are provided regarding the tabulated data:

All operating costs pertain exclusively to the mobile system and neglect all site-related functions, including oversight authority, certification authority, training, waste transportation (from storage to staging area), health physics, radiation safety, safeguards, etc. The role of site personnel in the operation of the system is determined by several factors. These factors include whether union involvement is mandated, whether cognizant engineers are required for data interpretation, and whether the waste characterization methodology is intrusive or nonintrusive.

Capital costs do not encompass ancillary documentation, including a health and safety plan, sampling and analysis plan, standard operating procedures, National Environmental Policy Act (NEPA) documentation, Safety Analysis Report (SAR), Quality Assurance Project Plans (QAPjPs), etc.

The majority of the mobile systems addressed in the table are not available off the shelf; rather, these systems are built on an as-needed basis. Consequently, manufacturing costs are best estimates due to limited production experience. The costs associated with field deployment of the systems are a function of several variables, including the number of operating personnel, anticipated maintenance and repair costs, transportation costs, rate of amortization on investment, training, calibration, etc.

Not included in the set-up and breakdown times are other factors that add significantly to the time required for accessing or departing a generator site. These factors include system inspection, decontamination (if applicable), administrative processing, approvals, etc.

The identified drum venting system uses an enclosure that completely surrounds the drum.

Data integration and compression are a consequence of the large volume of data associated with digital techniques typically used in NDA and NDE applications. Data fusion techniques using artificial intelligence serve to emphasize the need for a dedicated data integration and compression system.

Mobile box repackaging systems, although feasible in principle, are not practical due to the large trailer size required for housing the glove box. The use of tandem (side-by-side) trailers has potential liability due to the risk of contamination when coupling and uncoupling the two systems.

A decontamination unit is required if the mobile systems are to be self contained and capable of responding to a contamination occurrence.

Other data in the Table requiring edification are the quoted processing rates for several of the mobile systems. In particular the processing rate for the radiometric examination system needs to be qualified. For clarity, examples of radiometric examination include real time radiography (RTR), digital radiography (DR), and computed tomography (CT). Although RTR is the most prevalent method employed throughout the DOE complex, other methodologies are emerging and finding application at several of the generator sites.

Table I

Digital radiography has been incorporated in the Waste Receiving and Process facility at Hanford, and CT is being explored for use at the INEL. An examination of these varied methodologies and their associated operating procedures shows that a wide range of throughputs are feasible depending on several assumptions-the most important being the waste form under interrogation. In brief, there is no single value for throughput that is representative of the varied methodologies and waste forms found across the DOE complex. Resolution of this problem is best achieved by bounding the throughput, at least in the case of NDE and NDA. The other waste characterization methodologies and their associated throughputs reported in the Table are considered reasonable based on previous field experience.

For NDE systems, the lower bound, upper bound, and mean throughputs are estimated to be as follows:

Lower bound 4 minutes per drum (using DR)

Upper bound 2 hours per drum (using CT @ 2 mm per slice and assuming a full drum)

Mean = 20 minutes per drum (using RTR and assuming a full drum)

For NDA (gamma-ray and neutron) systems, the throughput is a function of the waste matrix and counting statistics (signal-to-noise ratio). Consequently, only the mean throughput rates are listed in the Table.

Using the data contained in this Table as input to the National TRU Waste System Model, output resulting from the computer simulations will provide information on a variety of system configurations as measured against related waste work-off schedules, costs, and throughput rates. Using various serial and parallel combinations of fixed and mobile systems, it is possible to arrive at the optimum TRU waste system configuration.

In comparison to stationary systems, which may take twelve or more years between concept and final construction of new facilities, the time to field mobile systems is relatively short. Capital costs are also modest in comparison with stationary systems. Processing rates for mobile and fixed systems are about the same, depending on the assumptions made.

Mobile System Capabilities (RH-TRU Waste)

Limited experience exists in the arena of RH-TRU waste characterization. This situation is due in part to the fact that quality assurance objectives (QAOs) are still in the process of being defined for RH-TRU waste data measurements. Without knowing a priori these performance requirements, it is impossible to design and develop new instrumentation or processes to characterize this waste category. Consequently, when polling potential suppliers to identify their capabilities for developing systems able to characterize RH-TRU waste, their responses usually return as a question (e.g., "What do you want?").

The minimum generic requirements for RH-TRU waste characterization include the following:

Dedicated/controlled areas and laboratories (either hot cells, special facilities, or remote field locations)

Robotics (designed to interface with each of the waste characterization methodologies). Waste handling involving 55-gallon drums and sample handling involving core specimens necessitate the need for two or more unique robot systems

Shielding (to be provided by either hot cells, portable constructions, or natural [earth] constructions)

Dedicated systems (the requirements for the use of dedicated/controlled areas, laboratories, and the use of shielding necessitate the use of two independent sets of waste characterization systems to address CH-TRU and RH-TRU waste)

Present commercially available technology using DR and/or CT facilitate the NDE of RH-TRU waste. Features such as background subtraction allow for the enhancement of the signal-to-noise ratio when working within intense background radiation fields. Image processing and enhancement can be used to provide automated pattern recognition of objects using a stored library of attributes associated with a set of preselected objects. Penetration of shielded containers is not a problem when a linear accelerator is used in place of the standard X-ray generators. In principle, NDE can be used for the characterization of RH-TRU waste, whether shielded or unshielded, up to the 1000 rem/hr limit allowed by the WIPP WAC. Although practical experience already exists in the NDE of fuel rod elements and tank waste core samples having extremely high dose rates, the application of NDE technology to RH-TRU waste has not been demonstrated. A technology demonstration to show that RH canisters and casks can be examined nondestructively constitutes the first step in validating the application of NDE to RH-TRU waste.

Though presently not one of the approved waste characterization methods listed in the QAPP, the use of X-ray CT also provides an alternative for performing visual examination of RH-TRU waste. This approach avoids the costly and time-consuming process of using a hot cell for unpackaging, inspecting, and repackaging of the waste. Image reconstruction using CT data has been demonstrated capable of identifying objects as small as a dime when buried within a simulated waste matrix consisting of portland cement.

In the case of the radioassay of RH-TRU waste, many of the problems identified as germane to CH-TRU waste will also apply to RH-TRU waste (i.e., nonideal matrix and source distributions in addition to self-absorption, self-shielding, and matrix shielding). The increased background radiation fields, however, will only serve to further complicate the measurement of RH-TRU waste. Discussions with NDA instrument developers and the review of published papers indicate the method of choice in the presence of high gamma fields (usually from fission and activation products) is one that uses neutron detection. Even this approach, however, has limitations as determined by the helium-3 tubes used in the process. Above 1 rem/hr, the performance of these tubes is no longer reliable. This value is a factor of 1000 below the upper allowed dose rate for RH-TRU waste. Ongoing research and development is expected to extend the operating limits of the tubes to 100 rem/hr within the next few years. In summary, the greatest risk in the process of characterizing RH-TRU waste appears to be the ability of NDA to comply

with applicable QAOs-assuming they are similar to the QAOs used for CH-TRU waste.

CONCLUSIONS

This analysis has shown the feasibility of using mobile systems to characterize CH-TRU waste contained in 55-gallon drums for purposes of transportation and disposal. The application of mobile systems to characterize boxed CH-TRU waste, although feasible in principle, is not practical based on the multitude of box sizes employed and the associated limitations of scale in performing NDA. Portable systems have application to RH-TRU waste due to the preference that all waste characterization measurements be performed within hot cells. Other limiting factors to RH-TRU waste characterization includes NDA.

With the opening of the WIPP rapidly approaching, this analysis has demonstrated the need for the establishment of a National Mobile Waste Characterization Program. The initial function of this program would be to identify the preferred method(s) for acquiring these systems (purchase, lease, or service contract), prepare solicitations, evaluate solicitations, make awards, and oversee the manufacturing of the systems. Before any mobile or portable waste characterization systems can be used in conducting a campaign across the DOE complex, sufficient time must be allotted for the systems to go through a rigorous environmental, safety, and health evaluation to identify all regulatory requirements. One such evaluation has already been performed by the LANL, and the results of that investigation constitute the first step in constructing a generic template for this process.

The data and results obtained by this analysis will be fed into the National TRU Waste System Model. Output from this model is expected to result in the identification of the optimum fixed/mobile system configuration(s) for the development of a comprehensive waste characterization strategy and reveal alternative opportunities for reducing cost and compressing the schedule for the preparation and flow of TRU waste.

ACKNOWLEDGMENTS

Technical input to the analysis was obtained from numerous sources, including the commercial sector, government laboratories, waste generator/storage sites, and support contractors.

Processing and final preparation of this report was performed by the Waste Isolation Pilot Plant Management and Operating Contractor for the U.S. Department of Energy Under Contract No. DE-AC04-86AL31950.

ABSTRACT
The development of a low-level radioactive waste (LLRW) disposal facility requires that a performance assessment be done to ensure that the effect of the LLRW on the surrounding environment is within regulatory limits. One of these assessments is the evaluation of the long-term performance assessment which typically includes the time frame from approximately when the facility stops receiving waste to a time in the distant future. This long-term performance assessment is usually dominated by a groundwater transport pathway. Because a typical LLRW disposal facility will contain in excess of 100 radionuclides that need to evaluated, a detailed groundwater transport evaluation of all the radionuclides in the LLRW disposal facility can be quite cumbersome. A systematic screening methodology is developed that considers the radionuclide half-life, daughter products, and partition coefficient between soil and water. The result for the site evaluated is that only 15 radionuclides (including daughter products) remain that require detailed groundwater transport evaluation. In addition, an inventory limit can be proposed on only 7 radionuclides and have confidence that the dose from the long term performance assessment will remain within regulatory limits.
INTRODUCTION
The licensing of a low-level radioactive waste (LLRW) disposal facility requires that a performance assessment be done to ensure that the effect of the LLRW on the surrounding environment is within regulatory limits. One of these assessments is the evaluation of the long-term performance assessment which typically includes the time frame from approximately when the facility stops receiving waste to a time in the distant future. The time in the distant future has been taken to be a period long enough that other large scale environmental effects could occur, such as weather variations and associated glaciations, and the environmental effect of the LLRW would be insignificant in comparison.
The long term performance assessment is typically initiated by evaluating the waste stream that is expected to be received at the facility. Evaluation of this waste stream typically results in excess of 100 radionuclides being present. A detailed evaluation of this large number of radionuclides can be quite cumbersome. In addition, the evaluation usually finds that only a small number of the radionuclides make a significant contribution to the performance assessment. During performance assessments, a number of the radionuclides are often evaluated individually and eliminated from further consideration. This paper presents a systematic criteria and methodology for determining the radionuclides that make a significant contribution to the long-term performance assessment of a LLRW disposal facility. Table I at the end of the paper provides an example matrix for a limited number of nuclides that can be used for this systematic screening.
Table I
SOURCE TERM
In order to evaluate the environmental effect of the LLRW disposal facility, an estimate of the waste to be received must be evaluated. A reasonable estimate of the future waste stream may be determined by evaluating the historical waste stream in the region the disposal facility is to serve. This information is readily available from the U. S. D.O.E. National Low-Level Waste Management Program, Manifest Information System (MIMS) that retains all commercial LLRW shipping manifest information. The information includes the radionuclides,

activity, and volume of LLRW shipped by waste generator, by state the generator is in, and by year of shipment. (The identity of the waste generator is not readily available because generators are labeled only by identification number.) Reports are readily available from MIMS for the states and time periods of interest.

The Central Interstate Compact (CIC) LLRW disposal project obtained radionuclide, activity, and volume information from MIMS for the 7 year period from 1986 through and including 1992 for waste shipped from the five states within the CIC region. This information was averaged over the seven years to obtain an average annual average total volume and activity by radionuclide shipped for disposal. This annual activity by radionuclide is input to a computer code (SOURCE2) that solves the bateman equations and determines the 30 year facility inventory including daughter products.

The average waste volume during this 7 year period was approximately 87,000 ft3/y, which would produce approximately 2.6 million ft3 in 30 years if waste generation remained at this average value. The design basis for the facility is 5 million cubic feet, therefore, the 30 year radionuclide activity from MIMS and SOURCE2 was multiplied by the factor of 5/2.6 = 1.9 to provide a 5 million ft3 equivalent inventory in 30 years of operation.

EVALUATION OF GROUNDWATER TRANSPORT

The long-term performance assessment of a LLRW disposal site usually requires an evaluation of groundwater transport because when a site is properly closed this groundwater pathway is one of the few credible ones that remains. In order to evaluate the effect from groundwater transport of radionuclides, the disposal site must be well characterized and include a model of groundwater flow in the region, a local model of groundwater flow beneath the disposal site, and regional meteorology. These models are matched against each other to arrive at appropriate boundary conditions. The model should also include a description of the geological strata at the site that is usually obtained from borings. The application of these models will produce a groundwater transport time to the site boundary. This time duration is important because the ingestion of water from a well that is drilled at the site boundary often dominates the dose assessment for the long-term performance.

The evaluation groundwater transport at the CIC site yields a mean transport time to the site boundary of 1420 years, and a bounding case transport time (conservatively assuming rainfall persists at a near record value and a corresponding high water table) of 240 years. The bounding case transport time of 240 years is used in the evaluation to provide confidence that a conservative analysis has been performed.

ESTABLISHING CUTOFF CRITERIA BASED ON HALF-LIFE

Many radionuclides in a LLRW disposal facility have a half life that is sufficiently short that they will decay to an insignificant quantity prior to reaching the site boundary. An initial estimate of a 10 year life was chosen as being the minimum half life that would make a contribution to the dose. For a radionuclide with a 10 year half life, and a site boundary travel time of 1420 years or 142 half lives, the activity in the original inventory would decrease by a factor of 2142, or approximately 2E-43 of the original inventory remains. For the bounding case travel time of 240 years, the 10-year half-life represents 24 half-lives, or a decrease in the original inventory by a factor of 224 , or approximately 6E-8 of the original inventory remains. The remaining

inventory fraction from both of these travel times is sufficiently small that one can confidently predict that there will be an insignificant contribution from radionuclides with a half-life of 10 years or less, and they can be eliminated from further evaluation.

EVALUATION OF RETARDATION OF RADIONUCLIDES BASED ON Kd

An evaluation of the groundwater travel time to the site boundary was provided above. This is the time period for the groundwater and chemicals and radionuclides that remain dissolved in the water to reach the site boundary. However, many chemicals interact with the soil that the groundwater travels through and the result is a retardation in the transport of the radionuclides. The time period in which it takes a particular chemical or radionuclide to move through soil is determined by multiplying the groundwater travel time to the site boundary times a retardation factor. The chemical parameter that is used to evaluate the retardation factor is called the distribution coefficient, Kd, and is related to the retardation by the following expression.

$$R_i = 1 + K_{di} * \text{bulk density}_j / \text{porosity}_j$$

where R is the retardation factor, Kd is the distribution coefficient, the subscript I indicates the chemical of interest and j indicates the material that the chemical is traveling through.

Values of the bulk density and the porosity of the soil can be obtained from site specific measurements. Kd values can also be obtained from site specific measurements, or may be obtained from previous tabulations such as are provided in Ref. 1.

An example of the application of this methodology is provided below using cobalt as a LLRW nuclide and soil properties from the CIC site. From Ref. 1, the Kd of cobalt in clay is 550cm3/gm. A conservative evaluation of the CIC soil properties provides for a bulk density of 1.533 gm/cm3 and a porosity of 0.4, or a ratio of bulk density to porosity of 3.83 gm/cm3. This ratio times the Kd of 550 cm3/gm yields 2107, and the addition of the constant 1 is clearly insignificant. The result is that cobalt released into the groundwater and traveling through clay will arrive at the site boundary 2107 times the groundwater travel time to the site boundary. The conservative bounding travel time to the site boundary is 240 years, therefore the cobalt may be expected to reach the site boundary after 506,000 years under these conditions.

ESTABLISHING A CUTOFF CRITERIA BASED ON Kd

The methodology described above can also be used to back calculate a Kd that correlates to a particular travel time to the site boundary. The travel time is taken to be a period long enough that other large scale environmental effects could occur, such as weather variations and associated glaciations, and the environmental effect of the LLRW would be insignificant in comparison. A time duration of 10,000 years fits this criteria.

Given the soil conditions at the site and a limiting travel time of 10,000 years, it is then possible to derive a limit on the Kd above which the radionuclides will not reach the site boundary in 10,00 years. The retardation factor is 10,000/240 = 41.7. Rearranging the expression for Kd above, and taking the constant 1 as an insignificant contributor, the result is

$$\begin{aligned} Kd &= R / (\text{bulk density}/\text{porosity}) \\ &= 41.7/(3.83) \\ &= 11 \end{aligned}$$

Therefore, one can establish a limiting Kd value of 11, and radionuclides with a Kd of greater than this value are not be expected to reach the site boundary within 10,000 years even under the conservative bounding conditions that would produce a 240 year groundwater travel time to the site boundary.

CONSIDERATION OF DAUGHTER PRODUCTS

An additional consideration that must be made is the contribution daughter products may make to the radionuclide concentration at the site boundary well. Daughter products are a different chemical species than the parent and therefore the Kd consequent transport properties would be different from the parent. These daughter products are treated in two different fashions. If the parent - daughter relation is not part of a continuing decay chain, and the half life of both radionuclides is short (10 years or less), neither the parent nor daughter will make a significant contribution at the site boundary. An example of this is zirconium-95. This radionuclide has a 64-day half-life and has a daughter product that is niobium-95, which has a half-life of 35 days.

If the daughters are part of a longer decay chain, the chain is reviewed more carefully. If the parent and all daughters in the chain have a large Kd (>11), the radionuclides do not make a significant contribution for the same reason that other radionuclides are eliminated on the basis of Kd. If one of the daughters has a small Kd (<11), then this daughter and all subsequent decay daughters are included in the evaluation. The subsequent daughters are included because they could arrive at the site boundary by being transported by a small Kd parent.

SUMMARY OF REMAINING RADIONUCLIDES

For the CIC project, the only radionuclides that remain after performing screening elimination described above are hydrogen-3, carbon-14, strontium-90, yttrium-90, technetium-99, iodine-129, americium-241 (and daughters neptunium-237, palladium-233, uranium-233, thorium-229, radium-225, actinium-225, francium-221, astatine-217, bismuth-213, polonium-213, thallium-209, and lead-209), and americium-243 (and daughter neptunium-239).

It is interesting to note that of these radionuclides, hydrogen-3, carbon-14, technetium-99, and iodine-129 are required to be listed on the shipment manifest in accordance with 10CFR20 Appendix F. Although common literature values (1) of Kd for strontium and americium would eliminate these radionuclides, a site specific measurement indicated that Kd for these radionuclides may be within the criteria and therefore they were retained. The strontium-90 daughter, yttrium-90, is retained because of the possibility of being transported by strontium-90. The americium daughters were retained because of the possibility of being transported by the parent americium.

A review of the inventory and dose effects indicated that the contribution from actinium-225 is negligible, and therefore contribution from the nuclides francium-221, astatine-217, bismuth-213, polonium-213, thallium-209, and lead-209 is also negligible. Therefore, these radionuclides were not evaluated further.

A long term performance assessment can then be performed using the inventory for these 15 radionuclides.

This methodology provides a systematic approach to determine a set of radionuclides that can be used in performing a long-term performance assessment. The approach greatly simplifies the actual evaluation of the dose assessment by justifiably reducing the number of radionuclides for

which a dose assessment needs to be performed. By restricting the dose assessment to the contributing radionuclides, resources are appropriately focused on evaluating and understanding the dose contribution from these significant contributors.
An additional use that can be made of the methodology and subsequent dose assessment is to determine a maximum radionuclide inventory that can be disposed and remain within regulatory limits. Of the 15 remaining radionuclides, one is a daughter of strontium-90, six are daughters of americium-241, and one is a daughter of americium-243. Because the inventory of the daughters is determined by the inventory of the parents, the inventory limit need only be established for the parents. Therefore, an inventory limit could be established for only seven radionuclides (hydrogen-3, carbon-14, strontium-90, technitium-99, iodine-129, americium-241, and americium-243) and have confidence about the resulting dose assessment. One could arbitrarily allocate a 1 mrem/yr dose to each of the seven radionuclides (including dose contribution from daughters) and then determine the radionuclide inventory in the LLRW disposal facility that would create this 1 mrem for each of these seven controlling radionuclides. This calculated inventory for the seven controlling radionuclides will result in a dose that is well within the regulatory limit of 25 mrem/yr.

ABSTRACT
Since disposal of low level radioactive waste from nuclear power plants in Japan began in 1992, the operation is proceeding favorably and approximately 50,000 of 200 -drums of waste have been disposed of in the Rokkasho Disposal Center up to May 1995.
The burial facility of the Rokkasho Disposal Center is equipped with a double cover soil layer. One is a bentonite/soil mixture that is less permeable than the surrounding soil and is installed at the side and the top of the burial pits against water permeation. The other is ordinary soil that is placed over the layer of the bentonite/soil mixture.
The Radioactive Waste Management Center has carried out a large scale tracer test for both layers under contract with the Science and Technology Agency from 1991 to 1995.

A large scale experimental facility equipped with the double cover soil layer, which is some meters wide and some meters long, was applied to this tracer test for the purpose of evaluating the performance of these natural soil barriers on restraining the migration of radionuclides. The following results were obtained by this test and the safety of the burial disposal was confirmed.

1. For ordinary soil cover, the following RFs (Retardation Factor) of imitative (nonradioactive) nuclides were calculated from the experimental data in the case of the 40 cm/day of groundwater velocity, and those convinced us that ordinary soil cover also has a certain barrier function.

RD of SR=67, RF of Co=121, Rf of Cs=107

2. Bentonite/soil mixture, which consisted of 10wt% bentonite and 90wt% sandy soil, reduced the velocity of groundwater to 1/1300 compared with that in the ordinary soil cover layer.

3. The behavior of radionuclides for long term was evaluated by using experimental data, and the following analytical results showed clearly the effectiveness of the bentonite/soil mixture.

a. In the case of the installation of the bentonite/soil mixture, migration of short-lived radionuclides such as Co-60 could be restrained remarkably and they would disappear by radiation decrement before release from the burial facility.

b. The maximum release rate of long-lived radionuclides such as Nb-94 or I-129 would be reduced by the factor of 1/1000 to 1/10000 and the time at the maximum release rate would also be delayed to 40,000 years for Nb-94 and 400 years for I-129 by installation of the bentonite/soil mixture.

BACKGROUND

Since disposal of low level radioactive waste from nuclear power plants in Japan began in 1992, the operation is proceeding favorably and approximately 50,000 of 200 -drums of waste have been disposed of in the Rokkasho Disposal Center up to May 1995.

One of the technical criteria in Japanese Regulations respecting disposal of low level radioactive waste established that a disposal facility should be covered with sand and/or soil, which is less permeable than the surrounding soil. In accordance with this criterion, the burial facility of the Rokkasho Disposal Center is equipped with a double cover soil layer. One is a bentonite/soil mixture layer (hereinafter "B/S mixture layer") that is less permeable than the surrounding soil and is installed at the side and the top of the burial pits against water permeation. The other is an ordinary soil layer that is placed over the layer of bentonite/soil mixture. Many disposal facilities of LLW in the world also have developed similar methods to inhibit water permeation to the facility and to restrain the migration of radioactive nuclides.

The Radioactive Waste Management Center in Japan has carried out a large scale tracer test for both layers (bentonite/soil mixture layer and ordinary soil layer) in the outdoor concrete vaults under contract with the Science and Technology Agency from 1991 to 1995.

The purpose of this tracer test is summarized in the three points that follow:

- to confirm that the bentonite/soil mixture layer has better ability to reduce the velocity of groundwater than the ordinary soil layer,
- to testify that both layers could restrain the migration of radionuclides,

to demonstrate the performance of a natural soil barrier and the safety of the disposal facility for the local government and dwellers in the vicinity of the disposal site.

EXPERIMENTAL METHOD

Experimental Facility

A large scale experimental facility equipped with a double cover soil layer was constructed for tracer tests. This facility has two concrete vaults. One for the test of the bentonite/soil mixture layer has a 6 m width, 4 m length and 7 m depth (Fig. 1a). The other for the test of the ordinary soil layer has a 6 m width, 6 m length and 6 m depth (Fig. 1b). Each vault was equipped with an intake and discharge water tank for giving a groundwater flow. Artificial precipitation equipment was installed at the top of each vault.

Fig. 1

Tracers

Table I shows the kinds of tracers and additive concentration. The injection of all tracers in a lump sum including bromine (Br-: tracer of water) was applied for the test of the bentonite/soil mixture layer. In the test of the ordinary soil layer, a constant and continuous injection was applied.

Experimental Condition

The specification of each soil layer and the experimental conditions are summarized in Table II. In the test of the ordinary soil layer, prior to the tracer test of imitative nuclides, bromine was injected singly to measure the velocity of groundwater.

Table I

Table II

EXPERIMENTAL RESULTS

The Velocity of Groundwater

The velocity of groundwater of each soil layer measured by the tracer test of bromine and by flow meter is summarized in Table III. By these experimental data, it was confirmed that the B/S mixture layer reduced the velocity of groundwater to 1/960~1/1300 compared with that in the ordinary soil layer.

Table III

Migration of Imitative Nuclides

Concentration in Groundwater

One tracer test using imitative nuclides in the bentonite/soil mixture layer was carried out for 908 days. In this test no imitative nuclides were detected at the two monitoring points which are 0.5 m and 1 m distance from the injection pipe.

The other tracer test using imitative nuclides in the ordinary soil layer was carried out for 797 days. In this test obvious migration of all imitative nuclides was observed, especially iodine and strontium, which were detected at the farthest monitoring well (No. 5 well 4.0 m from the injection point)(Fig. 1b). This means some of these tracers may go out to the discharge water tank through the ordinary soil layer. Though cobalt and cesium were also detected at the monitoring well, which are 0.5 m and 1 m from the injection point, the migration distance of these tracers was remarkably shorter than that of strontium.

Surface Concentration on Soil Layer

Four vertical cross sections describing the surface concentration contours of imitative nuclides in the B/S mixture layer are shown in Fig. 2. All imitative nuclides injected remained within the region of a few

centimeters from the injection pipe. This small migration distance was probably caused by the molecular diffusion of the tracer not by groundwater flow.
Three horizontal and three vertical cross sections describing the surface concentration contours of imitative nuclides in ordinary soil layer are shown in Fig. 3 and Fig. 4, respectively. And characteristics data summarizing the migration of the three imitative nuclides (Co, Cs, Sr) are summarized in Table IV. From Table IV obvious migration of these imitative nuclides was recognized. On the other hand, we confirmed that Co, Cs, Sr were absorbed on the surface of the soil in high concentration and their migration in the ordinary soil layer was certainly restrained. This result convinced us that the ordinary soil layer also had a certain barrier function.
Fig. 2
Fig. 3
Fig. 4
Table IV
Discussion about Mass Balance
Table V shows the mass balance of the three imitative nuclides in both soil layers. In these tracer tests, favoritable mass balance was obtained. It means that each tracer test had been carried out successfully and the concentration of the imitative nuclides in the water and on the soil was measured correctly.
Table V
Long-Term Evaluation of the Effect of the Bentonite/Sand Mixture Layer
We predicted the migration of radionuclides near the disposal facility, and assessed the effect of the B/S mixture layer as natural barriers.
Condition
As to shape and dimension of the disposal facility, the only parameters necessary to calculate are assumed, and we evaluated the effect of the B/S mixture by comparing the time dependence of the normalized fluxes for the following two cases, whose models are shown in Fig. 5
  case-1: with the B/S mixture layer
  case-2: without the B/S mixture layer
Fig. 5
Normalized flux (hereinafter 'NF') is defined by Eq. 1, so its dimension is meter/second (= (Bq/s/m2)/(Bq/m3)).
Eq. 1
We compared each flux at a downstream distance of two meters from the end of the disposal facility because that point is the border of the B/S mixture layer and the ordinary cover soil for case-1. Calculation is implemented for five radionuclides (Co-60, Cs-137, Sr-90, Nb-94 and I-129) and by using one-dimensional mass migration code that takes account of radioactive decay. Those radionuclides are assumed to be reduced by disintegration and release from the disposal facility. In the B/S mixture layer, migration by diffusion is predominant.
Parameters
Parameters for migration prediction, which are mainly gained by complemental laboratory tests, are shown in Table VI. In addition, groundwater velocity in the normal cover soil gained by the field validation test is so fast that we assume two values in the calculation prediction: one is an experimental value and the other is two orders lower.
Table VI

Results

Calculation results, shown in Fig. 6 except for Co-60 are as follows.

Co-60: Since water flow is very low in the B/S mixture layer because of diffusion predominant in the area, those nuclides whose half lives are lower than several years such as Co-60 decay to a negligible order during migration in the B/S mixture layer in case-1.

Cs-137: Those nuclides whose half lives are tens of years but whose Kd's are large enough such as Cs-137 decay to a negligible order by the sorption function of the B/S mixture layer at the evaluation point in case-1.

Fig. 6

Sr-90 and Nb-94: For such nuclides that have the following characteristics, the effect of the B/S mixture layer establishment is expected if the groundwater velocity in the ordinary cover soil is typical for repository site condition.

a. whose half lives are several tens of years and whose Kd's are not so large such as Sr-90

b. whose half lives are very long but whose Kd's are large enough such as Nb-94

I-129: Nuclides of very long half life and small Kd such as I-129 are all released from the facility within a finite period in the case of "without the B/S mixture layer (case-2)" where the flow rate is the larger, so NF of case-1 (with the B/S mixture layer) is greater than that of case-2 after that time as a calculation result. We interpret that the effect of the B/S mixture layer establishment is expected because the absolute value is small enough if the water velocity in the normal cover soil layer is typical for a repository site condition.

In the case of short-half-life nuclides, the release rate out of the B/S mixture layer is reduced drastically because of the reduction of the flow rate and the sorption property by the B/S mixture layer. In the case of long-half-life nuclides, the establishment of the B/S mixture layer is suggested to be effective from the point of Normalized Flux, if the groundwater velocity in the cover soil is typical for a site condition of shallow land disposal.

CONCLUSION

1. For ordinary soil cover, the following RFs (Retardation Factor) of imitative (non-radioactive) nuclides were calculated from the experimental data in the case of the 40 cm/day of groundwater velocity, and those convinced us that the ordinary soil cover also has a certain barrier function.

Rf of Sr=67, Rf of Co=121, Rf of Cs=107

2. The B/S (Bentonite/soil mixture layer), which consisted of 10wt% bentonite and 90wt% sandy soil, reduced the velocity of the groundwater to 1/1300 compared with that in the ordinary soil cover layer.

3. The behavior of radionuclides for long term was evaluated by using experimental data, and the following analytical results showed clearly the effectiveness of the B/S mixture layer.

a. In case of the installation of the bentonite/soil mixture, migration of short-lived radio-nuclides such as Co-60 could be restrained remarkably and they would disappear by radiation decrement before release from the burial facility.

b. The maximum release rate of long-lived radionuclides such as Nb-94 or I-129 would be reduced by a factor of 1/1000 to 1/10000 by the installation of a bentonite/soil mixture, and the time at the maximum

release rate would be also delayed, compared with the case of no bentonite/soil mixture, to 40,000 years for Nb-94 and 400 years for I-129.

ABSTRACT
Carbon-14 is an important radionuclide to retain in waste repositories and away from the environment. It has all the characteristics of a problematic radionuclide: long half-life; high mobility in most environments; high biological incorporation; and for some wastes, relatively high inventory. In Canadian CANDU power reactor systems, much of the 14C that is produced is captured and retained in various wasteforms. In previous studies, disposal in a deep plutonic-rock vault was assessed to be suitable for 14C in fuel wastes. Different disposal concepts were assessed for low- and intermediate-level wastes (L&ILW), and these included cementitious matrices and a carbonate rock formation. These concepts for L&ILW proved useful in a generic sense, although in stochastic simulations there were situations where average releases were higher than our target. Data were sparse for several features of the assessment, and these data needs are described.
INTRODUCTION
Of the many radionuclides in radioactive waste, 14C is unique because of a combination of important features. It has a long half-life. In many geochemical settings it behaves as a gas or as an anion, both with high mobility. It becomes chemically indistinguishable from the 12C in all life forms, and so is easily absorbed into biota including humans. At the same time, there is good potential to isolate 14C in durable wasteforms and repositories to keep it away from the surface, biosphere environment. In the Canadian radioactive waste disposal programs, 14C is dealt with in a number of ways that are estimated to lead to low or negligible doses. This report summarizes the concepts evaluated to date, with emphasis on low- and intermediate-level waste (L&ILW). The results presented here for L&ILW are preliminary, and should be interpreted as a scoping analysis only. Various assessment methodologies will be used before an assessment is considered complete, and this paper deals only with one, key, modelling approach.
CANADIAN DISPOSAL CONCEPTS
Canada has over 20 operating CANDU reactors, and all the waste is in interim storage awaiting final disposal. Several concepts for disposal facilities have been advanced. For nuclear fuel waste, the concept itself is now being formally evaluated by Federal agencies before there is any action taken toward siting. The nuclear fuel waste (NFW) disposal concept is for a disposal of aged but intact fuel bundles in corrosion-resistant metal (titanium or copper) containers. The containers are emplaced in clay-based buffer and backfill in disposal rooms mined into plutonic rock 500 to 1000m underground. The concept has been assessed (1) and is now under review, with hearings pending. If successful, a facility could be built in time for start-up in 2025. Documentation of the NFW disposal concept is complete and widely available (1, 2, 3, 4, 5), and so the

brief description of assessment results described here is only to show the relative effectiveness of various 14C retardation processes.
Disposal plans for L&ILW are at an even earlier stage: we are seeking and comparing concepts. Two concepts for L&ILW have been assessed to date, and several more assessments are underway. The documentation of the assessment results (6, 7) emphasizes the preliminary nature of these assessments and concepts.
The two concepts for disposal of L&ILW discussed here are disposal in glacial till, and disposal in carbonate rock. The conceptual till facility has a near-surface vault, and was deemed suitable only for low-level waste (LLW). This does include some 14C. The vault in till is constructed of reinforced, low-permeability concrete and is backfilled with porous concrete. The conceptual carbonate rock vault is at 150-m depth and was assessed for both LLW and intermediate-level waste (ILW), and contains substantial amounts of 14C. The vault consists of mined-rock rooms backfilled with porous concrete. Once a successful concept has been identified and approved, a disposal facility or facilities could be built in time for start-up in 2015.

WASTE STREAMS AND INVENTORIES

The NFW is expected to contain 5.0 x 107 Bq 14C per kg uranium, with a total inventory in the vault of 8.1 x 1015 Bq 14C (2.2x105Ci). This 14C will be present in the UO2 grains, with less than 0.1% in the grain boundaries and other gaps in the fuel bundle (1). The LLW assessed for the till vault is expected to contain 1.1x 107 Bq 14C (3.0x10-4Ci), all in readily leachable forms. The L&ILW assessed for the carbonate rock vault is expected to contain 1.1 x 1016 Bq 14C (3.0x105Ci) immobilized as calcite, 2.8x1015Bq (7.6x104Ci) 14C in metal components where the 14C will be released on corrosion of the metal, and 4.2x1012Bq (110Ci) 14C in high density concrete.

ASSESSMENT MODELS

The assessment models, used as part of the overall concept assessments, are quite detailed and are structured in three parts: vault, geosphere and biosphere. The combined models start with information about waste inventory and system properties and output dose estimates for humans and other biota with time after closure of the vault. These models are controlled through the executive SYstems Variability Analysis Code (SYVAC). Most parameter inputs are specified by probability density functions (PDFs) that described the most likely values, the variation about these values, and the upper and lower truncation limits. Parameters may also be statistically correlated, using a simple correlation coefficient. The SYVAC executive can operate the models in a probabilistic mode, where values are chosen randomly based on the PDFs, or in a deterministic mode. The deterministic mode used most often is one where the median values for each parameter is used. These are called median-values runs in this report.
When the models are operated in a probabilistic, Monte Carlo mode, they are run many times with many independent suites of parameter values. Typically >1000 runs are made to obtain meaningful probabilistic results. Although the dose estimates conform to a strongly skewed frequency distribution, the summation of interest to the regulator (8) is the arithmetic mean of these dose estimates.

RETARDATION AND DOSE-ATTENUATION PROCESSES IMPORTANT FOR 14C

In the NFW concept, a corrosion resistant container, a diffusion barrier adjacent to the waste containers and a long path length through the

plutonic geosphere to the biosphere are the major retardation features important to isolation of 14C. Geochemical retardation by processes such as sorption or isotopic exchange were assumed to be nil (9).

In the biosphere for both the NFW and L&ILW assessments, several processes built into the models contribute to dose attenuation (10, 11). A key one is an upper dose cutoff based on assumptions about specific activity in the geosphere. The 14C emerging into the biosphere from the geosphere will undergo isotopic exchange with 12C along the path. This is expected to be a massive dilution, especially in the biosphere, but it is difficult to model because the rate of mixing cannot be specified in a realistic yet conservative way. However, one defensible series of assumptions is that isotopic dilution is essentially irreversible, so that dilution that occurs at the discharge from the geosphere will be manifest throughout the biosphere. In fact, it will be augmented in the biosphere. The isotopic dilution in the geosphere is computed using the estimated 14C concentration in groundwater entering a bedrock well and the observed inorganic 12C concentration in groundwater at depths typical of bedrock wells. The values of the 12C concentration in groundwater are assigned using a PDF. The resulting isotopic ratio is then used to calculate a dose to humans and to other biota, assuming the same isotopic ratio throughout their bodies. The dose conversion factor is 2.5x10-7 Sv a-1 per Bq kg-1 soft tissue. The resulting dose estimate is assumed to be the highest dose that could happen, and implies that people and other biota derived all of their tissue C from the geosphere. Obviously, much really comes from the atmosphere.

The geosphere upper dose cutoff is used as a check of dose estimates derived through classical transfer parameter models (12). The lower dose of the two calculated in each run is used, and contributes to the arithmetic mean dose from all of the probabilistic runs. Sheppard et al. (11) describe the 14C biosphere model and the underlying parameter values in detail. Specific activity modelling is used in other parts of the biosphere model as well (5, 6), most notably for the soil-to-plant transfer of 14C.

For LLW disposal in till, wasteform degradation does not slow the release of 14C: it was assumed to be fully available for leaching once the vault barrier is breached. The 14C was moderately sorbed in the vault backfill concrete. The concrete will react with any aqueous 14C to form calcite reaction products, and this will further retard 14C migration (13). Isotopic exchange was not included in the present assessment. Once 14C is released from the vault, the configuration of the till disposal vault was such that groundwater flow was vertically downward through the vault and underlying till and into a carbonate rock formation underneath. Flow was then lateral towards a lake. Geochemical retardation was modelled in the carbonate geosphere. However, even here the retardation was set to nil in 10% of the runs to account for chemical species of 14C that may not be retarded by the carbonate rock.

For ILW, the wasteforms were an additional barrier, and the most important for controlling 14C migration. The 14C in metal matrices was released by corrosion of the metals. Most of the inventory of 14C is in cementitious wasteforms because here it will reside as calcite, which has been shown to be quite effective in attenuation of 14C (13). Laboratory experiments have demonstrated that the release of 14C from the calcite matrix is solubility-limited congruent release with no net dissolution of the calcite matrix. The geochemical aging of the concrete was also

modelled using the CHEQMATE code (14), and the results indicated that although pH decreased with aging, the original calcite remained stable and only a limited amount of 14C was released by isotopic exchange with inorganic C in groundwater. Once 14C was released from the vault, a long path length through a carbonate geosphere was modelled, with geochemical retardation in the carbonate rock in 90% of the runs.

RESULTS OF ASSESSMENT

The full assessment of the NFW concept embodied several approaches, only one of which was the running of the SYVAC simulations. Only SYVAC results are presented here.

The dose from the median-values runs and the mean dose from the probabilistic runs for the NFW concept were dominated by 129I, with 14C and 36Cl as the next most important radionuclides. The peak dose from 14C was 1.4x10-8Sva-1 at 4.0x104a. All doses were well below the regulatory criterion. The dominant pathway for exposure of humans to 14C (and 129I and 36Cl) was through irrigation of contaminated well water onto agricultural/gardensoils (2). The ratio of peak annual dose to humans per unit of 14C in the inventory was 1.7x10-24Sva-1 per Bq in inventory.

The LLW vault in till was assigned a relatively small inventory of 14C, and 14C was the eleventh highest dose-contributing radionuclide, with a peak dose in the median-values run of 2.5x10-10 Sv a-1 at 2.2 x 104 a. No radionuclides in this assessment gave unacceptable doses (Fig. 1), and the top dose contributor was 99Tc. For 14C, the ratio of peak annual dose to humans per unit of 14C in the inventory was 2.3x10-17Sva-1 per Bq in inventory.

The L&ILW vault in the carbonate rock is considered the major disposal facility for 14C, and the inventory here is the highest of the three conceptual facilities. In the median-values simulations, the top dose contributor was 36Cl, giving 1.3x10-5Sv a-1 at 4.4x 102 a (Fig. 2). The 14C in the calcite wasteform was the fourteenth highest contributor, giving 1.3x10-10Sv a-1 at 7.2x 104 a. This dose from 14C is both low and delayed because of the attenuation in the vault. For 14C in the median-values runs, the ratio of peak annual dose to humans per unit of 14C in the inventory was 1.2x10-26Sva-1 per Bq in inventory. This ratio is two orders of magnitude lower than that for the NFW, where the physical barriers were substantially greater. This indicates the importance of the geochemical barriers in the cementitious wasteforms and geological settings of the L&ILW concept.

The effect of geochemical retardation is well illustrated by the probabilistic runs. The median dose with time from these runs was dominated by 14C (Fig. 3), even though 14C was not an important contributor in the median-values runs. The peak mean dose was 7.0x10-5Sva-1 and occurred very early after closure of the vault. The reason 14C was important to mean dose and not to the median-values dose is that in the probabilistic simulations, the full range of possible parameter values was chosen. As an example, this included ~10% of the runs where the geochemical retardation mechanisms for 14C in the geosphere were nullified (Fig. 4). This is considered a very unlikely situation. However, the results of the probabilistic runs show how important it is to quantify these processes. An unacceptable outcome would result if the geochemical retardation mechanisms were less effective than expected.

Fig. 4

FUTURE DEVELOPMENTS FOR L&ILW

The retardation of 14C in geological materials must be well known. Sheppard et al. (15) reported solid/liquid partition coefficients, Kd or Rd, of 8 to 85 L kg-1 in carbonate minerals and soils, but zero values in clays. Clearly, host rock and, especially, cementitious backfill are indeed important to the isolation of 14C from the environment (16). More work is needed to ensure that the chemical species of 14C that may leave a vault are inorganic or are retarded to the same extent as inorganic species.

Degradation of the cementitious vault and the subsequent release of 14C are critical processes. Much of the information here must be based on geochemical models, but there is potential for important analogue studies such as the Maqarin site in Jordan (17).

Several other concepts for disposal of L&ILW will be assessed, one including a large concrete silo in a deep geologic vault, and another including co-disposal or co-siting with NFW disposal.

CONCLUSIONS

Carbon-14 is actively accumulated in the operation of nuclear power reactors in Canada. The inventories are substantial, and may be divided among three waste disposal facilities. The NFW facility will contain about a third of the 14C, and although it is not in a high-pH environment, it achieves effective isolation through container durability, substantial diffusion barriers and depth of vault. The LLW vault will have only a modest inventory of 14C, and the conceptual facility analyzed was effective in isolating the 14C. The L&ILW facility will have about two-thirds of the total 14C disposed waste, and the concept analyzed was successful when the cementitious vault and carbonate geosphere provided the expected attenuation of 14C. However, when these barriers were not as effective as expected, the 14C did result in estimated doses above our target. More work is required to gain assurance that the retardation of 14C in the cementitious vault and carbonate geosphere for the L&ILW repository are effective.

ACKNOWLEDGEMENTS

This project was supported by the CANDU Owners Group, funded jointly by Atomic Energy of Canada Limited and Ontario Hydro. The author has summarized the contributions of a large assessment team, and especially acknowledges the expertise and guidance provided by R. Dayal, J.D. Garroni, W.C. Hajas, C.I. Kitson, D.M. LeNeveu, J. McMurry, T.W. Melnyk, J.R.Ramsay, S.B.Russell, J. Torok, K.H. Witzke and D.M. Wuschke. This manuscript was improved by the thoughtful comments of R. Dayal, D.M.LeNeveu, J. Torok, M. ABSTRACT
The characterization of a waste package, consists in determining its specific properties.
For FRANCE, this involves ANDRA specifications, the Basic Safety Rules (les Rgles Fondamentales de Sret - RFS) of the Nuclear Safety Direction (Ministry of Industry).

INTRODUCTION

The characterization of a waste package consists of determining its specific properties.
In the characterization of nuclear waste, we restrict ourselves to the acquisition of characteristics which have to be known in order to obtain agreement on near surface disposal and to evaluate safety in temporary and permanent storage conditions.

OBJECTIVES OF WASTE CHARACTERIZATION AND CHARACTERIZATION TYPES

Five main objectives are looked for when performing a characterization test. The tests are intended to:

- guarantee the mechanical properties of the waste form and the matrix,
- test the durability of the physical and mechanical properties of the waste for the disposal duration,
- evaluate the behavior of radionuclides in the waste and the long-term waste-matrix interaction,
- calculate the loss rate by isotope leaching,
- compare the results with specifications, and rules specified by the Authorities and Safety notices

For FRANCE, this involves ANDRA specifications, the basic Safety Rules (les Rgles Fondamentales de Sret-RFS) of the Nuclear Safety Direction (Ministry of Industry).
Several types of characterization are necessary to cover all knowledge useful for storage and disposal of radioactive waste.
There are three main types of characterization :

- characterization of packages and materials,
- behavioral studies,
- long-term behavioral studies.

Characterization of Packages and Materials

This type of characterization can be defined as the acquisition of the characteristics of a coating, a package or a material in its initial state. This type of characterization is carried out in three steps :

- characterization of the waste itself,
- pre-characterization of the material and the matrix,
- characterization of the finished product (the package intended for storage or disposal).

Characterization of the Waste

This is defined as acquisition of data necessary for :

- producing the waste package,

classification for its activity and its destination :
- (class FA-MA-HA),
- (class or),
- (destination : surface disposal, temporary storage before repository in a geological disposal),

analysis of basic safety and its entry into the approval file.

Pre-Characterization (process and coating)

This is the essential stage for the evaluation of the quality of an embedding process resulting from all the pre-production steps (formulation, reference tests, terminal tests, sensitivity test, etc). Tests for this stage are carried out using reference materials.

Two types of objective are involved :

a comparison of the various performances of the conditioning process (embedding rate, formulation, etc),

a demonstration that the embedding, the packaging, and the finished products satisfy standards and specifications in force.

This step normally results in the production of a packaging specification and the production of nominal specifications for the waste form.

Characterization of the Finished Product

This stage involves three types of investigation :

examination of the intrinsic characteristics of packagings and embeddings,

checking the durability of these characteristics (degradability, confinement, etc),

define the influence of variations of the various process parameters (sensitivity tests) in order to guarantee the quality of the waste formcoated material.

Characteristics and acceptance criteria for the finished product are examined with in chapter 2 of this document.

Long-term Behavior

This type of characterization is defined as the acquisition of data for mechanisms dealing with slowly evolving phenomena. Two approaches can be used :

the behavior of natural counterparts,

the thermodynamic definition of slow phenomena.

The final result that is expected to be obtained from this last characterization stage consists of changing from "high bound" type modelling to a modelling system based on extrapolationon the Long Term of results required by way of short term experiments.

PACKAGE APPROVAL: SPECIFICATIONS, PROCEDURES AND ACCEPTABILITY CRITERIA

Inspection of the current situation in countries developing nuclear energy shows that most countries base approval of waste packages on three main data items:

specifications produced by the authorities,

procedures produced by approved laboratories and organizations,

acceptability criteria or quality criteria which should lead to the respect of specifications.

Although the organization of waste-related responsibilities and therefore the specifications issued by the various authorities vary between countries, all have established some characterization procedures and acceptability criteria for waste packages.

Procedures - Technical Sheets

In France, approval of the waste package is announced after inspection of experimental results and tests in accordance with the minimum characterization program defined by ANDRA.
This minimum program affects the three selected activity levels and the two classes of waste packages (homogeneous-heterogeneous). Tests and checks are classified into four categories :

- physical characteristics,
- mechanical characteristics,
- confinement properties,
- stability-degradability (maintenance of confinement properties).

In order obtain an harmonization of tests required for the approval file, the Confinement Checking and Evaluation Office (Bureau d'Evaluation et de Contrle des Confinements - BECC) has published a set of technical forms codifying a general method of executing these tests.
A block diagram has been produced by the Waste and Effluents Management for the approval procedure . Figure 1 summarizes the global routing of an approval circuit and specifies the role of each participant for wastes which can be delivered to ANDRA on a surface site.
Fig. 1
ANDRA approval of waste packages requires the production of the following documents:

- evaluation of activity contained in the waste,
- description of the production process for the package containing the waste,
- quality assurance program for the implementation of the package production process as described in the process description,
- package characterization test report (technical characterization files).

The characterization test report assumes that the producer has previously submitted a draft characterization test program to ANDRA. When this draft has been accepted by ANDRA, it then becomes the characterization procedure, containing a description of the checks and tests to be carried out.
Therefore, the creation of a test requires the following definitions (Table I):

- the number of samples,
- the size and characteristics,
- the test procedure,
- the results to be provided,
- the test report.

All reports for all tests described in the protocol must then be checked and used to produce a tests summary report, or a characterization technical file which is forwarded, as already stated, to ANDRA by the producer.
The procedure for measuring the initial activity of raw waste and packages which meets ANDRA's requirement for the monitoring of the activity stored on the site in order to respect the radiological capacity of the site for each radionuclides is very important.
Consequently, waste activity measurement (raw or waste form) is one of the most important criteria. Characterization therefore requires the implementation of an adapted measurement scheme for each waste or coating type.

Each type of waste has its own measurement planning for taking measurements and for monitoring the procedure so as to satisfy safety authority requirements.
The main procedure for coatings is shown in Table III. This table clearly shows the two recommended types of measurements :

non-destructive measurements :

gamma scanning spectrometry for the evaluation of the uniformity of the distribution wastes and radionuclides within encapsulation. This technics is applied on samples cores taken from a package and on drums of homogeneous waste:

tomography for non-destructive examination methods are particularly useful in the characterization of radioactive wastes. Radiographic examinations combined with tomodensitometric examinations using gamma ray photon source make it possible to carry out exhaustive testing of the physical homogeneity of a low or medium activity waste package in preliminary characterization, quality control of the produced packages and expertise

destructive measurements with the various related determinations.

Finally, to complete the execution of these measurements, Table IV defines the essential elements which must appear in the test report intended for the producer in order to prepare the summary report for all the tests, as required by the final management authority (ANDRA for FRANCE).

Table I

Table II

Table III

Table IV

Package Acceptability Criteria

For FRANCE, characterization deals only with conditioning and package quality criteria. These are listed in the minimum characterization program defined by ANDRA as recalled in section Procedures - Technical sheets

In view of the available characterization results for various matrices enclosing various types of waste, the BECC established a summary of packaging qualities, as a function of the main parameters.
Three types of parameters were used for this summary (Table II) :

quality of the conditioning-quality of package (RFS + ANDRA specifications),

implementation and feasibility,

control.

An evaluation was made for each type of parameter, matrix and waste type (homogenous - heterogeneous) based on the acquired characterization results.

CONCLUSION

For several years now, research on raw or conditioned waste characterization has been carried out in France, in particular those aspects concerning :

legislation,

regulations,

standardization of methods and techniques,

laboratory and test hall equipment.

The BECC provides the main communication link between the waste producer, ANDRA and the CEA which can perform all services related to tests and corresponding measurements, either as part of its own research and

development program. CEA resources, methods, laboratory and test halls, now form a characterization system adapted to each waste or packaging type to which a quality assurance program is applied.
BECC manufacturing experience enables it to give correct advice to the waste producer and any nuclear material safety unit, both on the selection of packaging and test procedures, and on equipment and the selection of characterization materials or the organization to be set up. In particular, we can provide the following services :

qualitative or quantitative analysis of radionuclides present in already packaged waste (including badly packaged evaluation of the main physico-mechanical and confinement characteristics),

technical assistance for the characterization of packages including :

- developing specific technical test forms according to the customer,
- establishing characterization coordination units and training corresponding personnel,
- transferring basic elements for the implementation of a quality assurance program for package characterization,
- establishing basic characterization method and packaging expertise planning,

technical assistance with the design and construction of characterization laboratories.

To conclude, we would like to emphasize that the objective of the various units in charge of characterization is to supply technical assistance in view of the harmonious development of waste approval files and the development of test techniques to improve knowledge of the intrinsic characteristics of packages waste. Above all, the framework in which these characterization activities are carried out must respect the special features of this characterization, which is at the very interface of the various radioactive waste management partners : safety authorities, waste management (ANDRA), waste producers, and the managers of research and development programs.

Session 17 -- HIGH LEVEL WASTE VITRIFICATION ACTIVITIES AT WEST VALLEY
Co-chair: Bob Lawrence, WVNS

17-1

DEPARTMENT OF ENERGY MANAGEMENT OF THE WEST VALLEY DEMONSTRATION PROJECT

Thomas J. Rowland
USDOE West Valley Area Office

ABSTRACT

The US Department of Energy (DOE), in cooperation with the New York State Energy Research and Development Authority (NYSERDA), has managed the West Valley Demonstration Project (WVDP) since 1982, as prescribed by Congressional Act. One provision of the Act stated that nuclear high-level waste remaining from reprocessing operations at the West Valley, NY site was to be solidified into a safe, durable, and storable product. Vitrification was selected as the method to best accomplish this charter. As the site readies for production of radioactive glass canisters beginning in 1996, the DOE has been successful in its management of the clean-up mission. The DOE has taken this Project from its developmental stage to vitrification readiness by adopting several practices to ensure the scheduled completion of radioactive operations. From the onset of the Project, the DOE has been a strong proponent of oversight by the US

Nuclear Regulatory Commission (NRC) and other external agencies. This practice has led to the up-front identification and resolution of concerns relative to worker and facility safety, long before they become an issue during actual operations. Delegation of authority has been transferred from DOE Headquarters to increase responsibilities at the lowest level. From the very beginning, an open door policy was instituted between the site and the general public, media, and stakeholders; making our programs and progress accessible for everyone. Regularly scheduled meetings are used to inform the public of pending site issues. Cooperative relationships have been established between DOE approval units for such items as Safety Analysis Reports, waste specification and qualification issues, and Operational Readiness Reviews (ORR). Technology that has been developed and refined during the Project's five-year nonradioactive test program has been transferred in the form of lessons learned to other government-owned operations in similar pursuits.

The WVDP's continued success through all stages of operation adds benefit to the DOE. Technologies developed at the WVDP have been applied to other DOE sites, and other DOE sites' technologies have been adaptable to the WVDP, thus playing an important role in reducing costs in government-managed operations. Research and development costs for proven engineering designs are minimized when the final designs are shared by the DOE's Savannah River, Hanford, Oak Ridge, and Idaho Falls sites. The exemplary safety record exhibited during construction, testing, and start-up activities at the Project has also been a direct contribution to schedule accomplishments.

This paper describes highlights of the vitrification process, the cooperative efforts involved in making this Project a success, the lessons learned during the evolution from research and development through construction and start-up, successful technology transfer, and the benefits to be gained by the rest of the DOE complex.

PROJECT HISTORY

The WVDP located in West Valley, NY is the site of a former nuclear fuel reprocessing plant. From 1966 to 1972, reprocessing operations at the West Valley facility generated high-level radioactive acid PUREX waste, THOREX waste, and contaminated condensate. These wastes were stored in separate underground tanks at the West Valley site. Neutralization of the PUREX waste resulted in precipitation of some materials that formed a sludge at the bottom of one of the high-level waste tanks. When processing of nuclear fuels was terminated and the facility was closed, these radioactive liquids/sludge remained in the tanks for the New York State government to manage.

In October 1980, the US Congress passed the West Valley Demonstration Project Act which directed the DOE to safely dispose of the high-level radioactive wastes left at the site by transforming these wastes into forms suitable for storage and transfer to a federal repository. The Act further directed the DOE to clean and close the facilities used and dispose of the low-level and transuranic wastes generated during Project operations.

In 1981, the DOE selected West Valley Nuclear Services, Inc. (WVNS) as their prime contractor. DOE and WVNS assumed operational control of the site in 1982. Project funding comes from both the DOE (90 percent) and NYSERDA (10 percent). A 1981 photo of the site appears in Fig. 1.

Fig. 1

HIGH-LEVEL AND LOW-LEVEL WASTE PROCESSING

By 1988, high-level radioactive waste processing had begun. In the high-level waste tank, the waste had separated into two layers: a clear liquid above a heavy layer of precipitated particles or sludge. Solidification of these separate layers required processing in two stages. The liquid portion or supernatant was sent through a synthetic clay material that removed 99.9 percent of the radioactive materials. The resulting low-level waste, containing salts and sulfates, was concentrated and blended with cement and stored in a shielded, above-ground cell. Supernatant processing was completed in 1990 with a total production of about 10,000 cement drums.

Mixing pumps were then installed in the high-level waste tank to mobilize the sludge for washing. Washing included the addition of process water to the tank to dissolve the salts and sulfates. The wash water was processed through the same liquid treatment system as the low-level waste and produced another 9,800 cement drums. Three washes of the sludge were performed, readying the mixture for vitrification operations.

From 1984 to 1989, the WVDP operated a full-scale glass production test facility. This nonradioactive Functional and Checkout Testing of Systems (FACTS Testing) determined the correct component configurations and confirmed the glass recipe to be used during radioactive operations. Conversion of this test facility for radioactive processing was completed in late 1994. Functional checkout, precommissioning testing, and commissioning testing of vitrification systems were completed in mid-1995. Several integrated operations runs were also executed to confirm proper performance of utility systems, operator actions, alarm responses, and remote equipment operation.

The vitrification process itself entails first combining all of the radioactive constituents into one tank prior to transferring the mixture to the Vitrification Facility. The washed sludge or slurry, the radioactive synthetic clay material from supernatant processing, and the THOREX waste was combined into the high-level waste tank. In the Vitrification Facility, the waste stream will be combined with glass-forming chemicals, concentrated, and fed to 52-ton ceramic melter. The melter will heat the mixture of glass formers and radioactive waste to 1150oC, and the resultant molten glass will be poured into stainless steel canisters. Approximately 300 canisters will be produced during this radioactive campaign and stored on site. All solidification operations and transfers will be performed remotely. Refer to Fig. 2 for a drawing of the vitrification facilities.

Radioactive tie-ins between the Waste Tank Farm piping and the high-level waste transfer trenches leading to and from the Vitrification Facility began in November 1995. Actual radioactive glass production is scheduled to begin June 1996.

Fig. 2

SAFETY

The WVDP operates under one singular tenet: there is nothing more important than personal safety. From the onset of the Project, safety in the workplace has been stressed through the continuing education of ourselves and our subcontractors. Safety programs, such as Conduct of Operations, Voluntary Protection Program, Radiation Safety Training, Behavior-based Safety Training, and numerous other site-wide programs, have led to the development of a comprehensive safety culture encompassing all site workers alike. The work force has been given the individual authority to stop any activity that might jeopardize a

person's well-being. To develop a stronger safety awareness among the many construction subcontractors for the vitrification facilities, safety field engineers were hired to walk down areas prior to and during construction to determine potential safety hazards and correct them before injuries could occur.

Additionally, a WVDP Conduct of Operations manual was developed specifically to augment DOE Order 5480.19, "Conduct of Operations Requirements for DOE Facilities." The WVDP manual outlines adherence to best management practices for every site activity including communications, logkeeping, operations turnover, equipment labeling, lock and tag, postings, and housekeeping.

According to the Bureau of Labor Statistics, the Total Recordable Case Rate (TRC) for all types of construction across industry is 12.2 (1). This figure is derived by taking the number of accidents, multiplying that by 200,000 hours, and dividing the result by the number of hours worked. In actuality, the case rate is representative of the number of OSHA-recordable injuries per 200,000 manhours, or the number of accidents per 100 full-time employees.

The TRC for all types of construction across DOE sites, including their contractors, is 6.8. For lump sum construction (the type of construction contracted at the WVDP), the TRC rises to 7.5. For comparison, the WVDP has maintained a TRC significantly lower than both private industry and DOE site averages. For construction of all the facilities necessary for radioactive glass production between January 1984 and December 1995, the TRC was 3.56. This figure is indicative of only 58 OSHA-recordable accidents in approximately 2,358,469 construction manhours worked over a period of almost 11 years. The Lost Work Day Case Rate (LWDC) figures for the site are also well below commercial and DOE averages, with the WVDP case rate for 1994 being 1.48 in comparison to the private industry rate of 5.5 and the DOE sites' rate of 3.6 for the same year. For all construction activities performed during 1995, the LWDC rate fell even lower to 0.59.

OPEN DOOR POLICY

At the time the DOE assumed management of the WVDP, the site was primarily closed to the media and public. Expectedly, media coverage was negative and activities occurring at the site were viewed somewhat with suspicion by stakeholders and surrounding neighbors. To remedy this condition, the DOE quickly adopted an Open Door Policy, inviting the public and media on site for briefings and tours to outline site characteristics and proposed clean-up activities. Additionally, a yearly Open House and regularly scheduled meetings were initiated so the public, local media, and government officials could tour the site and partake in numerous educational exhibits designed to explain waste processing operations. Attendance at the Project's Open House has averaged about 1,500 people per year (see Fig. 3). During 1995, the WVDP's Community Relations Department responded to over 200 inquiries, conducted approximately 60 site tours, and made about 50 off-site presentations to educational groups, technical societies, and institutions. The DOE and NYSERDA have also made general Project information available to the public and placed environmental documents in reading rooms located throughout the Western New York area.

This new, open communication policy between the DOE and its stakeholders has been greeted by both positive media coverage and increased public awareness of the site's radiological activities, thereby creating a

better understanding of future waste disposal and site closure activities. In February 1996, the site's draft Environmental Impact Statement (EIS), required by the National Environmental Policy Act, was issued for a six-month public review and comment period. This EIS document, developed jointly by DOE and NYSERDA, details five years of site characterization information and evaluates a full range of alternatives for Project completion and site management. A Record of Decision by DOE and NYSERDA with regard to which alternative is the best site closure and management method will be completed after public review and comment.

Fig. 3

PROJECT MANAGEMENT

DOE management of the WVDP has shifted from a long-term Cost-Plus-Award-Fee contract to a yearly performance-based contract. This type of contract, negotiated for the WVDP in 1995, outlines mutually developed milestones that represent a fairly accurate estimation of achievable goals by specific completion dates. These types of milestones carry added or reduced monetary incentives dependent upon early, on-time, or late completion of the milestone.

Performance indicators are similarly used to gauge the monthly progress of support activities for such items as, As Low As Reasonably Achievable (ALARA), LWDC, Occupational Safety Violations, Clothing and Skin Contaminations, Procurements, Waste Minimization, etc. Indicators also carry incentives for maintaining budgets under established limits. Performance-based contracts provide a clearer plan to follow for each year's activities. Milestones and performance indicators have focused the Project in its entirety on critical path events for radioactive vitrification operations, out-year environmental aspects, and long-term waste stabilization efforts. The prior subjectivity of a full cost-plus-award-fee contract has been eliminated and replaced with increased contractor accountability and measurable contract performance. For the WVDP, all 1995 milestones were completed on time with the majority of performance indicators accomplished within set boundaries.

EXTERNAL AGENCY OVERSIGHT

In the Project's early stages, the DOE recognized the benefits of inviting external agencies to provide oversight of upcoming radiological operations. Audit groups, technical review groups, and nuclear energy associations were given access to engineering calculations, drawings, and reports in order to independently determine the adequacy of seismic construction, radiation shielding, the Waste Form Compliance Plan, and the Waste Form Qualification Report. Regular site visits by the NRC established positive communication between the parties resulting in useful and prudent design modifications to the Vitrification Facility. NRC representatives were also brought in to evaluate the Safety Analysis Report for Vitrification Operations and High-Level Waste Interim Storage. Additional support was enlisted from a joint Technical Review Group, comprised of 35 individuals from DOE, private and commercial industry, and the NRC to verify safety analysis report accuracy and completeness.

TECHNOLOGY TRANSFER

Technology transferred and lessons learned, shared among DOE sites, have served to improve our operations and reduce costs by minimizing redundant research, development, and testing activities. The WVDP has benefitted from Pacific Northwest Labs' (PNL) glass technology, ceramic melter, and canister turntable designs. PNL also developed the titanium-treated

zeolite used in the WVDP's ion exchange process for separating radioactive elements from the chemical content of the high-level radioactive waste tank. From the DOE's Hanford site, the WVDP has adapted their hot cell, window and cell penetration, and remote handling tool designs. Hanford also fabricated all of the WVDP's Waste Tank Farm and In-cell remotely removable connecting pipes or jumpers. From the DOE's Savannah River site, closed-circuit television camera designs and nondestructive waste tank examination methods were transferred and utilized. WVDP modified and is using a remotely operated canister transfer cart design developed at the DOE's Oak Ridge facility. Industrial lighting for radioactive cells was revised and installed in the WVDP's Vitrification Facility from designs developed by the DOE's Idaho site.

Technology developed for use at the WVDP has similarly been made available to other DOE locations. Ceramic melter operating information and instructional programs have been given to the Savannah River Defense Waste Processing Facility (DWPF). The DWPF also received from the WVDP infrared level detection technology used for determining the radioactive glass level inside a stainless steel canister and Distributed Control System programming parameters and instructions. The DOE's Hanford site was the recipient of waste tank mobilization pump designs, pump operating information, and proven liquid waste pretreatment technologies.

Recently, through the WVDP's Invention Disclosure Program, a device for bolt fastening/capturing and a device for removing entrained condensate from horizontal pipe have been published by the US Patent Office and made available by the DOE for licensing to the private sector. Several other DOE-funded inventions, developed for use at the WVDP, will be available in the near future for transfer to general industry through publication by the US Patent Office and licensing agreements with the DOE.

DOE APPROVAL UNITS

In keeping with current approaches to transfer approval authority from DOE-Headquarters to units more familiar with and accessible to the WVDP, several document approvals were transferred from higher DOE offices. Two prominent examples of this strategy include: approval authority for the Safety Analysis Report for Vitrification Operations and High-Level Waste Interim Storage was transferred from DOE-Headquarters to DOE-Ohio; and approval of the Vitrification Operational Readiness Review Plan of Action was transferred from the Secretary of Energy to the Assistant Secretary for Environmental Management.

In both instances, transferring approval authority from higher levels within the DOE resulted in a more accurate determination of each document's validity and served to expedite review cycle times.

BENEFITS OF THE WVDP TO THE DOE COMPLEX

Clean-up operations at the West Valley site and strategies developed for use in this site's restoration have contributed to the overall environmental recovery mission of the DOE. What has been learned on a site-wide level; from waste remediation efforts, testing activities, safety programs, and waste minimization practices; is applicable to other DOE facilities and may serve to reduce costs and improve implementation schedules for these programs elsewhere. By the DOE's establishment of a total safety culture, the WVDP has been able to reduce lost work days for all personnel to levels lower than general industry and DOE averages. Subsequently, costs for interrupted work due to accidental injuries have been decreased.

CONCLUSIONS

Today, the WVDP stands on the verge of being one of the first jointly operated (DOE/NYSERDA), high-level radioactive waste vitrification facilities to operate in the United States. Solidification of radioactive waste into a stable, durable form is scheduled to commence in June 1996 and conclude in October 1998, with a total production of about 300 canisters. Canistered waste will remain on site in interim storage until a federal repository is designated. A photo of the WVDP as it appears today is shown in Fig. 4.

Our past success has been predicated on commitment to management involvement, worker safety, external agency oversight, open communication with stakeholders and the public, and technology transfer. Our continued success will build upon these fundamentals and proportionately expand to include new, innovative management techniques designed to correspond with the DOE's strategic alignment to focus energies on contract reforms and more prudent use of taxpayer dollars.

17-2

DESCRIPTION OF THE WEST VALLEY VITRIFICATION PROJECT

Victor A. DesCamp
West Valley Nuclear Services, Co., Inc.

ABSTRACT

The Vitrification Facility at the West Valley Demonstration Project (WVDP), West Valley, NY will be used to solidify residual high-level waste that was previously generated by an on-site nuclear fuel reprocessing plant. The Vitrification Facility has been constructed and radioactive operations are scheduled to commence in 1996. The facility, including both the pretreatment and vitrification processes, are described in this paper.

INTRODUCTION

By a Congressional Act in 1980, the West Valley Demonstration Project was created to, among other things, solidify the high-level radioactive waste that resulted from the former nuclear fuel reprocessing plant operations. Using existing and newly constructed facilities, vitrification and related systems were designed and installed to accomplish this Project mission.

Initial liquid pretreatment operations, completed in 1995, resulted in the decontamination of 6,400 cubic ft3 of liquid high-level waste and the production of 19,877 drums of cemented low-level waste. The Vitrification Facility is expected to produce about 300 stainless steel canisters 0.61 m in diameter by 3.05 m tall filled with the high-level waste encapsulated in borosilicate glass. The vitrification system uses a joule-heated melter that produces glass at a rate up to 30 kg/hr. The canisters will be stored on site until a federal repository is designated.

The paper describes the processes used for high-level waste pretreatment and vitrification, and the methods used to mix and combine the waste in one high-level waste tank prior to vitrification. The entire

Vitrification Facility is described and includes the vitrification remote process cell, vitrification process equipment, Cold Chemical Facility, Canister Storage Cell, computerized Distributed Control System (DCS) that monitors processing operations, and melter off-gas treatment system. Lessons learned throughout the Project are discussed.

PRETREATMENT AND VITRIFICATION PROCESS

Wastes of varying composition and radioactivity levels were stored in separate underground tanks at the West Valley, NY site. Tanks 8D-1 and 8D-2 are duplicate carbon steel tanks, approximately 21.3 m in diameter and 8.23 m in height. Tank 8D-2 contained about 2,420 m3 of neutralized PUREX waste, 170 m3 of that amount consisting of sludge. Tank 8D-1 was used as a spare for Tank 8D-2; condensate from Tank 8D-2's ventilation system gravity-drained to Tank 8D-1. Tanks 8D-3 and 8D-4 are also duplicate tanks made of stainless steel, and are approximately 3.7 m in diameter and 4.8 m in height. Tank 8D-4 contained approximately 35 m3 of THOREX nitric acid waste. Tank 8D-3 was originally used as a spare.

The neutralized PUREX waste stored in Tank 8D-2 required separate treatment methods for the liquid (supernatant) top layer and bottom sludge layer. The supernatant layer was decanted through zeolite-filled, ion-exchange columns suspended in Tank 8D-1 to remove cesium. The resulting decontaminated liquid was mixed with cement and solidified into about 10,000 square drums. The drums are stored above ground in a shielded cell on site.

Process water was then added to Tank 8D-2 to wash the sludge of crystallized salts and sulfates. Large pumps were inserted through risers in the tank to mobilize the sludge and mix it with the process water. Heavy particles were left to settle and the wash water was again decanted through the ion-exchange columns and solidified into cement. Two sludge washes were performed. Sodium hydroxide was next added to Tank 8D-2 to neutralize the incoming THOREX waste transferred from Tank 8D-4. Another wash was performed after THOREX transfer and neutralization to remove excess sulfates. These sludge washes resulted in the production of another 9,877 drums of cemented low-level waste.

Spent zeolite dumped in the bottom of Tank 8D-1 was passed through a grinder and returned to Tank 8D-2.

For high-level waste processing the radioactive slurry in Tank 8D-2 will be transferred to the Vitrification Facility for solidification in borosilicate glass. Slurry will exit the Tank Farm area via double-walled piping inside a concrete underground trench. Once inside the Vitrification Facility, the waste stream will be mixed with glass-forming chemicals delivered from the Cold Chemical Building, concentrated, and fed to a 52-ton ceramic melter. The melter will heat the mixture to 1150oC bonding the glass-forming chemicals to the waste. This molten mixture will then be poured into stainless steel canisters, remotely transferred to a lid welding station, a decontamination station, and positioned on a transfer cart for transport to the High-Level Waste Interim Storage Facility. Approximately 300 canisters will be produced during the Vitrification campaign and stored on site until a federal repository is ready to accept the waste. A diagram depicting low-level and high-level waste processing appears in Fig. 1.

Fig. 1

DESCRIPTION OF VITRIFICATION FACILITIES

Vitrification Cell

Radioactive glass production to specific requirements can only be accomplished by the integrated operation of numerous components, systems, and facilities. A brief description of the vitrification facilities and major components follows:

The Vitrification Cell holds the majority of the vitrification process equipment. The cell is a shielded, seismically designed, confinement boundary with interior dimensions of approximately 10.37 m (34 ft) by 16.6 m (53 ft) long by 13.11 m (43 ft) high. Cell walls are four foot-thick reinforced concrete and consist of prefabricated wall modules placed between previously cast-in-place concrete columns. Modules are constructed of a structural framework to support internal piping and penetrations for six shield windows and utility access. A solid stainless steel plate faces the radioactive cell interior. The modules were installed and filled with concrete, which formed the nonradioactive side of the finished module. A total of seven wall modules were installed and welded together to form an integral structure that serves as a radiological and seismic barrier. The cell floor is at elevation 100.00' or grade level, and the cell exterior roof is at elevation 145.00'. There are no intermediate floors in the Vitrification Cell. Surrounding the cell are three floors of operating aisles equipped with instrument racks, to control the delivery of cell services, and supporting utility rooms. Structurally, the cell was designed to withstand a design basis earthquake equivalent to a ground acceleration of 0.1g horizontal load, with a vertical component equal to two-thirds of the horizontal acceleration, and a design basis tornado based on detailed analysis of tornado occurrences in Western New York State.

Cell Components

Installed in the Vitrification Cell are the primary process tanks including a Concentrator Feed Makeup Tank and a Melter Feed Hold Tank. A 52-ton ceramic melter, Submerged Bed Scrubber, four-position canister turntable, canister cooling rack, canister lid welding station, decontamination station, and one of two off-gas systems also reside in the cell. The process tanks heat and concentrate the glass-forming chemicals, delivered from the Cold Chemical Building, and the waste delivered from the Waste Tank Farm prior to transfer into the melter. The melter is a stainless steel, water-jacketed box complete with corrosion-resistant interior and separate chambers for glass melting and glass pouring. Various types of thermal-resistant refractory brick line the melter interior. Joule heating of the slurry is performed by three metallic electrodes with regulating current. The canister turntable rotates empty canisters to a position beneath the melter pour spout and filled canisters to cooling positions. Viewing the glass pour level of the canister is performed by an out-of-cell-located infrared level detection system. The Submerged Bed Scrubber, designed to quench and scrub off-gas particulate from the melter, has the ability to circulate and remove entrapped liquids and solids to avoid buildup in the scrubber bed. The In-cell Off-gas System consisting of preheaters, HEPA filters, and mist eliminators removes the bulk of radioactive particulate from the off-gas stream. The lid welder remotely welds stainless steel lids onto filled canisters prior to decontamination activities. The Decontamination Station is used to submerge each filled and capped canister in a nitric acid-cerium (+4) solution to etch off a thin (3-5 micron) layer of the canister's exterior which may contain submicron particles of fixed contaminants. A recent photo of the Vitrification Cell appears in Fig. 2.

Fig. 2
Cell components are accessible via a crane system comprised of a 4.5-ton process crane, a 25-ton backup crane, an impact wrench, a bridge trolley and rails. Most major components in the cell are remotely removable using only crane-mounted equipment. Utility services to components are hooked up to in-cell components by crane-removable jumpers. High-dexterity jobs such as glass shard sampling are performed using manipulators. Floor rails enable the movement of a remotely operated canister transfer cart in and out of the cell through a large shield door. Viewing of cell operations and canister movement is accomplished by closed-circuit television.

Adjacent Shielded Structures

South of the Vitrification Cell is a shielded transfer tunnel, a sort of air lock with shield doors on either end, used to separate the cell atmosphere from the former plant's Equipment Decontamination Room (EDR). Located above the tunnel is the Crane Maintenance Room (CMR) and Crane Maintenance Room Operating Aisle (CMROA). The CMR will be used to service the cell cranes. South of the EDR is a former chemical process cell that will be used as the High-level Waste Interim Storage (HLWIS) Facility for approximately 300 canisters. The transfer cart will travel on floor rails between these facilities. Figure 3 outlines the canister travel path from the Vitrification Cell to the High-level Waste Interim Storage Facility.

Interior dimensions of the transfer tunnel are 4.88 m (16 ft) wide by 9.68 m (31 ft) long. A hatch in the ceiling of the tunnel allows for removal of inoperative equipment into the CMR. The tunnel has concrete walls and a sloped floor lined with 304L stainless steel to allow for decontamination. HVAC systems will maintain a negative pressure on the tunnel and direct the flow of contaminated air into the Vitrification Cell. A closed-circuit television camera mounted on the tunnel wall provides remote viewing capabilities.

The EDR was also part of the original plant and required considerable decontamination prior to use. This room will be used as an entry port from the Load-in Building for empty canisters, transfer cart maintenance, and recharging the cart's battery pack. The cell's concrete interior is epoxy coated and has dimensions of approximately 8.75 m (29 ft) wide by 13.33 m (43.7 ft) long by 7.62 m (25 ft) high. The walls are approximately 0.91 m (3 ft) thick reinforced concrete and the floor is 0.36 m (14 in) thick concrete. A ceiling hatch opens to the Chemical Crane Room located above for additional crane maintenance.

Storage of stainless steel canisters will be south of the EDR in the former Chemical Process Cell of the main fuel reprocessing plant. The HLWIS Facility is a shielded cell 28 m (92 ft) long by 6.70 m (22 ft) wide by 13 m (43 ft) high. Walls are 1.75 m (5 ft 9 in.) thick and the ceiling is approximately 1.52 m (5 ft) thick. Four shield windows permit viewing of the cell interior from the outside viewing aisle. The transfer cart enters the facility through another shield door. Individual canisters will be unloaded from the cart, by a 16-ton crane with grapple attachment, into storage racks. An additional crane also resides in the cell. A total of 11 storage racks, with a capacity of 36 canisters each, were installed in a two-tiered, interlocking system. Cranes requiring maintenance can be brought into the Chemical Crane Room located above the EDR. The cell has two closed-circuit television cameras for viewing unloading operations.

Load-in Building

The Load-in Building is located west of the EDR and will be used as the primary access for moving empty canisters into and filled canisters out of the Vitrification Cell. The building's concrete base mat and steel structures are designed to withstand a design basis earthquake of 0.1g. The floor is at grade elevation 100', and the roof rises to elevation 153'. A 15-ton crane provides canister and equipment transfer capabilities. Provisions have been made for a 50-ton crane to accommodate future load-out of the filled canisters into transportation casks. Canisters are loaded from the Load-in Building to the EDR horizontally by conveyor. A removable shield plug blocks the entry port into the EDR. When the shield plug is removed, canisters can enter the EDR (see Fig. 3). A tipping fixture uprights the canisters for placement onto a transfer cart. An area of the Load-in Building will also be used as a chemical staging area for nonradioactive chemicals used in melter feed preparation.

Fig. 3

Secondary Filter Room

The Secondary Filter Room, south and adjacent to the Vitrification Cell, houses two large filter units that provide filtering of the air exhausted from the Vitrification Facility. The room is a reinforced concrete structure with approximate dimensions of 6.70 m (22 ft) wide by 9.76 m (32 ft) long by 6.70 m (22 ft) high. Walls are reinforced concrete and vary in thickness from 0.61 m (2 ft) to 1.22 m (4 ft). An additional 4.27 m (14 ft) by 4.88 m (16 ft) area can be used for the maintenance of equipment.

Diesel Generator Room

The Diesel Generator Room, west and adjacent to the Secondary Filter Room, houses a 600 kW generator, switchgear, distribution cabling, and controls to provide backup power to selected loads in the event of a temporary or extended power outage. The room is designed to withstand the site's Design Basis Tornado and Design Basis Earthquake. Its dimensions are 12.20 m (40 ft) by 8.23 m (27 ft). Floor elevation is at grade level and the roof elevation is 111.50'.

01-14 Building

The four-story 01-14 Building was part of the original plant and reused as part of the vitrification facilities in keeping with the Project's objective to use existing buildings as much as practical. Off-gases produced from operation of the melter contain radioactive and nonradioactive components. The off-gases are treated by the scrubbing and filtration systems for removal in excess of 99.99 percent of the radioactive particulates. Subsequently, the off-gases are treated in the NOx Abatement System, that is designed to remove 91 percent of the oxides of nitrogen prior to exiting the Main Plant stack. The area used for vitrification-related off-gas components is 21.34 m (70 ft) by 9.15 m (30 ft) by 18.29 m (60 ft) high.

The 01-14 Building also houses the Cement Solidification System (CSS) that used to produce low-level cemented waste drums during earlier processing activities.

Vitrification Main Control Room

The Vitrification Main Control Room is located at elevation 114.6' of the Vitrification Facility. The computer area floor is raised to elevation 117.5' to accommodate cable access and routing. Refer to Fig. 4 for a photo of the Vitrification Main Control Room. The room is sealed for fire protection and access is only permitted by card reader. The control room

has two operator stations each with Distributed Control System monitors, Infrared Level Detection monitors for canister level detection, closed-circuit television monitors, and keyboards. HVAC monitoring panels, fire protection monitoring panels, and various other facility and utility indicators are located next to the operator stations. The shift engineer and shift supervisor stations are located on the upper level of the Vitrification Main Control Room. The shift engineer's station is equipped with a duplicate Distributed Control System monitor, Infrared Level Detection monitor, and closed-circuit television screens. The shift supervisor's station has the same equipment with the exception of the Infrared Level Detection monitor. Laser printers, VAX terminals, telephones, radios, and supporting system documentation are also present on both sides of the Vitrification Main Control Room.

Fig. 4

Distributed Control System

The data collection and control system for the vitrification process is a computerized system called the Distributed Control System (DCS). The system has four redundant work stations and is based in the Main Control Room of the Vitrification Facility. The DCS allows for monitoring, control, and supervision of vitrification processes. Control of process equipment can also be accomplished from remote control panels located in operating aisles adjacent to the Vitrification Cell. Data collection and control functions are performed for the: Cold Chemical Building; In-cell and Ex-cell Off-gas Systems; Ammonia Supply and NOx Analyzers; HVAC; Sludge Mobilization System; Cooling and Utility Water Systems; Steam; Utility and Instrument Air Systems; Canister Turntable; Waste Header and Vessel Vent Systems; Primary Vitrification Process System; Canister Decontamination; and Electrical Backup Systems.

Computer monitors display control functions in graphical form along with key operating parameters such as vessel levels, temperatures, valve positions, pressures, and flows presented in real time. Process inputs are audibly and visually alarmed. Certain functions such as set point changes have restricted access and electronic permissives are used to coordinate activities prior to implementation.

The DCS power panel is fed from an uninterruptible power supply that is a self-contained battery power source with diesel generator backup.

Vitrification Facility HVAC System and Considerations

HVAC zones in the Vitrification Facility are maintained by barriers such as walls, aisleways, and doors. The walls, aisleways, and doors prevent the spread of contamination between rooms. Differential pressure ranges are maintained with reference to atmosphere or adjacent zones throughout the facility. Zone I designated areas are those that may contain radioactive materials during normal operations. The Vitrification Cell, Transfer Tunnel, and Crane Maintenance Room are examples of Zone I areas. Zone II designates operating areas and other potentially contaminated areas surrounding Zone I. The EDR, Chemical Crane Room, and Load-in Building are examples of Zone II areas. Zone III HVAC areas are expected to be free of contamination. Ex-cell aisleways and the Control Room are examples of Zone III areas. Air flow is directed from Zone III designated areas into Zone II areas and from Zone II into Zone I, or from areas of lesser contamination potential into areas of higher contamination potential.

The HVAC System is comprised of a filtered air supply and exhaust, in-cell coolers, exhaust fans, Diesel Generator Room ventilation, Chiller

Equipment Room ventilation, a stairway pressurization system, HVAC Control Room supply and exhaust control dampers, electric unit heaters, the Chilled Water System, and Cold Chemical Building heating and ventilating. System criteria, as discussed above, is to maintain the release of radioactivity and airborne particulate below design limits.

CONCLUSION

Construction of the vitrification facilities was completed in 1995. Precommissioning and commissioning testing of components, and the functional checkout of systems were completed in early 1995. Performance testing of systems to Test Instruction Procedures was completed in December 1995. Integrated operations runs with a selected combination of systems began in September 1995 and are scheduled to be completed in May 1996. Preliminary preparations for radioactive tie-ins between the Waste Tank Farm and the vitrification facilities were initiated in November 1995; actual tie-ins are scheduled to be completed in April 1996. Vitrification of high-level waste is expected to begin in June 1996 with the pouring of the first production radioactive glass canister. Approximately 300 canisters will be produced during the expected two and one-half year long vitrification campaign.

Successful high-level radioactive waste solidification into borosilicate glass will be a significant milestone for the US Department of Energy, West Valley Demonstration Project, New York State Energy Research and Development Authority, and West Valley Nuclear Services, Co., Inc.

17-3

HIGH-LEVEL RADIOACTIVE WASTE PRETREATMENT AT THE WEST VALLEY DEMONSTRATION PROJECT

Daniel C. Meess
West Valley Nuclear Services Company, Inc.

ABSTRACT

The West Valley Demonstration Project (WVDP) has completed the pretreatment of the high-level radioactive waste (HLW) prior to the start of waste vitrification. The HLW originated from two million liters of plutonium/uranium extraction (PUREX) and thorium extraction (THOREX) wastes remaining from Nuclear Fuel Services (NFS) commercial and defense nuclear fuel reprocessing operations at the Western New York Nuclear Service Center (WNYNSC) from 1966 to 1972. The pretreatment process and subsequent vitrification of the HLW were authorized in 1980 by passage of the WVDP Act. This gave the U. S. Department of Energy (DOE) the responsibility to conduct a HLW management project at the WNYNSC to demonstrate viable decontamination and decommissioning techniques and stabilize the HLW stored on the site from prior reprocessing operations. HLW pretreatment operations, utilizing existing facilities to the maximum practical extent, were conducted to separate the radioactive portion of the waste from the salts found in the waste to minimize the quantity of vitrified waste that will be produced. The pretreatment process removed cesium as well as other radionuclides from the liquid wastes and captured these radioactive materials onto zeolites. The decontaminated salt solutions were volume-reduced and then mixed with portland cement and other admixtures. Approximately 19,900 square, 270-liter drums were filled with the cement-wastes produced from the pretreatment process. These drums are being stored in a shielded facility on the site until their final disposition is determined.

Over 6.4 million liters of liquid HLW were processed through the pretreatment system. PUREX supernatant was processed first, followed by two PUREX sludge wash solutions. A third wash of PUREX/THOREX sludge was then processed after the neutralized THOREX waste was mixed with the PUREX waste. Approximately 6.6 million curies of radioactive cesium-137 in the HLW liquid were removed and retained on 65,300 kg of zeolites. With pretreatment complete, the zeolite material has been mobilized, size-reduced, and blended with the PUREX and THOREX sludges in a single feed tank that will supply HLW slurry to the Vitrification Facility.

INTRODUCTION

Approximately two million liters of liquid HLW were produced by NFS in the reprocessing of commercial and defense nuclear fuel from 1966 to 1972 at the WNYNSC in West Valley, NY. The wastes consisted of alkaline PUREX sludge and supernatant, and a small quantity of acidic THOREX liquid. The PUREX waste was generated from reprocessing 640 metric tons of uranium oxide fuel to recover both uranium and plutonium. Sodium hydroxide was added to neutralize this acidic waste for safe storage in the 2.8 million liter, underground carbon steel storage tank, designated Tank 8D-2. Neutralization and concentration of the tank's contents caused insoluble hydroxides and other salts, notably sodium sulfate (Na_2SO_4), to precipitate out of the liquid supernatant and form sludge layers in the bottom of Tank 8D-2. Both hard and soft sludge layers were found to exist through sampling programs (1). Prior to the initiation of HLW pretreatment, approximately 100,000 kg of sludge (Sp.Gr.=3.3) and two million liters of supernatant (Sp.Gr.=1.32) were contained in Tank 8D-2. The major chemical and radionuclide constituents are listed in Tables I and II, respectively.

Table I

Table II

THOREX waste liquid was produced by reprocessing one core of mixed uranium-thorium fuel from the Indian Point No. 1 Nuclear Plant. This acidic HLW was stored in a 50,000 liter, underground, stainless steel storage tank, identified as Tank 8D-4. Approximately 31,000 liters (Sp.Gr.=1.84) of this waste, having the chemical composition shown in Table III and the major radionuclide content presented in Table IV, were present at the beginning of HLW pretreatment.

Table III

Table IV

PRETREATMENT PROCESS

Early in the Project, it was decided to pretreat the liquid HLW. This was necessary to remove those salts which have a detrimental effect on the final vitrified HLW form, notably sodium sulfate. Without pretreatment, the quantity of vitrified waste would have increased by at least tenfold to maintain the sulfate at acceptable levels in the glass.

Various pretreatment methods were studied and evaluated with the assistance of Battelle PNL, EBASCO, and others. Evaluation criteria included: process decontamination performance; equipment and process complexity; impacts on the vitrification system and the Liquid Waste Treatment System (LWTS), which volume-reduces the decontaminated HLW liquid; and safety and environmental considerations. The use of an inorganic/zeolite ion exchange process received the top ranking and was selected as the reference pretreatment technology (2).

INTEGRATED RADWASTE TREATMENT SYSTEM

The Integrated Radwaste Treatment System (IRTS) was specified to carry out the HLW pretreatment utilizing four separate subsystems: Supernatant Treatment System (STS), Liquid Waste Treatment System (LWTS), Cement Solidification System (CSS), and Drum Cell (DC). These subsystems were constructed using existing facilities and equipment whenever possible to minimize Project costs. The STS uses zeolite to separate the highly radioactive constituents in the HLW from the salt solution. The decontaminated salt solution is volume-reduced in the LWTS by evaporation to a concentration of 20 to 40 wt% Total Dissolved Solids (TDS), suitable for solidification with portland cement. The CSS mixes the decontaminated liquid concentrate with portland cement and other admixtures and remotely fills 270-liter square drums with cement-waste discharged from a high-shear mixer. These drums are remotely loaded onto a shielded, overland truck transporter that delivers up to eight drums at a time to the remotely operated DC. At the DC the drums are automatically off-loaded and placed into a compact storage array inside a shield structure enclosed by a weather shelter.

Supernatant Treatment System Facility Description

A simplified process flow diagram of the STS is shown in Fig. 1. Supernatant, and then later sludge wash, are transferred from Tank 8D-2, the 2.8 million liter underground HLW carbon steel storage tank, to the STS by a submersible vertical turbine pump (50-G-001) suspended in the tank. The pump has a floating suction to minimize the potential for sludge pickup and it is supported from the vault roof. Optional filtration (50-F-001) is provided to prevent process contamination by removing sludge particles suspended in the supernatant or sludge wash. The filter is capable of being pulsed and blown back with compressed air to clean the accumulated particles from the porous tube filtering surface.

The 6,400 liter Supernatant Feed Tank (50-D-001) serves as a surge tank for intermediate collecting and feeding of supernatant to the ion exchange columns. Supernatant, which is ready for ion exchange processing, is transferred from Supernatant Feed Tank 50-D-001 through Supernatant Cooler 50-E-001 by a canned centrifugal pump (50-G-002) at a rate of 8 to 30 lpm. The supernatant is cooled to less than 12C to improve the cesium removal efficiency and then is pumped downflow through three or four ion exchange columns (50-C-001, 50-C-002, 50-C-003, and 50-C-004) in series. Each ion exchange column contains 1,700 liters (1,630 kg) of zeolite.

Lab analysis is performed to determine the cesium loading in each ion exchange column. When the first column is fully loaded (saturated with cesium), supernatant processing is stopped. All columns are then flushed with demineralized water and the system is placed in recirculation through the second, third, and fourth ion exchange columns for the remainder of the shutdown to cool the column contents. The fully loaded zeolite in the first or lead column is then sluiced to the bottom of Tank 8D-1 with process water and is filled with fresh zeolite before the column goes back on-line in the last or polishing position. The loaded zeolite is temporarily stored under corrosion-inhibited water in Tank 8D-1 at approximately 50C until it is combined with the HLW sludge in Tank 8D-2 and delivered to the vitrification system.

Following ion exchange, the decontaminated supernatant is filtered through a sand filter to remove any suspended zeolite fines. The filtered and decontaminated supernatant is then transferred to existing

underground spare THOREX Waste Tank 8D-3. This tank has a working volume of 34,100 liters for STS processing and serves as both an intermediate storage tank and as a sampling tank. Sample analyses are performed to verify the cesium concentration and decontamination factor of each batch of decontaminated supernatant that is produced. Decontaminated supernatant is transferred to the LWTS from Tank 8D-3 in batches for volume reduction by evaporation.

Fig. 1

Liquid Waste Treatment System

The function of the LWTS is to reduce the volume of the liquid waste by boiling off excess water in a steam-fired evaporator/reboiler, which is run in thermosyphon mode. The major components of the system are located within the Main Process Building of the formal nuclear fuel reprocessing facility (3).

Decontaminated waste from the STS effluent tank is batch-transferred by a submerged, vertical turbine pump installed in Tank 8D-3 and an in-line booster pump to the 57,000 liter evaporator feed tank.

After sampling, the waste is slowly pumped at flow rates up to 40 liters/minute to the high-efficiency evaporator where the liquid is concentrated as desired for future solidification in cement, typically from 20 to 40 wt% TDS.

The distillate from the condenser is processed through a zeolite ion exchange column to remove cesium and strontium. This liquid effluent is then sent to the site's Liquid Waste Treatment Facility (LLWTF) for additional treatment prior to discharge to the environment. Gaseous effluents from the evaporation process are collected by the Vessel Off-gas (VOG) system, HEPA filtered, and then discharged through the Main Plant stack.

The concentrates produced in the evaporator are pumped through a water-cooled heat exchanger and fed to Tanks 5D-15A1 or 5D-15A2, having capacities of 19,000 and 38,000 liters, respectively. The concentrates are then batch-pumped to the 1,900 liter Waste Dispensing Vessel in the CSS. Instrumentation placed at strategic points throughout the system allow the process parameters to be monitored from the LWTS Control Room in real time. Feed and product tanks are sampled to ensure that the liquid waste stream is within process parameters. Typical activities of the concentrated liquid waste range from 0.01 to 0.5 mCi/ml cesium-137, with an upper design limit of 50 mCi/ml.

Cement Solidification System

The fully automated CSS receives concentrated liquid radioactive mixed waste and produces stabilized cement-waste which meets 10CFR61 criteria for low-level waste. The radioactive portions of the system are contained in the shielded confines of the 01-14 Building, which housed the acid recovery system during prior fuel reprocessing operations. A storage and transfer system provides silo storage for 70 cu. meters of the cement/calcium nitrate blend. This material is pneumatically conveyed into the 01-14 Building where a weight feeder batches it to the cement mixer (4).

Liquid waste is stored in the Waste Dispensing Vessel and recirculated through the piping system with a positive displacement pump to maintain a homogeneous mixture. Process control systems monitor, limit, and meter the liquid waste, additives, and the portland cement/calcium nitrate blend into a high-shear mixer. A data acquisition system records the weight of each additive, bar-coded drum number, and other process

information for record-keeping. After mixing, the cement waste is discharged into a 270-liter, polyethylene-lined square drum. Two mixer batches are required to fill each drum. The drum fill neck is then remotely capped and the drums move on roller conveyors to a remote smearing station. After cleanliness is verified, the drums are automatically sequenced onto the shielded, truck transporter which hauls up to eight drums at a time to the DC.

The CSS facility was designed for fully automatic processing of drums having radiation fields up to 1 R/hr at contact. Due to required maintenance activities, ALARA (As Low As Reasonably Achievable) typically limits operations to 100 mR/hr per drum, which is easily maintained by the excellent decontamination provided by the STS.

Drum Cell

The DC serves as a storage facility for the cement-waste produced by the IRTS, pending approval of the Environmental Impact Statement (EIS) and the Record of Decision (ROD) for final site closure. The facility was designed and constructed so that it can be converted to an above-grade tumulus disposal facility.

The facility consists of 50 cm thick concrete shield walls around a small drum unloading area and a 15 m wide by 105 m long by 4.6 m high drum storage area. A larger, sheet metal, weather structure encloses the shielded areas and also houses the Control Room and a crane maintenance area. The facility was originally designed to store 17,700 270-liter drums of cement-waste, stored 9 layers high (5). Upgrades to the remote drum lifter and other hardware/software modifications have expanded the drum capacity to 11 layers high, with a capacity of 21,200 drums.

Operations within the DC are fully automated. Drums are sequenced off the transporter onto a roller conveyor system that employs a bar code scanner to record the drum number into the data base, upends the drum on its side, and then tips the drum on its side edge. The remotely operated crane picks up each drum from the top and bottom edges and places it into the drum storage array, keeping the lower activity drums on top to provide shielding. The global X,Y,Z coordinates of each drum are logged into the data base, along with its serial number, for documentation and potential retrievability.

IRTS OPERATION

Supernatant Processing

The IRTS was operated from May, 1988 until November, 1990 processing 2.34 million liters of PUREX supernatant having cesium-137 concentrations ranging from 1,100 to 2,800 Ci/ml. Approximately 5.20 million curies of cesium-137 at a decontamination effectiveness of over 99.99% were removed from this liquid and adsorbed on 42,500kg of UOP IONSIVR IE-96 zeolite, which was stored under liquid in Tank 8D-1. The decontaminated supernatant, concentrated to a nominal 40% TDS, was solidified into 10,393 270-liter square drums. The cesium-137 activity in these drums totalled 302 curies. Through various test programs, this cement-waste has been shown to meet all U.S. Nuclear Regulatory Commission (NRC) requirements for a stabilized low-level radioactive waste form (6). Additional test programs also demonstrated that heavy metals contained in the liquid waste; primarily barium, cadmium, chromium, mercury, and selenium; are immobilized so that the solid waste is classified as Resource Conservation and Recovery Act (RCRA) nonhazardous. These drums are currently stored on site in the DC.

Sludge Washing

After completing laboratory simulation tests, preparations, and operational readiness reviews; both internal and DOE/NRC; the PUREX sludge in Tank 8D-2 was washed from October, 1991 to January, 1992. Washing consisted of adding a sodium hydroxide solution and additional water to increase the alkalinity of the liquid waste from an indicated pH of 10 to a pH of 12.5. This was done in conjunction with sequential operation and lowering of the five 150-hp mobilization pumps in the HLW tank to thoroughly mix the contents. This washing process dissolved the hard layer of sludge present in the tank, solubilized sulfate and other undissolved salts present in the sludge, and mixed the interstitial liquid trapped in the sludge with the wash solution. The alkalinity increase precipitated plutonium and uranium compounds formed so that these concentrations in the sludge wash were reduced by factors of 10 and 20, respectively. This was desirable since much more of these long-lived radionuclides would be vitrified with the sludge and not carried through to the cement-waste product.

Sludge Wash No. 1 Processing

Sludge wash no. 1 processing through the IRTS began in April, 1992 and finished in May, 1994. Over 1.55 million liters of the sludge wash no. 1 solution containing 910,000 curies of cesium-137 with concentrations between 520 and 850 Ci/ml were decontaminated using UOP IONSIVR IE-96 and TIE-96 zeolites. The TIE-96 zeolite was developed jointly by Battelle PNL, UOP, and West Valley Nuclear Services (WVNS), with its first commercial use at the WVDP during sludge wash no. 1 processing through the STS. In addition to cesium, the TIE-96 zeolite removes plutonium and strontium with typical decontamination factors of 10 to 100. By using this new zeolite, the amounts of these long-lived radionuclides that are solidified in cement-waste are minimized and the quantities vitrified are maximized. Six-thousand five-hundred kilograms of the TIE-96 zeolite and 4,900 kg of IE-96 zeolite were used during sludge wash no. 1 processing. The cesium activity passing through into the cement waste was 201 curies. Two new stabilized cement-waste forms were developed to solidify the new waste stream to newly revised NRC stability requirements. Portland Type V cement was used in one of the waste forms, instead of the Type I cement, to resist the impact of the increased sulfate content in the sludge wash and to increase the waste concentration from a nominal 20 wt% TDS to 30 wt% TDS. Approximately 7,280 270-liter square drums of cement-waste were produced from the decontaminated sludge wash no. 1 concentrate: 4,160 with Type I and 3,120 with Type V portland cement. Both waste forms were developed to meet applicable U.S. Environmental Protection Agency (EPA) and New York State Department of Environmental Conservation (NYSDEC) regulations for immobilization of heavy metals and the updated stability requirements contained in the 1991 NRC Branch Technical Position on Waste Form. Nearly all of the sludge wash cement-waste produced meets 10CFR61 criteria for a Class A low-level waste due to three factors: 1) precipitation of the plutonium in the alkaline sludge wash 2) plutonium and strontium removal provided by the TIE-96 zeolite and 3) the slightly lower waste concentration employed to adequately produce a stabilized cement waste with the much higher sulfate levels and limit precipitation of solids in the LWTS evaporator.

Sludge Wash No. 2 and Processing

A second sludge wash of the PUREX sludge was preformed during May and June, 1994 to further reduce the amount of sulfates in the HLW prior to vitrification. As with the first sludge wash, sodium hydroxide and water

were added to Tank 8D-2 while the mobilization pumps mixed the contents of the tank. Following the second wash, the wash solution was again processed through the IRTS from June to August, 1994. Approximately 1.35 million liters of wash no. 2 solution, containing 126,000 curies of cesium-137 at a concentration of 100 mCi/ml, were decontaminated in the STS with both types of UOP zeolites used earlier. Only 1,600 kg of zeolite were used during this processing. The cesium activity passing into the 750 drums of cement waste produced from the decontaminated sludge wash concentrate was limited to 21 curies. All drums meet 10CFR61 criteria for a Class A LLW.

THOREX Transfer and Neutralization

Following the completion of sludge washing, final preparations were made to complete the installation of the HLW Transfer System which links all three HLW tanks and the Vitrification Facility together with double-contained piping run in underground concrete trenches and pits. Vertical, turbine-type transfer pumps were installed in Tanks 8D-1, 8D-2, and 8D-4. Readiness assessments for the THOREX transfer and neutralization, THOREX-wash processing, and zeolite transfer were conducted by both WVNS and DOE, with oversight by the NRC. Tank 8D-2 was prepared for the acidic THOREX addition during November and December, 1994 by increasing its alkalinity with sodium hydroxide to approximately a pH of 13. Corrosion probes and a NOx monitor were employed to monitor and limit tank corrosion during the THOREX addition. Dilution air was added into the HLW tank vapor region to also minimize corrosion during the transfers.

The acidic THOREX was transferred from Tank 8D-4 to Tank 8D-2 and neutralized during January, 1995. The THOREX was brought over in three separate transfers. A first transfer of 18,000 liters, a second transfer of 38,600 liters of THOREX with water added to reduce its corrosion potential in Tank 8D-2, and a third transfer of 21,100 liters of a second THOREX dilution. In total, 98% of the THOREX waste was removed from Tank 8D-4 with the remainder left in the tank heel. The NOx monitor and corrosion probes in Tank 8D-2 indicated no significant increase in corrosion rate during the neutralization process. Following neutralization, sodium nitrite was added to Tank 8D-2 to minimize pitting corrosion that could result from the large amount of nitrates in the THOREX.

THOREX/PUREX Wash Processing

After mixing the contents of Tank 8D-2: washed PUREX sludge, sludge wash, THOREX precipitates, and THOREX solubles; the liquid THOREX/PUREX wash was processed through the IRTS. From January to May, 1995, 1.19 million liters of the THOREX/PUREX wash solution, containing 300,000 curies of cesium-137 at a 250 Ci/ml concentration, were decontaminated using 1,600 kg of UOP IE-96 and 1,600 kg of TIE-96 zeolite. The decontaminated THOREX/PUREX wash was concentrated to 20 to 29 wt% TDS in preparation for solidification in cement.

A new Type V portland cement-waste form for the THOREX/PUREX wash was developed and tested. Test data indicated that the waste form immobilizes the heavy metals; specifically barium, cadmium, chromium, mercury, selenium, and silver; so that the waste is classified as RCRA nonhazardous. Additional qualification tests were performed to demonstrate that the resulting cement-waste meets NRC requirements for LLW stability. Actual post-production waste analyses indicated that nearly all of the drums of solidified THOREX/PUREX wash meet 10CFR61 criteria for Class A LLW. This is attributed again to the effectiveness

of the alkaline wash of Tank 8D-2 to precipitate plutonium and the adsorption capability of the UOP TIE-96 zeolite in removing strontium and plutonium from the wash solution, in addition to cesium removal. Approximately 1,450 270-liter drums containing 46 curies of cesium-137 were produced from the decontaminated THOREX/PUREX wash concentrates, bringing the total number of drums stored on site in the DC to approximately 19,900.

Zeolite Mobilization and Transfer

The last pretreatment operation has been ongoing at the WVDP from July, 1995 to January, 1996. The 65,300 kg of zeolite stored in spare HLW Tank 8D-1 have been mobilized with five 150-hp mixing pumps installed in the tank. Once fluidized, the zeolite slurry was pumped from Tank 8D-1 through an in-line grinder that size-reduced the 20 to 50 mesh (840 to 300 microns) zeolite size to approximately 50 microns or less before the slurry was added into Tank 8D-2 and mixed with the PUREX and THOREX sludge. Once a zeolite transfer was completed, Tank 8D-2 liquid was then decanted back to Tank 8D-1 to aid in mobilizing and transferring the next batch of zeolite slurry to Tank 8D-2. Fifteen zeolite transfers have been accomplished with an estimated removal of 85-91% of the original zeolite stored in Tank 8D-1. To accomplish this, over 14 million liters of zeolite slurry have been transferred from Tank 8D-1 to Tank 8D-2. The amount of zeolite transferred has been estimated by the use of radiation probes placed along the transfer piping within the trench and video inspections of the heel remaining in Tank 8D-1. The amount of zeolite removed from Tank 8D-1 greatly exceeds the required quantity to begin HLW vitrification. Although zeolite mobilization and transfer are complete, additional flushes of Tank 8D-1 are scheduled to be performed in parallel with HLW vitrification to further remove zeolite from the tank heel.

SUMMARY AND CONCLUSIONS

The WVDP has completed its high-level radioactive waste pretreatment program begun in 1988. The pretreatment process consisted of four distinct phases: PUREX supernatant processing, sludge washing, THOREX waste neutralization and washing, and zeolite mobilization and transfer. Pretreatment of the HLW was specified to separate the majority of the radioactive species from the nonradioactive salts, specifically those of sulfate, in order to reduce the total volume of HLW glass.

The pretreatment process for the first three phases was similar. The HLW supernatant from the PUREX waste, sludge washing, and neutralized THOREX waste was processed through the STS where the cesium-137, and later the plutonium and strontium-90, radionuclides were adsorbed onto the zeolite. This system effectively removed these radionuclides, thereby providing decontamination factors of at least 1,000 for cesium-137 and approximately 10 to 100 for plutonium and strontium-90. The spent zeolite was stored in a spare HLW tank until later in the pretreatment process. The resulting decontaminated salt solutions were then volume-reduced by a steam-fed evaporator in the LWTS. The concentrated, radioactive mixed waste was blended with portland cements and special additives in the CSS that employed high-shear cement mixers. Specially constructed 270-liter square drums were filled with the cement-waste that met the NRC stabilization criteria for Class B and C LLW, as well as the EPA and NYSDEC Toxicity Characteristic Leaching Procedure (TCLP) requirements for heavy metals. Approximately 19,900 drums of four different stabilized cement-waste recipes; each meeting 10CFR61 criteria for Class A, B, or C

LLW; have been produced and are currently stored in the remotely operated DC awaiting final disposition. Table V presents IRTS processing totals.

Table V

The last pretreatment phase consisted of mobilizing approximately 85-91% of the 63,300 kg of zeolite stored under water in the spare HLW tank, size-reducing the particles from the original 570 m size (20 to 50 mesh) to less than 50 m, and transferring the slurry into the original HLW tank containing the washed sludges. The size-reduced zeolites have been blended with the sludges to form a homogenous HLW feed for the Vitrification Facility. The projected composition of the resulting HLW liquid phase is shown in Table VI.

Table VI

Many challenges presented themselves during the pretreatment of the HLW which led to the development of major technical innovations, including:

Development of cement-wastes that met increasingly more stringent stabilization requirements.

First use of square drums to minimize the size of the Drum Cell.

Design, fabrication, and use of specialized remote tooling to repair process equipment within HLW tanks where radiation fields range over 1,000 R/hr.

Development, commercialization, and use of the UOP IONSIVR TIE-96 zeolite that removes plutonium and strontium, as well as cesium. This allowed production of a LLW cement-waste having much lower concentrations of these radionuclides.

The use of fully remote drum handling and bar code tracking systems in the CSS and Drum Cell.

Safely neutralizing the acidic THOREX waste in the primary carbon steel HLW tank using in-tank corrosion probes and a NOx analyzer to monitor the process and ensure minimal corrosion.

Increasing the capacity of the existing Drum Cell from 17,700 to 21,200 drums by modifying hardware and software systems.

Removal of the zeolite from the spare HLW tank after up to seven years of storage in an alkaline environment.

Through innovative engineering and disciplined pretreatment operations, these and other challenges have been met and solutions achieved. Over 6.6 million curies of cesium-137 were removed from the HLW liquid and adsorbed onto the zeolite. The original two million liters of PUREX waste and 31,000 liters of THOREX waste have been processed to produce a slurry of approximately 1.1 million liters that contains washed sludge and size-reduced zeolite. The decontaminated salt solutions produced 19,900 cement drums, collectively containing 570 curies, for an average cesium removal efficiency of over 99.99%.

The WVDP Pretreatment Program has been completed and the accomplishments over the last seven years illustrate that HLW processing can be safely and successfully managed. In addition, the pretreatment processing is a success in that the WVDP cement-wastes have met commercial NRC stabilization requirements, and the heavy metals in the wastes have been immobilized below EPA and NYSDEC TCLP limits, producing RCRA nonhazardous wastes.

UNIQUE DESIGN FEATURES OF THE WEST VALLEY DEMONSTRATION PROJECT VITRIFICATION PROJECT

David K. Ploetz

Joseph J. May
US DOE - West Valley Area Office

ABSTRACT

The West Valley Demonstration Project (WVDP) has designed, built, tested, and operated a process for vitrifying high-level radioactive waste (HLW) in borosilicate glass. Components, systems, and facilities were designed to take advantage of commercial nuclear experience, control cost and schedule, maximize utilization of existing facilities and systems, and integrate functional requirements with the Project mission to vitrify the HLW as safely, quickly, and cost effectively as possible.

Unique design features which were developed for overcoming constraints that could have impacted the success of the Project are discussed. Among these constraints were limited space, the utilization of existing facilities, short operating life, cost minimization, and conversion from a pilot plant test facility to a remotely operated radioactive production facility.

BACKGROUND

At the WVDP, final preparations are underway for solidification of high-level radioactive waste (HLW) into borosilicate glass in the Vitrification Facility. The fundamental functional requirements for the WVDP Vitrification Project are comparable to those for vitrification projects at Savannah River's Defense Waste Processing Facility (DWPF), Japan's Tokai Vitrification Facility, and England's Sellafield site. However, differences in radioactive waste composition, operating schedules, budget constraints, facility size, and reuse of existing facilities, when combined with the ingenuity and creativity of design engineers, have resulted in the creation of many unique design features at the WVDP Vitrification Project. This paper describes a few of these unique design features.

VITRIFICATION FACILITY

It is often said that "Necessity is the Mother of Invention." In this regard, the Vitrification Facility provides fertile grounds for the growing and harvesting of fresh new ideas. Constraints placed on the design by a process that must be remotely operated, coupled with a number of diverse tasks that are involved in the production of vitrified HLW,

require the design engineer to develop innovative solutions to meet a wide variety of functional requirements.

The structure of the Vitrification Facility presents a case in point. Constructed in 1984 as a test stand for hands-on testing of vitrification equipment components, it was designed to be converted into a shielded, remotely operated facility for solidifying highly radioactive waste in borosilicate glass. The conversion process was started in 1989, after five years of nonradioactive testing. As part of this conversion, seven wall modules, which include all piping and electrical penetrations, were fabricated by an off-site vendor. The wall modules varied in size, with the typical module measuring 4.7 m wide by 7.1 m high by 1.2 m thick. Wall modules were installed into the Vitrification Facility using the same 25-ton overhead bridge crane that is being used for remotely operating the vitrification process. Using the inside stainless steel liner of the wall module as a concrete form, plasticized concrete mix was then pumped into the wall modules for shielding.

The use of these module units permitted testing of the melter in conjunction with the conversion of the Component Test Stand (CTS) into the Vitrification Facility shielded structure. In addition, accurate location of penetrations could be assured to support the fabrication of remote connection pipes or jumpers. This approach reduced the overall construction schedule by over six months.

Beyond the Vitrification Facility itself, there are a number of unique design features associated with the vitrification process equipment. A sampling of these unique design features follows:

Canister Lid Welder

The purpose of the canister lid welder is to achieve leak-tight canister closure after the canister is filled with HLW glass. A process called pulsed Gas Tungsten Arc Welding is used to weld the 16-inch diameter lid onto the canister without the use of filler metal. The welding machine, which is typically used for fully automated welding in the automotive industry, was adapted for remote operations in the WVDP Vitrification Facility (see Fig. 1). The effects of varying the primary process parameters of current, voltage, and travel time were characterized during early developmental testing by welding lids onto canisters or canister mockups and then hydrostatically burst-testing the canisters. Five welded canisters that were dropped from a height of 7 meters at Battelle Pacific Northwest Laboratory successfully passed subsequent helium leak testing.

Different remote tools have been developed for aiding the canister lid weld process. One of these tools, the flange conditioning tool, consists of an end mill and a wire brush, both of which are mounted on a carriage assembly. The flange conditioning tool can be used to clean the weld surface, perform local excavation for repair of nonconforming welds, or mill a groove for welding on a secondary canister lid, if a satisfactory weld of a primary lid is not possible.

Fig. 1

Evacuated Canister

The purpose of the evacuated canister is to allow the remote removal of radioactive molten glass from the melter during a planned melter shutdown. An L-shaped stainless steel dip tube (four inches in diameter), sealed at one end with an aluminum plug, is inserted into the molten glass in the melter. The aluminum plug melts after 3 to 8 minutes and the molten glass is then sucked into the canister by vacuum. The evacuated canister fills to approximately 85 percent full in 15 minutes with molten

glass that is initially at a temperature of 1150C. Surface temperatures on the outside of the evacuated canister approach 900C during the filling operation. A photo of the evacuated canister appears in Fig. 2.

Fig. 2

Slurry-fed Ceramic Melter

High-level waste slurry is fed to the ceramic melter where it is first dried and calcined and then gradually mixed with molten borosilicate glass. Slurry-fed ceramic melters at DWPF; Tokai, Japan; Karlsrhue, Germany; and PAMELA in Belgium all have refractory-lined melting cavities that are joule-heated. However, these melters differ in the method of pouring glass (side versus bottom), number and type of pipe penetrations, method of power/temperature control, and method of viewing the melter cavity.

The first WVDP melter used during cold testing had Inconel pipe nozzles. Due to corrosion experienced during testing, ceramic (alumina) liners were added to the current melter design. During functional checkout, these liners cracked due to a combination of physical stresses, thermal shock, and thermal expansion. They were subsequently replaced with a second, redundant Inconel liner that employs a passive air purge to sweep corrosive gasses away from the Inconel melter pipe nozzles.

Viewing the inside of the melter is important whenever feeding slurry. The melter viewing system, which is functionally similar to a periscope, is used to determine the extent the molten glass pool is covered by a floating island of drying slurry and calcined solids called a "cold cap." Adjustments of slurry feed rate are made based on the size of the cold cap. A similar device is used to view the glass during pours from the melter into each canister. Based on watching the orientation of the glass pour stream on their TV monitors, operators can make adjustments in the rate of glass pouring and, if necessary, terminate an off-normal pour. Figure 3 shows the melter viewing system.

Another method used to control glass height in the canister is an Infrared Level Detection System. This system indirectly monitors infrared emissions from a thermally hot canister during and immediately after glass pouring. This same system has also been adapted for use at the DWPF based on successful test results at the WVDP.

Fig. 3

Off-gas Treatment

Originally designed as a passive scrubber for venting reactor containments, the Submerged Bed Scrubber has been adapted for use in the WVDP Vitrification Facility. Hot gasses from the melter are introduced below a bed packed with spherical ceramic beads. The hot gases are immediately quenched (cooled) by the scrubber solution. As the remaining noncombustible gasses rise, they also cause the scrubber solution to rise by an air-lift type effect. The emerging scrubber solution overflows into a collection tank and recirculates by gravity back to the packed bed. Accumulated solids are periodically removed by creating a swirling action and then jetting the solids back to the front end of the vitrification process for recycling to the melter.

Various oxides of nitrogen (NOx) are produced as the solids in the melter feed decompose in the melter. Although radioactive contamination in the off-gas is effectively removed by multiple stages of scrubbing and filtration, including the Submerged Bed Scrubber, the nonradioactive NOx gases still remain. As a final step in off-gas treatment, the NOx is reacted with ammonia at a temperature of 400C in the presence of a

catalyst to form harmless nitrogen and water vapor. Two parallel, redundant NOx reactors were installed in an existing shielded facility to reduce Project costs. The removal efficiency of the NOx reactors, based on actual operating conditions, exceeds 90 percent and fully meets regulatory requirements.

Remote Handling

Operating and maintaining the vitrification process equipment using only cranehooks, impact wrenches, and a limited number of manipulators presents many opportunities for custom-designing equipment to perform highly specialized tasks.

The Vitrification Facility has an "extra pair of hands," the Telerobotic Manipulator or In-cell Robot, that will be used in a support role to assist the cranes, impact wrenches, and manipulators in remotely repairing and decontaminating equipment. The In-cell Robot consists of a stainless steel torso housing on a hydraulic power unit and two 6-1/2 foot-long titanium arms. A photo of the robot appears in Fig. 4. The robot is deployed in the Vitrification Cell using the overhead bridge crane. The robot's gripper jaw hands can be exchanged with a drill motor or other end effectors. An umbilical cable attaches the robot to the control panel located outside the shielded cell. Movements by the operator are duplicated by the robot's corresponding arms/hands. Movements can also be preprogrammed into the computer, saved, and then repeated.

Fig. 4

Canister Decontamination

The exterior of the stainless steel canisters require decontamination prior to shipment to a federal repository. The canister decontamination system at the WVDP uses a dilute solution of nitric acid and cerium (+4) nitrate to chemically etch the exterior surface of the filled and sealed canisters. Laboratory and full-scale testing of this unique system has confirmed the effectiveness of the chemical reactions in removing a predictable amount of the canister's surface, along with any embedded surface contamination. The amount of material removed from the canister surface is controlled by altering the amount of cerium (+4) in the initial volume of decontamination solution.

While the cerium (+4) decontamination solution, followed by an acid rinse with 0.5 molar nitric acid, was effective in removing 3 to 5 microns of the surface material and completing the cleaning process, consistent cleaning of the canister dished-bottom was not initially accomplished. By modifying the surface finish on the bottom of the canisters, acceptable cleaning was obtained based on both appearance and a slight increase in the amount of material loss.

Canister Transfer

Selecting the site for the location of the Vitrification Facility was relatively straight forward. It lies in close proximity to the HLW Tank Farm and aligns with the existing plant's Chemical Process Cell (CPC) where canisters of vitrified HLW will be stored. A shielded tunnel connects the Vitrification Facility and the existing plant. But, there remained the question, how are canisters of vitrified HLW transported from the Vitrification Facility into the CPC? Both the Vitrification Facility and the CPC are remotely operated canyons. That is, they are equipped with remotely operated overhead cranes. One logical alternative considered was to extend the crane rails from the Vitrification Facility into the CPC. However, separation distance (22.86 m), space constraints,

and the prohibitive cost of extending the Vitrification Cell shield walls ruled out this option. A shielded cask transport truck, similar to that designed for use at the DWPF, was also considered but ruled out based on cost factors. Ultimately, a radio-controlled, transfer cart was designed, fabricated, and tested for the transfer of canisters of vitrified HLW from the Vitrification Facility to the CPC, as well as for transferring empty canisters into the Vitrification Facility.

The transfer cart is designed to move a load of four filled canisters with a combined weight of over 10 tons from the Vitrification Facility to the CPC. Additional provisions for handling loads up to 25 tons are provided by trailer carts to handle vessels and load test weights. The transfer cart travels a rail system that connects with the existing rail system in the CPC. The transfer cart's movement is interlocked with the operation of three separate shield doors to assure that the transfer cart cannot be moved when the shield doors are being operated and vice versa. The cart is battery-powered with no trailing umbilicals. The battery pack is automatically recharged, without removing it from the cart, as the transfer cart passes through the charging location. The transfer cart electrical/control system is modularized for ease of remote changeout.

Canister Load-in

The Canister Load-in Facility was designed to introduce clean, empty canisters into the Vitrification Facility. Clean canisters are removed from a custom-designed cargo trailer with pull-out storage racks. They are then placed horizontally on a roller conveyor and manually pushed through an opening in the shield wall. As the canister passes through the shield wall, it engages a tipper device. The canister is slowly uprighted from a horizontal to a vertical position. The rate of motion of the canister in the tipper is mechanically controlled by counterweights and pneumatic cylinders. After the canister is uprighted, a 10-ton overhead crane picks up the empty canister and places it in the transfer cart.

High-level Waste Interim Storage

The High-level Waste Interim Storage (HLWIS) Facility, formerly called the CPC, was part of the original reprocessing plant. It has been redesigned and retrofitted for temporary storage of the estimated 300 canisters of vitrified HLW that will be produced in the Vitrification Facility. On-site interim storage of the vitrified HLW is necessary until the designation of a federal repository. The HLWIS Facility provides significant radiation shielding and cooling to maintain the centerline temperature of the borosilicate glass in the canisters below the repository limit of 400C. A systematic study was performed to evaluate the options for HLW interim storage and identify a cost effective alternative that meets WVDP's needs and requirements. Cost estimates for designing and constructing a new shielded storage facility were compared with the costs of upgrading operations and maintenance of the existing plant buildings. The CPC meets technical requirements for radiation protection, remote handling, transfer of filled canisters into the CPC, and eventual shipment of canisters. Adapting the CPC for interim storage of vitrified HLW canisters was a cost effective and technically feasible alternative for the WVDP.

Twenty-two canister rack storage modules and 1 cooler support module were fabricated at an off-site vendor. Each canister storage rack, consisting of a bottom module and top module, is 6.09 m long, 1.52 m wide, 5.18 m high and weighs approximately 8.5 metric tons. The racks were preassembled off site to assure that they could be remotely installed in

the CPC. After preparations in the CPC were completed, the modules were moved into the CPC on a cart and remotely stacked two-high using a 16-ton overhead crane. All of the racks were remotely joined, after placement, with high-strength pins using a specially designed impact wrench attached to the power manipulator tubes to form a continuous structure.

Each HLW glass canister initially gives off approximately 300 watts of decay heat. The canister storage rack modules are designed to facilitate passive cooling of the canisters through natural convection to maintain the glass centerline temperature below 400C. The sides of the racks are open and vent holes are cut underneath each canister's storage location. As an alternative, two cooler modules are also installed in the CPC. These cooler modules are designed to force cool air throughout the canister rack assembly to cool the canisters and ensure a uniform temperature distribution in the CPC.

A 16-ton overhead crane is used to remotely remove canisters from the transfer cart and install the canisters in the canister storage racks. To allow recovery from a failed crane hoist, a Load Lowering Device was designed and fabricated. This device allows a canister to be safely lowered in the event the hoist becomes inoperative. The Load Lowering Device works entirely on mechanical principles. There are no electric control devices. The rate of descent of the canister is governed by a gear reducer coupled to a fan blade. As the canister descends, the fan rotates. The resistance the fan blade encounters in moving the air governs the fan speed which, in turn, controls the rate of canister descent.

CONCLUSION

Radioactive vitrification operations are scheduled to begin in June 1996, with the entire production campaign scheduled to last about two and one-half years. All functions of the components and facilities directly related to glass production will be performed remotely. The features discussed in this paper are just a few examples of the unique designs developed to integrate these converted facilities for radioactive operations and canistered waste storage.

VITRIFICATION SYSTEMS TESTING TO SUPPORT RADIOACTIVE GLASS PRODUCTION AT THE WEST VALLEY DEMONSTRATION PROJECT

Steve M. Barnes
Vijay Jain
West Valley Nuclear Services Co., Inc.

ABSTRACT

Vitrification technology to immobilize the High-level Wastes (HLW) in a stable and nondispersible form has been successfully demonstrated, using

nonradioactive waste simulants, at the West Valley Demonstration Project (WVDP). This conclusion is based on a five-year test campaign, using prototypes of the major, full-scale process vessels and components planned for use during radioactive operations, and smaller scale flowsheet experiments. This experience provides high confidence that the radioactive glass production demonstration will be safely completed.

A series of potential waste-form compositions, based on borosilicate glass formulations, were tested against the Department of Energy Office of Environmental Management Waste Form Acceptance Product Specifications (EM-WAPS). (1) Based on the results of these tests, a target composition (termed Ref. 6) was selected for the radioactive vitrification campaign. This composition meets all of the acceptance requirements for eventual disposal in a deep, geologic repository.

This paper discusses the bases for the selection of the target glass composition and the verification that the process flowsheet produces an acceptable product. The data are based on both the full-scale tests, that produced approximately 150,000 kg of glass during 37 individual tests using simulated high-level waste, and small melter experiments. The one-eighth scale vitrification system was operated for eight months to further enhance understanding of the process chemistry, develop a feed make-up strategy and establish redox controls for the melter.

INTRODUCTION

Vitrification technology, ranging from the waste-form composition to the equipment needed to produce canistered waste forms, has been developed and tested for immobilization of the HLW stored at the West Valley Demonstration Project (WVDP). This waste was generated by the commercial reprocessing of 640 tonnes of reactor fuel at the Western New York Nuclear Services Center.(2) At the inception of the WVDP, two wastes were stored in underground tanks. The majority, 2,300 m3, was neutralized PUREX waste. Another 40 m3 of partially processed THOREX waste was also stored. The PUREX waste was washed to minimize the sodium and sulfate salts to be vitrified.(3) The original PUREX supernatant and wash solutions were decontaminated using a zeolite ion-exchange process to retain the cesium. Presently, the PUREX, THOREX and zeolite wastes have been combined, ready for vitrification.

As the previtrification waste treatment activities progressed, the facilities and equipment needed to solidify the waste in glass were installed.(4) In parallel, a borosilicate glass matrix, tailored for deep geologic disposal of the West Valley Site wastes, was developed and tested. The glass waste-form development and nonradioactive vitrification process demonstration activities are described in this paper.

WASTE-FORM DEVELOPMENT

As discussed above, the WVDP high-level wastes have been pretreated and combined, forming a single stream to be vitrified. The estimated composition of the individual wastes and the blended stream are shown in Table I. In addition to waste chemistry, the radionuclide content has also been characterized. The estimated activity of the combined wastes, decayed to a 1996 basis, is listed in Table II. These waste composition and activity data were the basis for developing a glass matrix to immobilize the West Valley HLW.

Table I

Table II

Two sets of glass properties formed the acceptance criteria as the waste-form composition evolved: the waste glass had to be processed using

demonstrated technology and it must have high leach resistance as measured by the Product Consistency Test (PCT) protocol. (5) The processability criterion required that the waste form be produced in a joule-heated melter using Inconela electrodes. This implies an oxidizing glass melted at a maximum average temperature of 1150C.

To assure that the glass was consistent with this technology, viscosity, electrical resistivity and liquidus temperature limits were established. These glass property limitations are shown in Table III.

Table III

To achieve the second glass development measure, PCT performance, the candidate waste glass leach rate must be lower than a glass standard. More specifically, the target glass composition performance has to be statistically demonstrated to be superior to the EA6 glass using the PCT. This performance criterion is stipulated by the EM-WAPS. (1) In order to assure a high quality waste form, this criterion was internally increased to require the glass to exhibit stable, low leach rate performance for a period of at least 28 days rather that the seven day period specified by the PCT procedure.

Using these waste-form composition selection criteria, a series of reference glasses evolved, (7) as shown in Table IV. The Ref. 6 glass formulation was ultimately selected as the final waste form using the criteria discussed previously. The measured processing characteristics of the Ref. 6 composition are listed in Table III. The major chemical additions needed to convert the blended HLW into the Ref. 6 waste-form are listed in Table I.

Table IV

VITRIFICATION PROCESS DESCRIPTION

The vitrification process can be separated into three phases: tailoring the waste slurry by adding glass-forming chemicals to achieve the desired composition, melting the waste slurry and casting the glass into canisters, and closing the canistered waste-forms. The overall process is shown in Fig. 1 and each of these phases are discussed in this section.

Fig. 1

The initial step in the vitrification process is pumping a batch of waste slurry from the storage tank to the Concentrator Feed Makeup Tank (CFMT) in the Vitrification Facility. Approximately 100 batch transfers will be required to process the HLW inventory. At the CFMT, the waste is sampled and concentrated by evaporating water from the slurry. Chemicals are added to the CFMT, based on the waste sample analysis results, to adjust the waste slurry to the Ref. 6 glass composition. Following confirmation that the desired slurry chemistry has been achieved, the slurried melter feed will be transferred to the Melter Feed Hold Tank (MFHT).

The second phase is initiated by pumping the waste slurry from the MFHT to the melter. At the melter, the remaining water is evaporated from the slurry and the waste fuses with the glass-forming chemicals producing the Ref. 6 product. Molten glass is periodically poured from the melter into 3 m tall by 0.6 m diameter stainless steel canisters. After the glass solidifies, the canisters are routed for closure, decontamination and on-site storage.

In the final process stage, the canisters are closed by welding a lid over the top opening. The welding technique is an automated, autogenous, pulsed gas tungsten arc welding process. (8) Following a visual quality verification inspection of the closure weld, the canisters will be decontaminated using a acidic, cerium-based, chemical oxidation

procedure. (9) After decontamination, the canistered waste-forms will be stored on site until they can be shipped off site to a Federal Facility for storage or disposal.

VITRIFICATION PROCESS TESTING

The WVDP vitrification process testing has been performed at scales ranging from full-sized production equipment to examine the interaction between the various unit operations, to bench-top procedures for studying process chemistry and waste-form performance issues. This section summarizes several of the test programs needed to develop the vitrification flowsheet or generate waste acceptance data required by the Department of Energy (DOE).

The full-scale vitrification process was tested using nonradioactive, simulated wastes at the West Valley Site from 1984 to 1989. (10) This testing developed the operating parameters and generated the waste-form acceptance data required by the DOE Office of Civilian Radioactive Waste Management. (11) The full-scale campaign, summarized in Table V, represents a significant step in the understanding of HLW vitrification processes. In fact, the quantity of glass melted during this testing represents approximately one-third of the total waste glass production planned during radioactive demonstration. The later stages of this testing sequence demonstrated that the Vitrification System consistently produces canistered waste-forms with predictable chemistry and properties. This was a milestone toward establishing that the radioactive waste glass product will meet or exceed all of the DOE acceptance criteria and was key to enabling the WVDP to be the first site to obtain DOE acceptance of its Waste Form Qualification Report (WQR) in August, 1995. As the WQR presents the data needed to demonstrate compliance with the DOE waste-form acceptance requirements, its completion is one of the most important accomplishments in the progression toward authorization for the radioactive demonstration campaign.

Table V

The full-scale testing also confirmed that controlling the oxidation state of the melt pool is an important process parameter for wastes containing multivalent elements. The oxidation state in the melt is inferred by measuring the ratio of ferrous to ferric ions in the glass. If the melt becomes too oxidizing (Fe+2/Fe+3 0.01), a stable foam layer develops at the glass surface, diminishing the glass production rate. Alternatively, if the glass becomes overly reduced (Fe+2/Fe+3 > 1), electrically conductive phases precipitate from the glass that interfere with the electrical current flow within the glass pool.

To avoid these extremes, a desired operating range of 0.05 Fe+2/Fe+3 0.5 was established to achieve optimum processing conditions. As there is no on-line method for determining this ratio under radioactive operating conditions, a function was developed to relate the glass oxidation state to the concentrations of the oxidizing and reducing species in the melter feed slurry.(12) This function, termed the Index of Feed Oxidation (IFO), is defined as:

Eq. 1

where [NO3] is the feed concentration of nitrates, f is the slurry solids fraction and [TOC] is the feed concentration of total organic carbon. The correlation between the IFO and the logarithm of the iron ratio data measured during the full-scale campaign is shown in Fig. 2.

Fig. 2

Nonradioactive waste glass melting operations resumed in early 1995, using a one-eighth scale melter, to augment the training of the radioactive campaign operating staff. One objective of these tests was to confirm the IFO functional response using an updated simulated waste. These tests showed that the glass oxidation state responded more rapidly to IFO changes than before, as shown in Fig. 2. The difference was traced to the presence of nitrite salts in the revised waste simulant. The nitrite salts are now included in the simulated waste to reflect the decision to add sodium nitrite as a waste tank corrosion inhibitor. Using the revised iron ratio response curve, and accounting for differences observed previously between the full-scale and mini-melter systems (13), a target IFO value of 3.0 was selected for the full-scale Vitrification Facility startup tests. This IFO value has consistently produced glass with a Fe+2/Fe+3 ratio of 0.1 to 0.15, which is well within the desired oxidation state range.

Laboratory experience has shown that both reducing the oxidation state of waste glasses or slowly cooling them can affect the PCT measurement. Crucible tests were performed with Ref. 6 glass to verify that neither of these variables significantly affect the PCT results, relative to the EA glass standard. Results from PCT testing of Ref. 6 glass, reduced to an iron ratio of 0.3, and heat-treated for extended periods at 800, 700 and 600C are listed in Table VI. The actual canister centerline temperatures are in the 800C temperature range for less than a hour, the 700C range for approximately three hours and the 600C range for five hours. These heat treatments produce less than 4.5 volume percent crystals in the glass, as measured by x-ray diffraction. The table clearly shows that these processes have only a minor effect on the PCT response of the Ref. 6 glass with respect to the EA glass acceptability standard.

Table VI

The PCT testing described thus far was performed using the correct glass chemical formulation, generally with nonradioactive isotopes of the elements. Given the vitreous nature of glasses, potential damage to the waste-form matrix from radiation exposure is not expected to impact the PCT performance. To enable the DOE to perform relevant glass performance studies with the actual WVDP waste-form, WVDP waste samples have been melted to form Ref. 6 glass at the Pacific Northwest Laboratory Materials Characterization Center. This glass will be shipped to the Argonne National Laboratory for inclusion in their long-term glass performance testing program.

CONCLUSION

In summary, we have successfully demonstrated the performance of the technology and process for transforming simulated waste slurry into a canistered, borosilicate glass waste-form. Based on the one-eighth scale melter data, the IFO of 3.0 was determined to be an optimum condition for melter operation. This determination was confirmed using the full-scale system during Vitrification System startup testing.

The WVDP testing has also shown that the target glass composition, Ref. 6, meets all of the acceptance requirements for a geologic repository. Crystallization remains low in this formulation under very slow cooling conditions and this minor devitrification does not affect waste-form leachability. The PCT leaching data on the target glass are almost an order of magnitude lower than the DOE acceptance standard specified in the WAPS. Under all process conditions, the viscosity and electrical resistivity of the glass is within the processing range and has been

shown to provide adequate melting and production rates in the full-scale production melter.

This data has enabled official DOE acceptance of the WVDP Waste Qualification Report. Following successful completion of the Operational Readiness Review Process, the West Valley Vitrification System will initiate fully radioactive operations.

START-UP/TESTING OF VITRIFICATION AT THE WEST VALLEY DEMONSTRATION PROJECT

Clifford J. Winkler
West Valley Nuclear Services Company, Inc.

ABSTRACT
The West Valley Demonstration Project (WVDP) vitrification start-up effort, like other start-up efforts, transformed many challenges into success stories. An integrated schedule, in conjunction with regular meetings to resolve issues, kept the start-up effort on track. The use of summary tables greatly facilitated overviews of the test program and enhanced its credibility. The WVDP used operators to perform the testing. This was the right decision for the WVDP due to the high degree of finesse required to operate the Vitrification Facility. The WVDP committed early in the test program to perform around-the-clock testing. This was a great way to jump start the test program. Portions of testing and construction were performed in parallel. Up front planning to facilitate parallel construction and testing was proven to be effective at the WVDP.

INTRODUCTION

The initial operation of major equipment and systems is always a challenge and the integration of systems to result in a fully operational facility is usually an even greater challenge. This paper will not dwell on the challenges of start-up; it will, however, present information with regard to the WVDP vitrification start-up program. Hopefully, readers can utilize this information to emulate some of the processes that went well at the WVDP. Specific solutions to problems will be presented. Start-up management will be discussed as well as the testing documentation. Finally, a critique of the key decisions will also be presented.

SPECIFIC PROBLEMS AND SOLUTIONS

This section reviews specific solutions to problems at the WVDP.

Melter Dry-out Improvements

Prior to heating up a ceramic melter, the refractory must be "baked" free of moisture. The previous WVDP melter was "baked" by flowing steam through the cooling jacket of the melter. The baking process for the current WVDP melter was substantially improved. The new process injected hot/dry air into the main melter cavity. This sounds like a minor difference, but it resulted in a 50% schedule improvement for the dry out -- a savings of two precious weeks in the schedule.

Like the Word "Temporary"

Commencing the start-up program as early as possible requires an evaluation of the cost and time for temporary equipment versus waiting for the permanent equipment. The WVDP discovered several opportunities in which substantial testing progress could be made with simple temporary measures. A very basic, temporary blower was used to simulate the permanent Off-gas blowers months before the permanent Off-gas blowers were ready for operation. The temporary blower provided the same flow rate and negative pressure as the permanent Off-gas blowers; therefore, the temporary blower was sufficient to commission the In-cell Off-gas equipment, verify tank-to-tank transfers at the design negative pressures, perform initial slurry testing, verify turntable in-leakage, and commission melter vacuum controls. This saved over a month in the schedule. Some small, temporary programs were used to check instrumentation and electrical inputs and outputs very early in the program. Load banks were used to checkout much of the electrical power system early in the program. For example, the start-up heater power system, discharge heater power system, main melter power supply, Off-gas heaters, and diesel generator were all commissioned early using load banks.

Alarm Management During Testing

One of the great challenges of start-up is to provide operators with accurate, relevant information. Obviously, alarm management is a very important part of the challenge. If left unchecked, nuisance alarms can easily deter proper response to important alarms. The WVDP implemented a program to inhibit alarms for nonoperating systems that utilized the control system's delete feature, as appropriate, and conditionalized alarms to the maximum extent practical. These efforts maintained the alarms in the Control Room at a level that permitted proper response. Inhibiting alarms was cautiously implemented. The establishment of correct criteria for obtaining permission to inhibit an alarm or group of alarms, mandating a daily review of all inhibited alarms, and properly using temporary plant modification procedures results in a safe, sound program.

Using the control system's delete feature was approached with even more caution than inhibiting alarms; but once the feature is properly understood, it makes perfect sense. The easiest way to explain the delete feature is with an example. Say, a pump fails and a low-pressure alarm results. The operator acknowledges the alarm and makes the appropriate alarm response. Upon investigation, the operator discovers that the pump requires repair. The operator then initiates the delete feature for the low-pressure alarm. The alarm will automatically be reset when an acceptable pressure is sensed in the system or, in other words, when the pump is fixed and is operational.

Conditionalizing alarms is activating alarms in accordance with the operating status of the primary component in the system. For example, if the HVAC fans are shut down, there will be a low-pressure differential across the filters. The purpose of this alarm is to indicate potential problems with the filter. At zero flow through the filters, the pressure differential will always be zero. Therefore, the alarm would be of no value and should not distract the operator from other important information.

Through much of the test program, the WVDP was able to manage alarms to a degree that a day's (24 hours) listing of alarms was less than a page.

Level Detection in a Slurry

This problem was actually solved during an earlier melter testing period at the WVDP. Current testing verified that the solution was and remains a good one for an age-old problem. The engineers involved in solving this problem researched many sophisticated level-detection devices before settling on a simple device. The level-detection instruments in the slurry tanks at the WVDP are bubblers. As might be expected, the major problem with bubblers in a thick slurry is that they become plugged. The solution is simple: unplug them while they are easy to unplug. The WVDP bubblers are serviced with air, water, and steam blowdown capability. The air and water blowdowns are automatically performed at predetermined frequencies. Steam is available when more aggressive cleaning is required.

Managing a Short-term Hazardous Waste Stream

In the WVDP vitrification system, the waste is concentrated (boiled) prior to glassmaking operations. The 15,000 liters of condensate produced during each batch of waste will be directed to the installed, low-level waste treatment system once radioactive system tie-ins are made. During testing, this condensate needed to be collected and disposed of using an alternative method. Even though the fluid was condensate, it was

characterized as hazardous wastebased upon pH and the potential for hazardous metals. The first step in implementing the alternative method for waste handling was to modify an existing tent so that it could accommodate two 30,000-liter tanker truck trailers. A working tanker and two spares were determined to be necessary due to the aggressive testing schedule and the need to ship out waste as soon as possible. An inflatable berm was purchased and installed, and a temporary delivery system was designed, installed, and connected to the tankers. The company that provided the tankers was also a waste disposal company; therefore, the contract was written to include provisions for them to transfer the contents to another tanker for off-site shipment. This solution was simple and quickly implemented, and just as simple and quick to decommission.

Progressive Levels of Difficulty

Progressing from simple tasks to more difficult tasks is a basic practice. It worked so well at the WVDP that it is worth discussing. We have heard over and over again, learn to walk before you run. The WVDP test program adapted this philosophy and started with the basics, then progressed to increasingly difficult operations. Calibrations, component testing, and commissioning of utilities led to system testing with water and control system testing. Once systems passed the water testing, testing with slurry was initiated. After slurry testing was completed, integrated testing was initiated. Simple, but effective!

MANAGEMENT SYSTEMS

Agility is one of the key words for success in the '90s. The need for agility was realized throughout the start-up effort at the WVDP. Just about the time a new strategy was implemented and starting to work smoothly, circumstances required that it be thrown out for an even newer strategy. Strategies required changing as the Facility ownership transitioned from construction to testing and changed again as Facility ownership transitioned from testing to operations.

The initial start-up efforts were performed by a small engineering group. This group had previously supported full-scale melter testing. Several test engineers were hired from U.S. Navy programs to supplement this small group. This single group directed the start-up testing of the Sludge Mobilization System (THOREX transfer and zeolite transfer were accomplished using this system) and vitrification's Cold Chemical Facility. As the start-up effort began to grow, the testing organization was then substantially strengthened with the addition of managers, engineers, and operators from other areas of the site. This enhanced organization performed water testing, slurry testing, melter start-up, Ex-cell Off-gas system testing, HVAC testing, and integrated operations. A few changes were made internally to this organization to support changing needs. These changes were generally made as the needs for field engineering versus the needs for producing testing paperwork changed. The design organization spearheaded significant modification efforts during this period. The testing/operations organizations supported the design organization's efforts with a team of engineers to facilitate lock-and-tag support and a team of engineers devoted to work group coordination. The majority of the modification work was performed by a time-and-materials contractor, though smaller, specialized contracts were written to handle several of the unique modifications.

One of the major tools used by the WVDP management team was coordination meetings. The meetings, in general, had very specific objectives and

appeared or disappeared as needed. Most of the meetings had a tie-back to the integrated schedule. In fact, my opinion is that the stronger the connection between the meeting and the integrated schedule, the more effective the meeting. The following discussion will timeline the key meetings. The WVDPstart-up effort can be divided into four major periods. They are:

1. Heavy construction, light testing
2. Heavy testing
3. Transition to operations
4. Operations proficiency, cell closure, hot tie-ins.

During the heavy construction, light testing period, a Plan-of-the-Day meeting and a Weekly Production meeting were the major meetings used by WVDP management to monitor and plan the start-up activities. The activities statused in the Plan-of-the-Day meeting were the activities from the integrated schedule due to be completed in the near term. The Weekly Production meeting looked ahead several weeks to identify and resolve items with unacceptable schedule float. The integrated schedule was updated weekly in support of the Weekly Production meeting. A weekly testing/operations interface meeting was also held to maintain a monthly testing plan. A senior and middle management meeting was held twice a week to facilitate resolutions to tough issues. This meeting was affectionately called the Barrier Busters meeting.

The heavy testing period required the formation of one additional meeting. A Preplan-of-the-Day meeting was developed to capture the overnight testing activities, plant status, items requiring repair, and to status construction interfaces. Also, the weekly testing/operations interface meeting transitioned into a daily construction, maintenance, operations, and testing interface meeting. This meeting gathered information to develop the worksheet for the next 24-hour period. Activities were listed in order of priority. Activities listed in this meeting were only those items requiring operator action. That is, testing and lock-and-tag activities. Construction submitted service requests during this meeting as the initiator to any operations activity required to support the construction activity. Test engineering support in the field was increased by a factor of four during this period to provide the required level of technical knowledge and to facilitate prompt resolutions to problems.

The transition-to-operations period continued in all the aforementioned meetings with the exception of the Weekly Production meeting. Changes occurred too rapidly for a weekly meeting to be beneficial; therefore, weekly meetings, such as the Weekly Production Meeting, were cancelled. Also, the Preplan-of-the-Day meeting was transitioned from a testing meeting to an operations meeting. An integrated operations run plan has become the controlling document for plant operations.

As this paper is being prepared, the transition-to-operations period is ending. Some activities of the operations proficiency, cell closure, and hot tie-ins period have started. A run plan will continue to control the operation of the plant. Longer range planning meetings are resuming.

In summary, the management tools transitioned from longer term during heavy construction and the initial testing efforts, to very short term during heavy testing, and then back to longer term for the operators' proficiency, cell closure, and hot tie-ins period. In other words, as the predictability of events decreased, the speed in which the organization addressed potential delays increased. For example, the number of

technical people in the field increased substantially during heavy testing. The time at which technical support was needed could not be predicted and the area of the plant which required technical support could not be predicted; therefore 24 hour-a-day technical support for all areas of the plant was provided.

TESTING DOCUMENTATION

System description documents were written for all the major vitrification systems. Included as part of these documents were the system/component test requirements. Test Instruction Procedures (TIPs) were written, based upon system description requirements, to direct and complete each performance test. The WVDP was aware of the fact that the test program required a high degree of credibility and outside reviewers would want some assurance that: all of the test requirements specified by the system description documents were met; the data from the tests were reviewed by the test engineer, system's engineer, and the Joint Test Committee; and all test results were found to be acceptable. To help achieve this credibility objective, the start-up test organization required a test results table be included at the end of each TIP. This table lists the test requirements, test results, name of the test engineer, name of the system engineer, and Joint Test Committee concurrence that the test results were satisfactory. Taking the credibility objective a step further, the start-up test organization developed a matrix that listed all the test requirements, the TIPs, and the dates that the TIP results tables were approved by the Joint Test Committee. All personnel assigned to review the test program were provided copies of the testing matrix and any test results tables as were requested. The start-up test program was found to be satisfactory by all of the reviewers.

HINDSIGHT IS 20/20

The following decisions were key to the success of the WVDP start-up program:

A. Using the WVDP operators to perform start-up testing.

B. Starting 24-hours-a-day, 7-days-a-week testing, even with a cushion of over one month of float in the schedule.

C. Testing in parallel with construction.

This section presents a critique of these decisions.

The major obstacle with using the WVDP operators for testing was that they were required to perform two critical priorities essentially simultaneously: training and testing. Testing is so demanding that tolerating delays due to Operations personnel performing training objectives becomes very difficult. On the other hand, it was apparent that the experience that Operations personnel gained during testing and by working through some of the testing problems was very valuable. Training cannot be complete until operators can demonstrate that they are proficient using complete and accurate operating procedures. Complete and accurate operating procedures, however, are not always available until system testing is complete and the procedure has been validated using the actual system. Therefore, a very strong argument can be made for testing with a contractor and then training the operators on a working machine with actual working documents. The missing part of the discussion, so far, is the finesse items: manipulator, crane, and Distributed Control System (DCS) operations. Productivity and efficiency on these items require more than a few pass-throughs under ideal or close-to-ideal conditions. Based on the WVDP start-up experience, start-up of a facility that does not require a lot of finesse to test and operate could be

effectively performed by a contractor. A facility, like the WVDP Vitrification Facility, which requires a lot of finesse should be tested and operated initially by the Operations personnel assigned to the facility.

Early in the WVDP test program, Operations announced a commitment to transform to around-the-clock shift coverage. Initially, start-up test engineering was concerned about this decision. How could our engineers support that much testing in the field when the need for test procedure writers was at a maximum? Could enough test paper be produced fast enough to avoid the phrase, "We're waiting on paper?" Test engineering started sprinting; that is, the cycle time for writing and reviewing test procedures was cut in half. This set the pace for the test program. What a way to jump start a program!

Performing work in parallel is one of the most common strategies for shortening a schedule. Also, allowances must be made to let Construction fix things during testing. Therefore, construction and testing must be performed in parallel and the only question remaining is how to accomplish both effectively. My answer to this question is that planning for parallel construction and testing needs to start at a project's conceptual design phase. At the WVDP, the sequencing of the Cold Chemical Facility, the main Vitrification Facility, and the Ex-cell Off-gas system facilitated parallel testing and construction activities. All projects fight to control the seemingly never-ending need for change and the management of punchlist items. The WVDP formed a middle management group to control changes. This group evaluated all changes to baseline documents against specific criteria and any change that did not meet the criteria was either cancelled or sent back for reevaluation.

CONCLUSION

Base the management of start-up activities on a good integrated schedule. Provide an easy method for reviewers to review your test program. Provide a fast pacesetter for your test program. Innovative minds will find a way to keep up. Facilitate parallel construction and testing at the conceptual design stage. And, finally, if your facility requires a great deal of finesse to operate, heavily involve the operators in start-up activities.

Session 18 -- FIFTY YEARS OF NUCLEAR WASTE MANAGEMENT POLICY AND PRACTICE I

Co-chairs: Stephen P. Cowan, USDOE
Ray D. Walton, Jr., ANL

18-1

THE DEVELOPMENT OF WASTE MANAGEMENT POLICY - AEC TO DOE

James E. Dieckhoner
BDM Federal, Inc.

ABSTRACT

The goal of the Federal government's policy for the management of radioactive waste from its nuclear materials and weapon programs was, and is, to protect the health and safety of those working in these programs, the members of the public and the environment. What has changed since the days of the Manhattan Project are the specific technical solutions pursued, the implementation schedules and the projected cost to the American taxpayer. Although some of these changes are due to non-technical and political issues, many have been the result of knowledge gained from research and development programs, scientific over-optimism,

and an unrealistic appreciation of the cost and schedule impacts of required stakeholder involvement.

The fundamental policy goal established at the outset of this activity, namely the protection of people and the environment from the real and potentially harmful effects of these materials, is still valid. But the challenge that faces the U. S. government, and all who are committed to the technically sound solution of this national problem, is to see that its implementation continues to be based on good science and sound public policy. This will only be possible if we work patiently, and relentlessly, with those in our government who bear the program responsibility and all other stakeholders, reserving our passion for the attainment of the goal, not for any particular solution, facility or schedule.

This goal of this paper is to review the development of waste management policy from the early days of the Atomic Energy Commission to the present. The current generation of policy makers, and their critics, will be greatly aided in their tasks if they have a general understanding of what events have occurred over the past half century which have led us to the current situation.

The past fifty years have clearly demonstrated that it has been far easier to get agreement on general policies than to get political and public agreement to actually implement the resulting permanent solution. This has apparently been true because policy is an internal decision within the government/technical community while implementation is an external decision involving many more players and is often more heavily influenced by non-technical factors.

OVERVIEW

The need to protect people and the environment from the potentially harmful effects of the products of nuclear development was recognized from the outset of the nuclear age. In the earliest days of the Manhattan Engineering District (commonly known as the Manhattan Project), and the basic research and development activities which preceded it, the scientists and engineers gained a healthy appreciation of the hazards inherent in what they were doing and applied what they believe were prudent management policies, based on the best information available to them. With the limited amount of available information expanding rapidly, and with the pressures of the political, military and security aspects of the nuclear program ever present, they did an excellent job.

With the creation of the Atomic Energy Commission (AEC) in 1946, and the end of the frenetic wartime rush to develop the atomic bomb, a conscious, serious attempt was made to establish an effective policy basis and specific implementation plans for the management of the growing volume and diversified spectrum of wastes being disposed of or being placed into engineered storage. The "Cold War" period did not bring the hoped for period of calm. Instead, it brought a continuation of a sense of urgency to the programs responsible for developing nuclear weapons, peaceful uses of atomic energy, and other applications of a rapidly growing nuclear technology to the AEC, the Energy Research and Development Administration (ERDA) and the Department of Energy (DOE).

These agencies were also responsible for continuing and improving the waste management programs started earlier. Their tasks became more difficult as the volume and variety of waste steadily grew, and the public interest in their work and public expectations similarly increased. Over the past fifty years, and especially in the past few,

much more previously classified information has been released to the public. During World War II and throughout the Cold War period, almost all information related to nuclear weapon production was closely guarded and certain waste management data fell into this category.

The various agencies created and recreated internal organizations specifically charged with the responsibility to establish sound policies and effective programs to carry these policies out (Fig. 1). Each reorganization was intended to better focus the growing level of resources, both in number of personnel and funding, to speed the program along and to improve the safety and efficiency of the activities. The agencies also had to implement bureaucratic procedures, arising from Congressional actions to assure that environmental, safety and health aspects were given adequate consideration in policy and programmatic decisions, and also to take into account and respond to the concerns and interests of potentially affected stakeholders.

Fig. 1

It is of little benefit to anyone to now attempt to judge past actions by the current state of knowledge of the health, safety and environmental impacts arising from the management of these wastes and other nuclear materials. If judging is the aim, then conclusions must be reached based on what was known at the time decisions were made. The goal of this paper is to review the development of waste management policy from the early days of the AEC to the present state of affairs within the DOE. This paper will briefly discuss the policy which was established by the AEC, ERDA or DOE and comment on the context in which it was established. Primary attention will be placed on the management of high-level waste (HLW), but transuranic (TRU) and low-level waste (LLW) management will also be discussed. The formal definitions of these waste types are shown on Fig. 2.

Fig. 2

The discussion will not be complete, that is a task of genuinely Herculean proportion. Additionally, it is not of great interest or import to ongoing public discussions of what is currently planned by the DOE. What is needed by the current generation of policy makers, critics and other commentors is a more general understanding of what has transpired in the U.S. waste management policy world over the past fifty years. Reference will be made to selected AEC, ERDA, and DOE documents which chronicle the development of waste management policy throughout the past fifty years. Hopefully, this discussion will promote a better understanding of the policy evolution that has occurred and put it into context, so the government, public and private sectors can rationally approach the creation of future policy. It must be clearly understood that policy and the means of implementing it are subject to a constantly expanding information base and impacted by change. Public policy and implementation methods must be subjected to periodic re-examination and all involved groups must retain an open mind about changes which reflect the latest and best information available.

WASTE MANAGEMENT UNDER THE AEC

The policy and related implementation decisions concerning HLW were first made by the AEC and, before its establishment in 1946, by the Manhattan Project. In the very beginning in 1942 there were few detailed health and safety requirements, but the HLW was clearly recognized as being extremely hazardous and the program took what was, at that time, considered to be a very safe approach. A few examples are the

establishment in 1950 of the "as low as reasonably achievable" principle, the setting of specific exposure limits for normal operations, and the decision to store rather than to immediately dispose of the most potentially dangerous liquid waste streams.

HLW was also seen as a valuable resource, due to the amounts of valuable uranium and plutonium contained in it. The waste was stored as a neutralized or basic solution in underground steel tanks, normally located within concrete vaults, with what were then considered to be appropriate environmental safeguards. This was the practice that was followed as the Hanford and Savannah River facilities were developed. In the 1960's the Idaho facility initiated stainless steel tank storage of acidified HLW, processing it into a solid form, and storage in large steel bins within concrete structures.

Research and development programs were started to focus advanced waste processing approaches to move from interim storage in buried tanks or bins to an approved final disposal facility. Within the interim storage programs at the several sites, designs progressed from single shell tanks to increasingly more secure versions (e.g. cup and saucer designs) leading to the current double shell tanks designs.

The AEC was assisted in its waste management program from 1955 to 1965 by the Committee on Geologic Aspects of Radioactive Waste Disposal of the National Academy of Sciences - National Research Council (NAS-NRC). The NAS-NRC served as advisors to the AEC's Division of Reactor Development and Technology (RDT), which was responsible for the AEC's commercial nuclear power program. The NAS-NRC's responsibilities were the geologic aspects of RDT's R&D program; however, they broadened their charter and considered all aspects of ground disposal of radioactive waste and drew conclusions on overall waste management practices.

In May 1968, the General Accounting Office (GAO) reviewed the AEC's HLW program (1) and concluded that the AEC "needed to devote more vigorous attention to advancing the technology required to permit long-term storage at its Richland and Savannah River sites." GAO also suggested that the AEC establish a Headquarters office vested with the responsibility for policy making and overseeing radioactive waste management activities. Such an office was established in the Spring of 1970, and has continued through many reorganizations to this day in both the Nuclear Regulatory Commission (NRC) and the DOE.

AEC policy recognized from the outset that the practices for handling HLW need not be uniform at all sites. This policy was confirmed by a Task Force established by the AEC General Manager in 1968. That Task Force's conclusions, which were subsequently approved by the Commission, stated that, in view of the differing nature and status of the programs, there was no need for uniformity between programs at AEC installations and those prescribed at the commercial facilities that were licensed by the AEC (2).

High-Level Waste (HLW)

The AEC defined HLW by reference to its origin (i.e. liquid waste from the processing of irradiated spent fuel, solid waste derived from those liquids, irradiated spent fuel which won't be processed, or materials with an equivalent hazard potential). This "genetic" definition of HLW, based on the process by which it was created, has effectively continued to the present time. This waste was normally generated at AEC facilities during the chemical reprocessing of irradiated production reactor fuel in order to recover the weapon grade materials and unused uranium. Similar

waste was also generated by the processing of commercial reactor fuel to recovery unused uranium for recycling back into the commercial fuel cycle. The volume of HLW generated and placed in storage grew during the peak Cold War years and then decreased and has effectively stopped. We are now left to contend with this backlog or "legacy" waste.

The basic 1968 AEC policy (2) for managing HLW was "... that all liquid high-level radioactive waste should be suitably contained with adequate provision for control or recovery in the event of leaks or accidental spillage." It should be noted that this policy has not materially changed in almost thirty years. The AEC policy further stated that "Storage of such wastes as liquid in storage tanks shall not be regarded either as disposal or as an acceptable practice for long-term handling; rather, waste management programs should provide for either a) reduction of such wastes to solid form for long-term storage, or b) transfer of such wastes to long-term storage in deep underground locations, either approach to provide high assurance of isolation of wastes from the biosphere, be resistant to credible internal or external forces, and not be dependent upon mechanical cooling methods. Unless the Commission authorizes an exception, such long-term storage methods should not preclude removal of the wastes from such long-term storage locations for relocation should such ever become necessary or desirable."

The GAO reviewed the AEC program again in 1971 and concluded "Although AEC has assigned a high priority to radioactive waste management problems, GAO believes that the level of effort given to these programs should be increased in view of their extraordinarily complex characteristics. The problems and delays being experienced are attributable primarily to a need for definitive technology and such matters as the relative merits of alternative practices and proposals for interim and long-term storage."

These policies and planned implementation programs were contained in the 1973 Plan for the Management of AEC Generated Radioactive Waste (3). The plan guided the field offices in updating their individual waste management plans and their budget requests to implement the policies and planned programs defined in it. In addition to the policies discussed above (conversion to a solid form and isolation from the environment under all credible accident conditions with minimal reliance on perpetual maintenance and surveillance) the plan also established policies on the interim storage of liquid HLW in engineered storage systems, the requirement of retrievability, the need for spare tankage in case of leaks, and the need to reduce the volume in storage.

Low Level Waste (LLW)

The AEC defined low level waste (LLW) as basically all radioactive waste that didn't fit under the HLW definition (a definition by exception). Its disposal was to be by shallow land burial in a facility and geology which would isolate it from the general environment for its hazardous lifetime, assumed to be about 300 years. The facility was to be either on Federal or State owned property. Initially, the AEC accepted the small volume of LLW that was generated by the fledgling commercial nuclear industry. Starting in the early 1960s the AEC (and later the NRC) licensed six commercial low level waste disposal sites across the country, and the AEC even sent some of its waste to these sites. In the late 1970s ERDA stopped using the commercial sites and directed all ERDA LLW to its own disposal sites.

Transuranic (TRU) Waste

In 1970 the AEC defined Transuranic (TRU) waste, a new class of waste which required special management considerations. They defined TRU waste as LLW contaminated with long lived transuranic isotopes (primarily of plutonium and americium) at or above a 10 nanocuries per gram level. The primary isotope of interest was Plutonium-239 which had an approximately 24,000 year half life. The AEC directed that TRU waste should be packaged and stored for a minimum 20 year period in a retrievable manner for later disposal in a geologic repository which would isolate it from the environment over its hazardous lifetime.

WASTE MANAGEMENT UNDER ERDA

When ERDA was established by the Energy Reorganization Act of 1974, it assumed responsibility for the AEC's waste management policies and programs not given to the NRC, which was created at the same time. It continued the AEC policies and programs, but now with the increasing involvement of the Environmental Protection Agency (EPA) and the public, following implementation of the National Environmental Policy Act (NEPA) in 1970. NEPA required a much greater degree of openness and the disclosure of many aspects of waste management plans and operations which previously had been classified or closely controlled.

Major advances were made in the 1970's in implementing the programs for improving interim storage of HLW and the desired transition to the geologic disposal of stabilized, volume reduced HLW. NEPA-required documents were issued by each of the major ERDA sites detailing their specific plans. In 1976 ERDA issued "Alternatives for Managing Wastes from Reactors and Post-Fission Operations in the LWR Fuel Cycle" (4) which led to many fruitful technical and policy discussions, conferences and symposia.

High-Level Waste

No significant changes were made in either the policy or the routine implementation practices for HLW under ERDA. Progress was made in improving the safety of the tank stored waste through programs to reduce the volume and mobility of the waste by removal and evaporation of liquids and the isolation of the tanks to prevent the accidental addition of more liquids. Confirmed and suspected instances of tank leakage were dealt with and questionable tanks were emptied of removable waste. Additional double shell tanks were built and all newly generated wastes, and wastes removed from unsound tanks were routed to them for safe storage.

Low Level Waste

No significant changes were made in the definition of LLW or ERDA's management practices, but closer, cooperative ties were developed between ERDA's LLW operations and those of the commercial sector. In the 1960s and 1970s, both ERDA and the NRC, along with the EPA, supported the Waste Management Task Force of the Conference of Radiation Control Program Directors, a group of state officials responsible for regulation or oversight of the six commercial low level waste disposal sites. They provided a forum in which the states could benefit from the exchange of information from the experiences of the AEC and ERDA in LLW disposal since the Manhattan Project.

Transuranic Waste

Studies were made under ERDA to investigate and resubstantiate the threshold concentration level of transuranium isotopes in waste which defined it as TRU waste. After an extensive technical review, the concentration level was changed from 10 to 100 nanocuries per gram and

the formal definition change was issued by DOE in 1981. The management of TRU waste, along with commercial HLW, was discussed at length by ERDA in 1974 in WASH-1539, "Management of Commercial High-Level and Transuranium-Contaminated Radioactive Waste", a document that was widely reviewed and commented on by the technical community, industry and the public (5). Previous site-specific waste management activities certainly interested those communities and citizens in the immediate vicinity of the AEC/ERDA sites. However, these national programs (especially the nation-wide search for geologic repository sites which gained increased momentum in the middle 1970's) developed a broader audience of stakeholders interested in the ERDA's policies and programs for the long-term management of its still growing inventory of long-lived radioactive waste.

It was during the ERDA era (and the early days of the DOE) that the radioactive waste management program was broadened to include hazardous waste, and the complex problem of "mixed waste" first arose. Mixed waste is waste containing both radioactive materials (regulated under the Atomic Energy Act) and hazardous materials (regulated under the Resource Conservation and Recovery Act). ERDA was self-regulating for the radioactive component, but subject to regulation by the Environmental Protection Agency (or individual states) for the hazardous component. The jurisdictional issues associated with dual regulatory situation with mixed waste are still being sorted out.

WASTE MANAGEMENT UNDER DOE

In 1977, the Federal government again reorganized itself and formed the DOE. The search for a permanent organizational home, with the responsibility for establishing and executing DOE's waste management program, finally led in 1989 to the creation of DOE's Office of Environmental Restoration and Waste Management, later renamed the Office of Environmental Management (EM). The many attempts to document DOE's policies and plans to the public and other Stakeholders led to the creation of the annual Five-Year Plan, Site Specific Plans and Activity Data Sheets. The annual update to the Five-Year Plan has since been replaced by the Baseline Environmental Management Report (BEMR).

DOE also formed the Office of Civilian Radioactive Waste Management (RW) which was given the responsibility for the establishment of a disposal facility for HLW and spent fuel from the commercial sector. Eventually, the disposal facility will also accept DOE immobilized HLW. The RW program will be covered in detail in other papers.

During the same time period, the growing influence of the EPA and states, which had regulatory powers over some DOE operations, became major factors in the selection and implementation of the DOE waste management program. Under DOE, and earlier under ERDA, lawsuits became a popular enforcement tool and often led to government commitments to specific acts and remedy implementation schedules. The 1980 Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), the 1984 Resource Conservation and Recovery Act (RCRA), and the 1992 Federal Facility Compliance Act (FFCA) are examples of legislation which have often been the foci for actions against ERDA and DOE by EPA, the States and others groups and individuals.

DOE's response to these pressures has been to devote a much greater level of attention (and funding) being devoted to openness and proactive communications with stakeholders. DOE's attempts to understand and respond to the concerns of its critics, and the budget restrictions that

have developed as the EM program has matured, have contributed to some delays in implementation.

THE CURRENT SITUATION

After fifty years of dealing with radioactive waste management, these are the basic policies:

- HLW: The 1968 AEC policy (i.e. safe interim storage, volume reduced and immobilized waste form, leading to geologic disposal) is the basis for DOE's program.
- TRU: The 1970 AEC policy (i.e. retrievable storage leading to geologic disposal) is the basis for DOE's program.
- LLW: The AEC policy (i.e. near surface disposal in geologic media which prevents the transport of waste to the general environment, for its hazardous lifetime, on Federal or state land) is the basis for DOE's program.

The expected implementation dates for the geologic disposal of HLW and TRU waste have slipped significantly from the days of the AEC to the present and the estimated costs have grown enormously. 1996 should see the initial operations of two HLW vitrification plants at Savannah River and West Valley. The date for the opening of a geologic repository is another question, with perhaps as many political as technical issues involved. No one in 1960 would have believed the amount of money spent in the last 35 years to address the HLW disposal problem, and it's not finished yet.

The schedule for the geologic disposal of the government's TRU waste has also slipped and the estimated cost also continues to grow. The Waste Isolation Pilot Plant (WIPP) has yet to receive its first waste and may have to re-mine some of the underground space due to the schedule. No government officials now pledge to stay on the job until WIPP opens, as some did in the past. This is not said to criticize, but as a caution to all on underestimating society's inertia when it comes to making profound, long lasting decisions, such as the siting and operation of geologic disposal facilities for TRU waste which will long outlive the decision-makers.

The policy of permanently disposing of long-lived waste garners support from practically all reviewers. The decision to actually implement "permanent" solutions may cause many to pause and relook at these implementation plans. While everyone can understand, and to a small degree condone, this philosophy, eventually society must find the courage to act. If the policy is valid, society must not shirk from implementing it. The permanent geologic disposal policy is technically sound and also sound from a public policy perspective. It is now clearly time to move ahead and support the steps necessary to implement it. Forty years of R&D have increased our knowledge of how the waste and the environment will perform, and recent experience has shown us how to assure that responsible dialogue is conducted with the affected stakeholders.

BUDGET GROWTH AND SCHEDULE SLIPPAGE

In the 1974-1976 period two ERDA Task Forces were very instrumental in establishing a renewed interest in the entire waste management program issue. One led to the issuance of ERDA-33 "Nuclear Fuel Cycle", which resulted in bringing all aspects of the commercial nuclear fuel cycle under one organization head with the establishment of the Division of Nuclear Fuel Cycle and Production. The other led to the issuance of ERDA-48 "A National Plan for Energy Research, Development and Demonstration", which was required by the act which established ERDA and the NRC. This

report explicitly stated the urgency for resolution of radioactive waste management policies and practices for the commercial nuclear fuel cycle. The management of commercial wastes will be addressed by other papers at this conference.

The chronicling of the growth of the budget allocated to implement Federal policy for the management of its radioactive waste is not the primary purpose of this paper, but it is interesting to note what happened to the waste management budget in just the last twenty years. As discussed previously, very little has actually changed in the policies. What has happened has been an enormous attempt to implement both improved interim measures like storage and waste stabilization, conduct necessary R&D, and to initiate final disposal.

Twenty years is a good period to choose for this comparison. In 1976 a series of large, public meetings were held by ERDA to discuss the range of disposal options then thought to be worthy of consideration (including continental U.S. geologic options, sub-seabed disposal, ice cap disposal and even disposal in space). Several technical societies, such as the AIChE, the ACS and the ANS held topical meetings on various technical aspects of radioactive waste management at that time.

The FY 1976 waste management budget totaled $30.6M ($18.6M for ERDA waste and $12.0M for commercial waste). The FY 1977 budget represented an enormous increase to $90.3M ($30.3M for ERDA waste and $60.0M for commercial waste); almost a tripling of the budget in one year. The FY 1996 budget represents an almost one hundred fold increase. The FY 1976 budgets included funding for extensive R&D programs. The development program for four HLW processing technologies were to be completed between 1979 and 1981 and the resulting technologies were to be ready for commercial application between 1983 and 1985. In the HLW terminal storage program (now known as the Yucca Mountain Program), the site for the first of several pilot plants was to be selected by 1978 and begin operation by 1984. In the terminal storage for TRU waste (the WIPP program), the site was to be selected by 1977 and operations started by 1983.

Hindsight tells us that the technical issues facing both the Defense and the Commercial programs were underestimated and adequate thought was not given to how society was going to satisfy the valid interests of the many individuals and groups that these policies would touch. The ensuing twenty years has clarified the primary technical issues, and time has also helped develop an understanding of the value of openness and the rights of our citizenry.

CONCLUDING THOUGHTS

The technical policies and broad program goals for the long-term management of the waste from the Nation's nuclear weapon production and energy development activities have remained essentially constant for over thirty years. The plans for implementing those policies (i.e. the establishment of long-term disposal or storage facilities) have, unfortunately, languished and had tremendous increases in their estimated costs. 1996 will finally see two major advances in implementation of the program to dispose of HLW, the initiation of radioactive operations at the West Valley and Savannah River HLW vitrification plants. While a clear path or an early resolution to the commercial repository situation is not readily apparent, our Nation looks for steady movement leading to the start of waste receipts at the Waste Isolation Pilot Plant yet this decade.

What has been learned from the past fifty years of establishing and implementing policy is that it is far easier to obtain general agreement on what we want to do, than it is to obtain agreement on how to do it. The former decision is reached primarily on the basis of fact, good science and technical judgment. The latter decision has broader criteria to contend with than policy establishment. For the most part, policy is established within the system; decisions on implementation are made in the real world. Program leaders must recognize the fact that in addition to environmental criteria, valid criteria relating to economic, social, cultural and political factors will have an oftentimes controlling role to play. Sensitivity to these criteria will better prepare all of us to assist decision-makers in moving the system from considering implementation to actually doing it.

RADIOACTIVE WASTE MANAGEMENT IN THE U.S. - 1950-1970
AN OVERVIEW OF THE AEC PROGRAM AND R&D HIGHLIGHTS

Walter G. Belter
U.S. Department of Energy, Retired

ABSTRACT

After World War II, the "new world of atomic energy" and the development of peaceful uses of the atom were assigned to the newly formed Atomic Energy Commission (AEC). During the period of 1947-1970, one of the major AEC programs involved the development of nuclear power reactors under the Division of Reactor Development (DRD). A small group of sanitary engineers and scientists was formed within DRD to assist in the siting and operation of power reactors and the development of the Commission's R & D program in radioactive waste management and related environmental research.

During this period, numerous low-level waste (LLW) treatment systems were studied and used at AEC sites, with closely monitored discharges of liquid, solid, and gaseous effluents to the environment. During the 1960's, extensive laboratory and pilot plant studies were carried out at Oak Ridge and Hanford on advanced LLW treatment systems such as scavenging-precipitation ion exchange, foam separation, steam stripping, filtration, two-stage ion exchange, electrodeionization, water recycle, and asphalt solidification. Some of these systems have been used at commercial nuclear power stations. By the end of 1969, more than 20 years of high-level waste (HLW) tank storage experience had shown it to be a practicable means of interim handling. During 1950-1970, an extensive HLW solidification R&D program was carried out at 5 AEC sites; the program culminated during 1964-1972 with the installation of an engineering scale

Waste Solidification Engineering Prototype (WSEP) at Hanford. Three processes (the ORNL pot-calciner; the BNWL spray calciner-melter, and the BNL phosphate glass system) were demonstrated with full-scale radioactivity. Design concepts for a 5 tonne/day commercial reprocessing plant were developed for industrial application. Ground disposal research (1957-1970) for liquid and solid HLW was carried out in 1) bedded salt formations in Kansas; 2) impermeable bedrock at the Savannah River Plant; and 3) deep permeable formations (3,000-12,000 feet) containing connate brine.

INTRODUCTION

The nature of radioactivity as a potential hazard to man and his environment and the importance of satisfactory effluent control were recognized when the atomic energy program was conceived under the auspices of the Manhattan Engineer District in 1942. After World War II and the formation of the Atomic Energy Commission (AEC) in 1946, the initial AEC programs in radioactive waste management and related environmental research and development were planned and carried out under the Division of Engineering, which later became the Division of Reactor Development (DRD). The early programs, commencing in 1947, were formulated in the Sanitary Engineering Section (SES), under the direction and leadership of Mr. Arthur Gorman and Dr. Joseph Lieberman, Sanitary Engineers, with the author joining the program in 1957. Many exciting aspects of the program occurred during the 1960's. Because of time and space limitations, only highlights of radwaste activities across AEC for the 1950-70 period will be presented. Excerpts from the "author's archives", i.e., numerous papers, speeches, internal reports, and book chapters which were authored or co-authored during this time, form the major basis for this paper. The history of the 1947-1970 time frame provides an excellent foundation for the succeeding quarter century (1970-1995), when we consider where we are now, or where we should be.

EARLY DEVELOPMENTS (~1947-60)

We start our historical trek along "nostalgia trail" by noting that sanitary engineering activities in the early AEC days focused on three major areas: 1) radioactive waste handling and disposal, 2) water supply, and 3) environmental concerns. The following activities were directly related to all AEC operations, including the development of a new nuclear energy industry through commercial enterprises:

Siting: An important aspect of the early program was the function of technical consultation in the selection of sites for nuclear energy facilities at AEC and industrial sites. In the 1950's and 1960's, the sanitary engineering staff established working relationships through comprehensive, cooperative interagency programs with the U.S. Geological Survey (USGS), the U.S. Weather Bureau (USWB), the U.S. Coast and Geodetic Survey (C&GS), the Bureau of Mines (BuM), the U.S. Public Health Service (USPHS), the Corps of Engineers, and the Fish and Wildlife Service (USF&WS). The experience and technology of specialists in these agencies were combined with AEC and DRD staff in the selection of suitable sites for all types of nuclear installations such as reactors, chemical processing plants, research laboratories, etc. Example sites included the National Reactor Testing Station (NRTS); the Savannah River Plant (SRP); the Experimental Gas Cooled Reactor at Oak Ridge (EGCR); and the West Valley, NY, Chemical Processing Plant. A special note is made of the geologic and hydrologic programs which were conducted by the USGS. These studies provided essential geohydrologic data and reports as

required for the location, design, construction, and operation of all AEC facilities. The siting and satisfactory operation of these installations required quantitative data and knowledge also on the seismology and meteorology of the proposed site area.

The environmental scientists from the agencies noted above were assigned to various AEC sites and the DRD Environmental & Sanitary Engineering Branch (ESEB, formerly SES) to aid in the data collection required in the assessment of the transport, diffusion, and behavior of radionuclides in the hydrosphere, lithosphere, and atmosphere. Through the 1950's, this expertise was used in the evaluation of proposed commercial reactor sites, their waste handling systems, and all other environmental aspects. Preliminary and final safety analysis reports were reviewed for the Advisory Committee on Reactor Safeguards (ACRS), prior to licensing the construction and operation of electric utility power reactor facilities.

Early R&D: The initial phases of the DRD-ESEB radwaste R&D program are summarized in Fig. 1. In the early 1950's, the program consisted of approximately 20 projects with universities, federal agencies and AEC sites. The possibility of using biologic treatment methods to remove low levels of radioactivity, such as the trickling filter and activated sludge processes, used in municipal and industrial waste treatment, was studied at several universities. Even at this time, a major portion of the program was directed at the high level waste (HLW) problem.

As also shown in the figure, satisfactory working relationships had been established with several river advisory boards, such as the Ohio River Valley Water Sanitation Commission, the Mohawk River Advisory Group, the Savannah River Advisory Board, the Columbia River Advisory Group and the New England Interstate Water and Pollution Control Commission. These groups were primarily concerned with atomic energy installations located on streams within their jurisdiction and with liquid waste effluents discharged to these streams. It was the policy of AEC, and a function of the DRD-ESEB program, to provide these groups with design and operating information on the waste handling facilities at AEC installations, and the associated monitoring, for assuring that water quality was not being deleteriously affected. In addition, the R&D program was guided in its development by consultation with the top scientists and engineers in the U.S., mainly through interaction with several divisions of the National Academy of Sciences (NAS), the National Committee on Radiation Protection (NCRP), and the American Standards Association (ASA).

Program Objectives: In the 1950's, to assure that nuclear energy operations would not affect the health and safety of the public and its environment, the AEC-DRD radioactive waste management R&D program followed three major objectives:

1) Develop practical systems for the safe handling and ultimate disposal of gaseous, liquid and solid wastes with emphasis on waste emanating from chemical processing plants and certain types of reactors;

Fig. 1

2) Evaluate quantitatively dilution and/or concentration factors in nature in order to determine the degree of treatment actually required prior to release of effluents to the ground, atmosphere or surface waterways, thus taking into account a proper economic advantage of these environmental factors;

3) Obtain increased knowledge of the fundamental phenomena and processes involved in disposal of radioactive and toxic wastes to achieve more efficient and economical methods. Although the basic principles of

radioactive effluent control and environmental and public health protection in the nuclear industry were similar to those which applied to other chemical or heavy industries, there was one significant difference between this industry and others. From its inception, the nuclear industry was acutely aware of the potential hazardous effect of its wastes and focused detailed attention on these problems. Waste management in all atomic energy operations must control radiation hazards not only during operations but also after the waste products are discharged to the environment.

Radioactive Effluent Control Operations: Three basic approaches were used:

1) Dilute and disperse was used only with low-hazard-potential wastes, in which the radioactivity could be reduced to acceptable levels (either directly or following treatment) by dilution in nature--air or water. Quantitative physical, chemical, and biological data were obtained continually on such things as dispersion phenomena and reconcentration factors, demonstrating the validity of this approach without compromising health and safety standards. I cannot over stress the favorable siting characteristics of large controlled areas and low population densities, which permitted safe development of the nuclear energy industry within the AEC complex. The procedure has not been used in commercial electric power reactor effluent control.

2) Concentrate and contain is used for HLW originating from chemical processing of irradiated reactor fuel. The radioactivity was concentrated by volume reduction and then confined or isolated in a controlled area such as specially designed underground storage tanks, away from man and his natural resources. Containment is essential for HLW because small volumes would require excessive amounts of environmental dilution.

3) Delay and decay was used to discharge certain kinds of liquid wastes to the ground at suitable locations. Soil holdup or exchange capacity is used in this concept. Either direct discharge to the environment or discharge after conventional treatment were used.

In establishing engineering or operational criteria for satisfactory waste management systems, detailed quantitative consideration was always given to:

The specific nature and quantity of radioactive wastes being handled.

The characteristics of the receiving environment.

The interaction between the two.

The basic radiation protection guides or standards, as established by the Federal Radiation Council (FRC) or the National Council on Radiation Protection and Measurements (NCRP). I cannot overemphasize that these guides or standards were the overall "driving force".

Early Liquid Waste Management: Early development work centered on the handling and disposal of high volume, liquid low level wastes (LLW), airborne particulate wastes and evaluation of the effects of radioactivity in these wastes on public water supplies and domestic waste treatment facilities. Sources of liquid LLW included reactor cooling systems, laboratories, hospitals, fuel fabrication, laundering, and other operations.

Conventional liquid waste treatment systems were studied and used at the AEC sites during the 1950's. These included sedimentation in baffled tanks, seepage ponds, evaporation, decay storage, co- precipitation, ion exchange, and direct discharge to nature without pretreatment; the type of treatment required depended upon the character of waste involved and

the environmental conditions at the site. Examples of this latter operation were liquid waste discharges from Knolls Atomic Power Laboratory (KAPL) to the Mohawk River, the Pressurized Water Reactor (PWR) at Shippingport, PA, and the Savannah River Plant near Aiken, South Carolina. In the late 1950's, the USPHS carried out detailed monitoring studies below each of these plants to determine the fate of specific nuclides discharged in these effluents. These comprehensive studies included the uptake of activity by suspended and colloidal material, by bottom silts, by aquatic organisms, and by fish and plant life--all were assessed to assure that no environmental radiation hazards existed.
In ground disposal operations, the "delay and decay" approach to effluent control was extensively used for large volume, LLW at most AEC sites. For example, large government installations located in isolated or remote areas such as Hanford, Washington, or the National Reactor Testing Station (NRTS) in Idaho, were able to operate safely under less restrictive effluent standards than could be utilized by smaller facilities in urban areas. Various ground disposal systems included retention basins, cribs, swamps, trenches, seepage pits, and an injection well at NRTS. Extensive monitoring systems ranging from over 30 wells at NRTS to over 200 wells on the Hanford reservation were used to determine the distribution and migration of radionuclides in the lithosphere and to assure that the safe capacity of the environment was not exceeded. The USGS, with specific competency in radio-geohydrology, cooperated with on-site scientists and engineers in developing the safe parameters needed for carrying out these operations.

Early Land Burial: One of the more important operating problems, during the 1950's, involved the satisfactory disposal of solid radioactive wastes. Activity levels varied from a few times background to levels requiring remote handling or shielding. Conventional sanitary landfill procedures similar to municipal refuse disposal were used. Burial of such wastes were done at sea and in established burial areas at large AEC production and research sites. During the 1950's, land burial areas were operated at Oak Ridge, Savannah River, Idaho, Los Alamos, and Hanford. Large installations such as KAPL, Argonne National Laboratory (ANL), and Mound Laboratory, Miamisburg, Ohio, all shipped packaged solid wastes to Oak Ridge for disposal. Westinghouse Atomic Power Development (WAPD) at Bettis Field, Pittsburgh, PA, and Brookhaven National Laboratory (BNL) disposed of their solid packaged wastes off the Atlantic Coast through arrangements with the U.S. Navy.

With the end of the 1950's, there was an increasing need by both AEC contractor and licensee operations for establishment of a regional land burial area in the northeastern United States. In December, 1959, a decision was made that regional disposal sites other than the existing AEC installations could be established, as required, on state or Federal Government owned land. As we leave the 1950's, it is noted that geohydrologic surveys were being conducted in several areas of the country for selection of additional burial ground(s). It was hoped that this facility would become a commercial operation, since it was believed that this was one area where industrial participation was feasible and desirable.

Early Sea Disposal: Sea disposal of small quantities of radioactivity had been accomplished since 1946 through arrangements with the U.S. Navy off both the Atlantic and Pacific Coasts. Monitoring investigations of both the Atlantic and Pacific disposal areas revealed no readily

detectable radioactivity from the above operations. Because of increased interest by both waste disposers and regulatory agencies, the Committee on Oceanography of the National Academy of Sciences (NAS) at the request of the AEC, identified a number of inshore disposal areas off the Atlantic and Gulf Coasts. A similar survey of the Pacific Coast sea disposal areas was made during 1959.

Early Airborne Waste Management: In regard to airborne particulate material, it was discovered early that conventional dust control equipment could not meet the extremely small permissible concentrations of various nuclides in the atmosphere. An important milestone in the air cleaning field was the successful development of a high efficiency filter, capable of routinely removing 99.95% of particles 0.3 microns in diameter, and placing the unit into commercial production. Another notable achievement in the air cleaning field was the development of a silver nitrate packed tower unit which was capable of removing iodine131 from gas streams; satisfactory plant operation was obtained with efficiencies greater than 99.99%.

In related work, the scientific achievements of the U.S. Weather Bureau are recognized; this group investigated meteorologic parameters such as atmospheric diffusion and transport in quantitative terms at all major AEC operating sites; these data were used in the over-all design of gaseous effluent facilities, i.e. stack height and location, and also for nuclear safety assessments under normal and accidental operating conditions. Their contribution of "Meteorology and Atomic Energy" in 1954 was a textbook for environmental and radiological safety evaluations.

Tank Storage & Early HLW R&D: By the end of 1959, approximately 65 million gallons of HLW from the chemical processing of irradiated fuel were being safely stored in underground carbon steel or stainless steel tanks at Hanford, SRP, and NRTS. Because of inherent limitations on long-term tank storage as an ultimate disposal system, the AEC-DRD program began investigating, in the early 1950's, the conversion of high-level liquid wastes to a solid form. Laboratory investigations began in 1955 at ANL and later at the Idaho Chemical Processing Plant (ICPP) on a heated fluidized bed technique for conversion of aluminum nitrate wastes (from aqueous processing of uranium-aluminum alloy fuels) to an oxide form. At the end of the 50's, a prototype pilot plant was installed at ICPP to test the process on a large scale. In another pioneering effort, BNL studied the fixation of liquid wastes in solids by adsorbing the radioactivity from the liquid onto montmorillonite clay. The actual fixation of fission products in the clay mineral was accomplished by heating the clay to about 1700oF.

Early Deep Underground Disposal R&D: The AEC ground disposal R&D program received its initial stimulus in September, 1955, when a committee of geologists and geophysicists was established by the National Academy of Sciences-National Research Council. The AEC requested this group to study the possibilities of disposing of HLW on land and to indicate what research was needed to determine feasibility. Similarly, during 1957-58, the American Petroleum Institute (API) was requested to review the problems of deep well disposal and to suggest specific approaches to the problem. This study would guide research, development and field testing operations required for the establishment of a safe and economical high-level liquid waste disposal process. In 1958, the American Association of Petroleum Geologists (AAPG) responded to a request from the AEC to assist in the evaluation of geologic basins as

possible sites for the safe subsurface disposal of radioactive wastes. These three consultations with NAS, API and AAPG (1955-58) provided the support for AEC-DRD to carry out extensive laboratory and engineering field demonstration studies in the 1960's on 1) salt formations; and 2) deep permeable and impermeable formations. This R&D will be discussed further in the second half of this paper.

1959 JCAE Hearings: At this point, note that the planning and conduct of the radwaste R&D program was under a continuing review and assessment by the Joint Congressional Committee on Atomic Energy (JCAE), several committees of the NAS and various national radiation protection groups. Perhaps the most comprehensive set of hearings held on any one facet of the atomic energy program were the ones held during January, February, and July 1959, on Industrial Radioactive Waste Disposal. The author had the pleasure of working with JCAE staff in the organizing and conduct of these hearings. Over 150 experts in all phases of radioactive waste management presented oral and written testimony for these hearings. Representatives from all major AEC production, reactor development and laboratory research installations, universities, electric power, coal and oil industries, the NAS, National Council on Radiation Protection and Measurements, various government agencies such as the USWB, USGS, and the USPHS, and several state health departments all participated in the hearings. About 3200 pages of hearing record described and discussed all aspects of 1) radioactive waste management operations, 2) research and development on waste treatment and disposal and associated environmental studies in meteorology, geology, hydrology, and oceanography, 3) the future problem, including estimates of the magnitude and economics, 4) federal and state activities in regulating waste disposal, and 5) international activities in this area. Among the salient conclusions reached as a result of the exhaustive JCAE hearings were:

1) Radioactive waste management practices had not resulted in any harmful effects on the public, its environment or its resources.

2) The general problem of radioactive waste need not retard the future development of the nuclear energy industry with full protection of the public health and safety.

EXPANDED PROGRAM (1960-70)

The Congressional Hearings provided a "springboard" for an expanded R&D program during the 1960's. A number of laboratory research projects advanced to an engineering scale and several ground disposal projects reached the field demonstration phase. There were so many exciting things happening in the 1960's, that I will only highlight some of the operational and R&D achievements in both AEC production and research facilities, and the emerging nuclear power industry (1957-70).

Operational

New LLW and Intermediate Level Waste (ILW) Facilities: 1) New alpha waste treatment facility at Los Alamos Scientific Laboratory (LASL), (1962); 2) new LLW treatment plant for ANL (1964); 3) new LLW treatment plant for Oak Ridge National Laboratory (1964); 4) new storage tanks and evaporator facilities for the treatment of ILW from Oak Ridge National Laboratory (ORNL) (1966); 5) new hydraulic fracturing plant at ORNL for disposal of evaporator slurries and ILW sludges, a culmination of the successful R&D program (1966). This technique, which was obtained from the petroleum industry, received extensive development at ORNL during the early 1960's. The method consisted of injecting a waste-cement-clay mixture under high pressure into impermeable geologic formations (like

Conasauga Shale at Oak Ridge) where it solidified in the form of a thin horizontal sheet. With the advice of the NAS, the technique was applied in a different geologic setting during the 1969-70 time period; the project was carried out as a joint effort with ORNL and USGS working with the state of New York at the Nuclear Fuels Services (NFS) Chemical Processing Plant site in West Valley, NY.

Land Burial: The 1960 decade was marked by the entrance of commercial industry into land burial operations, i.e., industrial services were initiated for the collection, packaging, transport, and disposal of low-hazard-potential solid wastes. Two interim land burial sites, one at Oak Ridge and the other at NRTS, were established pending the later designation of permanent regional sites to serve various parts of the country. During the period from 1960-63, the AEC carried out an "interim land burial program" during which time the radioactive waste burial grounds at Oak Ridge and the NRTS were made available. In the three years during which the interim land burial program was in operation, over 7 million cubic feet of solid radioactive wastes were disposed of by land burial.

In August, 1963, the AEC withdrew from its interim low-level waste burial program for licensees, based upon the availability of commercial burial sites at Beatty, NV, and Morehead, KY. In November, 1963, NFS established a LLW disposal facility near West Valley, NY. Other commercial burial grounds were established in 1965 and 1967 at Richland, WA, and Sheffield, IL, respectively. In April, 1971, a sixth commercial land burial ground was established by Chem-Nuclear Services, Inc., in Barnwell County, SC.

Sea Disposal: In the early period of atomic energy development in the U.S. (1946-62), the AEC disposed of small quantities of solid, packaged wastes at designated locations in the Atlantic and Pacific Oceans. With the advent of commercial land burial operations in the early 1960's, a steady decline of sea disposal occurred. Because of the availability of commercial land burial services of low-level radioactive waste materials, the AEC requested all of its contractors in 1963 to evaluate the economics of both disposal methods for their specific operation. With approximately 3/4 of a sea disposal container volume required for concrete ballast to assure its sinking to the 1,000 fathom depth in the ocean, it was determined that land disposal economics would eliminate sea disposal operations.

Incineration: The disposal of low-level combustible solid waste by incineration was practiced at various AEC and power reactor facilities during 1955-70, although not as extensively as at foreign atomic energy installations. As a waste disposal method in the U.S., it had to compete with compression, baling, and shipment of solid waste off-site for land burial. In general, incineration systems used by AEC sites failed to provide the desired performance and were costly to maintain. Extensive developmental efforts were carried out at the Harvard Air Cleaning Laboratory, ANL, KAPL, BuM, and the Army Nuclear Defense Laboratory. Experience with experimental and operating field installations revealed problems in combustion, air cleaning, and corrosion--all which required careful study and control in order to achieve satisfactory operating results. At that time, incinerators were operated at the Rocky Flats and Hanford plants for recovery of plutonium from burnable scrap.

First HLW Solidifier: The Waste Calcining Facility at the NRTS became the world's first plant-scale facility for converting actual high-level

radioactive wastes to a safer, solid form (December, 1963). The plant satisfactorily operated for the rest of the 1960's; it was shut down for about one year while additional solids storage bins were constructed.

Power Reactor Waste Management: While power reactor waste management systems (1957-1970) differed from one plant to another, they included decay hold-up tanks, evaporators, ion exchange units, steam stripping, catalytic recombination of hydrogen and oxygen, fixation of solids and liquids in concrete, incineration, baling, and liquid and gas filtration. In many cases, large waste volumes were processed by storing the material for a period of time to permit decay of radioactivity, and by dilution of the effluents with condenser cooling water prior to discharge from the plant site. Very small amounts of radioactive material which remained were permitted under AEC regulations to be released in liquid and gaseous effluents after careful monitoring.

In order to evaluate the waste management experience of civilian nuclear power plants, Oak Ridge National Laboratory, as an integral part of the AEC's effluent control R&D program, conducted a survey of these practices and operating experience during the period of 1960-67. All plants had operated well within their operating limits, and generally, at a small fraction (less than 5%) of radiation protection standards. It was seen that the management of radioactive wastes produced at nuclear power stations had not been a major factor in influencing the early development and growth of nuclear power.

Research and Development

Some of the more exciting R&D efforts in the 1960's are identified in the following:

LLW Treatment: Programs involving the development, testing, and application of improved systems for the handling, treatment, and disposal of low and intermediate level wastes received extensive efforts during the 1960's. For purposes of this discussion, a low level effluent is arbitrarily defined as one requiring a decontamination factor (DF) in the range from 10 to 103, and an intermediate level effluent as one requiring a DF in the range from 103 to 105. At ORNL and Hanford, extensive laboratory and pilot plant studies were carried out on advanced waste water treatment systems such as scavenging-precipitation ion exchange, foam separation, steam stripping, filtration, two-stage ion exchange, electrodeionization, water recycle, and asphalt solidification. DF's of several thousand were obtained for strontium and cesium in these systems and the average activity concentrations in the various process effluents were only a few per cent of accepted health and safety standards. Parts of this technology were used in the design of commercial power reactor and future fuel reprocessing waste management facilities.

Stream Studies: Supporting stream studies on the Clinch River below Oak Ridge and the Columbia River below Hanford were conducted as an adjunct to the LLW treatment R&D program. During the 1960 decade, the program developed quantitative data and knowledge on dispersal phenomena, reconcentration factors, biological uptake, etc., to assist in the evaluation of waste discharge systems below AEC sites. In its environmental pollution R&D programs, the AEC pioneered the use of a "team approach", e.g. on the Clinch River, the combined engineering and scientific competencies of ORNL, the U.S. Geological Survey, the Tennessee Valley Authority, the Tennessee State Department of Public Health, and the Tennessee State Game and Fish Commission were all integrated into a cooperative river study program. In the 1960's,

additional comprehensive environmental assessments were made of stream conditions in the Savannah River below SRP, and the Mohawk River below KAPL.

Meteorologic Research: In another environmental area, the USWB, now the Environmental Science Services Administration (ESSA), under interagency agreement with DRD, expanded its meteorologic studies on atmospheric transport and diffusion as it applied to the safe disposal of radioactive effluents to the atmosphere. ESSA scientists conducted on-site research in the vicinity of Oak Ridge, NRTS and BNL. Atmospheric transport and diffusion data were used in environmental monitoring of these sites and also in reactor safety assessments. A new volume of "Meteorology and Atomic Energy"--1968 replaced the original publication of 1954, and updated the knowledge and techniques used in the estimation of downwind atmospheric transport and diffusion.

At this point, it is appropriate to summarize briefly the ground disposal research conducted in the 1960's, as recommended by the National Academy of Sciences in 1957. They are: 1) Disposal in salt; 2) Excavation in impermeable formations; and 3) Deep permeable formations (3,000-12,000 feet) containing connate brine.

Disposal in Salt: In response to the NAS suggestion, a major part of the AEC ground disposal R&D program during the 1960's was directed at establishing the suitability of using underground salt formations for the disposal of high-level solidified radioactive waste. Bedded salt formations were chosen as the most optimum disposal media because of their unique geologic characteristics. Salt formations are dry, impervious to water, and not associated with usable groundwater sources. Because of its plasticity, fractures in salt seal or close rapidly. Deposits of rock salt underlie some 400,000 square miles of the United States and may represent some of the few naturally occurring dry environments in the eastern part of the country. Extensive laboratory investigations at ORNL and field studies in the Carey Salt Mine, Hutchinson, KS, were most promising. Project Salt Vault (a demonstration disposal of high-level radioactive solids in a Lyons, KS, bedded salt mine, using Engineering Test Reactor fuel assemblies in lieu of actual solidified waste) successfully demonstrated waste-handling equipment and techniques similar to those required in an actual disposal operation (1965-67). This part of the "salt disposal story" ends at the end of 1969, with ORNL preparing a preliminary design for an operating salt disposal facility, which would handle HLW solids to be generated in the reprocessing of irradiated reactor fuels during the mid-1970's.

Deep Impermeable Formations: Research on the use of deep impermeable formations for the ultimate storage or disposal of HLW was extensively studied at the AEC's Savannah River Plant (SRP) during 1961-63. An intensive exploratory drilling program was conducted to determine the hydraulic and physical characteristics of the basement rock and the overlying aquifer as well as the compatibility of the rock with the waste to be stored. Results of the overall comprehensive study program were reviewed by the NAS Committee on Geologic Aspects of R/A Waste Disposal and outside consultants. Their recommendation was to seek Congressional funding in FY '70 for an exploratory drilling program to provide field verification testing and final engineering design; while the concept appeared technically and environmentally sound, it was canceled after contact between the governor of South Carolina and the U.S. JCAE.

Deep Well Injection: The third geologic concept involving deep well injection was first suggested by the NAS (1957) and the API (1958). The API group studied the problems associated with deep well disposal of HLW to determine whether the techniques used for oil-field brine disposal might be adapted to R/A waste disposal. At this time, the injection of liquid HLW was suggested as an alternative to solidification and transport of the solid waste containers to an off-site underground disposal site. Of course, a suitable deep well (a confined, thick, permeable sandstone in an area of no actual or potential oil production) was conceived as part of the siting criteria for commercial fuel reprocessing plant(s). With the success of the solidification program (in the 1960's), the deep well injection approach was discarded; however, there were some thoughts that the concept might have application to the larger-volume LLW streams which also would emanate from commercial reprocessing plants.

By the end of 1969, more than 20 years of continued tank storage experience had shown it to be a practicable means of interim handling. Over 80 million gallons of radioactive solutions and sludges were stored in nearly 200 underground tanks throughout the AEC complex. Although corrosion data indicated expected tank life-times of 40 to 50 years, there were reported instances of tank failure, all in carbon steel systems at Hanford and Savannah River. Stress-corrosion cracking and/or thermal stress of the reinforced concrete structures were established as causes of these tank leakages, and these factors were taken into account in improved design and construction of new interim tank storage. While tank storage practices were successful in preventing significant quantities of radioactive materials from escaping to the environment, these operations required continual surveillance and tank replacement. This need for surveillance, as well as the necessity of transfer of liquid waste from tank to tank over periods of hundreds of years, were compelling factors for the HLW solidification and deep underground storage programs in the 1960's.

HLW Solidification R&D: With the support of the JCAE in 1959, several processes for conversion of liquid waste to thermally and radiolytically stable solids were investigated. These processes included the use of fluidized beds (ANL & NRTS), a rotary ball kiln at BNL, ceramic sponges at LASL, heated pots at ORNL, and radiant heated spray columns at Pacific Northwest Laboratory (PNL). The addition of glass-forming materials, such as phosphoric acid, lead oxide, sodium tetraborate, etc., for the purpose of providing a relatively non-leachable final product was also intensively studied. The fluidized bed, pot, spray, and phosphate glass processes underwent extensive engineering development during the 1960's. Detailed descriptions of these processes are provided in the references. The Waste Calcining Facility (WCF) at NRTS demonstrated the use of the fluidized bed process during the period of 1963-70 (as noted earlier), principally on waste from the processing of test reactor fuels.

The highlight of the DRD-ESEB HLW solidification R&D program in the 1950's and 60's was the design, construction and operation of a Waste Solidification Engineering Prototype (WSEP) plant at the Hanford Battelle-Northwest Laboratories (BNWL). The engineering-scale technology for solidification of HLW from power reactor fuel reprocessing using the ORNL pot calciner; the BNWL spray calciner-melter; and the BNL phosphate glass system was demonstrated during 1966-72. Thirty-three demonstration runs were completed on the three processes; more than 50 million curies

of radionuclides were processed and collected in 6, 8, and 12-inch diameter containers. Results from WSEP were used to develop design concepts for a 5 tonne/day commercial reprocessing plant and waste management economics for application of the WSEP solidifiers in industrial plants. An overall comparison of the WSEP type solidification processes indicated an apparent slight preference for the spray solidification process over pot calcination, with the phosphate glass process having a fewer number of advantages for the cases studied.

Long Range Evaluation Studies: During the 1960's, the DRD effluent control R&D program utilized ORNL for conducting detailed engineering, economic, and safety evaluation studies to aid the AEC in its planning of future waste-management programs. In these studies, the objective was to evaluate the economics and hazards associated with the treatment of HLW and their storage in ultimate disposal sites as part of a nuclear power economy. These studies indicated that a series of operations consisting of interim liquid storage for five years, solidification, interim solid storage on-site for an additional five years, followed by shipment of the waste and disposal in a salt formation, could be carried out for approximately 0.03-.05 mills/kwh. It was not expected that the costs for waste management, including perpetual storage in a federal repository, would be a significant factor in either the fuel cycle or over-all costs of nuclear power (estimated as less than 1 percent of total power cost).

New HLW Regulatory Policy: As culmination of the R&D program of the 1950's and 1960's, note that in 1969-70, significant policy and regulatory changes occurred in the overall AEC regulatory program. Waste treatment and disposal technology which was developed through the DRD research, development and demonstration programs during the 1960's, was utilized as a basis for the establishment of new waste management policies and revised regulatory procedures. The planning and orderly development of this technology was considered most timely, since we were entering a period in our nation's development which was termed by many as a decade for "environmental action". Protection of the environment had become a major political concern. This resulted in numerous Congressional hearings, including the comprehensive hearings by the Joint Committee on Atomic Energy on the Environmental Effects of Producing Electric Power, which were held in late '69 and early '70.

Prior to these regulatory changes, AEC staff, with assistance from major contractors such as ORNL, PNL, DuPont, Atlantic Richfield, and the Idaho Nuclear Corporation conducted an intensive study in 1968-69 to determine the needs and bases for establishing a siting policy for commercial fuel reprocessing plants and related waste management facilities. General guidance on the handling of liquid HLW inventories at the plant, the conversion of HLW to a solid form, and transfer of these solids to a federally owned and controlled repository were described in the AEC regulatory policy statement of November 14, 1970 (Appendix F). With the continued growth of nuclear power and indications of substantial industrial interest in the construction of fuel reprocessing plants, both contributed to a general feeling of optimism that the fruits of 20 years of R&D would be realized with the operation of a HLW solidification unit and underground repository by the mid-1970's.

FINAL REFLECTIONS

As we conclude our trek down "memory lane", I would like to share some reflections with you. The 1950's and 60's were exciting times in the nuclear energy field, in general, but even more so in the radwaste R&D

area. New technology was being created and demonstrated, and it was most satisfying to be a small part of it. But on the "other side of the coin"--it has been most discouraging to not see the application of fully engineered HLW solidification technology, integrated with the first HLW repository. With the establishment of a HLW repository resisted by political opposition (the NIMBY syndrome), the past 25 years have been a major disappointment. At long last, plant-scale HLW solidification systems at West Valley and SRP are scheduled to go "hot" in early '96. However, the "dream" of seeing a full scale HLW underground repository in operation in Nevada or elsewhere may never be realized in my lifetime.

DEVELOPING NUCLEAR WASTE POLICY AND REGULATION WITHIN THE CONTEXT OF CHANGING POLITICAL AND SOCIAL ISSUES

ABSTRACT

Since the end of World War II, the development of nuclear waste management policy and regulation has been influenced by social and political events. Our use of nuclear materials during the 1940's was greatly influenced by World War II and the need to develop weapons. The nuclear establishment was primarily mission oriented - developing weapons to protect us from a perceived threat. Post war political priorities were focused on making the world a safer place; nuclear weapons development was seen as a key element of protection from a perceived future threat. Social priorities emphasized physical and emotional recovery from the war, security, and prosperity. Nuclear waste management, for the past 50 years, has reflected changing social needs and political situations. Post-war protectionism, escalating cold war, rising environmental awareness, economic prosperity and recessions, rapid technology development, increased public awareness and participation in political processes have all affected national waste management policies and practices and our ability to effectively and efficiently manage radioactive waste. In some programs, the result has been implementation of responsible decisions that protect public health and the environment. Other programs are still struggling. In the 1990s, the challenge remains to develop solutions that acknowledge social, economic, and political influences and provide flexibility to accommodate these changing factors.

REGULATORY BEGINNINGS

After World War II, legislation was developed that started our national policy toward atomic energy and eventually the management of nuclear waste. On August 1, 1946, the Atomic Energy Act was signed into law by President Harry S. Truman. This law gave the federal government exclusive authority over the development and application of atomic energy and provided for federal control over regulating the use of radioactive materials. The Atomic Energy Commission (AEC) was established to fulfill this authority. Within this Act, Congress also created the Joint Committee on Atomic Energy to provide Congressional oversight over the operations of the AEC for non-classified aspects of the program.

Even during these early days of operations, certain concerns were raised about waste management practices, especially at Hanford where high level liquid waste was being stored in tanks. Reactor cooling water passed directly into the Columbia River and other liquids were discharged directly into pits (cribs) and allowed to percolate into the soil and eventually into the Columbia River. In 1948, the AEC s Advisory Committee on Nuclear Safety noted these practices would lead to long-term contamination and should be discontinued. The AEC however, indicated that no money was available to explore other disposal methods.

During this early period the AEC adopted health and safety codes and standards. In June 1949, the AEC issued AEC Bulletin GM-133 which instructed its operations to comply with standards developed by the National Committee on Radiation Protection (NCRP) with respect to radiation exposure. The NCRP was actually founded in 1928 as part of the National Bureau of Standards and was originally known as the Advisory Committee on X-ray and Radium Protection. In 1946, the name was changed to the NCRP to reflect its expanded scope work.

In September 1949, the National Bureau of Standards issued Handbook 42 which set forth a maximum whole body dose standard of 300 mrem per week. On an annual basis this is the equivalent of a whole body dose of 15,600 mrem per year.

The 1950's brought an eventual lowering of the permissible doses from radiation, but not until 1958. On June 29, 1951, the National Bureau of Standards issued Handbook 47, which restated the 300 mrem per week radiation dose standard. On March 20, 1953, the National Bureau of Standards issued Handbook 52, which discussed not only permissible amounts of radio isotopes in the body, but in air and water as well. This standard continued the guideline of 300 mrem per week of radiation exposure. In September 1954, National Bureau of Standards Handbook 59 continued the same 300 mrem per week radiation exposure standard. Of significance in Handbook 59 was its discussion of non-occupational doses. Specifically, it required that, with respect to non-occupational exposure of minors, no minor was to receive radiation at a weekly rate higher than one-tenth the respective basic permissible weekly doses for critical organs. However, no changes were made with respect to the standard for non-occupational exposures to adults.

The 300 mrem per week standard was in place until 1958 when the AEC published the AEC Manual Chapter 0524. This manual set forth a new standard for radiation exposure for members of the general public, i.e., non-occupational exposure. This new non-occupational standard was significantly lower than the permitted occupational exposures, and set at 500 mrem per year for whole body exposure and 1,500 mrem per year for specific organ exposures.

In the 1950's two pieces of legislation were significant, the Atomic Energy Act of 1954 and its Amendment in 1957, incorporating the Price Anderson Act. The Atomic Energy Act of 1954 re-authorized the AEC and government control over atomic energy activities. This Act also reestablished authority for protecting the health and safety of the public. At this time, significant interest in commercial generating of electrical power fueled by the peaceful atom was developing. This commercial development required large-scale uranium exploration and mining. In Colorado and other western states, this mined ore was milled and enriched to provide fuel for the new reactors. The potential for accidents and liability for their occurrence became evident. Mining and milling operators, as well as nuclear plant operators pushed forward with legislation to protect their interests. The 1957 Price Anderson Act amendment to the Atomic Energy Act of 1954 provided for liability and compensation in the event of a nuclear accident, should it be transportation or operations related. It was specifically designed to protect the nuclear industry should an accident occur that was so large as to threaten the future of nuclear power.

The AEC was largely self regulating, especially on the classified side, and on a learning curve in waste management. Ocean dumping of low level

waste was common practice, as was trench burial. Usually the low-level waste was categorized according to hazard levels and packaged accordingly before it was placed in the trenches. High level waste was found to be more difficult to contain in some instances, especially during the separation experiments with plutonium at the national laboratories. Several accidents at some of these facilities caused off site releases to the environment. The AEC maintained limited environmental monitoring, primarily of effluents and health testing procedures to maintain compliance with the standards. These monitoring procedures usually took the form of specific AEC Orders.

During the 1960's the Cuban Blockade, Vietnam War and the Civil Rights movements largely distracted government administrations from nuclear activities. Antiwar sentiments were the focus of social issues; weapons testing and reactor building continued with little public opposition or awareness. The need to regulate the building of reactors dominated regulatory development work. Disposal of spent fuel was not yet an issue because the industry planned to reprocess its fuel. However during the late 1960's plans to dispose of high-level wastes from reprocessing emerged with the studies of the Lyons Kansas Project Salt Vault. Other nuclear activities continued under the Swords to Plowshares project, where large potential storage caverns were excavated in salt domes by nuclear detonations.

RISING ENVIRONMENTAL AWARENESS

During the late 1960's the environmental movement gained momentum and signaled the beginning of public involvement in waste management issues. Passage of the National Environmental Policy Act in 1969 required that federal government actions undergo thorough environmental review and that the public participate in the review process. NEPA mandated that all federal agencies consider the impacts to the environment that their actions may incur. The Council on Environmental Quality (CEQ), established to implement NEPA, promulgated regulations that defined environment in its broadest sense to include physical, biological, and human components. It also required a thorough evaluation of alternatives, coordination and consultation with other agencies, and public participation in the review and decision making process.

In the 1970's a number of events strengthened the environmental movement. The 1976 Resource Conservation and Recovery Act addressed the widespread problem of contamination resulting from municipal solid and hazardous waste. This act established a broad policy that governments and industry alike must minimize the amount of waste they produce and find environmentally safer ways to store and dispose of wastes.In 1974, the need for independent regulation of AEC activities led to its reorganization into the Energy Research and Development Agency (ERDA) and the formation of the US Nuclear Regulatory Commission (NRC). The NRC was responsible for developing and enforcing regulations for ensuring the public health and safety from all of the Atomic Energy Act activities. The US Department of Transportation was given the responsibility for developing and implementing safety standards dealing with transportation of nuclear materials. This 1974 reorganization lasted three years, until 1977, when ERDA became known as the US Department of Energy.

Several events in the late 1970's influenced public opinion of nuclear power and subsequent waste management policies and practices. The film China Syndrome and in its wake, the accident at Three Mile Island heightened public awareness and fear of nuclear energy and the potential

consequences of nuclear accidents. Another factor was President Carter's 1978 decision not to pursue development of commercial nuclear fuel technology or permit construction of commercial fast breeder reactors, a component of the existing nuclear fuel reprocessing program. This decision was based primarily on nuclear proliferation fear and fueled public fears of the potential for nuclear war and devastation. Carter's decision also resulted in different and more immediate needs for fuel storage and disposal facilities. Disposal efforts now had to be directed toward spent rather than reprocessed fuel. Power plant operators were forced to take a serious look at storage options for spent fuel. Several states passed legislation banning further development of nuclear power until the disposal problems could be solved.

In terms of low-level waste, states became aware of practices that had resulted in groundwater and soil pollution at several disposal facilities. By 1978, only three commercial low-level waste disposal sites remained in operation. These three sites were to receive all the nations commercial low-level waste resulting not only from nuclear power plants, but also from medical and industrial sources. The governors of these three states gave notice they were going to either close their sites in the near future, or cut down on the quantities of waste that they would be accepting. In this atmosphere of concern, Congress began considering legislation to deal with the radioactive waste disposal problems. With these evident changes, the NRC set about looking at criteria for deep geologic disposal of spent fuel, and land burial of low-level waste, even in the absence of legislation.

CONGRESSIONAL ACTION

In the 1980's, Congress passed several key laws which reflected the need for better management of our nuclear waste streams. The first was the Low-Level Radioactive Waste Policy Act of 1980. Under this law, each state was given the responsibility for ensuring adequate disposal capacity for waste generated within their borders. The act encouraged states to form compact agreements so that joint regional disposal facilities could be developed. States could also receive authority to regulate these facilities from the NRC as Agreement States. States were also given the ability to have a role in the regulation of transportation of nuclear waste. The 1980 Act laid out a time table for developing disposal capacity. This time table proved unworkable and the Act was subsequently amended in 1985 and again in 1987, to give states more time to provide such facilities. However, strict time schedules and penalties also were delineated.

By 1982, nine interstate compacts agreements to site low-level disposal facilities had been ratified by Congress. In December of 1982, the NRC promulgated 10CFR61, Licensing Requirements for Land Disposal of Radioactive Waste, which set the technical requirements for the newly formed compacts' siting efforts. Shortly afterward however, public distrust of land disposal techniques led to recognition that this out of sight, out of mind philosophy was not publicly acceptable. This public opinion steered disposal practices to above ground or above grade facilities, where this waste could be more easily monitored. This attitude led to the revision of 10CFR61 to provide guidance on siting above ground and above grade facilities.

The Nuclear Waste Policy Act of 1982 (NWPA) incited intense public debate, especially in states that appeared promising for hosting disposal facilities, such as Nevada and Washington. Until then, there had been no

legislation governing the search for technically and scientifically suitable sites for the disposal or storage of civilian high-level waste or spent fuel (League of Women Voters, 1993. The NWPA laid out several policies:

A high priority was given to waste disposal. Schedules for repository development and operations were delineated for two repositories, one in the east and one in the west. This provision was carefully negotiated by governors of western states, who felt that it was unfair to put all of the waste in the west when most of the waste was generated in the more industrial east.

Interim storage was to be permitted on a limited basis. Schedules were developed for siting and constructing a monitored retrievable storage (MRS) facility.

Interactions between the states, local governments, Indian tribes were defined. These interactions included such things as financial assistance to states to review activities defined by this act for health and safety and environmental impacts and rights to information. It also provided veto authority to the host state.

Specific federal agency functions were defined; the DOE was to be the repository developer, the US Environmental Protection Agency (EPA) was to set health standards, and the NRC was to implement the EPA standards and promulgate regulations on repository siting, operations and closure.

Rulemaking

In February 1981, the NRC issued their proposed rule, 10CFR60, Disposal of High-Level Radioactive Wastes in Geologic Repositories and final rule in June of 1983, in consultation with the EPA.

In May 1984, the EPA issued their proposed rule, 40CFR191, Environmental Standards for the Management and Disposal of Spent Nuclear Fuel, High-Level and Transuranic Radioactive Wastes. This proposed rule established release limits and dose requirements for deep geologic disposal of these wastes for two principal stages: the period of management and operations and the period after waste disposal had been completed. The EPA finalized this rule in September of 1985. Once this rule was finalized, the NRC had to then issue conforming amendments to 10CFR60, which was done in June of 1986.

10CFR60 and its conforming amendments established procedures and technical criteria for disposal of high-level waste in a geologic repository. These technical criteria were sometimes quite specific (subsystem performance requirements), yet attempted to give the Applicant (DOE) flexibility to develop the repository to meet the overall EPA standard.

In 1984, court challenges brought about a stricter adherence to environmental standards by the DOE when the Legal Environment Assistance Foundation and the Natural Resources Defense Council brought suit against the DOE. The law suit challenged the DOE's right to set and enforce their own regulations. The court found the DOE in violation of environmental standards and ruled that federal environmental laws, and certain state and local laws also apply to weapons production activities. This action led to more public scrutiny of DOE weapons facilities. In 1989, the DOE announced that cleanup and compliance with environmental laws would have a higher priority within the DOE. The office of Environmental Restoration and Waste Management was created to handle this responsibility.

Other laws such as the Clean Air Act and the Clean Water Act heightened public understanding of the contamination problems faced by the nuclear

and hazardous waste industries. These industries became the focus of environmentalist actions. Generally environmental standards became more strict and prescriptive.

NWPA Amendments

Concerned with the escalating costs of finding a repository site for spent fuel and high level wastes, Congress passed the Nuclear Waste Policy Act Amendments Act of 1987. This Act revised some of the policies which were established in the 1982 Act including:

Congress directed the DOE to abandon all sites under consideration except Yucca Mountain in Nevada. The DOE was to characterize this site in order to determine its suitability as a repository and to postpone consideration of a second repository.

Siting, construction and operation of a MRS was authorized and the Office of the Nuclear Waste Negotiator was created to identify, in participation with a state or tribal government, a MRS host.

External technical oversight was increased through the Nuclear Waste Technical Review Board, by onsite oversight by the host states and local governments, and by increased local government participation.

The action of dropping all other sites except Yucca Mountain lead to confrontation with the State of Nevada. Additionally in 1987, the existing EPA standard 40CFR191 was remanded and the EPA was ordered to reconsider the disposal provisions and consistency with other existing laws.

PUBLIC PARTICIPATION

The 1970s and 1980s saw an increase in public involvement in government actions and decisions. Social activism during the Viet Nam War, increased distrust of government as a result of Watergate, and disclosures of health and safety issues associated with hazardous waste disposal practices stimulated a public demand for opportunities to participate in government decision-making. Environmental legislation, led by the NEPA, responded by requiring that federal agencies consider and incorporate public input in the environmental review process. Other environmental legislation also included provisions for public involvement and implementation of community relations programs. It was primarily through the NEPA process that citizens became involved in nuclear waste management issues. Initially, this public involvement took the form of review and comment on environmental documentation, such as the Statutory Environmental Assessments under the Office of Nuclear Waste Isolation Program. Public hearings on the environmental documentation, required under NEPA, were most often contentious and, in fact, the format of such hearings promoted an adversarial relationship. There was little evidence that public comments affected decision-making and the "decide-announce-defend" process most often prevailed. This attitude increased public distrust and led to formation of well organized, well funded and active public interest groups. Federal agencies struggled to respond orienting activities toward public information and education, providing fact sheets and newsletters and holding public informational meeting in local communities. "Educating the public" became the primary focus of these efforts and the unspoken attitude was "then they will understand."

CHANGES IN THE 1990s

The 1990's has brought a new attitude. With remediation costs escalating, an uncertain economy, an increasing federal deficit and political pressure to balance the budget, prioritization was required. The thinking has switched from prescriptive to risk-based standards. Awareness that

current environmental policies may restrict our technological future has emerged with a concerted effort to revamp our environmental and nuclear waste policy laws and subsequent regulation. Likewise, the Yucca Mountain project costs were also escalating. With the existing standard remanded and DOE claiming the strictness of the standards for this predicament, the DOE subsequently requested the National Academy of Sciences to look at the existing standards for waste disposal and to determine if a risk based standard, specific for Yucca Mountain would be desirable. The Academy did question the existing standards in terms of length of time the facility should be regulated and in terms of population dose. These results will now be considered by the EPA to determine if a new standard will be promulgated and if so, will lead to further conforming regulations for the NRC for 10CFR60.

Long term effects of low-level waste are also being examined by the states. This work could lead to changes in the low-level waste regulatory structure, as well. Budget cuts have also affected the role of the NRC in low-level waste regulation. With a need to cut back, one option being considered within the NRC is to turn all regulation of low-level waste over to the states.

The Nuclear Waste Policy Act of 1982 and its 1987 Amendments are being discussed again within the Congress. Several bills have been drafted that could eliminate major state oversight and lead to less outside review of DOE activities. Recent budget problems have left no money for state oversight and led to plans by the DOE to cut the states out entirely. Changes in the development of Yucca Mountain may include less interaction with the NRC and perhaps not even applying for a License to Construct, after all these years of work and expenditures that exceed $6 billion to date.

The 1990s has seen new directions in public involvement, directions that have resulted in meaningful, result-oriented input by citizens. Public scoping meetings and public hearings on NEPA documents have been revamped and now stress public-agency interaction. A meeting facilitator has replaced the administrative court judge in these hearings. Site specific citizen advisory boards have had varying success providing review and oversight of DOE programs. This participation uses the skills and knowledge of citizens and acknowledges the value of stakeholder concerns in establishing priorities that result in technically sound and acceptable decisions. Unfortunately, these directions have not been consistently implemented within the DOE but have focused on the Environmental Management cleanup and remediation programs while waste management programs such as Yucca Mountain have eliminated state funding for technical oversight and public participation remains focused on informational activities.

In general the 1990's has been a period of uncertainty. Much rethinking has gone on with respect to our national waste management programs. While revamping is often necessary and constructive, confusion is not. After 50 years of regulation there is still no long-term strategies for spent fuel and high-level waste disposal. The DOE needs a consistent long-term approach to be efficient, a goal difficult to attain in light of changing political and social priorities. Perhaps the answer is to reach consensus on the framework for decision making rather than determine specific waste management solutions. Models of public participation used in DOE's Environmental Management Programs could provide the basis for developing a strategy for making waste management decisions. If agreement can be

reached on how to make decisions, then specific solutions can be flexible and responsive to site specific conditions and issues and changing social and political climates. A long-term strategy must be developed and implemented to finally result in disposal (or reprocessing) of radioactive wastes. Perhaps the greatest challenge is to consider and incorporate public, political and social issues in this strategy to enhance its implementability and lead to a truly long term solution.

EVOLUTION OF SPENT NUCLEAR FUEL REPROCESSING TECHNOLOGY AND HIGH-LEVEL WASTE MANAGEMENT

William H. McVey
The CADMUS Group, Inc.

ABSTRACT

The volume and physical form of high-level waste resulting from the reprocessing of spent nuclear fuel is determined by several factors, the more important of which are fuel type, reprocessing technology used, and waste treatment following reprocessing. The first plutonium production fuels were natural uranium metal slugs clad with aluminum. The first reprocessing technology was the batch bismuth phosphate precipitation process that recovered only the plutonium from the irradiated fuel; the uranium was sent to waste with the fission products resulting in large waste volumes. Storage in carbon steel tanks required the use of sodium

hydroxide to neutralize the acid waste, further exacerbating the quantity of inert materials present. Technologies were developed to recover uranium as well as plutonium during reprocessing and to recover uranium from the high-level waste tanks; these were the continuous solvent extraction processes known as the Redox and TBP (tri-butyl phosphate) processes. The Redox process did require the addition of inert process chemicals that again contributed to the solids in the high-level waste tanks. The Redox process was soon supplanted by the more desirable Purex continuous solvent extraction process that required the addition of very little inert material. Later defense fuels and research and test reactor fuels used highly enriched uranium in fuels that were composed of uranium aluminum alloy clad with aluminum or uranium zirconium alloy clad with zirconium. Reprocessing techniques were developed for these fuels based on Purex technology. Usually it was not possible to separate the clad and alloying material from the fission products during reprocessing so these materials also contributed to the inert materials in the high-level waste in storage. Except at one site, the use of carbon steel for storing high-level waste continued requiring continued waste neutralization. Technologies have been developed for the recovery of power reactor fuels that can produce very concentrated high-level waste streams, so concentrated that the space required in a deep geologic repository could be determined by the fission product heat output rather than the volume of waste. The benefits of these advanced reprocessing technologies have yet to be realized because of the present status of nuclear power in the U.S.

PURPOSE AND SCOPE

The purpose of this paper is twofold, to examine: 1) the principal determinants of the characteristics of the nation's inventory of high-level waste as it was initially generated and stored and 2) how reprocessing technology initially selected to meet wartime mission needs evolved in response to the needs for improved, more economic and efficient waste management techniques. Concluding remarks include observations on the prospects for reprocessing and waste management in the United States. The evolution of reprocessing technologies is limited in scope to aqueous systems since all of the inventory of high-level waste in the U.S. has been derived from those systems.

INTRODUCTION

In the beginning of the U.S. nuclear program, in the early 1940's, the pressing program requirement was for plutonium in significant quantities. The plutonium was to bede contaminated from fission products, to be available as rapidly as possible with all operations carried out with due regard for the health and safety of the worker and the public. The reprocessing technology used was based more on established techniques rather than optimization with respect to, for example, waste management. In this regard, the program was highly successful; the requisite material was produced on a remarkably short schedule. The focus here will be on the development of those technologies that have been put to large-scale use in the U.S.; that is, aqueous technologies and, in particular, precipitation and solvent extraction processes. It is the use of these processes that has produced all the high-level waste in existence in the U.S.

DEFINITIONS AND OVERVIEW OF REPROCESSING TECHNOLOGIES

High-level Waste (HLW) Definition

It had been recognized from the beginning of the nation's nuclear programs that wastes from the reprocessing of spent nuclear fuels were "high-level wastes," that is, highly radioactive. The definition was made more formal for civilian fuel reprocessing wastes in Appendix F to Title 10 of the Code of Federal Regulations Part 50 (10 CFR 50) in 1970 and for all wastes generated from spent fuel reprocessing, defense and civilian, in the Nuclear Waste Policy Act of 1982 (NWPA) (1). Currently high-level waste is source-defined, as in the NWPA, as the highly-radioactive material resulting from the reprocessing of spent nuclear fuel including the liquid waste produced directly and any solid material derived therefrom that contains a combination of transuranic waste and fission products in concentrations requiring permanent isolation. It should be noted that spent nuclear fuel is not defined in the NWPA as high-level waste, but as spent nuclear fuel: nuclear fuel that has been withdrawn from a nuclear reactor following irradiation the constituent elements of which have not been separated by reprocessing.

Reprocessing Definition and Technologies

Most of the nuclear fuels that have been reprocessed in the U.S. are uranium, either low or highly enriched in the isotope U-235. After irradiation, the spent nuclear fuel that was low enriched contained plutonium and residual U-235 whereas spent nuclear fuel that was highly enriched contained a significant quantity of U-235 but very little plutonium. Nuclear fuel reprocessing is the separation of uranium and plutonium from fission products and transuranic (TRU) elements other than plutonium, including the separation of uranium and plutonium from each other. For thorium fuels, of which there are almost none (e.g., Ft. St. Vrain and one loading from Indian Point reactor), reprocessing means the separation of uranium (U-233) from thorium and fission products. Several basic procedures can be used to effect separations; precipitation and solvent extraction have been used at Department of Energy (DOE) sites. In addition, aqueous and non-aqueous technologies have been carried through various stages of development, demonstration, and practical use. Non-aqueous fluoride volatility and pyrometallurgical processes, such as melt refining and salt transport, have been investigated through pilot-scale.

Reprocessing Unit Operations

Reprocessing operations involve several unit operations that can be broadly classified as activities involving 1) the head-end, 2) fissile/fertile/fission product separations, and 3) primary waste treatment. The head-end activities include clad/fuel separations and fuel dissolution resulting in cladding wastes and most of the off-gas wastes (for some fuels, it is necessary to dissolve the clad and fuel together because of the similarity of the clad and fuel; e.g., aluminum-clad uranium-aluminum alloy fuel). Separations activities, precipitation or solvent extraction, which isolate fission products and non-Pu transuranium elements from the useful constituents, were the principal sources of high-level wastes. The primary treatment for storage of liquid high-level waste, as it left the reprocessing plant, was usually neutralization of the acid effluent with sodium hydroxide to allow storage in carbon steel tanks such as those at Hanford and Savannah River; sodium nitrite was also added for corrosion control. Neutralization actually resulted in an alkaline waste in which sludges developed over time. At the beginning of the plutonium production program, there was a severe shortage of stainless steel with which to build large (about one-half million gallons) high-level waste storage

tanks; therefore, carbon steel was used thus precluding storage of acid wastes. High-level wastes are now stored as acid wastes in cooled, stainless steel tanks at the Idaho Chemical Processing Plant (ICPP) because of the possibility of mercury corrosion of stainless steel at high temperatures.

HIGH-LEVEL WASTE IN STORAGE

Determinants of High-level Waste Composition

The characteristics of the high-level liquid waste produced in reprocessing and stored as a liquid in tanks depend primarily on five factors: 1) the fuel type and radiation history, 2) the reprocessing technology employed, 3) the primary waste treatment and storage conditions, 4) subsequent waste treatment and storage conditions, and 5) the cooling time since the end of irradiation and the storage time since reprocessing. Because the composition of fuels and radiation histories are generally fixed, it is through development of reprocessing and waste treatment technologies that the greatest improvement on waste management can be realized. Primary waste treatment refers to the treatment of newly generated HLW before it can be stored, usually as liquid waste in tanks. Subsequent waste treatments to minimize storage risks or to prepare the waste for ultimate disposal will be covered only briefly. The source of all wastes generated throughout the nuclear fuel cycle is shown in R. L. Philippone's paper.

Quantities of DOE High-level Wastes in Storage

Particular emphasis is placed here on the high-level waste generated from the reprocessing of Atomic Energy Commission (AEC), Energy Research and Development Administration (ERDA), and Department of Energy (DOE) defense and test reactor fuels since these wastes represent most of the high-level waste in storage in this country as shown in Table I (2). Most of the high-level waste volume is at the Hanford site, most of the high-level waste curies are at the newer Savannah River site, and most of the curies at the Idaho site have been incorporated in a calcine. In total in the U.S. there are about one hundred million gallons of high-level waste in storage amounting to close to a billion curies of radioactivity. DOE high-level wastes in storage exist in several physical forms because of the principal determinants of the waste; that is, as liquids, slurries, sludges and salt cakes.

Table I

EVOLUTION OF REPROCESSING TECHNOLOGY - CHEMICAL SYSTEMS

Reprocessing facilities have been constructed in the U.S. employing several different technologies as shown in Table II.

Table II

First Separations Process - Bismuth Phosphate

The separations process chosen to meet early program requirements was the Bismuth Phosphate batch precipitation process for the bulk separation of plutonium from everything else followed by steps to decontaminate and concentrate the plutonium further; the uranium was not recovered but sent to waste. The Hanford reactor plutonium-production fuels were aluminum-clad uranium metal slugs. In the head-end, the aluminum was dissolved in sodium hydroxide and the uranium metal in nitric acid. The caustic aluminate cladding removal waste could be used, in part, to neutralize the acid reprocessing waste. This process that began operation at Hanford in December 1944, while it met the objectives set for it and did respect health and safety requirements, did produce very large quantities of high-level waste that contained all the uranium initially present. Later,

recognizing that much of the U.S. supply of uranium was being housed in Hanford's high-level waste tanks, processes were developed to remedy this situation.

First Solvent Extraction Systems - Hanford Redox and TBP

In 1952 the Redox plant was completed and went on line to recover both uranium and plutonium as Hanford defense fuels were reprocessed and the unused wartime U-plant was refitted as the Metal Recovery Plant (also known as the TBP (tri-butyl phosphate) Plant) to recover uranium from the bismuth phosphate tank wastes. The Redox process was the first continuous solvent extraction process and the first process for the recovery of both plutonium and uranium from nuclear fuels employed anyplace in the world. Both the Redox and TBP processes were continuous solvent extraction processes; Redox employed methyl isobutyl ketone ("hexone") as the organic extractant for uranium and plutonium. The metal recovery process utilized tributyl phosphate in a kerosene-like diluent as the uranium extractant. Continuous solvent extraction processes had many advantages over a batch, precipitation process. Disadvantages of the Redox process include an extractant (hexone) that had an undesirably low flash point and was reactive toward high concentrations of nitric acid. The use of hexone required the addition of aluminum nitrate as a "salting agent"; that is, a source of nitrate ions needed to favor the extraction of uranium and plutonium into the organic hexone phase. This inert material followed the fission products into the waste tanks thus increasing the waste volumes that had to be dealt with later.

Subsequent Processes - Purex Process

The TBP process evolved into the mainline Purex U/Pu recovery process that went into operation at Hanford in 1955 and in 1954 and 1955 at the Savannah River Plant. This process had the advantage that nitric acid could be used as a "salting agent" with the potential of substantially reducing HLW volumes. Not all the potential volume reduction available from the Purex process was realized because the continued use of carbon steel tanks required neutralization of the acidic high-level waste from the reprocessing operations, thus introducing inert sodium nitrate into the stored liquid high-level waste from the reaction between sodium hydroxide and nitric acid. Subsequent evaporation and concentration of the liquid high-level waste, left a solid "salt cake" composed largely of sodium nitrate.

Reprocessing Technologies for Specific Spent Defense Fuels

Highly enriched Al-clad, U/Al-alloy fuels as used in driver fuels in defense materials production reactors and in research and test reactors were integrally dissolved, clad plus fuel, in mercury-catalyzed nitric acid; a modified Purex solvent extraction process was used that recovered the uranium but not the plutonium, which went to waste, since there was so little of it in irradiated fuels that were highly enriched in U-235. In the case of zircaloy-clad/zirconium-uranium alloy fuels, the clad and fuel were dissolved together in an ammonium fluoride-ammonium nitrate mixture (zirflex process) or dissolved in boiling hydrofluoric acid (STR process) (3). Before solvent extraction, aluminum nitrate was added to complex with, and to render less corrosive, the fluoride present in solution. At Idaho, some aluminum-bearing wastes were added to the zirconium (and fluoride)-bearing wastes, again to render the fluoride less corrosive. Again, a modified Purex process was used to recover the uranium.

Advanced Purex -Commercial Fuels

Commercial zircaloy-clad slightly enriched uranium oxide fuels have been reprocessed using a shear-leach Purex process. In the head-end of this process, the fuel is mechanically sheared into small 1 to 2-inch segments and the uranium oxide fuel dissolved with nitric acid, leaving the clad as contaminated hulls to be disposed as waste. The uranium solution is reprocessed using Purex modified to minimize the number of waste streams and the addition of inert materials. For example, plutonium oxidation-state adjustment (used to partition uranium and plutonium) can be performed electrolytically without the addition of any chemicals. Plutonium can be further decontaminated from fission products and concentrated using ion exchange. The high-level wastes can be stored in cooled, stainless steel tanks thus avoiding the need for addition of neutralizing agents such as sodium hydroxide. This both increases the safety of waste management and facilitates subsequent waste management activities such as vitrification. This description closely fits the Barnwell Nuclear Fuels Plant in South Carolina, a full-scale plant (5 metric tons of commercial spent fuel per day) that was largely completed in 1977 in South Carolina but never operated because of nuclear weapons proliferation considerations at the time. About 600 tons of power reactor and AEC fuels were reprocessed in the period 1966-1972 in an earlier, smaller commercial solvent extraction plant operated by Nuclear Fuels Services at West Valley, New York, that produced a relatively small quantity of high-level waste. A wet/dry hybrid, Aquafluor, was installed by the General Electric Company in a small plant, the Midwest Fuel Reprocessing Plant, near Morris, Illinois, which never operated because of technical difficulties.

EVOLUTION OF REPROCESSING TECHNOLOGY - MECHANICAL EQUIPMENT

There have been developments in mechanical equipment that parallel the developments in chemical technologies; that is, the development of the actual mechanical devices in which head-end and separations processes are conducted. Mechanical devices did not have as significant an influence on waste management as did the process chemistry. The mechanical separation of cladding from the fuel by shearing and leaching eliminated the clad from the high-level waste. The success of a particular chemical technology did depend on the availability of appropriate mechanical equipment.

Decladding and Dissolution

Initially, fuel was declad chemically and dissolved in the same batch dissolvers from which oxides of nitrogen and gaseous fission products were emitted, principally krypton and iodine and sometimes ruthenium as the tetroxide. With some fuels, as mentioned earlier, the clad and fuel alloy were batch-dissolved simultaneously. There have been many dissolver designs proposed and tested. One of the more interesting is a continuous, rotary countercurrent dissolver has been shown for commercial-type fuels to provide a high degree of control of dissolution and digestion rates and off-gas evolution. It has also been shown that the oxides of nitrogen can be converted back to the original nitrate form (also called fumeless dissolution) and that all the volatile fission products can be trapped. Separations The bismuth phosphate precipitation process used centrifuges for solid/liquid phase separation but that process was supplanted by liquid-liquid solvent extraction processes before any major equipment improvements were needed. Solvent extraction processes involve the transfer of chemical species between immiscible aqueous and organic phases. Such transfer is enhanced by a large interfacial area obtained by

intimately mixing the two phases. In order to effect countercurrent stage-wise operation of solvent extraction equipment, not only must there be mixing, there must be phase separation. In some aqueous-organic systems it is difficult to mix the phases but easy to separate them (e.g., water-hexone); in others it is easy to disperse the phases but difficult to separate them (e.g., water-tributyl phosphate/normal hydrocarbon). Phase mixing and separation depend on many things, the more important of which are interfacial tension characteristics and density differences. Solvent extraction equipment that has been used successfully includes packed columns, pulse columns, mixer-settlers, and centrifugal contactors. The first application of the Redox process employed packed columns some 50 feet in height. Fifty feet of column height means fifty feet of shielding height and a high capital cost for the facility. The pulse column, while shorter than a packed column, still requires considerable cell height, though with proper piping, the headroom required can be decreased by dividing the column into two or three concatenated sections located side by side. Mixer-settlers, in which the two phases are mixed in one chamber and separated by gravity in another, use much less headroom than columns. One of the more remarkable pieces of solvent extraction equipment ever devised is a form of mixer-settler called the centrifugal contactor that uses much less space. It provides for excellent mixing and outstanding phase separation, taking place as it does in a centrifugal field. It is stagewise very efficient, has a high throughput in compact equipment with a short residence time, and can be shut down or started up in a very short time. The compact equipment minimizes shielded cell space and, coupled with short residence time, minimizes in-plant process solution inventory that in turn facilitates materials safeguards. A packed column is a relatively simple device whereas pulse columns, mixer settlers, and centrifugal contactors are progressively more mechanically complex.

HIGH-LEVEL WASTE STORAGE, TREATMENT AND DISPOSAL

High-level Waste Volumes

Comparison of the relative volumes of high-level waste generated by the processes just discussed is enlightening as shown in Table III (4)(5). There was a dramatic decrease in waste volume in going from the bismuth phosphate process (that resulted in a uranium-bearing waste stream) to the Redox and Purex solvent extraction processes (that provided for the recovery of uranium). Because the continued use of carbon steel tanks (except at the Idaho site) required neutralization, inert materials (particularly sodium nitrate) continued to be added to the high-level waste, as noted earlier. The volumes estimated to be produced from commercial power reactor fuels using advanced Purex technologies are so small that extensive cooling would be required to prevent unwanted boiling and the wastes may be more concentrated than can be handled comfortably during vitrification and subsequent storage and disposal.

Table III

Further Treatment of High-level Waste

Over the years, the high-level waste at Hanford has been treated for various reasons. For example, to acquire more tank space, a process was developed at Hanford in the 1950s to scavenge radiocesium from tank waste liquids. In implementing this process, approximately 140 metric tons of ferrocyanide were added to 24 single shell tanks (6). The presence of ferrocyanide must be considered in managing these particular wastes. In the future, it is planned to treat the high-level waste at Hanford and

Savannah River to separate the high-level waste into two fractions; one largely free of inert materials but containing most of the radioactivity and the other, produced incidental to concentrating the high-level waste, containing most of the inert materials (e.g., sodium, aluminum, zirconium nitrates) but little of the radioactivity. The larger volume of incidental or low-activity material would be immobilized and disposed on-site and the smaller volume of high activity material would be converted to glass, placed in stainless steel canisters, and stored on-site pending removal for disposal in a deep geologic repository. It is estimated that at Savannah River, for example, by the year 2020, there will be over 300 megacuries of radioactivity in a little over 3,000 cubic meters of glass and about 60 kilocuries of radioactivity in about a million and a half cubic meters of saltstone, a cementitious material (7).

High-level Waste Disposal - Repository Criteria

Up to this point, the discussion has focused on the evolution of chemical technologies that have been devised to minimize volumes of waste in storage. But repository space requirements for disposal are determined by both volume and heat output. The Waste Acceptance System Requirements Document (WASRD) (8) published by the Office of Civilian Radioactive Waste Management (OCRWM) specifies that high-level waste destined for disposal in a repository be borosilicate glass sealed in right circular cylinders of austenitic stainless steel of height 3 meters, diameter 61 centimeters (interior volume 887 liters), a maximum of 2,500 kilograms mass, and a maximum heat output of 1,500 watts. For Savannah River, it is estimated that, in the year 2015, the heat output from high-level vitrified waste in canisters would average a little over 100 watts per canister (7), well below the maximum allowed. It is clearly an advantage to minimize the volume of the high-level waste glass as will be done at Savannah River and other DOE sites.

The situation would be substantially different if commercial power reactor fuels were to be reprocessed. The average heat output from all irradiated fuels in storage in year 2000 from U.S. commercial power reactors is estimated to be about 3,000 watts per metric ton of spent fuel (7). If this "average" fuel were to be reprocessed using advanced Purex technology followed by vitrification of the high-level waste, the heat output would exceed the 1,500 watts per canister limit by several fold, meaning that the final waste form would be heat, not volume, limited. In this case, the advantage of the Purex technology would be to allow adjustment to the composition of the high-level liquid waste to minimize the waste volume to the extent practicable and to facilitate durable glass formation on vitrification.

CONCLUSIONS

From beginnings in 1943, through expansions of the 1950's, to the decisions of 1992 to phase out reprocessing at DOE sites, there has been an ever growing concern for an increasing number of regulatory requirements and for the proper management of nuclear wastes including ultimate disposal. Part of this waste management challenge has been met with the development of reprocessing technologies more compatible with safe and economic storage, treatment and disposal of nuclear wastes. In the event that commercial reprocessing of power reactor fuels should ever again take place in the U.S., advanced technologies could be employed that would be optimized, with respect to health and safety, environmental concerns, accountability and safeguards, and economics for all aspects of fuel reprocessing and waste management. However, for the foreseeable

future, the leadership that the U.S. clearly once held in reprocessing technology is essentially lost. Beginning with the Atoms-for-Peace program that was announced by President Eisenhower in December 1953, other countries learned much in commercial applications of nuclear technology from the U.S. With time, other countries had much to offer to the U.S. and technology exchange agreements were initiated to further the transfer of information in both directions. In the past few years, all reprocessing technology development in the U.S. has been abolished along with the relevant international exchange agreements. Not only is our technological base being eroded, we have lost the ability to remain knowledgeable of, or have significant influence on, developments abroad. Should nuclear fuel reprocessing be needed in the U.S. in the future, and no one can say it will not be, the U.S. can always turn to France, the UK, or Japan (or all three) for a turnkey reprocessing plant and trained crews to operate it. Nor should we be surprised if, unbeknownst to us, some unlikely country (or countries) turns up with a nuclear fuel reprocessing capability.

No reprocessing of commercial fuels is now taking place in the U.S. but Purex-related systems are in current use elsewhere in the world as is well covered in R. L. Philippone's paper. The spent fuel from nuclear power reactors in storage in the U.S. (about 29,000 metric tons of uranium as of the end of CY 1994) that contains a considerable amount of potential [nuclear] energy (e.g., 250 metric tons of plutonium and 240 metric tons of U-235), is now destined for deep geologic disposal. This uranium, if available for reenrichment, would be equivalent to about 37,000 metric tons of natural uranium that, on enrichment, would produce about 5,400 metric tons of power reactor fuel enriched to 3.2% U-235 that would fuel the 99,000 electric megawatts of U.S. nuclear power for about two years. If licensed for such use, commercial reactors could also use the plutonium in mixed oxide fuels.

THE CIVILIAN HIGH LEVEL RADIOACTIVE WASTE PROGRAM

Ralph Stein
Golder Federal Services, Inc.

ABSTRACT
After years of false starts and neglect, Congress in 1982 finally prepared all encompassing legislation for the storage, transportation and disposal of high level radioactive waste and spent nuclear fuel produced by the civilian sector. The House Science and Technology Committee had the Congressional lead for development of the Nuclear Waste Policy Act of 1982 (Act). As part of the legislation the Department of Energy's Office of Civilian Radioactive Waste Management (OCRWM) was created. Over the years, since 1982, there have been numerous articles, testimony, statements at hearings, State and Indian Nation meetings and other discussions which have been critical of the Program. A particular concern has been the date for the Department to take title of the spent fuel for disposal purposes. The 1998 timeline has become a vanishing dream.
Four organizational entities can be primarily identified as contributing, in varying degrees, to the present state of the Program. These entities are: Congress; the Department of Energy (DOE); the Utility Industry and the media. Each of these entities who were influential on the course of the OCRWM Program are addressed in this paper; however, it must be understood that each interacted with the other and frequently influenced the course of action in often unexpected ways. Further, there were many other players in the process of influencing the Department's decision-making, including the affected States, Indian Nations, regulatory bodies, and other.
Once legislation had been signed into law by President Reagan, the Department of Energy (the Department) initiated the provisions of the Act, building upon work that had already been done. The initial step, rapidly implemented, was the reduction of nine candidate sites, previously identified, to five sites (all west of the Mississippi). The next step was the further reduction of the five sites to three sites. These final three sites were to be characterized in detail, thus permitting the Department to proceed with selection of the repository

site. The decision of the repository site would be supported by an Environmental Impact Statement and a recommendation to the President on the selected site. There would also be an opportunity for Congress to reject the site, if so petitioned by the State in which the site would be located.

If all other provisions of the Act were met, a license application would be prepared for submission to the Nuclear Regulatory Commission, for approval to proceed to construction. Selection of the three sites was achieved by using a multi-attribute utility method to rank the five sites and provide the decision-makers with another vehicle to support the selection. Concurrent with the first repository activity, but off-set by one to two years, was initiation of a second process for identification of a second repository to be located east of the Mississippi. The entire repository Program as mandated by the Act was to achieve equity in the selection of sites. As noted later in this paper, the identification of three sites seemed to be the trigger for the process mandated by the Act to start to come apart.

Of all the forces acting upon the Department, none has been of greater influence, for obvious reasons, than the Congress of the United States. For about 10 years, prior to 1982, Congress has tried to pass some all-encompassing legislation to provide legislative direction and legal coverage for permanent disposal of the high level waste and spent nuclear fuel accumulating at an ever increasing rate within the DOE complex and at the utility pools. In the waning days of 1982, Congress was finally successful and passed the Nuclear Waste Policy Act of 1982 (Act). However, from that point on, Congress continued to provide close management and direction of the Program, with politics playing a key role in the Department's decision making. As examples of Congress providing basic direction, albeit indirect through the Department's leadership, two events are significant. First, in the early stages of the Program, Congress made it clear that there were some sacred cows (sites), such as the salt domes along the Gulf coast, and language was added to the Act to preclude selection of certain of these sites. Language was also added that effectively prevented the start of shaft sinking at Hanford and delayed site assessment until the site was legislatively terminated. Probably the clearest signal of congressional management of the Program was the indefinite delay, announced by and attributed to the Department, of further investigations associated with the selection of a second site in an eastern state as required by the Act. Finally, in 1987, Congress passed legislation, the 1987 Amendments to the At, which profoundly changed the course set by the original Act. Basically, the Amendments took away the fundamental basis of the Act, which was equity, and left the Department with only one site to characterize and a second repository relegated to an uncertain future. There was no backup for an unsuitable site; all the effort was to be focused on an unproved site in a State that was, and remains, adamantly opposed to the site, and has taken numerous steps, within its own regulatory framework, and in the courts, to prevent and/or delay the siting process.

During this period from 1983 to the present, the Department of Energy has had only 3 permanent Directors. The first was appointed and confirmed in 1984, a year after the law was enacted and left the program in 1987. It wasn't until 1990 that the second Director was in place, and the third came into office following the 1994 Presidential elections. These extended periods with acting Directors in place were characterized by

status quo, since it was frequently difficult for the Acting Director to take significant new initiatives. The result could be described as stagnation in program direction and inability to deal decisively with issues inside DOE and with outside entities, i.e., Stakeholders (the states, Indian Nations, the utilities and Congress). The most significant progress (both positive and negative) during these periods followed the appointment of the permanent Directors, when significant initiatives were undertaken to move the Program forward. But again, the Department was frequently stymied by the inability to gain consistent funding, coupled with specific direction written into the reports (often the personal bias of Congressional staffers) which accompanied the funding legislation. Further, the ability of the Department to move forward was frequently thwarted by the Stakeholders who exerted considerable influence on the Department's decision-making process. A prime example of this influence was associated with the second repository effort. The Act provided for a second repository site to be identified in the East, thus providing equity with the selection of a site in the West. The second repository siting process was characterized by strict groundrules which severely limited the siting managers from gathering specific information on potential sites. The process was further complicated by the strong negative and well orchestrated reaction of the local Stakeholders to siting a repository in their backyard (NIMBY). Following some particularly contentious public meetings where the DOE representatives had to be protected from very hostile audiences, the Department abruptly announced that the second repository was not needed until some time into the next century. Interestingly, it was not long afterwards that Congress passed the Amendments Act which eliminated the siting process for the second site until well into the next century.

The Utilities, through their industry representatives, became increasingly critical of the Department and its progress. Over the course of several years, it became obvious that the Department would not be able to meet a 1998 date for taking title to the fuel, as the utilities believed was mandated by the Act. The Department, on the other hand, did not believe they had the obligation, pending the siting of either a repository or a monitored retrievable storage facility. In the utilities' view, the Act's requirement that large amounts of the utility money be transferred from the nuclear utilities to the Waste Fund in order to support the Program was not producing the expected results. Instead, the utilities saw the funds going into a perceived sink hole without any visible progress toward meeting the 1998 date. As a result, the utilities became increasingly strident in their criticism of the Department and lobbied Congress continually, seeking additional changes to the Act and hope for relief regarding payment of ratepayer funding in the Waste Fund. Currently, the utilities are supporting legislation that will basically transfer the burden of paying for storage from the utilities to the Government. This will, again, fundamentally change the approach initially established by the 1982 Act.

Finally, it is worthwhile to review the media's role. Of all the parties, the media would describe its role as merely a bystander reporting the facts. Unfortunately, this was not the case in the vast majority of newspaper and journal articles and broadcasting. Typical of the attitude and tone set by the media is the reported comment of a nationally syndicated columnist who states, when her facts were challenged, that the staff just did not understand. As she stated, "...This is theatre...there

is no story in the mundane reporting of things going well." These comments set the stage for what has been the tone whether in the written or broadcast format. Generally, the Department, notwithstanding these periodic negative shots across the bow has handled the situation with reserve and dignity. Nevertheless, the result of all the negative publicity is to set a view in the public's mind that there is no safe way to dispose of the "waste."

What has been the results of this experience over the last 16 years? Basically, the Program has become increasingly more institutionalized and moribund in its ability to move ahead. The present OCRWM management seems to have set a plan into motion that appears to have the attributes for success, basically, determining in the shortest possible time whether or not Yucca Mountain is a suitable site. But weighed against this plan are large budget cuts which impact the progress of the program and the myriad of bills that Congress has in the hopper to once again make changes which only the future can tell whether they will be successful.

UPDATE ON FINAL WIPP COMPLIANCE CRITERIA (40 CFR PART 194)

Mary Kruger
Elizabeth Forinash
U.S. Environmental Protection Agency
401 M Street, NW (6602-J)
Washington, D.C. 20460
(202) 233-9310

ABSTRACT

The purpose of the meeting presentation is for the Environmental Protection Agency (EPA) to provide an up-to-date status of the Waste Isolation Pilot Plant (WIPP) Compliance Criteria rulemaking (40 CFR part 194). As of January 1996 (the time of this summary), the final rule has cleared the Office of Management and Budget (OMB) review process pursuant to Executive Order 12866. It is not appropriate for the Agency to discuss the final contents of 40 CFR 194 until the rule is signed by the EPA Administrator; however, this summary will discuss, in general terms, the status of the rulemaking. It is expected that the final rule will be signed prior to the meeting, so detailed information can be provided during the oral presentation.

INTRODUCTION

Since the Federal Register notice containing the Final Rule should be published in February 1996, the EPA should be in a position to discuss and articulate the explicit requirements in the final compliance criteria during the meeting. The EPA will also report on the last year's events that occurred in finalizing the criteria. These events will include: meeting of the National Advisory Council for Environmental Policy and Technology (NACEPT); lawsuits filed against the Agency regarding OMB review, timeliness of rule promulgation and the compliance application guidance; proposed legislation limiting the EPA's role in certifying compliance with the disposal regulations; and finally, last steps taken to finalize the rule.

BACKGROUND

The EPA regulates the release of radionuclides from the management, storage and disposal of radioactive waste in order to protect public health and the environment. The WIPP, which is under development by the Department of Energy (DOE), is a potential geologic disposal system for defense transuranic (TRU) radioactive waste. Pursuant to the 1992 WIPP Land Withdrawal Act, the EPA is required to perform several activities including, but not limited to: 1) finalizing safety standards for radioactive waste disposal; 2) issuing criteria for determining whether the WIPP complies with the radioactive waste disposal standards; 3) certifying whether the WIPP complies with the standards before waste disposal can begin; and, if the EPA certifies that the WIPP complies; 4) determining (or "re-certifying") whether the WIPP continues to be in compliance with the disposal standards every five years after initial receipt of waste at the site for disposal. In December 1993, the EPA completed the first of these activities by issuing the final radioactive waste disposal standards (40 CFR part 191), which place limits on the releases of radionuclides from waste management, storage and disposal facilities. Then, in January 1995, the EPA issued proposed compliance criteria (40 CFR part 194), intended to implement the 40 CFR part 191 disposal standards specifically at the WIPP.

In February 1996, after extensive consideration of public input, the Agency expects to issue the final compliance criteria. This program is unique because the EPA's approach taken at the WIPP may set precedent for future approaches taken at other radioactive disposal facilities. Many of the nuclear waste issues that are of considerable concern to the public will be addressed in this rulemaking.

The EPA's final compliance criteria are specific to the WIPP and its compliance with the disposal regulations found in subparts B and C of 40 CFR part 191. The primary goal of the compliance criteria is to make compliance at the WIPP as straightforward as possible. The criteria are aimed at clarifying the requirements of the radioactive waste disposal regulations and explaining procedural aspects involving the EPA's certification and re-certification of compliance at the WIPP. The final criteria are intended to support a "reasonable expectation" of compliance and include:

General Requirements, which include provisions for EPA inspections, quality assurance, computer models and codes, waste characterization, future states assumptions, expert judgment, and peer review.

Provisions addressing the Containment Requirements of 40 CFR part 191. These requirements address methodologies for considering inadvertent human intrusion and conducting probabilistic performance assessment.

Provisions addressing the Assurance Requirements of 40 CFR part 191. The Assurance Requirements are qualitative in nature and complement the numerical containment requirements. They are intended to provide added confidence in the performance of the disposal system or "defense in depth."

Provisions addressing the Individual and Ground-Water Protection Requirements of 40 CFR part 191. These requirements apply to undisturbed performance and limit exposures over 10,000 years, with the specific requirement of no more than 15 millirem per year per individual. The final criteria address methodologies for conducting compliance assessments against these requirements, appropriate assumptions, uncertainty considerations, and information needed to judge the results of such considerations.

Public Participation Requirements, which describe public opportunities for providing input to the certification rulemaking process.

APPROACH

The Agency's approach to WIPP's compliance demonstration will be presented during the oral presentation. For example, the EPA will describe its approach to assumptions regarding future human activities at the WIPP site (perhaps the most critical scenario in a WIPP performance assessment) that will have to be considered in demonstrating the disposal system's performance and its ability to contain the waste for 10,000 years. In addition, the EPA will discuss its consideration of the level of proof necessary to acquire confidence in the WIPP's ability to comply with the disposal standards. Additional confidence can be achieved through the successful implementation of the assurance requirements (e.g., institutional controls, monitoring, engineered barriers) of 40 CFR 191.

Throughout the rulemaking process, the EPA has been interacting with stakeholders on all aspects of the compliance criteria. The EPA is committed to achieving logical, reasonable compliance criteria that are protective of the public and the environment. To this end, the EPA has worked, and will continue to work, to gather input and promote understanding among key stakeholders. For example, the EPA: 1) circulated and obtained comments on an early, pre-proposal draft of the criteria; 2) participated in numerous technical meetings with the DOE; 3) hosted a technical workshop on several important compliance-related issues; 4) solicited comment on the proposed criteria and held three public hearings in the State of New Mexico; and 5) held a meeting of the NACEPT WIPP Review Committee to discuss critical compliance issues. Issues that have been complex and of intense concern include human intrusion, "credit" for passive institutional controls, monitoring, engineered barriers, peer review, waste characterization, and the qualification of "old" data. After promulgation of the final compliance criteria, the EPA will be responsible for ensuring that the criteria are properly addressed in the DOE's compliance certification application. And, upon review of the application, EPA will make a determination as to whether or not the WIPP complies with the Agency's radioactive waste disposal regulations. If so, the EPA will certify compliance and the facility will be allowed to open and accept waste for disposal.

THE WASTE ISOLATION PILOT PLANT REGULATORY COMPLIANCE PROGRAM*

James A. Mewhinney
U.S. Department of Energy
Carlsbad Area Office
Carlsbad, NM 88221
Robert F. Kehrman
Westinghouse Electric Corporation
Carlsbad, NM 88221

ABSTRACT

The passage of the WIPP Land Withdrawal Act of 1992 (LWA) (1) marked a turning point for the Waste Isolation Pilot Plant (WIPP) program. It established a Congressional mandate to open the WIPP in as short a time as possible, thereby initiating the process of addressing this nation's transuranic (TRU) waste problem. In addition, the LWA established the

Environmental Protection Agency (EPA) as the regulator for the WIPP and provided a schedular framework in which the EPA is required to work. Finally, the Congress provided for the oversight of certain WIPP activities by numerous other federal agencies, the National Academy of Sciences (NAS), the state of New Mexico, and the Environmental Evaluation Group (EEG).

The DOE responded to the LWA by shifting the priority at the WIPP from scientific investigations to regulatory compliance and the completion of prerequisites for the initiation of operations. Regulatory compliance activities have taken four main focuses: 1) preparing regulatory submittals; 2) aggressive schedules; 3) regulator interface; and 4) public interactions.

Four major compliance submittals are being prepared including a supplement to the Environmental Impact Statement (SEIS), a hazardous waste permit application, a no-migration variance petition (NMVP), and a compliance certification application (CCA). The WIPP Disposal Decision Plan (DDP) (2) was issued in May 1994 to show the DOE's aggressive commitment to opening the WIPP in 1998. Regulatory agencies that are dealt with on a day-to-day basis include the Environmental Protection Agency (EPA) and the New Mexico Environment Department (NMED). More than a dozen stakeholder meetings have been conducted to discuss various aspects of the WIPP program and to obtain input from the public. The WIPP stakeholder list includes 2650 individuals and organizations. The DOE has been highly successful in its strategy, meeting all milestones and holding frequent technical exchanges with the regulators. The DOE anticipates a continuation of this success as it continues toward an April 1998 opening of the WIPP.

INTRODUCTION

The DOE made a significant decision when it decided to abandon further on-site testing at the WIPP in favor of laboratory testing. This decision marked the transition from a facility for the collection of scientific information to an operating facility with the mission of disposing nearly 176,000 cubic meters of TRU waste. This transition was not easy. Experimental staffs had to be reduced as regulatory compliance staffs increased. Discussions with scientific organizations had to be augmented by discussions with regulatory organizations. These challenges notwithstanding, numerous factors contributed to the DOE's decision to proceed to operations. Among them were the LWA (1), the increasing emphasis on environmental remediation at DOE's weapons sites, and the general recognition that enough on-site testing had been done and further tests could be performed in laboratories.

THE TRANSITION TO DEMONSTRATING COMPLIANCE

The WIPP Land Withdrawal Act of 1992

When the LWA was passed in the waning days of the 102nd Congress, it received overwhelming approval. This had dual significance. First, it indicated that nuclear waste disposal is still a national priority and second, that Congress is anxious to see significant progress toward that end. While the LWA contained provisions for continued testing in support of the WIPP, that testing was required to be focused and relevant to demonstrating compliance with regulations applicable to the WIPP. One of the key features of the LWA is the schedules that Congress mandated. Key among these is Congress' intent that WIPP begin disposal operations within 7 years of initiating the on-site Test Phase. Even though the on-site Test Phase has been abandoned, the intent is clear--get on with

disposal. Recent attempts in Congress in both the House and Senate to amend the LWA have, as a common element, the establishment of a date certain for WIPP's opening--clearly reiterating Congress' intent to open WIPP.

Another important aspect of the LWA was the establishment of the EPA as the final approval authority for compliance with the long-term performance regulations in 40 CFR 191 Subparts B and C. Congress did this by requiring the EPA to establish criteria for the "certification" of the DOE's compliance with 40 CFR Part 191. This action has initiated activity by both the DOE and the EPA to ensure that the EPA has sufficient information to perform its duties.

Finally, the LWA requires numerous rulemaking processes including input from the public.

Regulatory Framework Documents

The first step the DOE took was the preparation and issuance of several documents to define the framework within which WIPP compliance will be demonstrated. These included the Regulatory Criteria Document (RCD) (3) which establishes general policy for compliance for TRU waste repositories and makes key interpretations of those portions of the environmental regulations that apply to the unique nature of the WIPP as a mined geologic repository for TRU and TRU mixed waste. In addition, the RCD provides a common basis for the implementation of similar requirements in the various environmental standards. The RCD specifically addresses the radiation standards in 40 CFR Part 191 (4), the hazardous waste standards in 40 CFR Part 264 (5), and the Land Disposal Restrictions in 40 CFR Part 268 (6).

The second regulatory framework document prepared by the DOE is the WIPP Regulatory Compliance Strategy and Management Plan for Demonstrating Compliance to Long-Term Disposal Standards (RCSMP) (7). The RCSMP detailed the WIPP specific activities needed to reach compliance and discussed the interrelationships among the various elements of the compliance and the experimental programs. This strategy called for preparation of numerous documents and compliance submittals that now appear on the WIPP DDP.

In addition, the Format and Content Guide for Title 40 CFR 191 and Title 40 CFR 268.6 Compliance Reports (FCG) (8) provides the framework for the documents that will be submitted to regulatory agencies. The DOE prepared the FCG as a means of assuring proper content and organization of the topics needed for a demonstration of compliance. Preparation was made with limited guidance from the EPA. The FCG has been useful in the preparation of the submittals that have been finished to date. The flexibility of the FCG has allowed the DOE to tailor the submittals to the specific regulations and regulators.

WIPP Disposal Decision Plan

The regulatory framework documents became the basis for preparing the WIPP DDP (2) which is shown in Fig. 1. The regulatory compliance schedule became the driver for the integration of other project activities such as experiments, waste characterization, public outreach programs and transportation system and facility readiness. The WIPP DDP is the tool for integrating these activities and for tracking progress. The DDP was most recently revised in October 1995 (Revision 2).

Fig. 1
Establishment of the Carlsbad Area Office

In order to provide proper focus on the compliance programs and to provide a single contact with regulatory agencies and with stakeholders, the DOE established an area office in Carlsbad in early December 1993. The Carlsbad Area Office (CAO) has total responsibility for the WIPP Program and for the implementation of the National TRU Waste Program. This combination provides complete interaction and coordination among the various WIPP project elements (DOE, Sandia National Laboratories, Westinghouse, Generator Sites) and the public, including the City of Carlsbad, a staunch supporter of the WIPP Project. The improved communication and coordination inherent with a centralized administrative function is paramount to the successful progress of the WIPP in light of its aggressive schedule.

Systems Prioritization Method

The Systems Prioritization Method (SPM) (9) was developed as a decision-aiding tool to aid in the process of identifying and selecting those experimental activities that will facilitate compliance. The SPM integrated standard decision-making tools with the performance assessment tool developed by Sandia National Laboratories to evaluate experimental activities based on their expected outcomes. The result was the specification of eight activities that could be completed within the desired time frame and which provide high confidence that compliance will be demonstrated.

ELEMENTS OF THE REGULATORY COMPLIANCE PROGRAM

The DOE regulatory compliance program comprises four major elements. These elements have been defined by asking three fundamental questions. First, what has to be done, by whom, and when? Second, How are they to be prepared? Third, who is the audience? Each of these questions is discussed in the subsequent text.

What? Whom? When? Schedule and Resources

The first task for the DOE was to identify all of the submittals that were needed for compliance and the times by which the submittals must be in the hands of regulators to assure timely processing. Five required submittals were identified. Given the unique nature of the documents and the time frames over which final information would be available, the DOE decided that the best way to handle these five submittals was through the preparation of seven separate documents as shown on the WIPP DDP (Fig. 1). In addition, the DOE identified two other support documents that would facilitate the compliance process. A summary of these documents is presented below.

The DOE addressed the resource issues by forming a compliance integration committee made up of managers from the CAO, Westinghouse, Sandia National Laboratories, and the DOE's technical support contractor. This committee addressed schedule and resource issues and conflicts, and interfaced with DOE upper management to assure timely availability of needed resources. In addition, the committee dealt with compliance issues and provided guidance on addressing issues in compliance documents. Since the inception of the accelerated compliance program, funding of compliance activities has received priority.

How? The Application Process

One of the greatest challenges facing the DOE with regard to regulatory permitting and certifying at the WIPP facility is the lack of regulatory precedent. For example, there are no other permitted mined geologic repositories. There are no other permitted TRU waste repositories. There are no other disposal facilities seeking a variance from the land

disposal restrictions. There are no permitted hazardous waste disposal facilities in the state of New Mexico. The EPA has never certified another federal agency's compliance with applicable regulatory requirements. This lack of precedence impedes the regulatory compliance program because both the WIPP and the regulators have to weigh each decision in light of the letter of the regulation, and where the letter of the regulation is unclear, in light of the spirit of the regulation. Unfortunately, in some instances, regulations conflict, or are inconsistent with each other.

In order to overcome some of the problems associated with the lack of precedent or with the conflict among regulations, the CAO has adopted an aggressive approach to compliance. One of the keys to the DOE's progress is the preparation of draft documents for review by regulators and the public. This allows for open discussion of issues in the context of the DOE's overall compliance strategy. While the number of comments becomes burdensome at times, the DOE treats each comment as a valid input into the application process.

With regard to application format, the DOE has used the FCG as the standard for applications. Since the FCG has roots in the NMVP process, it has proven to be acceptable to the EPA's Office of Solid Waste (OSW). Likewise, the EPA's Office of Radiation and Indoor Air (ORIA) considers the FCG an adequate framework for preparing the CCA. However, the actual content will have to conform to EPA's certification criteria to be promulgated as 40 CFR Part 194.

Whom?

The answer to this question is two fold--the regulators and the public. Both entities have a vested interest in the process and the outcome.

Regulator Interface

Interfacing with the regulators has been a major priority for the CAO. Three primary regulators involved are: the EPA ORIA, the EPA OSW, and the NMED, each with differing levels of familiarity with WIPP. Most of the CAO's efforts have, to date, focused on ORIA, since it has not been previously exposed to the WIPP. On the average, bimonthly technical interchange meetings have occurred and have covered major topics such as geology, hydrology, numerical model development, scenario screening, waste characterization, and others.

The CAO has tried to focus on current issues and their resolution. However, historical issues are also of interest to the regulators and, consequently, these have also been discussed. For example, deep dissolution was debated for many years at WIPP. Dissolution-related features in the vicinity were investigated to determine their likelihood of occurring at the WIPP site. Features such as the Wink sink, which is generally accepted to be human induced dissolution associated with oil and gas production, were also studied. None were determined to be likely at WIPP due to the lack of fresh water aquifers in the vicinity. Nonetheless, with new regulatory agencies involved, and new personnel, these old questions resurfaced and must be addressed.

Stakeholder Interface

Interface with stakeholders is a key aspect of the aggressive regulatory compliance strategy. Stakeholder input is mandated by federal and state laws and implementing procedures. The CAO concluded that the sooner the process began, the better for achieving the schedule and for minimizing "surprises" during public comment periods. The CAO defines WIPP stakeholders as those persons or organizations who have a vested interest

in the outcome of the permitting process. This includes the local population, many state and national organizations, individuals along transportation routes, populations at generator sites, and other interested parties. The WIPP stakeholder list includes 2650 individuals and organizations.

CAO stakeholder outreach has taken four forms. First, the DOE convenes general stakeholder outreach sessions to provide summaries of WIPP progress and to obtain general input. Second, the DOE has stakeholder meetings on specific topics to provide opportunities to inform and discuss specific technical issues of concern. Third, the DOE has formed stakeholder focus groups to obtain input on narrow issues. Fourth, stakeholders are asked to comment on numerous DOE documents prior to final issuance. In addition, stakeholders are kept informed about technical exchange meetings with the regulators and some stakeholders regularly participate in these meetings.

Of course, the success of the stakeholder outreach program lies in the CAO's ability to incorporate stakeholder views and comments into the WIPP program. While the CAO is still working toward a formal mechanism to do this, it is being done informally. During the SPM stakeholder meetings, numerous suggestions by stakeholders with regard to process, documentation, and content were provided and addressed by Sandia National Laboratories (9).

The CAO is committed to continue the stakeholder process. There are still plenty of topics to discuss, not the least of which will be the final conceptual models and the final data inputs used for compliance calculations.

ACCOMPLISHMENTS

The CAO has been able to maintain the aggressive schedule that it committed to in 1994. The following is a summary of the documents that have been published to date and the nature of the reviews that have been conducted.

Compliance Status Report

The Compliance Status Report (CSR) (10) was completed in March 1994. It provides the status of the compliance program. The CSR is broad in scope and covers both the radioactive waste and hazardous waste components. It identifies over 40 issue areas needing additional research or the preparation of final documentation. It served the purpose of providing the framework for starting discussions with regulators and stakeholders. The CSR generated over 280 written comments. In addition, the DOE and the EPA have had several technical exchanges to address these issues.

Project Technical Baseline

The Project Technical Baseline (PTB) (11) was conceived and prepared to be a compendium of established information regarding the WIPP site, with emphasis on information needed for environmental compliance documentation. It was issued early in the compliance program, as a draft in April 1994, to assure a level of consistency in documents being prepared for compliance. The latest revision is April 1995, although several changes are being processed at this time in preparation for the final NMVP and the CCA. The PTB is held under configuration control which means that it can only be changed with DOE's approval and after all users have had an opportunity to review the changes. It will be updated quarterly while applications are in process and probably less frequently after all regulatory submittals are complete. Documents that use the

information in the PTB include the NMVP, the RCRA Permit Application, the Draft CCA and the CCA, the Safety Analysis Report (SAR), and the SEIS.

Biennial Environmental Compliance Report

The first Biennial Environmental Compliance Report (BECR) (12) was issued October 1994 to satisfy the LWA requirement for a biennial assessment of compliance. It addresses 24 separate federal laws and state of New Mexico counterparts. The BECR is currently being reviewed by the EPA.

Draft Compliance Certification Application

The Draft CCA (13) was issued to ORIA in March 1995 in nine volumes. It describes the 40 CFR Part 191 compliance program status as of March 1995 for requirements that model undisturbed performance. The Draft CCA was supplemented in July 1995 (14) for requirements that model disturbed performance. The Draft CCA uses the projected outcome of the experimental activities identified in the SPM. The EPA has provided general comments and more detailed comments on the Draft CCA are expected in early 1996. The Draft CCA is based on 40 CFR Part 191 and does not incorporate the proposed 40 CFR Part 194 criteria since it was not available in final form at the time the Draft CCA was prepared.

Phase I No-migration Variance Petition

The Phase I NMVP (15) was submitted to OSW in May 1995 in seven volumes. It principally addresses emission issues. The EPA provided public notice of the Phase I NMVP, however, it received no public comments.

Revision 5 of the RCRA Permit Application

The DOE submitted Revision 5 of the RCRA Permit Application to the NMED on May 1995 (16) in ten volumes. The application has been re-scoped for disposal phase operations and closure. Discussions with NMED are ongoing. A notice of deficiency covering any remaining technical issues is expected in February 1996. The notable issues that the DOE and the NMED are discussing are waste characterization, RH-TRU waste, and closure.

FUTURE ACTIVITIES

In order to finally obtain permits and approvals, several key future activities are anticipated. These will constitute final submittals, and, to some extent are awaiting either final data on experiments or final rules from the EPA or both.

Phase II No-migration Variance Petition

The Phase II NMVP is due to the EPA in June 1996 after Sandia National Laboratories finalizes the conceptual models, the shaft seal design, and the numerical codes. It will contain the long-term performance calculations required to demonstrate no-migration for 10,000 years. The same calculational methods that were developed for the radioactive components of the waste will be used, along with the same conceptual model of the disposal system. A final decision by the EPA is expected by June 1997.

Hazardous Waste Permit

A draft hazardous waste permit is expected in the spring of 1996. The public will be provided an opportunity to comment on the NMED's permitting proposal. It is likely that public meetings and hearings will be scheduled. A final permit decision is expected before the end of 1996.

Supplemental Environmental Impact Statement

In the Supplemental Environment Impact Statement (SEIS) prepared for the Test Phase, the DOE committed to issue another SEIS to support the decision to begin waste disposal operations. Current plans call for the draft SEIS to be issued in May 1996. After a public comment period including public hearings in June 1996, the final SEIS is expected in

January 1997. A Record of Decision (ROD) is scheduled for issuance in March 1997. Among the issues being looked at are transportation, operational life, waste characterization, treatment to meet the waste acceptance criteria, backfill, and RH-TRU waste.

Final Compliance Certification Application

The DOE will prepare the CCA for submittal to the EPA in October 1996. However, the DOE needs the final data and conceptual models to prepare the CCA. These are due to be completed by March 1996. The CCA cannot be prepared prior to the issuance of final certification criteria, 40 CFR Part 194, by the EPA in February 1996. The proposed criteria were issued in January 1995 (17). The DOE has commented extensively on these proposed criteria (18, 19). In addition, the EPA is preparing a Compliance Application Guidance document to provide information relative to the level of detail expected in the CCA (20). An EPA certification is anticipated by October 1997.

SUMMARY

The DOE has successfully made the transition to demonstrating regulatory compliance at the WIPP. This transition is supported by an aggressive schedule that involves the DOE, its contractors, regulators, oversight organizations, and the public. The accelerated compliance process has been marked by numerous successes, including the resolution of issues and the identification of major topics to be addressed between now and the final submittal of applications. Major issues that are currently discussed include peer review, waste characterization, the use of engineered barriers, quality of old data, and computer code documentation. While many of these issues represent a significant amount of work, none appear to be obstacles to completing the compliance tasks in a timely manner.

THE WIPP RCRA PART B PERMIT APPLICATION FOR TRU MIXED WASTE DISPOSAL*

Jack E. Johnson
Westinghouse Waste Isolation Division
Craig A. Snider
U.S. Department of Energy
Carlsbad Area Office

ABSTRACT

In August 1993, the New Mexico Environment Department (NMED) issued a draft permit for the Waste Isolation Pilot Plant (WIPP) to begin experiments with transuranic (TRU) mixed waste. Subsequently, the Department of Energy (DOE) decided to cancel the on-site test program, opting instead for laboratory testing. The Secretary of the NMED withdrew the draft permit in 1994, ordering the State's Hazardous and Radioactive Waste Bureau to work with the DOE on submittal of a revised permit application. Revision 5 of the WIPP's Resource Conservation and Recovery Act (RCRA) Part B Permit Application was submitted to the NMED in May 1995, focusing on disposal of 175,600 m3 of TRU mixed waste over a 25 year span plus ten years for closure.

A key portion of the application, the Waste Analysis Plan, shifted from requirements to characterize a relatively small volume of TRU mixed waste for on-site experiments, to describing a complete program that would apply to all DOE TRU waste generating facilities and meet the appropriate RCRA regulations (Title 40, Code of Federal Regulations, Parts 260-270). Waste characterization will be conducted on a waste stream basis, fitting into three broad categories: 1)homogeneous solids, 2)soil/gravel, and 3)debris wastes. Techniques used include radiography, visually examining waste from opened containers, radioassay, headspace gas sampling, physical sampling and analysis of homogeneous wastes, and review of documented acceptable knowledge. Acceptable knowledge of the original organics and metals used, and the operations that generated these waste streams is sufficient in most cases to determine if the waste has toxicity characteristics, hazardous constituents, polychlorinated biphenyls (PCBs), or RCRA regulated metals.

The repository is composed of eight panels and two panel equivalents (access drifts), with each being designated as an independent Hazardous Waste Management Unit (HWMU). Revision 5 of the Permit Application introduces partial closure of each underground HWMU when filled, and final closure of the entire repository following decontamination of the Waste Handling Building (WHB). Panel closure is accomplished by a multipart engineered panel closure system to be installed in the entries of each HWMU, keeping the emitted Volatile Organic Compound (VOC) concentrations well below environmental performance standards.

The NMED may issue a Notice of Deficiency (NOD) upon completion of the technical review and interactive discussions held with the DOE. The NMED will publish a draft permit and schedule a comment period and public hearings, following the DOE's response to the NOD.

INTRODUCTION

The WIPP site has been set aside from public use to host a deep geologic repository for TRU mixed waste. The WIPP has both surface and underground facilities constructed and ready to begin disposal operations. The underground repository has been partially mined 650 m beneath the surface within a thick bedded salt formation. The repository is eligible for permitting as a miscellaneous unit under state and federal regulations (RCRA). A permit is required under the New Mexico Hazardous Waste Act and its implementing regulations for hazardous waste management operations.

In September 1994, the NMED withdrew the draft hazardous waste permit at the WIPP facility (issued in August 1993) after the DOE elected to cancel the in situ tests that were covered by that draft permit, requesting the DOE to submit a revised permit application.

The revised Part B Permit Application is organized in accordance with the RCRA application checklist (1). The NMED issued numerous comments as

their technical review proceeded. Most of the comments were requests for more detailed information. The DOE responded to each comment and drafted new text and supporting information where appropriate. These revisions were discussed during meetings with the NMED prior to their issuing the NOD letter.

TRU mixed waste to be received at the WIPP exists in a variety of physical forms, ranging from unprocessed laboratory trash (e.g., tools, paper, glassware, gloves) to solidified wastewater treatment sludges resulting from plutonium reprocessing and fabrication as well as from research and development activities at various DOE defense program facilities. Most TRU mixed waste is contact-handled (CH) but some with a higher intensity of radioactivity is remote-handled (RH). In the future, significant quantities of TRU mixed waste may be generated from environmental restoration, decontamination, or decommissioning activities. TRU mixed waste containers are required to be vented through high-efficiency particulate air (HEPA)-grade filters to preclude pressurization caused by potential gas generation.

PERMIT APPLICATION

The permit application is organized into 13 chapters, with headings and subheadings in accordance with the RCRA application checklist (1).

Chapter A, "RCRA Part A Application Certification"

Chapter A consists of Part A of the application. The Part A contains the facility's owner and operator information, type of facility, capacity, process information, estimated annual waste receipts, and certification. The DOE is the WIPP facility owner/operator, and, in accordance with DOE policy, the Management and Operating Contractor, Westinghouse Waste Isolation Division, has signed the certification as co-operator.

Chapter B, "Facility Description"

The facility description includes some history of the site selection and the development leading up to construction. The basic requirements of the WIPP Land Withdrawal Act of 1992 are presented. Eight underground panels of seven rooms and two access drifts each comprise the repository and are to be permitted as HWMUs. The disposal area access drifts will probably also be used in the future as panels 9 and 10. As each panel is filled, it will be closed off to isolate that waste from the rest of the facility.

The WHB areas used for waste receipt, handling, inspection, etc., are included for permitting as container storage units (HWMUs), consisting of the CH Bay, the RH Bay and hot cell complex in the WHB, and the parking area south of the WHB. Waste is received in TRU Package Transporters (TRUPACT-II) and road or railroad casks (designed to meet Department of Transportation Type B requirements), which are unloaded inside the WHB. Both road and rail transportation accesses are available.

The CH waste containers will be inspected in the CH bay as they are removed from the TRUPACT-II, loaded onto a facility pallet, moved to the waste hoist conveyance, and lowered down the shaft to the repository horizon via the waste hoist conveyance, and transported to the HWMU where the waste is disposed. The road cask with RH waste is unloaded in the RH bay into the hot-cell complex remotely, where the waste container can be identified, checked for external contamination, and loaded into the facility cask for transport underground via the waste hoist conveyance. The facility cask is transported to the HWMU and set on the emplacement machine, which faces a drilled hole in the salt. Shield valves allow the waste container to be pushed into the hole without exposing the operators

to radiation. A shield plug goes into the hole afterward to assure safe personnel access to the room for CH waste stacking activities after the emplacement machine has been removed.

Other information in Chapter B is provided on location, topography, distance from bodies of water, prohibition of hydrocarbon wells on the site, vicinity of water wells, lack of nearby population centers, cattle grazing leases, site access control, and compliance with other portions of the regulations, including the floodplain and seismic standards. The only pathway for hazardous emissions is by air, either from the underground or the WHB exhaust.

Chapter C, "Waste Analysis Plan"

Generators are required to characterize all wastes planned for disposal at WIPP, using formal programs adhering to the requirements of the Waste Analysis Plan (WAP), the WIPP Waste Acceptance Criteria (WAC), and the TRU Waste Characterization Quality Assurance Program Plan (QAPP). Both sampling and analysis programs and acceptable (process) knowledge will be used in classifying the wastes. Some wastes have been in retrievable storage since 1970 and others will be generated in the future.

The previous permit application for test waste required characterizing 100 percent of the waste, although waste quantities were small and only two DOE generators were involved. The revision for disposal applies to all DOE TRU waste generator sites, possessing the full spectrum of waste streams. Waste characterization requirements for disposal have been developed to balance the quantity of data required to satisfy the regulator, yet prevent extensive increases in generator personnel exposure and excessive expense. Thus, the WAP establishes new WIPP TRU waste characterization requirements for all DOE generator sites planning to dispose of their TRU waste.

Waste characterization will be done on a waste stream basis. The waste streams fit into three broad categories: 1) homogeneous solids, 2) soil/gravel, and 3) debris wastes. Techniques to be used include radiography, visual examination of opened containers, headspace gas sampling, physical sampling and analysis of a statistically determined amount of homogeneous wastes, and review of documented acceptable knowledge.

Radiography is used to noninvasively examine waste containers (required for all stored waste and judiciously applied to newly generated waste) for physical form of the waste and to detect free liquids and other prohibited items.

Visual examination, an invasive technique, will be conducted on a statistical sample of waste containers from each waste stream and used to inspect waste contents and verify radiography results.

Headspace gas sampling and analysis are used to determine the concentrations of VOCs, hydrogen, and methane within the headspace of waste containers.

A statistically selected portion of homogeneous solids and soil/gravel wastes will be sampled for hazardous waste constituents and toxicity characteristic. Samples will be analyzed for VOCs, semi-VOCs, and metals.

Acceptable knowledge is used to classify debris waste. Knowledge of the original organics and metals used and the operations that generated these waste streams is sufficient to determine if the waste has a toxicity characteristic, hazardous constituents, PCBs, or RCRA-regulated metals. RCRA-regulated metals present in debris waste are associated with specific waste materials (e.g., lead in leaded rubber gloves).

Radiography, visual examination, and headspace gas sampling are used to collect data to provide confidence in acceptable knowledge.

Generator waste characterization also includes quality assurance (QA) requirements, applied through meeting the QAPP requirements by implementing site-specific QA Project Plans (QAPjP), which are submitted to the WIPP for review and approval. The WIPP personnel will perform audits of the generator site waste characterization programs to verify that implementation of the QAPjPs is consistent with the requirements of the QAPP and the WAP.

There are three phases to waste shipment screening and verification. The first step involves submittal of a Waste Stream Profile Form to the WIPP for review. The next phase occurs prior to shipment wherein the electronically transmitted data package is reviewed and accepted by WIPP personnel after extensive edit and range checks conducted by the WIPP Waste Information System (database). This acceptance is based on successful completion of the WIPP audits of the generator's QAPjP activities, and a determination that the data meet the acceptance criteria. The third phase occurs after the shipment has arrived, but before it is accepted. This includes 1) a determination of the completeness and accuracy of the EPA Hazardous Waste Manifest, 2) a determination of waste shipment completeness, 3) a determination of land disposal restriction notice completeness, and 4) an identification and resolution of any waste shipment irregularities.

Chapter D, "Facility and Process Information"

Facility and Process Information includes the TRU waste management facilities, equipment, and operations described in Chapter B, and compliance with the environmental performance standards for the WIPP.

The physical attributes of the WIPP site contribute to the ability of the facility to isolate TRU mixed waste and ensure that human health and the environment are protected. The average annual precipitation is only 30 cm, 96 percent of which is returned to the air through evapotranspiration. The geologic sequence at this site mainly consists of three evaporite-bearing formations, the Castile (deepest), Salado, and Rustler. The repository is located in the Salado formation, an approximately 610 m thick bedded halite, with some carbonates, anhydrites, and clay seams. It is regionally extensive, has extremely low permeability, behaves in a plastic manner under pressure, contains only fluids that are saturated with salt, and lies between the other two formations which contain highly impermeable layers that offer further confinement for the waste.

Four shafts connect the underground area with the surface. The Waste Shaft is located within the WHB. The Air Intake Shaft and the Salt Handling Shaft provide ventilation underground. The Exhaust Shaft serves as a common exhaust air duct for all underground areas.

The WHB was designed to withstand a design basis tornado with a maximum windspeed of 294 km/hr and a design basis earthquake acceleration of 0.1 g.

Release of hazardous waste or hazardous constituents to the air that may have adverse effects on human health or the environment is unlikely. VOCs constitute the greatest hazard, but the maximum concentration of any VOC release has been calculated to be at least two orders of magnitude below the environmental performance standards.

Chapter E, "Groundwater Monitoring"

In the past, groundwater monitoring at the WIPP has focused on the Culebra member of the Rustler Formation above the repository, as it represents the most permeable and most likely hydrologic contaminant migration pathway. No credible pathway has been established for contaminant transport to aquifers below the repository horizon, as there is no hydrologic communication between the two. It is the DOE's position that the migration of hazardous waste or hazardous constituents from the WIPP repository to the environment through groundwater is unlikely. The bedded-salt formation acts as an extremely low-permeability regional barrier isolating the repository from water-bearing units. Also the plasticity and geologic behavior of halite will tend to close any potential pathways created by excavation.

For hazardous waste or hazardous constituents to migrate from the repository to groundwater-bearing units, there must first be a pathway, such as a shaft. All four shafts extending to the repository horizon have been constructed to minimize the infiltration of water from the overlying water-bearing units into the repository during its operational life. After waste emplacement, the shafts will be filled with permanent low-permeability seals and plugs designed to inhibit migration of fluids to and from the repository.

Surface water is generally absent in the immediate vicinity of the WIPP facility.

Chapter F, "Procedures to Prevent Hazards"

Security, facility inspections, structures, equipment, procedures, and other measures taken to prevent hazards during the disposal operations are described.

Security requirements are met by 24-hour surveillance and a barrier to control entry to the facility at all times.

Equipment instrumental in preventing, detecting, or responding to environmental or human health hazards is inspected periodically for malfunctions, deterioration, potential for operator errors, and discharges which could lead to a release of hazardous waste constituents to the environment, or pose a threat to human health.

The WIPP facility has a variety of communications systems and emergency response equipment and possesses a continuous water supply to meet emergency situations. The intraplant communication systems include two-way communication by the public address (PA) system and its intercom phones and paging channels, an intraplant telephone system, mine phones, pagers and plectrons, portable two-way radios, and local and facility-wide alarms. External communications are provided by the commercial telephone system and two-way radios for summoning emergency assistance from off site or communicating with outside agencies.

The water supply system is for domestic use and fire control for the maximum credible fire. The underground has no water supply, but has fire extinguishers of various types and a rescue truck with chemical and foam extinguishers.

Diesel generators provide power in the event of utility power loss and the uninterruptible power supply is always available to supply important monitoring systems. Thus, during a power outage, the ventilation systems are powered by the diesel generators and all waste handling operations are shut down into a mode providing personnel and facility safety.

Chapter G, "RCRA Contingency Plan"

The Contingency Plan defines responsibilities, provides guidance for coordination of activities, and minimizes hazards to human health and the

environment from fires, explosions, or any sudden or nonsudden release of hazardous waste or hazardous waste constituents to air, soil, or surface water. In case of an emergency where a release results that may threaten human health or the environment, the RCRA Emergency Coordinator will activate the Contingency Plan. The provisions of the Contingency Plan apply to all HWMUs, the Waste Shaft, and supporting TRU mixed waste handling areas. Nonradioactive hazardous substances, hazardous materials, and hazardous wastes will also be managed in accordance with the Contingency Plan.

A RCRA Emergency Coordinator will be on site at the WIPP 24 hours a day, seven days a week, with the responsibility for coordinating emergency response measures. Persons qualified to act as the RCRA Emergency Coordinator are thoroughly familiar with the Contingency Plan, the TRU mixed waste and hazardous waste operations and activities at the facility, the locations of TRU mixed waste and hazardous waste activities, the locations on site where hazardous materials are stored and used, and the locations of waste staging and accumulation areas. Other personnel identified are 1) the Central Monitoring Room Operator, 2) the Emergency Response Team, 3) the Emergency Services Technicians, 4) the First Line Initial Response Team, 5) the Mine Rescue Team, 6) the Office Wardens, 7) the Chief and Assistant Chief Office Wardens, and 8) the Security Fire Support. The Contingency Plan will be activated only when the RCRA Emergency Coordinator determines that the activation criteria are met.

If notification of local authorities and or regulatory agencies is determined to be necessary, the RCRA Emergency Coordinator will assure that those notifications are made. The DOE policy is to provide accurate and timely information to the public by the most expeditious means possible concerning emergency situations at the WIPP site that may affect off-site personnel, public health and safety, and/or the environment. Supplementing the on-site capabilities for emergency response, the DOE has Memoranda of Understanding with off-site emergency response agencies for fire response, medical assistance, and law enforcement. Since the WIPP facility is owned and operated by the DOE, other off-site DOE emergency response organizations could be called in for support.

Any incident requiring activation of the Contingency Plan will be reported to the operating record in detail. Notifications required by regulations will be made to the required regulatory agencies within the allotted time span.

Chapter H, "Personnel Training"

The WIPP's personnel training program meets the requirements of the RCRA. Preparing personnel to operate the WIPP facility in a safe and environmentally sound manner is the primary objective of the training program. All on-site personnel are provided with an introduction to RCRA and emergency preparedness within 30 days of employment. Other relevant training is provided to employees and their supervisors whose jobs are such that their actions or failure to act could result in a spill or release or the immediate threat of a spill or release of hazardous waste. Required RCRA-related training is conducted by certified instructors and consists of classroom instruction and on-the-job training as appropriate. Certain positions require formal certification and are identified by Department Managers based on safety, complexity, and involvement with hazardous waste handling operations.

Hazardous waste management courses are offered at a frequency that ensures that new hires or transfers can receive relevant training within six months of assuming their new position. Employees do not work unsupervised in hazardous waste management positions until they have completed the requisite training.

The training program for emergency response ensures that personnel are able to respond appropriately and effectively to emergency situations by providing thorough training, including fire response elements, 40-hour miner training, Mine Safety and Health Administration requirements for medical and mine rescue, and lifesaving elements.

Chapter I, "Closure Plans, Post-Closure Plans and Financial Requirements"

This chapter was extensively revised to contain descriptions of the activities necessary to close the WIPP facility at the end of it's life and provide surveillance after closure. The previous revision detailed "clean closure" based on the possibility of having to retrieve and return all of the test waste. The WIPP is a federal project, so financial assurances for closure are not required to be addressed. The underground HWMUs (panels) will be closed individually as they are filled, with barriers constructed to limit accessibility of the hazardous constituents to the environment during continuing operations. Partial closure of each HWMU will be considered complete when the panel closure system is emplaced and operational, and the NMED has approved the closure. Possible backfilling of access drifts, plugging and sealing of the shafts, and dismantling of surface facilities will constitute final closure.

For the purposes of establishing a schedule for closure, the operating life may last 25 years, followed by a closure period of ten years for decontamination (both radiological and chemical), decommissioning, and final closure. The WIPP surface and subsurface facilities are planned to be dismantled (except for the hot cell portion of the WHB, which will remain as a portion of the Permanent Marker System) and either salvaged or disposed of. Paving and caliche will be removed and the surface area recontoured and revegetated. During the closure period, the DOE will continue to demonstrate compliance with applicable permit requirements. Facility monitoring procedures in place during operations will remain in place through final closure.

Decisions about closure activities may be based in part on analyses of potentially contaminated surfaces and media. Reliability of analytical data will be accomplished by following a Quality Assurance/Quality Control (QA/QC) program that mandates precision and accuracy of laboratory analyses. The documented QA/QC program currently in place at the WIPP meets the DOE QA requirements.

Final closure of the WIPP facility will prevent the intrusion of fluids into the repository, prevent human intrusion after closure, and minimize future physical and environmental surveillance. Access to the site of the repository's surface footprint will be controlled by the federal government as long as practicable and at least for the 100-year period considered under 40 CFR Part 191. This active control will preclude inadvertent intrusion into the disposed waste by deep drilling or mining natural resources.

The post-closure care period begins after completion of final closure of the facility and continues as long as necessary to satisfy regulatory requirements and to protect human health and the environment. During the post-closure period, the WIPP site will be maintained in a manner that complies with the applicable environmental performance standards. No

post-closure monitoring for detection of releases is proposed since the migration of contaminants is unlikely. However, because there are other regulations that apply to the WIPP long-term performance, several techniques need to be evaluated (e.g., geophysical techniques and subsidence monitoring).

Chapter J, "Corrective Action for Solid Waste Management Units"

The solid waste management units (SWMU) within the 41.4 km2 WIPP site boundary were identified by the EPA Region 6 as requiring further investigation. Corrective actions are required only for SWMUs from which releases of RCRA hazardous wastes or hazardous constituents have occurred.

The definition of a SWMU has not been finalized by the EPA yet. WIPP uses the definition presented in the proposed Subpart S of 40 CFR Part 264. This definition states that SWMUs are "any discernible unit at which solid wastes have been placed at any time irrespective of whether the unit was intended for the management of solid or hazardous waste. Such units also include any area at or around a facility at which solid wastes have been routinely and systematically released." 16 SWMUs requiring further investigation have been identified by the NMED, which conducted a RCRA Facility Assessment for the EPA. Seven others were created by the DOE since the filing of the Revision 3 of the Permit Application for the test program. Units that are similar in physical characteristics or waste type are grouped within an SWMU description for the particular type of discernible unit.

The DOE will institute corrective actions necessary to protect human health and the environment for any release of hazardous waste or hazardous constituents from SWMUs at the WIPP facility. Authority for regulating corrective actions recently passed to the NMED.

Chapter K, "Other Federal Laws"

Other federal laws, Executive Orders (EO), and regulations which deal with environmental protection, or were evaluated for applicability to the operation of the WIPP facility, are listed. These were all assessed because of the nature of the WIPP's proposed activities and the proposed land use.

Chapter L, "No-Migration Variance Petition"

The history of the DOE's submittals of a No-Migration Variance Petition (NMVP) is summarized, as is the subsequent addendum to the EPA to demonstrate that the site characteristics, operational practices, and waste characteristics were sufficient to prevent migration of hazardous constituents beyond the unit boundary during the period planned for the test program.

The EPA issued a Conditional No-Migration Determination for the Test Phase. Subsequently, however, the DOE abandoned plans for testing waste at the WIPP. The DOE submitted a new Draft NMVP for the waste disposal in May 1995. A final NMVP for both operations and post-closure will be submitted in June 1996.

Chapter M, "Certification"

This is a statement of the DOE being the owner and operator of the WIPP facility with the Westinghouse Waste Isolation Division as the co-operator. Managers of both organizations have signed this certification.

RECENT ACTIVITIES

The NMED determined the permit application to be administratively complete and during their subsequent technical review, hosted interactive discussions with the DOE and contractors for both organizations. The

major comments received from the NMED were for much more detail to be supplied.

The DOE set a goal of receiving the Permit in August 1996. The DOE attempted to resolve the NMED's comments with expanded descriptions of all aspects of the facility design and operation, even those associated with the radiological controls. The DOE also attempted to reduce the quantity of comments in the NMED's Notice of Deficiency (NOD) letter via the interactive comment resolution process. All activities under DOE control continue to be aimed at meeting the set goal.

The DOE submitted a final response to the NMED's comments in mid-January 1996, following the early January technical exchange meeting with the NMED. The NMED told the DOE that, based upon the contents of the final response, they would review the responses and revised text, and issue the NOD in mid-February, which they did. The DOE was given 30 days to respond to the NOD, after which the NMED would develop the draft permit.

Upon issuance of the draft permit, a public comment period will be established. Public hearings are anticipated at various cities in New Mexico, in which the DOE will participate. The NMED will consider the testimony from the hearings and all comments received, and craft a final permit (or a denial) with all conditions they believe are necessary to protect the public safety and the environment from harm by the waste disposal operations at the WIPP facility.

CONCLUSION

The WIPP disposal-phase operating permit application was submitted to the NMED by the DOE in May 1995, and is described in some detail. Following a period of technical review, the NMED issued a number of comments, to which the DOE responded with draft revisions to the permit application. After several technical exchange meetings, the NMED issued an NOD in February 1996. A new revision to the application will be completed, along with written responses to each deficiency, and submitted to the NMED within the prescribed response time.

The next step is for the NMED to draft the permit, supplying their conditions for facility operations, and hold public hearings. Upon consideration of the oral and written responses during and after the hearings, the NMED is expected to issue the permit.

THE WASTE ISOLATION PILOT PLANT NATIONAL ENVIRONMENTAL POLICY ACT DISPOSAL DECISION*

Harold E. Johnson
U. S. Department of Energy
Carlsbad Area Office

Miriam E. Whatley
William A. Most
Westinghouse
Waste Isolation Division

ABSTRACT

To strengthen the effectiveness of the Department of Energy's (DOE) environmental clean-up efforts, a number of individuals have petitioned

for the accelerated opening of the Waste Isolation Pilot Plant (WIPP). The longstanding mission of WIPP is to demonstrate the safe disposal of transuranic (TRU) waste resulting from United States defense activities. In 1980, to comply with the National Environmental Policy Act (NEPA), the DOE completed its first environmental impact statement addressing TRU waste disposal options which compared the impacts of several alternatives for TRU waste disposal. Based on the 1980 analyses, the DOE decided to proceed with the construction of the WIPP facility in 1981. In a 1990 decision based on the examination of alternatives in a 1990 Supplemental Environmental Impact Statement, the DOE decided to continue development of the WIPP by proceeding with a testing program to further examine WIPP's suitability as a TRU waste repository.

In June 1994, the U.S. Secretary of Energy issued a policy designed to reduce the cost and time required to complete DOE environmental impact statements. Now, as the DOE attempts to complete its regulatory obligations to begin WIPP disposal operations, the DOE is developing the WIPP's second supplemental environmental impact statement (SEIS-II). To complete the SEIS-II in full compliance with NEPA and the stringent requirements of the secretarial policy, the DOE's Carlsbad Area Office will have to successfully rise to a number of challenges. These challenges include: preparing the SEIS-II, while simultaneously finalizing other critical-path compliance documents; controlling SEIS-II costs, while pursuing timely completion and ensuring consistency with compliance documents; keeping stakeholders involved with the NEPA process; and developing contingency plans to address factors that could affect the SEIS-II completion.

INTRODUCTION

To strengthen the effectiveness of the Department of Energy's (DOE) environmental clean-up efforts, a number of individuals have argued in favor of the accelerated opening of the Waste Isolation Pilot Plant (WIPP). In an August 1995 congressional task force report to Speaker Newt Gingrich, entitled The Top 20 Ways to Turbocharge DOE Cleanup (1), task force members made the following statements:

The WIPP is a world-class facility designed specifically for the management of transuranic waste. Unfortunately, it presently sits idle. The facility costs American taxpayers millions of dollars to maintain, while related testing and regulatory hurdles are ongoing. Failure to open WIPP also costs taxpayers millions in related storage, inspections, and monitoring for waste destined for shipment to the WIPP, but which currently remain stored at numerous sites around the country. It's time to open this critical facility.

BACKGROUND

From the late 1970s to date, the DOE and its regulators have scrutinized the WIPP facility to ensure that applicable environmental and safety standards are being met. The DOE has continued to assess the WIPP facility in order to ready the WIPP to demonstrate the safe disposal of transuranic (TRU) waste resulting from United States defense activities. The National Environmental Policy Act (NEPA) (2) requires that federal agencies consider potential environmental impacts of its proposed action and alternatives before deciding to proceed with new projects and activities. NEPA also encourages the DOE consider public comment in its decision making process.

In 1980, to comply with NEPA and further the DOE's decision-making process, the DOE prepared an environmental impact statement (EIS) (3) and

issued a Record of Decision (ROD) (4) in early 1981 to initiate the first phase in development of the WIPP, i.e., to construct the WIPP surface and underground facilities.

In 1990, DOE issued a supplemental EIS (SEIS) (5) to analyze potential environmental impacts resulting from "new information or changed circumstances" (6). These changed circumstances included the elimination of planned experiments with high-level radioactive wastes, and the introduction of phased experiments. These circumstances further defined the proposed actions presented in the 1980 EIS.

The 1990 SEIS ROD (7) stated that the DOE would continue with the WIPP's development by conducting test phase activities in the WIPP underground facility to demonstrate compliance with applicable radioactive disposal regulations. Since that ROD was issued, the DOE announced that it would conduct tests in above-ground laboratories rather than the WIPP's underground facility to save time and costs while obtaining comparable test results(8).

Now, in 1996 the DOE's Carlsbad Area Office (CAO) is facing the final round of regulatory challenges associated with initiating disposal operations at the WIPP. Among these challenges will be the expeditious completion of a second Supplemental Environmental Impact Statement (SEIS-II). The SEIS-II is being prepared, in part, to fulfill a commitment made in the 1990 ROD, which stated that prior to making a decision to proceed into full disposal operations, another supplemental EIS would be prepared. The SEIS-II will examine the impacts of pertinent "new information or changed circumstances" relative to WIPP disposal operations that have become apparent since 1990.

A MORE EFFICIENT NEPA PROCESS; DOING MORE FOR LESS

All government agencies are faced with doing more for less, and the DOE is no exception. In June of 1994, the Secretary of Energy, Hazel R. O'Leary, issued The Secretarial Policy on the National Environmental Policy Act (9). Her proclamation, later formalized within the DOE's NEPA Compliance Order of July 1995 (10), challenged the DOE to minimize costs and the time required for EIS preparation and review. The policy introduced numerous reforms including the requirement that the median preparation time for DOE EISs would be reduced to 15 months, with no decline in quality. It further required that each EIS be assigned a specific DOE document manager to oversee the EIS during all stages of its development. Briefly stated, the policy set goals for the DOE to perform its NEPA business better, faster, smarter, and cheaper.

To complete the SEIS-II in compliance with NEPA and meet the goals set by the Secretarial NEPA Policy, the CAO will have to successfully rise to a number of challenges. The following are samples of these challenges:

- Preparing the SEIS-II, while simultaneously finalizing other critical-path, compliance documents
- Controlling SEIS-II costs, while pursuing timely completion
- Ensuring completion of an objective, thorough analysis
- Ensuring stakeholder involvement in the NEPA process
- Developing contingency plans to address factors that could affect the SEIS-II completion.

SIMULTANEOUS DEVELOPMENT OF COMPLIANCE DOCUMENTS

Between now and October of 1997, the CAO intends to prepare and obtain regulatory approval several compliance documents. Major compliance documents include:

- the No-Migration Variance Petition

the revised Resource Conservation and Recovery Act Part B Application
the 40 CFR 191 Compliance Certification Application.

During this same time frame, the CAO must also demonstrate its readiness to receive and dispose of TRU waste by performing an operational readiness review (ORR). The ORR is a formal process that evaluates all aspects of the WIPP facility's ability to accomplish its mission of the safe disposal of TRU waste in a geologic repository.

Without explicit coordination and planning, concurrent document preparation and completion of the ORR could present stumbling blocks to reaching an expeditious, disposal decision. Coordinating the flow of information is not an easy task. Using the most current information and analyses as they become available will be crucial to make the SEIS-II a quality, decision-making document.

To turn potential stumbling blocks into stepping stones, the SEIS-II team is reviewing data from WIPP's other compliance documents and studies as they are developed to "feed" the SEIS-II analysis. As new data become available, preparation team members glean information, and review it within the context of the NEPA analysis. The SEIS-II team is practicing the teamwork philosophy set forth in the secretarial policy and new DOE Order by working together with the CAO compliance manager, thus assuring that consistency is preserved in the WIPP's regulatory compliance documents.

CONTROLLING THE SEIS-II SCHEDULE AND COSTS

Controlling costs and compressing the schedule for EIS development were clearly priorities in the Secretarial policy. Fulfilling these expectations while developing the SEIS-II will be especially demanding. The SEIS-II will examine environmental impacts throughout the DOE complex and discuss issues that generate national interest. To control costs and keep the analysis on schedule, the CAO is pursuing a number of strategies.

A reference library was created prior to beginning the preparation of the SEIS-II. A full-time librarian began gathering needed reference documents in advance of the SEIS-II Notice of Intent (11) so most of the required reference documents would be available when document preparation began. When the SEIS-II contractor analysts began their work, much of the needed reference materials were already at their finger-tips.

Extensive use of information contained in other available WIPP studies and compliance documents was also planned to avoid rewriting "boiler plate information" or reanalyzing topics already covered within another report. The WIPP's Annual Site Environmental Report (12) is being used to capture data on the existing environment data. Analyses contained in the draft EM Programmatic Environmental Impact Statement (13) are being used to present data on the impacts of waste characterization, packaging, and treatment at the generator sites. The WIPP's Safety Analysis Report (14) is being used to present analysis of potential routine operations and accident scenarios. Existing electronically filed documentation is used whenever possible, rather than retyping text requiring little or no change.

The CAO is relying on a cohesive, DOE management/review team to assist in controlling SEIS-II schedule and costs. The team is comprised of staff-level personnel from the CAO and various branches of the DOE Headquarters who are responsible for reviewing and approving the SEIS-II during all phases of its development. The management/review team is working to assure that a high quality document is prepared and that it is consistent

with DOE's programmatic policies. The management team has concurrently reviewed planning documents such as the SEIS-II annotative outline (15) and the SEIS-II Implementation Plan (16). The team will take the same concurrent approach for reviewing the draft SEIS-II, the final SEIS-II, and its resulting draft ROD. Reaching early agreement on which alternatives should be evaluated in the SEIS-II and the overall approach for that evaluation is reducing the probability of midstream changes in course that would delay the SEIS-II preparation.

For SEIS-II scoping meetings, the CAO chose locations where stakeholders have traditionally demonstrated the most interest in the WIPP. This strategy enabled the CAO to reach the most interested people with the least number of meetings. The process applied a "lesson learned" from the SEIS of 1990. In some of the 1990 scoping meetings, DOE representatives outnumbered the public attendees five to one (17), which did not represent an efficient use of taxpayer dollars.

To reduce travel expenses, the SEIS-II public outreach team chartered its air travel, and used community centers whenever possible for stakeholder meetings. The document preparation team uses phone and video conferences in place of face-to-face meetings whenever feasible. These measures allow participants from Carlsbad and Albuquerque, New Mexico; Richland, Washington; and Washington D.C.; to interface regularly while minimizing travel expenditures.

The CAO is obligated to assure that mitigation-measure benefits are commensurate with their costs. To responsibly manage taxpayer dollars, each mitigation commitment will be carefully reviewed before it is recommended for inclusion in the ROD. This will ensure that necessary precautions are taken for the protection of the workers, the public, and the environment, and that the maximum value is added for mitigation dollars spent.

ENSURING COMPLETION OF AN OBJECTIVE THOROUGH ANALYSIS

The DOE has already prepared two environmental impact statements, and through the NEPA process, has reached decisions relative to proceeding with construction and development of the WIPP. This has led many people to question whether the SEIS-II will really support DOE decision making or merely justify a disposal decision that is the logical result of the phased development process DOE has been pursuing since the 1980 EIS.

The CAO is dedicated to making the SEIS-II more than NEPA lip-service; more than a paper-trail of formality. It is important that the DOE remain open to changing its course of action, even at this late date, if new information or changed circumstances reveal that TRU waste in its current form is unsuitable for disposal at the WIPP. However, even if it is assumed that SEIS-II analysis does not change earlier conclusions, it will still inform the CAO throughout its decision-making process. For example, the WIPP Waste Acceptance Criteria (18) could be further modified as the analysis in the SEIS-II is completed. The DOE has yet to make a final decision whether to backfill the repository, or what other engineered alternatives might be used in addition to shaft seals. These and other engineered barrier alternatives will be explored in the SEIS-II.

ENSURING STAKEHOLDER INVOLVEMENT

Although scoping is not required for supplemental EISs (19), the CAO recognizes the importance of public participation during all phases of its decision making. Stakeholder participation was also emphasized in the

secretarial policy reforms. For the SEIS-II, planning, planning, and more planning have been the keys to maximizing stakeholder input.

Following the issuance of the Notice of Intent in August 1995, the CAO began working with the public outreach team in earnest, preparing the participants to become less threatening, less bureaucratic, and more responsive to public concerns. Training sessions (complete with practical exercises) were conducted for potential public outreach team members, and a format was set for the scoping meetings that would encourage and stimulate public comments.

Two of the topics emphasized during the training (20) were the importance of being an active listener and not a lobbyist. CAO representatives were urged to view stakeholders opposed to WIPP not as adversaries, but rather as individuals who are genuinely concerned about the problems posed by TRU waste disposal. Role playing exercises were conducted and potential public questions were fielded.

The SEIS-II scoping meetings were conducted as simple, information fairs. Members of the public were invited to join with CAO's representatives for round-table discussions, view several information displays, and ask questions. To stimulate discussion, information booths were arranged with challenging questions posted at the top of each. Members of the public were encouraged to ask questions or give comments as they preferred. Comments were recorded by note takers on flip charts and posted on the walls so that everyone could see what comments had already been made. SEIS-II team members asked clarifying questions if comments were unclear. Finally, the DOE extended the official time frame for scoping and receiving public comments (21) and held an additional scoping meeting for stakeholders in the Denver metropolitan area. The additional meeting was held in response to concerns that stakeholders had been faced with schedule conflicts (another scoping meeting was being held during the same time frame for a different DOE EIS).

CONTINGENCY PLANNING

Properly applied, the NEPA compliance process leads to informed decisions - decisions that are made with the full knowledge of their likely environmental impacts and the public's input regarding what the DOE decision should be. However, as the producer and custodian of radioactive wastes and materials perceived by many as extremely dangerous, the DOE's decisions are often scrutinized to a greater degree than those of other government agencies. Years of experience preparing EISs have demonstrated that the NEPA compliance process is frequently a point of attack for those who disagree with the DOE's decisions and wish to delay or stop DOE projects.

With the high potential for litigation in mind, the CAO formed a contingency planning group. This group included members of the SEIS-II preparation team, compliance personnel, and legal counsel. Together, members identified potential risk factors, weighted these risks by priority, and evaluated mitigation actions to reduce or eliminate these risks.

CONCLUSION

The CAO is dedicated to completing the SEIS-II in a manner that is consistent with the secretarial policy, preparing this environmental impact analysis concurrently with other key compliance documents, while controlling schedule and costs. The American taxpayers and WIPP stakeholders have a right to expect that decisions surrounding the operation of the WIPP facility are environmentally sound, and that a cost

effective solution for TRU waste disposal is implemented. The CAO, together with DOE Headquarters representatives, its contractors, and stakeholders will assure that the SEIS-II NEPA disposal decision is sound, timely, and cost effective, and that the public is given the opportunity to be involved in the DOE decision making process.

RISK ASSESSMENT FOR WASTE EMPLACEMENT AT THE WASTE ISOLATION PILOT PLANT

Richard F. Farrell
U.S. Department of Energy
Carlsbad Area Office
Carlsbad, New Mexico

ABSTRACT

Administered by the Carlsbad Area Office, the Waste Isolation Pilot Plant (WIPP) is designed to permanently dispose of transuranic waste left from U.S. nuclear weapons research and production. Project facilities, located 26 miles east of Carlsbad, New Mexico, include disposal rooms mined 2,150 feet beneath the earth's surface in a stable, ancient salt formation. The U.S. Department of Energy has established and analyzed the safety basis for handling and emplacement of contact-handled transuranic waste for disposal at the WIPP. The safety basis consists of management, design, construction, operation, and engineering characteristics necessary to protect the public, workers, and environment from the safety and health hazards posed by waste handling and emplacement operations. An assessment of hazards and the associated risk to safety was included in the effort.

The hazard assessment technique used at the WIPP is a creative systematic interaction of a multi-disciplinary team that could be applied to other waste management activities. The qualitative assessment approach, which ranks hazards by likelihood and significance of consequence, would be useful for wide range of risk analysis efforts.

Hazards were systematically identified and assessed to evaluate the potential internal, external, and natural phenomena events that can cause the identified hazards to develop into accidents. The hazard assessment employed at the WIPP identified deviations from the intended design and operation of the waste handling system, analyzed potential accident consequences to the public and workers, estimated likelihood of occurrence, and evaluated associated preventative and mitigative features. It was concluded from the assessment that proposed WIPP waste emplacement operations and design are sufficient to ensure safety of the public, workers, and environment.

FACILITY BACKGROUND AND MISSION

The U.S. Department of Energy (DOE) was authorized by Public Law 96-164 (1) to provide a facility for demonstrating the safe disposal of transuranic (TRU) wastes from national defense activities and programs of the United States exempted from regulation by the U.S. Nuclear Regulatory Commission. The Waste Isolation Pilot Plant (WIPP), located in southeastern New Mexico (as shown in Fig. 1), was constructed to determine the efficacy of an underground repository for safe disposal of TRU wastes.

Fig. 1

In accordance with 1981 and 1990 Records of Decision (2,3), the development of the WIPP was to proceed with a phased approach. Development of the WIPP began with a siting phase, during which several potential sites were evaluated. The present site was selected based on extensive geotechnical research, supplemented by testing. The site and preliminary design validation phase (SPDV) followed the siting phase, during which two shafts were constructed, an underground testing area was excavated, and various geologic, hydrologic, and other geotechnical and geochemical features were investigated. The construction phase followed the SPDV phase during which surface structures for receiving waste were built and underground excavations were completed for commencement of waste emplacement. At the conclusion of the construction phase, the DOE proposed a test phase, to be followed by the disposal phase for waste emplacement operations. The test phase was to involve the use of limited quantities of contact-handled (CH) TRU waste to conduct tests in the WIPP repository to provide data for reducing the uncertainties in the performance assessment required for compliance with the long-term waste isolation regulations of the U.S. Environmental Protection Agency (EPA), Subpart B of 40 CFR Part 191 (4). To enable the receipt of CH TRU waste at the WIPP site for the tests the Congress enacted the WIPP Land Withdrawal Act of 1992 (Public Law 102-579) (5). The law also provides for authorizations of detailed regulatory requirements for the WIPP by the EPA.

As a result of major program redirection in late 1993, the WIPP test phase was modified by substituting the previously planned WIPP underground radioactive tests with laboratory tests. In conjunction, WIPP operations will proceed directly with the disposal phase. CH TRU waste emplacement operations are currently scheduled to start in October 1998, assuming successful demonstration of compliance with applicable federal and state laws and regulations, and successful completion of the WIPP CH TRU operational readiness review. The CH TRU operational readiness review will closely examine the safety bases of the facility and the status of attendant conformance to ensure that the facility is operationally ready and that contact-handled waste emplacement operations will be conducted safely.

The disposal phase is scheduled to last 35 years, will consist of receiving, handling, and emplacing TRU waste in the repository for disposal, and will end when the design capacity of the repository has been reached.

FACILITY DESIGN

The WIPP is located in Eddy County in southeastern New Mexico, as shown in Fig. 1. The amount of land that has been set aside for the WIPP comprises an area of 16 square miles (mi2). The WIPP is located in an area of low population density with less than 30 permanent residents living within a ten-mile radius. The area surrounding the facility is used primarily for grazing and development of potash, oil, and gas resources. Development of these resources results in a transient population (non-permanent) consisting principally of workers at three potash mines that are located within ten miles of the WIPP. The largest population center nearest the WIPP is the city of Carlsbad, 26 miles to the west, with approximately 25,000 inhabitants. Two smaller communities, Loving (population approximately 1300) and Malaga (population approximately 200), are located about 20 miles southwest of the WIPP site. As the result of land use restrictions imposed by the U.S. Bureau

of Land Management, and administrative action by the DOE to purchase lease holdings, no resource development is allowed within the 16 mi2 that have been set aside for the WIPP (with the exception of existing leases). The WIPP is designed to receive and handle a maximum of 500,000 cubic feet per year (ft3/yr) CH TRU waste and 10,000ft3/yr remote handled (RH) TRU waste. The CH TRU waste will be contained in 55-gallon drums and standard waste boxes. The WIPP facility is designed to have a disposal capacity for TRU waste of 6.2x106 ft3. Current design is that RH waste will be packaged in steel canisters and transported to the WIPP facility in shielded road casks. The WIPP facility has sufficient capacity to handle the 250,000 ft3 of RH TRU that was established in the 1981 Record of Decision as a total volume. In addition, the Consultation and Cooperation Agreement (6) between the State of New Mexico and DOE and the Land Withdrawal Act of 1992 limit the total RHTRU activity to 5.1 x 106 curies.

CH TRU* wastes will be disposed of in a 100-acre disposal area located 2,150 feet beneath the surface in a deep bedded salt formation. Waste will be transferred from the surface to the disposal area through a waste shaft using a hoisting arrangement. The disposal phase is currently scheduled to last for 35 years, followed by a 10-year decontamination, decommissioning and closure phase.

The WIPP facility is divided into three basic structural components: surface structures, shafts, and subsurface structures as shown in Fig. 2. The WIPP surface structures accommodate the personnel, equipment, and support services required for the receipt, preparation, and transfer of waste from the surface to the underground. The surface structures are located in an area within a perimeter security fence. The primary surface operations at the WIPP are conducted in the Waste Handling Building. The CH TRU waste handling area includes the entrance air locks, CH Bay, a shielded holding area, an overpack and repair room and CH TRU support facilities.

Fig. 2

FACILITY OPERATIONS

The principal operations of the WIPP facility involve the receipt of TRU waste and TRU waste mixed with hazardous waste, unloading, moving and emplacement of the waste in underground rooms. Transporters carrying TRU waste arrive at the WIPP and are unloaded outside the Waste Handling Building. The shipments are surveyed for external contamination prior to their movement into the Waste Handling Building for unloading.

CH TRU waste will be shipped to the WIPP in Nuclear Regulatory Commission certified shipping containers. After the CH TRU waste shipping container is inspected for contamination, the loaded shipping container is moved into the Waste Handling Building and placed on a handling dock. The container is opened, surveyed for radiation and contamination levels, and the waste containers are removed and placed on a facility pallet. This pallet is then transferred to the conveyance loading car, which is moved into the hoist cage in the Waste Shaft for transfer to the underground disposal horizon. At the disposal horizon, the pallet is removed from the hoist cage, placed on the underground transporter, and moved to a CH TRU waste disposal room. In the disposal room, the containers are removed from the pallet and placed in the waste stack. The empty pallet is returned to the surface for reuse.

The waste received for disposal at the WIPP facility must conform with the WIPP Waste Acceptance Criteria (7). The operational philosophy at the

WIPP facility is to start radiologically clean and stay radiologically clean. Consequently, any containers of waste that are found to be externally contaminated or damaged will be decontaminated or placed in a larger container as required. Also, any local area of contamination will be isolated and/or decontaminated prior to continuation of the waste handling process.

HAZARD EVALUATION

The WIPP CH TRU waste handling process was qualitatively evaluated using a Hazard and Operability Study (HAZOP) (8). This systematic approach to hazard analysis was conducted by a leader knowledgeable in the HAZOP methodology and consisted of personnel from various disciplines familiar with the design and operation of the WIPP (HAZOP Team). The HAZOP Team identified deviations from the intended design and operation of the waste handling system that could: 1) result in process slowdown or shutdown, 2) result in worker injury or fatality, and 3) result in the release of waste container radiological and nonradiological materials. The HAZOP Team assigned a qualitative consequence and likelihood ranking for each deviation as discussed below. A hazard evaluation ranking mechanism utilized the likelihood and the most significant consequences to separate the low risk hazards from high risk hazards that may warrant additional quantitative analysis. Based on that ranking approach a basic set of accidents was chosen for further quantitative assessment in the 1995 WIPP Safety Analysis Report (SAR) (9).

HAZARD AND OPERABILITY STUDY METHODOLOGY

The HAZOP technique, based on a creative systematic interaction of a multi-disciplinary team, evaluated the significance of deviations from the normal waste handling process. The HAZOP Team consisted of experienced personnel from Facility Operations, Maintenance Operations, (including previously certified waste handlers experienced in Transuranic Package Transporter (TRUPACT) and drum handling activities), Industrial and Nuclear Safety, Engineering, and Regulatory Compliance.

The HAZOP Team started by examining the process for receipt of a CH TRU waste transporter at the front gate and ended with the process for emplacement of CH TRU waste in a underground disposal room. HAZOP nodes (process steps) were selected to define the movement of CH TRU waste through the WIPP facility. Deviations of proposed waste handling operations were postulated for each node and once the deviation was confirmed to be plausible, the HAZOP Team determined the possible causes for the deviation. The resulting potential consequences were explored without taking into consideration any mitigating features. An evaluation was made to determine if mitigating safeguards were in place to alleviate the consequences. Some of the potential deviation consequences or concerns identified by the HAZOP Team are:

- Worker injury or fatality;
- Process slowdown or shutdown;
- Internal and external conditions may result in breach/rupture of waste containers resulting in the airborne release of radiological or nonradiological hazardous materials (loss of primary confinement);
- External waste container surface contamination and need for decontamination;
- Worker and public exposure to radiation and airborne radiological and nonradiological hazardous materials; and
- Potential for receipt of damaged waste containers and need for overpack operations.

The HAZOP deviation ranking process used a two-number system, consisting of a qualitative severity classification and a qualitative likelihood classification. The qualitative severity (consequence) classification was ranked without consideration for mitigation. The qualitative likelihood was ranked taking into consideration the probability of failure of identified safeguards and mitigation for that deviation.

SELECTION OF CH POTENTIAL ACCIDENTS

The HAZOP provided a list of deviations that were qualitatively ranked by relative consequence and probability using the 'total rank' consequence criteria of Table I and the probability criteria of Table II. This resulted in the 'total rank' that combines both hazard consequence and probability ranking components (see Fig. 3). As stated in the HAZOP, the consequence ranking of each deviation included both the resultant consequence to the worker and the radiological and nonradiological consequence to the offsite public.

Table I

Table II

Fig. 3

In order to select potential CH TRU waste handling accidents for quantitative accident analysis, the total list of hazards was narrowed to focus on risk posed by radiological and nonradiological hazardous material. This eliminated occupational deviations exclusive of the hazardous materials involved, providing a subset 'hazard rank'.

In order to determine the risk associated with each deviation, the relative probability and hazard consequence ranking were combined. The deviations were then categorized as low, moderate, or high risk based on the Relative Probability and Consequence Ranking Matrix (Fig. 3). Those deviations with a combined 'hazard rank' of less than four were excluded from further quantitative evaluation in the 1995 WIPP SAR, with the exceptions of the waste hoist drop (CH5), earthquake (CH6), and aircraft crash (CH8). The waste hoist drop (CH5) was selected for its significant interest to external organizations, as well as the earthquake (CH6) as a natural event and the aircraft crash (CH8) as an external event. A list of the selected deviations for further consideration in the 1995 WIPP SAR accident analysis is provided below.

Operational Events

CH1 Spontaneous Ignition (Drum) in the Waste Handling Building

CH2 Crane Failure in the Waste Handling Building

CH3 Puncture and Drop of Waste Containers by Forklift in the Waste Handling Building

CH4 Drop of Waste Containers by Forklift in the Waste Handling Building

CH5 Waste Hoist Failure

CH7 Spontaneous Ignition (Drum) in the Underground

CH9 Drop of Waste Containers by Forklift in the Underground

Natural Events

CH6 Seismic Event

CH10 Tornado Event

CH11 Underground Roof Fall

External Events

CH8 Aircraft Crash

PROTECTION OF WORKERS FROM ACCIDENTS

The HAZOP analyses of the CH TRU Waste Handling System identified a number of waste handling process hazards that could potentially lead to events resulting in work injury or fatality, or exposure to radiological

and nonradiological hazardous materials. Consistent with the defense-in-depth philosophy, and the philosophy of Process Safety Management, as published in 29 CFR 1910.119, "Process Safety Management of Highly Hazardous Chemicals," (10) reduction of the risk to workers from accidents is accomplished at the WIPP by identifying controls to prevent the event from happening. Total risk is therefore lowered by reducing the likelihood of the event, as opposed to focusing on post accident consequence mitigation through the performance of quantitative consequence calculations for workers.

The HAZOP Team identified a significant number of existing preventative safeguards that lower the likelihood of occurrence of each deviation, substantially reducing the risk to workers. The HAZOP Team concluded substantial safeguards currently exist at the WIPP to prevent or reduce the likelihood of such deviations from occurring. Identified preventative safeguards generally include the following:

Facility and equipment design, application of appropriate design classification and applicable design codes and standards;

Programs relating to configuration and document control, quality assurance, and preventative maintenance and inspection; and

Administrative controls including the WIPP Waste Acceptance Criteria, waste handling procedures and training, and the WIPP Emergency Plan and associated procedures.

Because of the importance of these preventative features in WIPP defense in depth and worker protection from accidents, Technical Safety Requirement Administrative Controls are assigned in Chapter 6 of the 1995 SAR and required in the WIPP TSR Document.

CONCLUSIONS

The HAZOP Team reviewed the WIPP CH TRU waste handling system to identify deviations from the intended design and operation that could result in hazards that could create adverse consequences to the public and the worker, or result in a process slowdown. Each step of the waste handling process was evaluated, and recommendations were made, where appropriate, to preclude undesirable consequences.

Some of the identified potential hazards or concerns are:

Personnel exposure to radiation and airborne radiological an nonradiological hazardous materials;

Personnel injury or fatality;

Potential that internal and external conditions may result in breach/rupture of waste containers resulting in the airborne release of radiological or nonradiological hazardous materials (loss of confinement);

Potential for external waste container surface contamination and need for decontamination; and

Potential for process slowdown or shutdown.

As stated above, the consequences of each deviation were developed without considering any existing mitigating systems. Identified unmitigated potential airborne release of radiological or nonradiological hazardous materials may result in varying degrees of consequences to workers and the offsite public. However, the HAZOP Team identified:

Substantial safeguards currently exist at the WIPP to prevent or reduce the likelihood of such deviations from occurring. Identified safeguards include procedures, training, preventative maintenance and inspection, and administrative controls including the WIPP Waste Acceptance Criteria.

Substantial mitigation exits to reduce the consequences of any postulated deviation to acceptable levels. Identified mitigation includes the design of the WIPP confinement/ventilation systems and associated HEPA filtration systems.

Postulated credible scenarios that may result in worker injury or fatality, or potential airborne release of radiological or nonradiological hazardous materials and potential exposure to workers and the offsite public, will further be analyzed quantitatively in the WIPP Safety Analysis Report.

However, as qualitatively concluded from the HAZOP analysis, the adequacy of the design of the WIPP CH TRU waste handling system ensures the safety of the public and the worker. The HAZOP Team identified no substantial recommendations for the WIPP management to consider to reduce the severity or likelihood of any of the postulated deviations. Thus, the WIPP facility is ready to commence safe TRU waste handling and emplacement operations.

ACKNOWLEDGMENTS

The Westinghouse Waste Isolation Division team that prepared the WIPP Safety Analysis Report (SAR) (November 1995) included Messrs Doug Gerstner, Fred Bourger, Carl Ortiz, James McCormick, and Dan Standiford. The subject of this report was a small component of the effort that resulted in the 1995 WIPP SAR. I thank them for that job well done and the useful discussions and input that contributed to this report.

QUALITY ASSURANCE PLAYS A KEY ROLE IN GETTING THE WASTE ISOLATION PILOT PLANT TO OPERATIONAL STATUS

R. Dennis Brown

U.S. Department of Energy
Carlsbad Area Office
P.O. Box 3090, Carlsbad, NM 88221

ABSTRACT

There are many regulatory requirements that must be met before transuranic (TRU) and transuranic mixed wastes are emplaced into the Waste Isolation Pilot Plant (WIPP) for final disposal. These requirements will be satisfied by the Department of Energy (DOE), through the DOE Carlsbad Area Office (CAO) and will be verified through the development and implementation of a performance-based quality assurance program, consisting of numerous quality assurance program plans and procedures. These plans and procedures relate to experimental programs, performance assessment, operations, waste characterization, and waste certification. Effective implementation of quality assurance principles have played and will continue to play a critical role in supporting the WIPP certification and operations processes.

For example, in order for the CAO to receive and dispose of TRU Waste, it must submit a Compliance Certification Application to the U.S. Environmental Protection Agency (EPA), demonstrating that the disposal of TRU Waste at the WIPP complies with the environmental radiation protection standards promulgated by the EPA in the final disposal standards, i.e., the Code of Federal Regulations, Title 40, Part 191 (40 CFR 191), Protection of the Environment-Environmental Radiation Protection Standards for the Management and Disposal of Spent Nuclear Fuel, High-Level and Transuranic Wastes. Likewise, to receive and dispose of mixed TRU Waste, the CAO has to demonstrate to both the EPA (No-Migration Variance Petition) and the New Mexico Environment Department (NMED) (Resource Conservation and Recovery Act Part B Permit) that disposal of mixed TRU Waste does not impose undue risks to present and future generations.

QA REQUIREMENTS

The WIPP project is subject to the requirements of 40 CFR 191 and 10 CFR 830.120, Nuclear Safety Management, Quality Assurance Requirements. 40 CFR 191 requires that the DOE implement a quality assurance (QA) plan. This QA plan is expected to meet the requirements of the American Society of Mechanical Engineers (ASME) NQA-1, Quality Assurance Program Requirements for Nuclear Facilities, NQA-2 (sub-part 2.7), Quality Assurance Requirements of Computer Software for Nuclear Facility Applications, and NQA-3, Quality Assurance Program Requirements for the Collection of Scientific and Technical Information for Site Characterization of High-Level Waste Repositories. Also, DOE contractors are required to meet the QA requirements of 10 CFR 830.120.

CAO QAPD

The CAO Quality Assurance Program Description (QAPD) establishes the QA requirements for WIPP. The quality assurance requirements from the applicable federal, state, and DOE rules, regulations, and orders are identified in Table I. Figure 1 shows the flowdown of QA requirements into the lower level QA plans and procedures. The QAPD is structured in accordance with the requirements of NQA-1 and DOE Order 5700.6C, Quality Assurance. Software QA requirements from NQA-2, Part 2.7 are also included in the QAPD. Since WIPP is also a research and development project, involving scientific investigation, the DOE also implements the applicable portions of NQA-3.

Table I

Fig. 1

PARTICIPANT QA REQUIREMENTS

Each participant is required to prepare, implement, and maintain a QA program that meets the CAO QAPD. Participant QA programs are approved by the next higher organizational level of WIPP participant. Participants use a "graded approach" to implement their QA program requirements. The QA plans are implemented through instructions and procedures at each participant level. The requirements of the QAPD are applied to activities and items important to nuclear safety, waste isolation, regulatory compliance, and the WIPP mission. Participants determine the level of controls that are necessary to meet all the applicable QA requirements; these controls are reviewed and approved by the next higher organizational level. This determination is reviewed by the CAO staff during oversight activities such as audits, surveillances, and program reviews.

CAO QA

In 1995, the CAO decentralized the QA organization and placed QA engineers into each of the technical organization. The CAO QA Manager retains the responsibility and authority for the overall QA program. Each QA engineer now works directly with the CAO technical teams and offices to implement the QAPD, both internally and at the participants.

SNL QA

Most of the WIPP experimental work over the past 20 years has been conducted through the offices of Sandia National Laboratories (SNL) and Los Alamos National Laboratory (LANL). Much of the data was not collected under a QA program that was based on NQA-1. Consequently, CAO and SNL have had to establish methods for qualifying existing data. The methods being used were developed using the guidelines described in NUREG 1298, Qualification of Existing Data for High-Level Nuclear Waste Repositories. Since this process has to eventually receive approval of the Environmental Protection Agency (EPA), the CAO has been pro active in facilitating the oversight and informal acceptance of the process by the EPA Office of Radiation and Indoor Air (ORIA) and the Environmental Evaluation Group (EEG).

Additional experimental programs work has been supported through the auspices of SNL subcontractors. These include the Pacific Northwest Laboratory (PNL), Argonne National Laboratory-West (ANL-W), Lawrence Berkeley Laboratory (LBL), Florida State University (FSU), Stanford University, RE/SPEC, Intera, and several dozen more. SNL performs annual audits of the QA programs at the subcontractor sites. CAO has observed several of these audits over the past two years to assure that SNL is performing comprehensive and effective audits.

SNL is also responsible for implementing the repository performance assessment (PA) activities. PA involves millions of data points collected from hundreds of different data sources, feeding into several dozen major PA computer codes. SNL has recently completed a significant amount of work to upgrade their software documentation and practices to meet the requirements of NQA-2, Part 2.7. CAO has the responsibility to perform oversight of the SNL activities to assure that the requirements have been met.

QA FOR GENERATOR SITE WASTE CHARACTERIZATION AND CERTIFICATION

Another large part of the WIPP QA program activities involves the waste characterization and waste certification activities at the generator sites. CAO oversees QA program activities at the Idaho National

Engineering Laboratory (INEL), Los Alamos National Laboratory (LANL), Rocky Flats (RF), the Hanford Facility (HF), the Savannah River Site (SRS), Oak Ridge National Laboratory (ORNL), and the Nevada Test Site (NTS). Since WIPP will initially receive waste from INEL, RF, and LANL, CAO has concentrated oversight on these sites. CAO performs generator site audits and surveillances of activities such as waste characterization, transportation, packaging, handling, and waste certification.

WID QA

Westinghouse is the Management and Operating Contractor for the WIPP site. CAO performs an annual audit and periodic surveillances of the Westinghouse QA program. These assessments are performed in order to evaluate site activities and areas subject to the controls of the CAO QAPD. These areas include waste handling, hoisting, environmental monitoring, safety, maintenance, configuration management, design, and training. One of the more important Westinghouse QA program elements is the control of QA records. Westinghouse has been tasked with maintaining the overall QA records storage facility for the WIPP. Controlling QA records is critical to proving that CAO and participants have adequately addressed and effectively implemented QA programs. These records will be reviewed over and over and evaluated by our regulators in the upcoming years.

REGULATOR QA INTERFACE

Interface with our regulators has been and will continue to be crucial to the success of the WIPP project. The EPA has been reviewing and commenting on WIPP QA plans and procedures since 1993. Also, the EPA has participated as observers on numerous QA audits and surveillances since early 1994. These overview activities enable the EPA to gain confidence in the CAO and participant QA programs. The New Mexico Environmental Department (NMED) will also observe audits in the near future. NMED, to this point, has also been reviewing various CAO QA program documents.

SUMMARY

In summary, the QA activities supporting WIPP are being planned, implemented, and verified in a comprehensive and effective manner. This level of implementation must and will continue in the future. It is essential that WIPP participants continue to meet their diverse QA programs throughout the life of the project. The CAO will continue to perform assessments of QA program implementation to demonstrate to DOE, the regulators, and the public that effective controls are in place to assure that the WIPP facility will not allow the release of radiation that may be harmful to the public or the environment.

Session 20 -- FEDERAL FACILITY COMPLIANCE ACT (FFCA) IMPLEMENTATION--HOW DID WE DO?

Co-chairs: Lawrence H. Harmon, MACTEC

20-1

THE FEDERAL FACILITY COMPLIANCE ACT - CONTINUING THE DIALOGUE

Patrice Bubar
U.S. Department of Energy
Headquarters
Office of Strategic Planning and Analysis

Julianne Dodds

BDM Federal

ABSTRACT

The Federal Facility Compliance Act of October 1992 required the Department of Energy to prepare an inventory of all mixed waste and to prepare site treatment plans for mixed waste. Mixed waste is defined as waste containing both hazardous and radioactive constituents. The Act also waived sovereign immunity for storage violations of mixed waste subject to land disposal restrictions, but allowed the Department three years to put treatment plans in place that were subject to approval by the States and the Environmental Protection Agency. The Department effort to inventory and plan for the treatment of mixed waste began with the involvement of the State and EPA regulators early in the process. The success of this effort is due, in large part, to the interactive cooperation between the Department and the regulators that developed from working the issues related to this Act.

This success can be measured in two ways:

By October 6, 1995, over 90% of all mixed waste, 95.9% of all mixed transuranic waste, and 99.9% of all high level waste was covered with a negotiated agreement. The remaining waste was either covered by a unilateral order or an order pending completion by the States with letters in place stating that enforcement action would not occur while the States were completing their orders.

Compliance orders are in place as follows:

- Twenty-five (25) negotiated compliance order and one negotiated unilateral order were in place on October 6, 1995.
- Three unilateral orders were in place October 6, 1995; of which only one order requires appeal by the Department.
- Six other compliance orders were well developed such that no significant potential for fines and penalties existed.

However, there are larger successes that occurred as a result of the activities started under the framework of the Federal Facility Compliance Act. The process begun in the Act has had far-reaching effects on how the Department conducts business with both the regulators and the sites. An integrated budgeting process implemented by the Assistant Secretary in an effort to satisfy conflicting state and local needs with constrained funding is an indication of a partnership established between regulators and DOE during the three year process. The balance of all environmental restoration and waste management activities at a site now reflects the desires of DOE and the stakeholders.

BACKGROUND SUMMARY

The magnitude of the project begins to define the complexity of the issues. Site treatment plans were required for over 2,200 separate waste streams consisting of approximately 471,000 cubic meters of high-level waste, 129,000 cubic meters of mixed low-level waste, and 52,000 cubic meters of mixed transuranic waste located at 41 sites in 22 states.

The Department decided early that the site treatment plans would be drafted in a three-phase approach. The conceptual plans would be delivered to the States/EPA in October 1993, the draft plans in August 1994, and the proposed or final plans in March 1995. This would allow time for feedback from stakeholders as each phase of the plan was completed. It would also allow the States approximately seven months to approve, disapprove, or approve with modifications the site treatment plans. A schematic of this process is presented in Fig. 1.

Fig. 1

The early attitudes of both DOE and the States were not cooperative and clearly provincial. Each state wanted to be independent with no waste being transferred in or out of their state. DOE wanted a more national approach using better economies of scale with fewer treatment facilities, saving more dollars, but transferring more waste out of state.

To involve the States/EPA, the Department initially held a meeting of state/EPA representatives in December 1992 and suggested a national compliance plan, a top-down approach. The States responded negatively to this suggestion, requesting the Department provide a bottom-up approach--each site should decide for itself how to treat its waste and then begin the discussions with its regulators. This resulted in an initiative between the regulators and the Department to work jointly on this project. The Department funded the National Governors' Association to act as the channel for information between the States/EPA and the DOE. This liaison provided the cornerstone for improved communication between DOE and the States/EPA.

The iterative process initiated between the States/EPA and DOE only worked with considerable effort to engage all the parties. The communication effort included the Policy Coordinating Group, the Options Analysis Team, the National Governors' Association, DOE senior management, DOE site management, DOE site representatives, State regulators, EPA regulators, State Governors, Indian Tribal Nations, and public stakeholders. A description of the roles of the ad hoc groups involved in the process is given in Table I.

Table I

ISSUES RAISED AND RESOLVED

Many issues became non-issues when raised with all the parties involved. The most significant examples of these complex issues include duplicate treatment operations among the sites, off-site waste shipments, treatment plans for mixed transuranic waste, and the impact of major funding shortfalls on meeting the objectives of the plans.

After the submittal of the draft site treatment plans, the States/EPA and DOE met to discuss further development. In a marked departure from the initial attitudes, the States/EPA requested DOE to eliminate the duplication of treatment operations, even at the expense of increasing offsite waste shipments. Involvement of the National Governors' Association in the Options Analysis Team meetings as a representative for the States/EPA facilitated a mixed low-level waste configuration that was more cohesive, less costly, and more acceptable to all the parties.

The issue of offsite waste shipments was an area of potential conflict because the States/EPA wanted no waste coming into their particular state or region. DOE wanted to ship waste offsite for treatment because of economies of scale in building one treatment plant rather than several. This issue was resolved by a compromise that satisfied most of the State principles in handling offsite waste shipments and met DOE's objective of fewer new treatment facilities.

The issue of treatment for mixed transuranic waste was raised later in the process. A near-term compromise solution was reached as the deadline for submitting the plans approached. The compromise recognized the lengthy process involved in reaching agreement on a mixed low-level waste configuration and allowed for an interim action. In the interim, the States/EPA agreed to beginning negotiations on the mixed transuranic issue if the scheduled opening of the Waste Isolation Pilot Project is

delayed beyond 1998. Work continues toward defining a mixed transuranic configuration.

The issue of funding shortfalls is perhaps the area of greatest achievement for the process. In late 1994, funding constraints imposed by Congress mandated that DOE work out longer schedules for treatment milestones than originally planned. In order to fully engage the States/EPA in this scheduling process, DOE invited the States to become partners with DOE in setting budget priorities for their states including all aspects of Environmental Management--Environmental Restoration, Waste Management, and Nuclear Materials and Facility Stabilization. This process was to prepare the FY97 budget submission and will continue into the foreseeable future with each site preparing an integrated budget, balancing the needs of that site with available funding. The budget process was successful due to the previous working relationships established in preparing the site treatment plans.

RESULTS OF THE PROCESS

In the last three years, DOE has forged a new way of doing business with the States/EPA. The process implemented under the Act includes open, honest, and frequent communication to better understand and match both the needs of the regulators with the Department. The primary result has been a gradual change in attitudes as seen by the original "Do not send waste to my state" syndrome to one of partnership in addressing waste management and remediation needs.

The effects of this partnership can be measured in terms of a new method of doing business that includes open communication and full sharing of information, successful negotiated compliance orders that cover the majority of mixed waste, no fines or penalties to date, and the continuing priority setting process established for all aspects of Environmental Management at the individual sites.

FEDERAL FACILITIES COMPLIANCE ACT YEAR-3: IMPLEMENTATION, STATUS AND ISSUES STATES PERSPECTIVE: HOW DID WE DO?

Brian Kelly
Office of the Governor-State of Tennessee

ABSTRACT

The paper presents the status regarding development of Site Treatment Plans and implementation of the Federal Facility Compliance Act in terms of significant issues. Interested persons may find useful the more detailed information which follows.

INTRODUCTION

Over the last several years papers have been submitted concerning the Federal Facility Compliance Agreement (FFCA) from a states perspective. As the process has evolved from the first forum in 1994, we have now reached the critical question. How did we do? The states perspective can be a bit broad knowing that each state has a variety of wants and needs. However, through the efforts of the National Governors Association FFCA task force states were given an arena to pool their needs and wants as a unified body to achieve a much greater degree of success.

The NGA FFCA task force is comprised of a policy representative of the gubernatorial offices and state agencies, as well as regulatory staff from each state. The states included on the task force are those hosting DoE facilities with mixed waste treatment issues. Each state receives input from community and citizen groups, tribal representatives, legal

council and the states business leaders concerned with waste treatment. Each state brings to the table a broad perspective of issues and actions that offer a good building block for dealing with these complex problems. As DoE revamped their decision making process to give greater authority to the regulating agencies and the affected states we have seen a greater willingness on states not to feel their role as antagonist but as partners in addressing the treatment needs of each site and community. As each state has shared information on actions with other states this has allowed the dialogue to focus not only on site specific but DoE complex wide initiatives. As we have seen for the most part, the outcome of decisions from the regulatory authorities (states) in conjunction with DoE and EPA have been better than many could have hoped.

The following is a report completed by states with the NGA and the FFCA process. Ross and Associates out of Seattle help collect much of the data. As you will see much has been accomplished but their is still much to be done.

Report Card

Key requests from states -- What DOE Delivered

- Maximize use of on-site treatment
  - 1.6% of MLLW is targeted out-of-state
- Evaluate use of mobile treatment units to minimize waste movement
  - 10,000 m3 of waste targeted to mobile units
- Use existing facilities wherever possible
  - About 19% of MLLW is targeted to existing facilities
- Evaluate a nearest-site scenario for waste sent out-of-state
  - OAT Team evaluated nearest-site configuration
- Establish satisfactory schedules for waste treatment
  - Consent orders signed or expected in 16 of 20 states
- Address disposal of treated mixed waste
  - Disposal process on-going

The NGA along with participating states formed an Options Analysis Team. This group met with the idea of developing innovative ways to clean the mixed waste at existing sites. Below is a breakdown of their findings.

Options Analysis Team

The Options Analysis Team met in August to determine future configuration changes that might be taken to decrease cost and improve schedules for the treatment of mixed waste.

"...faster or cheaper..."

Potential changes were generally intended for consideration after the approval of STPs, unless earlier consideration was requested by the site's host state (e.g., Ohio).

The OAT Team dealt only with MLLW and Alpha-MLLW. The Carlsbad Area Office is conducting a similar effort to improve the costs and scheduling for mixed transuranic waste.

The OAT team operated under the assumption that treating waste at vendor (commercial or private) facilities would provide cost savings and improved schedules.

Sites identified which treatment options in their plans they expect to propose (after October 1995) to shift to vendor treatment or another DOE facility. The OAT Team also determined which proposed new facilities and wastestreams should be listed as additional "candidates" for vendor or alternate DOE facilities.

Results of OAT meeting: Sites expect to propose shifting about 1,900 m3 to vendor treatment, and identified roughly 10,000 m3 as

"candidate" waste to shift from new DOE facilities to vendor facilities, pending further analysis.

The results of the OAT Team analysis are expected to be proposed to states by the individual DOE sites as orders are reopened for revision. One of the main focuses running not only through DoE but all of the federal government is the move to privatization. This is somewhat a nebulas concept that has not fully been explored by the federal government. With the move to the private sector many of these programs, DoE and many other agencies face a new challenge of defending their existence.

Privatization

STP configuration shows approximately 17% of mixed waste is now targeted to commercial treatment (PSTP configuration was about 6%).

DOE has privatization efforts underway at several sites, including major efforts at Fernald, Hanford, INEL, Oak Ridge.

DOE has established a Commercial Options Analysis Team (COAT)

- COAT's mission is to provide recommendations to DOE on optimization of commercial capability...a national procurement strategy.
- Chaired by Rick Korynta, DOE-Oak Ridge

Conclusion: The STP configuration represents a snapshot in time--the configuration will continue to change, possibly significantly as privatization efforts proceed.

Table I

Mixed Low Level Waste

Most changes affect on-site treatment.

At INEL: A number of treatment units have been consolidated. Some of these treatment units were originally individual treatment steps within larger treatment facilities. The Advanced Mixed Waste Treatment Project (AMWTP) has replaced all of the steps of the previous IWPF and other proposed facilities. All remote-handled and HLW waste will now be treated at one remote handled treatment facility.

Ohio in-state treatment totals decreased 2,647 m3.

At the Portsmouth Site: the site is no longer proposing a Mixed Waste Treatment Facility. A large portion of the waste is now targeted for "commercial offsite incineration," while the remaining waste will be treated on-site by vendors in mobile treatment units.

In-state treatment in Tennessee increased by 5,897 m3. This can be attributed to a large increase in waste awaiting CERCLA RODs at ORNL and Y-12 Sites. This accounts for 5,294 m3 of the increase. Oak Ridge has also added a transportable vitrification system, which will treat 1,870 m3 of waste. Waste with treatment location not specified at Oak Ridge decreased by 2,947 m3. This waste originally had no designated treatment site; it is now bound for on-site treatment and commercial options.

Highlights of changes: PSTP (4/5/95) Configuration to STP (10/4/95)

In-state treatment in Washington decreased by 6,949 m3. Waste targeted to the WRAP IIA facility decreased 2,149 m3, and waste targeted to the commercial thermal treatment facility decreased by 4,799 m3.

The Oakland Area Office (California Sites & Univ. of Missouri Site) re-targeted a total of 32 m3 of waste from WRAP IIA at Hanford to treatment at INEL, due to the uncertainty of the WRAP IIA facility.

Ames Laboratory in Iowa shipped its current inventory to SEG in Tennessee for treatability studies. The site expects to generate waste in the future.

The Nevada Test Site is now targeting 1.8 m3 of waste to the TSCA incinerator in Tennessee.

Many smaller changes occurred in several states. (See State-to-State "mileage charts" for more information.)

Mixed Transuranic Waste

At INEL: alpha-MLLW is now proposed to be treated in conjunction with MTRU waste at the private AMWTP facility.

MLLW FOR WHICH TREATMENT LOCATION IS NOT SPECIFIED

STP Configuration

(23% of 123,455 m3 -- 28,568 m3)

This represents a 9.5% decrease from the amount of waste with no specified treatment location in the April database.

Most of this waste is in TN & OH:

- TN 23,254 m3. 22,214 m3 of this total is targeted for the Oak Ridge Commercial Option. 1,040 m3 is targeted for "commercial disposal".
- OH 3,712 m3. 3,558 m3 of this waste is targeted by the Portsmouth facility for a "Commercial Offsite Incineration Facility."

74% of targeted MLLW is proposed for treatment at new in-state facilities (was 80% in PSTP configuration).

The volume of waste targeted for in-state treatment at new facilities has decreased:

Hanford: 6,949 m3 decrease due to reductions in waste targeted to WRAP IIA and the commercial thermal treatment facility.

Portsmouth: 5,814 m3 reduction due to waste now targeted to "commercial offsite incineration." This waste has been designated as "treatment location not specified."

5,295 m3 of waste at Oak Ridge (Y-12, ORNL) has neither a "new" or "existing" designation; this wastes' treatment is being driven by CERCLA Records of Decision.

Profile of Mobile Treatment

Table II

Volume targeted to mobile (m3)

The amount of waste targeted to mobile treatment units increased by 7,664 m3. The majority of this change can be attributed to the amount of waste targeted for the "Ohio Option - Stabilization Project"(on-site mobile vendor). A total of 5,906 m3 of waste is targeted to this option by Portsmouth (5,487 m3) and Fernald (417 m3).

Six field offices representing six states (ID, NM, OH, SC, TN, TX) are targeting waste for treatment at various mobile facilities.

Five field offices representing six states (ID, NM, OH, SC, TN, TX) will be hosting mobile treatment at their various sites.

4 existing mobile facilities would be used to treat waste in the STP configuration: a lead decontamination trailer from Los Alamos, a Portable Wastewater Treatment Unit at INEL, a sort/survey/char/decon team from Grand Junction, and Thorium Nitrate Tank T-2 at Fernald. 20 new mobile facilities are proposed. Note: DOE-Albuquerque plans to delete several mobile treatment units (other options now believed to be more cost-effective).

Profile of Incineration Facilities

The STP configuration targets waste to the following incineration/thermal treatment facilities:

Three existing DOE facilities (in ID,TN, and SC)

Four existing commercial facilities (in FL, TN(2), and TX)

Two proposed incinerators:

- AMWTP (formerly IWPF) at INEL, Idaho (a proposed private facility)
- Commercial Thermal Treatment Facility, Hanford Site, Washington

Portsmouth is targeting 3,558 m3 of waste to an unspecified commercial offsite incinerator.

Table III

Schedule

The STP database does not provide a coherent look at the schedules for treatment of mixed waste. Schedule information in the STP database is not complete, and the reliability of schedule information that is available is variable. Most schedule information must be surmised from the years that a facility is shown as being funded.

The database does not indicate schedules for specific wastestreams to be treated.

STP documents generally include better schedule information than the database, at least for on-site waste targeted to on-site facilities. However, the STPs do not embody a complete complex-wide integrated schedule for treating MLLW.

MTRU facility schedules appear to more closely match up with WIPP's 25-year operating period (1998-2023) than they did in the PSTPs, although facility operations at Savannah River and Hanford still extend beyond 2023.

Table IV

Costs shown are total life cycle costs (capital plus operating) in constant FY95 dollars for the fiscal years 1995 through 2093, based on verified cost estimates from DOE Operations Offices.

MAJOR CHANGES IN COST ESTIMATES FOR MIXED WASTE TREATMENT

High Level Waste

INEL's New Waste Calcining Facility (NWCF) dropped in cost by $1.2 billion.

INEL's Waste Immobilization Facility (WIF) was deleted (- $4.5 billion) and replaced with the ICPP-Remote Handled Immobilization facility (+ $1.93 billion).

Mixed Transuranic Waste

Oak Ridge's TRU Processing Facility dropped in cost by $0.5 billion.

Hanford's WRAP I facility dropped in cost by $0.6 billion.

Mixed Low Level Waste

Net result of the change from the IWPF facility to AWMTP facility at INEL is a decrease, amount not yet determined.

Virtually no costs are included in the latest database for Hanford's WRAP IIA facility (previously $0.64 billion). Estimated costs of TSCA incinerator increased by $0.59 billion.

Summary of key observations:

Many changes have occurred in the configuration since the 4/5/95 configuration.

The volume of waste targeted to move out-of-state for treatment remained stable at 2,000 m3 (1.6% of MLLW); this represents 24% of the total number of wastestreams (497 wastestreams).

The total number of pairs of states where waste is targeted to be exchanged is now 45 (reduced from 47 in April). Tennessee and Idaho would receive 96.6% of all waste targeted out-of-state. (Increase of 2.6%)

The volume of waste designated as "No treatment location specified" has decreased slightly from 24% to 23% of the MLLW inventory. The "Oak Ridge Commercial Option" (including commercial disposal) accounts for 81% of this category.

The waste volume targeted to mobile treatment increased to about 10,700 m3 from 3,050 m3 in the 4/95 configuration.

According to current plans, nearly all MTRU waste would be treated in-state to meet WIPP Waste Acceptance Criteria, and ultimately shipped to WIPP for disposal. All HLW would be treated on-site for ultimate shipment to the geological repository.

Estimated costs to treat all mixed waste are now estimated to be $45 Billion in constant 1995 dollars. The cost to treat HLW is 88% of this total.

STPs do not embody a complex-wide integrated schedule for treatment of MLLW.

Conclusion: The STP configuration represents a snapshot in time; DOE's desired configuration will continue to change, possibly significantly as privatization efforts proceed. Such changes are now subject to the revision process as specified in each FFCA order.

Finally, the FFCA model has been look at be all the states with different views. However, each sees it as a positive step in the right direction. Some states may view the process as the main problem solving tool for mixed waste. Others may view it as a means to an end on much larger issues of their DoE complexes. In Tennessee we view as both but with a new twist. The following is a focus on Tennessee's perspective in not only environmental issues and cleanup but economic and jobs.

TENNESSEE PERSPECTIVE

Background

The Tennessee Department of Environment and Conservation's Division of DOE Oversight (the Division) was established in July 1991. Due to its level of involvement with the Public, local government, the Department of Energy (DOE), and their Contractors, the Environmental Protection Agency (EPA), other DOE host states and local, federal and state agencies the Division is located in Oak Ridge, Tennessee. The operation of the Oak Ridge Reservation (ORR) for more than 50 years has resulted in the contamination of over 500 sites on the ORR. Surface and groundwater have been contaminated both on and off the ORR. Most contamination is located on the ORR but a significant amount has entered the off-site environment including the East Fork Poplar Creek which runs through Oak Ridge and the sediments in Watts Bar Reservoir. The contamination includes, but is not limited to, radioactive material, mercury, asbestos, PCBs, and other organic chemicals.

DIVISION AGREEMENTS

The Division was established by agreements with DOE. Its purpose is to implement the Tennessee Oversight Agreement (TOA), the Federal Facility Agreement (FFA) and to reduce cost to Tennessee. Since being established, the Division has added Natural Resource Damage Assessment (NRDA) and Federal Facility Compliance Act (FFCAct) activities to its list of responsibilities. The purpose of the TOA is to assure the citizens of Tennessee that their health, safety and environment in and around the ORR are being protected by DOE through a program of independent monitoring and oversight by the state. The FFA is an agreement between the Tennessee Department of Environment and Conservation (TDEC), the Environmental Protection Agency (EPA) and DOE. The general purpose of the FFA is to ensure that the environmental impacts associated with the past activities on the ORR are thoroughly investigated and the appropriate remedial action is taken to protect public health and the environment. The NRDA is a federal program to allow for the recovery of the cost for environmental

resources lost due to pollution. The FFCAct is a federal requirement for the DOE to provide the State with a plan for the treating of its mixed waste inventories. Mixed wastes are those wastes that are both hazardous and radioactive. The state is responsible for reviewing, approving and assuring the implementation of DOE's plan.

DIVISION RESPONSIBILITIES

The Division's responsibilities include assuring DOE is in compliance with all environmental regulations; monitoring surface water and on-site discharges; biomonitoring; public drinking water supply monitoring; fish and wildlife monitoring; groundwater monitoring; air quality monitoring; and radiological surveillance. Monitoring efforts extend both on and off the ORR. A critical aspect of the radiological monitoring is that it allows the State to inspect, review, and comment on DOE's activities in this area without regulatory authority. DOE is "self regulating" in radiological materials handling, treatment, and disposal. Additional responsibilities involve coordination of activities involving DOE with TDEC, other State, Federal, and Local Agencies, including but not limited to the Governor's Office, the Tennessee Emergency Management Agency (TEMA), Tennessee Wildlife Resource Agency (TWRA), the Environmental Protection Agency (EPA), the Tennessee Valley Authority (TVA), the Corp. of Engineers (COE), and the Oak Ridge Reservation Local Oversight Committee (LOC) and participating in community outreach activities.

CONTRACTS

The Division is funded through a grant from the DOE to TDEC. Grant funds are also used to establish contracts with other state and local agencies. The Division acts as a lead in each of these contracts. TDEC has a contract with the Department of Health's Division of Epidemiology for the analysis of historical releases of toxic and radioactive materials from the ORR in an attempt to reconstruct the potential impact on human health received by the public. A Tennessee Wildlife Resources Agency (TWRA) contract performs independent monitoring of toxic materials in fish flesh, mussel tissue, and in sediments from Melton Hill and Watts Bar Reservoirs. A contract with the Oak Ridge Reservation Local Oversight Committee (LOC) includes citizens and representatives of local governments from the city of Oak Ridge and the counties surrounding the ORR and the Watts Bar Reservoir. It is a forum to increase public awareness and understanding of the issues involving the DOE ORR operations and impacts on surrounding communities. The contract with TEMA provides for the development of an Emergency Response Program. The Division's Federal Facilities Compliance Act activities are funded through the TDEC Division of Solid Waste Management's Mixed Waste Treatment Plan Review Fee Rule.

DOE BUDGET AND PROJECT FUNDING PRIORITY

The Division provides lead for Department review of DOE funds for Environmental Management including prioritization based on risk to human health, risk to environment, regulatory compliance, public concerns, and mission. The range of involvement begins at the Oak Ridge Office base program and extends to the National level with other DOE host States and DOE Headquarters to resolve issues of equity, risk debate or compliance agreements. Budget review is a cross cut effort to assure that the most important problems are addressed first. The Division works with DOE and regulators (TDEC, EPA, Defense Nuclear Facility Safety Board (DNFSB)) to seek compliance in a cost effective manner.

STATE EQUITY

The Division is the contact for DOE, DOE host States, EPA, industry and the public to express needs or recommendations concerning treatment, storage or disposal of waste on the Oak Ridge Reservation. The Toxic Substance Control Act (TSCA) Incinerator located at K-25 is used to incinerate mixed waste and PCB's. It is permitted by TDEC (air, water and hazardous waste) and EPA. TSCA is the only permitted mixed waste incinerator in the country and is the preferred treatment facility for numerous out of state DOE facilities. The Oak Ridge Reservation is limited
in disposal options and disposal of most TSCA residuals on-site is not an alternative. The Division is working with DOE and other States to resolve disposal issues.

MEMORANDUM OF UNDERSTANDING (MOU)

The Division is an integrated program with memoranda of understanding establishing the roles and responsibilities with the environmental regulatory Divisions of the Department. The purpose being to reduce state/federal cost, minimize regulatory overlap and facilitate coordination.

The Division serves as the state lead for the Watts Bar Reservoir Interagency Working Group MOU between DOE, TVA, COE, EPA, AND TDEC. The propose being to review and expedite processing of public and private sector applications for dredging and other sediment disturbance activities impacted by DOE release of mercury and radioactive materials into the Clinch River.

The Division serves as lead for the DOE, TDEC and Department of Interior MOU for Oak Ridge Reservation Natural Resource Trustees. The purpose being to establish a Natural Resource Trustee Council to consolidate NRDA efforts, share information, reduce cost and seek uniformity in damage assessment relating to the damage or loss of natural resource to Tennessee. The Commissioner of Environment and Conservation is currently the Natural Resource Trustee for the State.

REUSE AND ECONOMIC DEVELOPMENT

The Division interacts with the Department of Economic and Community Development, DOE, local governments, Chambers of Commerce, East Tennessee Economic Council, Community Reuse Organization of East Tennessee, the Oak Ridge Waste Management Association and private groups or individuals as State focal point for DOE and private sector economic development plans to utilize buildings, surplus materials and/or infrastructure As missions change and the complex is downsized the Division shares with EPA and DOE in the important decisions relating to, site remediation, decontamination activities, environmental regulation, and funding schedules. As the Environmental Remediation industry continues to expand as one of the fastest growth industries how can the state tap into the wealth of jobs and companies involved in this industry? Can partnerships be developed with DoE and EPA for massive privatization of cleanup programs to grow this industry in East Tennessee? Is there a benefit for the Oak Ridge area to be known as the silicon valley of environmental remediation. Note this would not be storage but recycling and returned to the originator.

BENEFIT

The measurement of benefits relates to the primary purpose the agreements which is to ensure compliance with applicable laws and to assure the citizens of Tennessee that their health, safety and environment are being protected through existing programs and new commitments by DOE and through a program of independent monitoring and oversight by the State.

Substantial cost savings well in excess of the State grants have been achieved by DOE through the implementation of recommendations or decisions made by the State. Substantial success has been made by DOE in environmental management through problem identification and cooperative technical assistance in problem solving without enforcement. Substantial reduction in violations and enforcement actions resulting in orders and fines by regulator have resulted from increased oversight. Coordinated review of monitoring activities have identified off-site contamination problems, risk evaluation and at the same time success has been made toward overall reductions in monitoring activities and cost. A notable benefit to the Tennessee taxpayer and the Department has been the DOE workload reduction on central or field office regulatory programs. Reductions in DOE activities allowed for increased regulatory program staff response to industrial, commercial, public and private sectors concerns.

ABSTRACT
For almost a decade, the Department of Energy (DOE), like other members of the regulated community, has worked steadfastly to attain compliance with the Resource Conservation and Recovery Act (RCRA). And, like the private sector, DOE largely has been able to manage its hazardous waste in accordance with RCRA. However, DOE waste management activities are confounded and complicated by the presence of radioactivity. In fact, most DOE waste is either radioactive or radioactively contaminated hazardous waste commonly known as "mixed waste". Treatment and disposal capacity for mixed waste has been and continues to be extremely limited because mixed waste must be managed in accordance with the requirements of the Atomic Energy Act (AEA) and RCRA. Although early efforts to demonstrate inconsistencies between RCRA and the AEA failed to identify any, the absence of risk-based requirements or non-regulatory thresholds for both radioactive and hazardous waste forces wastes posing little to no risk or risks dominated by either the radioactive or hazardous waste component of mixed waste to be managed in strict compliance with the full gamut of RCRA and the AEA requirements. The lack of risk-based mixed waste regulations drives up the waste management costs without a concomitant increase in protection of human health and the environment. The Environmental Protection Agency (EPA) intends to issue a final hazardous waste identification rule in late 1996, which for the first time, will establish concentration based exit levels for hazardous waste. This risk-based regulation would allow hazardous wastes below the identified concentrations to be disposed in Subtitle D or other non RCRA regulated facilities. Mixed waste containing hazardous waste below the

exit concentrations would be disposed as radioactive waste. Development of risk based waste management requirements should consider all hazards posed by the waste management requirements necessary to safeguard against those hazards. In the case of mixed waste, waste management requirements should consider the requirements necessary to safeguard the radioactive component as well as the hazardous component in establishing not only exit criteria under HWIR but risk based regulations that enhance protectiveness rather than merely complicate compliance.

Risk based approaches to managing mixed waste can and should be considered in the HWIR rule. Contingent management, dominant hazard, and technology driven regulations are waste management options that would allow mixed waste to be managed consistent with the risk posed by the waste. Efforts to foster consideration these options, their technical basis and justification, and implementation scenarios are being discussed.

For almost a decade, the Department of Energy (DOE), like other members of the regulated community, has worked continually to attain compliance with the Resource Conservation and Recovery Act (RCRA). DOE has largely been able to manage its hazardous waste in accordance with RCRA. However, DOE also manages large quantities of mixed wastea, and the presence of radioactivity complicates the waste management activities. Treatment and disposal capacity for mixed waste has been extremely limited because the mixed waste must be managed in accordance with the requirements of both the Atomic Energy Act (AEA) and RCRA.

Under the authority of the AEA for radioactive waste, DOE has relied on the performance of a system expressed as a radiation exposure limit and has left the decision regulating the appropriate engineering design to the regulated community. DOE also reduces radiation exposure to personnel and workers by applying the "As Low As Reasonably Achievable" (ALARA) principle with radiation protection guidelines. These guidelines generally state that worker exposure to radiological hazards should be maintained at a minimum and assure that exposures are justified by benefits produced by the activity.

In contrast to waste management principles under the AEA, RCRA contains numerous prescriptive design requirements that give the regulated community less flexibility in designing a waste management system on the basis of performance or risk. One example where the RCRA framework does not account for associated risks is listed hazardous waste. Under RCRA, solid wastes are designated as listed waste if they are used in a particular way, such as solvents, or if they come from a particular process, such as sludge from an electroplating process. In order to prevent "dilution as the solution" to managing that particular waste stream, RCRA requires that once a waste is a "listed" hazardous waste, it remains a listed hazardous waste regardless of the hazardous constituent concentration. The RCRA regulatory framework has other provisions including: 1) the "mixture rule" which states if a solid waste is mixed with a listed hazardous waste then the entire mixture must be managed as a listed hazardous, 2) the "derived from" rule which states that wastes generated from the management of listed hazardous waste are themselves listed hazardous wastes, and 3) the "contained in" policy that requires environmental media (i.e., groundwater) contaminated with a listed waste to be managed as a listed waste. Currently, the only option available to the regulated community is to have a waste "delisted," which is a relatively expensive and time-consuming process, especially when applied

to mixed wastes. This prescriptive approach ignores the idea that protection of the radioactive component of mixed waste provides varying degrees of protection for the hazardous component, depending on the nature of the mixed waste.

We recognize, however, that Environmental Protection Agency (EPA) has made attempts at establishing a risk-based regulatory framework. On May 20, 1992, EPA published a Notice of Proposed Rulemaking (NPRM) regarding Identification and Listing of Hazardous waste [57 FR 21450]. In the preamble EPA indicated that it would "begin tailoring the scope of its hazardous waste program to reflect how wastes are actually managed, rather then how they might be managed under a worst-case analysis," after the D.C. Circuit Court remanded EPA's 1980 mixture and derived from rules. The May 1992 proposed rule allowed low concentrations of hazardous constituents to no longer be regulated as hazardous waste and managed as sanitary waste. Mixed waste, with low concentrations of hazardous waste would likewise be managed as low-level radioactive waste. On October 30, 1992 [57 FR 49280], however, EPA withdrew the May 20, 1992 proposed rule due to the opposition it received from the public, Congress and the States.

Since EPA withdrew the proposed rule they have been working with the States and representatives from industry and environmental groups in the development of the Hazardous Waste Identification Rule (HWIR). The HWIR committee disbanded in September 1994 after making its recommendations to EPA. Essentially EPA developed two rules under HWIR, one for process waste which was proposed in November 1995 which EPA intends to finalize in late 1996, and a second for contaminated media which is expected to be proposed in early 1996.

The HWIR rule for process waste, for the first time, will establish concentration based exit levels for hazardous waste. This regulation establishes concentrations for various listed constituents, which will allow hazardous waste to be disposed in a Subtitle D or other nonRCRA regulated facility, based on a risk of 10-6 (for cancer-causing constituents) and hazard quotient (HQ) not exceeding 1 (for noncancer risks). EPA has determined, using a multipathway risk assessment methodology, that hazardous waste containing low hazardous constituent concentrations will not present significant risks to human health and the environment if managed in land disposal facilities not regulated under Subtitle C requirements. EPA analyzed over 400 hazardous constituents for exit levels. EPA's analysis assesses risks to humans and ecological risks from two categories of wastes, wastewaters and nonwastewaters. The analysis also compared risks posed by management of these wastes in five different types of waste units.

Since early 1995, DOE has identified and evaluated several areas of RCRA regulations that if modified, could result in substantial cost savings or cost avoidance, yet pose no adverse impacts to human health and the environment. DOE's focus is on risk-based regulatory changes related to the mixed waste management. DOE has developed the following specific regulatory reform proposals for consideration by EPA:

- Immobilized Mixed Waste Debris
- Vitrified Waste
- Contingent Management

The following provides short discussions on these regulatory reform proposals.

DISCUSSIONS OF DOE'S PROPOSALS

Immobilized Debris Proposal

Debris is defined as "solid material exceeding 60 mm (2.5 inch) particle size that is: (1) a manufactured object; or (2) plant or animal matter; or (3) natural geologic material (e.g., cobbles and boulders), except that any material for which a specific treatment standard is provided in Subpart D, part 268, is not debris" (40 CFR 268.2). Debris are routinely generated from activities such as construction, maintenance, routine operations, closure of facilities, and environmental remediation. Examples of debris include pieces of concrete, metal (e.g., piping), wood, plastics, used personal protective equipment, and other similar wastes. The types of debris normally found at DOE sites do not contain high concentrations of hazardous contaminants.

As part of Phase I Land Disposal Restrictions (LDR) rule, EPA promulgated the Final Rule on Hazardous Debris (Debris Rule) in August 1992. This rule allows hazardous debris treated by extraction or destruction technology to exit RCRA Subtitle C control provided that treated debris does not exhibit a characteristic of hazardous waste (57 FR 37222, August 18, 1992).

At the time the Debris Rule was enacted, EPA chose not to allow debris treated with an immobilization technology to exit Subtitle C control. The rationale for this was that there was not sufficient data available to demonstrate that, absent Subtitle C management, contaminants would not migrate from immobilized debris at levels that could pose a hazard to human health and the environment (57 FR 37240). However, EPA invited the regulated community to submit data on immobilization of debris and requested comments on whether immobilized debris should exit from Subtitle C regulations as part of the proposed Phase II LDR rulemaking (58 FR 48144, September 14, 1993). EPA indicated that the HWIR may be the appropriate rulemaking for this issue. As part of its final Phase II rulemaking, EPA stated that if the technical data were submitted, the Agency would exclude immobilized debris from Subtitle C control (59 FR 48012, September 19, 1994).

In Winter 1995, DOE developed technical data package supporting the proposal that mixed waste debris treated by immobilization, followed by disposal in a low-level waste (LLW) facility is protective of human health and the environment and therefore, should be allowed to exit Subtitle C controls. The basis for this proposal is the combination of the integrity of the encapsulated debris waste form, coupled with the protectiveness of a LLW disposal facility. This technical data package was submitted to EPA in July 1995. On October 20, 1995, DOE supplemented the July 1995 report to EPA with a report entitled "Performance Evaluation for RCRA Toxic Metal Disposal in DOE Low-Level Radioactive Waste Disposal Facilities."

Technologies for immobilization/encapsulation of solids are classified depending on whether the encapsulant is interspersed with the waste (microencapsulation) or surrounds the waste (macroencapsulation). EPA defines macroencapsulation as "the application of surface coating materials such as polymeric organics (e.g., resins and plastics)..." to "...completely encapsulate the debris" (57 FR 37235, August 18, 1992). Furthermore, the encapsulating material must be resistant to (i.e., unreactive with) the debris it encapsulates and other materials it may come in contact with after disposal (i.e., leachate, other wastes and microbes). Microencapsulation is defined as stabilization of debris with Portland cement and lime/pozzolans (fly ash and cement kiln dust) and may

include such additives as iron salts, silicates and clays (57 FR 37235). The resulting encapsulated waste form can be a free-standing monolith, depending on the size of the waste unit, or small pellets (60-mm size limit).

EPA currently recognizes polymeric organic materials as acceptable macroencapsulating agents and only Portland cement and lime/pozzolans as acceptable microencapsulants. Several other encapsulating agents including hydraulic cement, sulfur polymer cement, polyethylene, phosphate ceramics, epoxies, urea formaldehyde polymer and asphalt, have been developed and tested. Because the performance of some of these materials is comparable or superior to that of the accepted microencapsulants, these alternate encapsulants (sulfur polymer cement, polyethylene, phosphate ceramics) have been included in DOE's proposal. For each of the proposed encapsulating materials DOE assembled data on waste form leachability and/or permeability, biodegradation, radiation stability, and long-term environmental stability.

To assure the mixed debris treated by immobilization and placed in a low-level waste disposal facility is sufficiently protective of human health and the environment, DOE proposed that the final waste form meet or exceed an established performance criteria. Because EPA's performance standard for microencapsulated waste is that the "leachability of hazardous contaminants must be reduced" (57 FR 37235) various tests have to be performed on the final waste form to meet that criteria. DOE proposes that testing of immobilized debris be conducted in two tiers. Tier one consists of the following:

Microencapsulated debris - Toxicity Characteristic Leaching Procedure (TCLP) as per EPA Model 1311, or the Synthetic Precipitation Leaching Procedure (SPLP) as per EPA Model 1312.

Macroencapsulated debris - A modified TCLP or SPLP, possibly using an encapsulated coupon of the debris, and waste form integrity testing via a non-destructive test such as real-time radiology, ultrasound, or x-ray. The standard leachability test method is not appropriate for macroencapsulated debris because it would require breaking the protective encapsulant layer and allow the leaching solution to be in contact directly with debris. This is contradictory to the intention of the macroencapsulation process, therefore, the integrity of the final waste form should be verified using non-destructive methods.

Tier two tests could include the following: a compressive strength test, non-destructive test, long-term immersion in water, radiation stability, biodegradation, freeze-thaw cycling, and wet-dry cycling. One or more of the tier two tests would be performed on the waste, based on the tests which are appropriate for a particulate disposal facility location, to demonstrate the integrity of the final encapsulated waste formb. DOE recommended that these tests be done initially as proof of process tests and then periodically repeated as quality assurance checks. DOE sites would work with their respective regulator to decide which tests are appropriate for the treated mixed waste debris after considering the type of encapsulation and the characteristics (e.g., climate, depth to groundwater, etc.) of a disposal site.

Both, RCRA Subtitle C and DOE LLW disposal facility requirements share a common goal of maximizing the protection of human health and the environment from the hazards contained in each type of facility. These two facilities also have several common elements, including limiting the amount of free liquids that may be present, requiring groundwater

monitoring and specifying a period of active institutional control after site closure. The primary difference between the two types of facilities is the RCRA requirement for waste unit double liners and a leachate collection system. This difference is the result of two different philosophical approaches to waste management that have evolved due to fundamental differences in the nature of the hazards associated with RCRA and LLW. The EPA waste management philosophy under RCRA is to treat hazardous constituents to safe levels before land disposal. Radioactivity, on the other hand, cannot be treated to safe levels (excluding transmutation), but can only be eliminated as a result of natural decay. This has led to the waste management philosophy of immobilizing/isolating radioactive waste from the public and sensitive environments until natural decay renders the residuals safe. The extent of immobilization/isolation varies from hundreds to thousands of years, depending on the half-lives of the radionuclides and the curie content of the waste. However, unlike their radioactive counterparts which eventually decay in innocuous levels, the RCRA toxic metals are persistent in the environment. This fact lessens the importance of the effects of a disposal facility's engineered barriers and increases the importance of the site geology.

While EPA has a prescriptive approach to disposal of RCRA hazardous waste, DOE takes a performance-based approach to radioactive waste disposal which allows the disposal site to design and operate the facility as appropriate to achieve the required performance standards. Depending upon characteristics of the disposal site (i.e., geology, meteorology, etc.), designs can range from shallow land burial to containment in above or below-ground concrete enclosures. Facility acceptability is determined via a performance assessment that verifies the ability of the facility as designed and operated to meet the performance objectives prescribed in DOE Order 5820.2A.

In DOE's report, "Performance Evaluation for RCRA Toxic Metal Disposal in DOE Low-Level Radioactive Waste Disposal Facilities", a risk-based analysis evaluated the environmental transport of RCRA toxic metals from six DOE LLW disposal sites. The analysis focuses on the toxic metal component of the mixed waste debris (the principal contaminants in DOE's mixed LLW debris) and the groundwater contaminant pathway, because it is the dominant transport pathway for human exposure from land disposal facilities. The analysis estimates permissible leachate concentrations of toxic metals by using Maximum Contaminant Levels (MCL) concentration values in groundwater at a receptor point along the performance boundary (100 m from the disposal facility boundary), and attenuation factors associated with site-specific conditions. The report concludes that arid DOE LLW sites appear to provide a greater degree of protection of human health and the environment than humid DOE LLW sites based on higher attenuation and longer contaminant travel times. However, even at relatively humid sites most RCRA toxic metals (except for arsenic and selenium) are immobile in the subsurface environment.

In summary, the DOE's proposal is based on the integrity and stability of the immobilized mixed waste debris treated in accordance with 40 CFR 268.45. Protection of human health and the environment is achieved via the combination of this treatment and disposal at LLW disposal facilities regulated under the requirements of the AEA. This proposal allows for a reasonable mixed waste management approach without compromising

protectiveness of human health and the environment, and at the same time would result in substantial cost savings to the regulated community.

Vitrified Waste Form

Vitrification is the process of converting materials into a glass-like substance, typically through a thermal process. Vitrification thermally destroys organic contaminants and stabilizes inorganics and metals by incorporating them into the glass structure. Vitrification has four major advantages over other methods of waste treatment. The primary advantage of vitrification is that it produces durable waste glass. With proper formulation, this waste glass performs exceptionally well in leach tests. The second major advantage of vitrification is the ability of the waste glass to incorporate a wide variety of contaminants and accompanying feed material in its structure, without a significant decrease in quality of the final waste form. The third advantage is that the vitrification process can accommodate both organic and inorganic contaminants of various amounts. Lastly, vitrification typically results in significant volume reductions of waste material. One significant disadvantage of the vitrification technology is the high cost.

Vitrification is a desirable treatment option for long lived radionuclides, despite the cost, because the vitrified waste forms will resist degradation for the thousands of years necessary for radioactive decay to lessen the threat to human health and the environment. During this decay period, the metals and inorganics are chemically bonded in the glass matrix. Due to these features, EPA has declared vitrification to be the specified treatment technology for mixed high-level waste (55 FR 22627, June 1, 1990). DOE will vitrify high-level waste and may propose to vitrify certain other mixed low-level waste where it is economically feasible to do so. The mixed low-level waste candidates for vitrification are predominantly sludges, slurries, and metal/metal oxides.

On October 20, 1995, DOE submitted to EPA a technical data package to support its proposal to exempt vitrified mixed waste forms from RCRA Subtitle C regulations. The proposal would allow vitrified mixed waste forms which have been treated under an environmental permitting process to exit from RCRA hazardous waste regulations based upon inherent destruction and immobilization capabilities of the technology. The technical data package also includes DOE's proposal of an alternative sampling and analysis strategy for certain highly radioactive mixed waste forms. The proposed sampling strategy considers the radiological hazard associated with testing of the final product. For wastes with low radiation hazard, sampling and analysis is performed on the final product. However, sampling and analysis of highly radioactive wastes is performed on surrogate vitrified wastes that are chemically equivalent to the actual waste. DOE believes that this alternate testing strategy provides results with an equal level of confidence as sampling and analysis of the final waste forms, as suggested by 40 CFR 261.36.

DOE proposes performance characteristics for vitrified waste forms with glass compositions that meet or exceed the performance standards of the Environmental Assessment (EA) glass developed as the standard for the immobilization of high-level waste. The EA glass is a borosilicate glass which has been selected as the preferred waste form by the United States and other countries involved with high-level waste management. The EA glass was specifically formulated to retard the release of radioactive components in the waste, but has also been shown to retard the release of non-radioactive components.

Vitrification requires a process control protocol for key operating parameters in order to yield a glass product consistently falling within a pre-defined acceptable performance envelope. The process control is defined by performing treatability studies on either the actual radioactive waste or an appropriate surrogate. The treatability studies provide information on glass formulation process and the balance of operating variables, such as waste loading and viscosity, while ensuring the durability of the final waste form. Once the parameter values, which produce a durable glass are determined, they are used to define the Process Control Program. Therefore, DOE's vitrification proposal is contingent on the required use of the Process Control Program that ensures desired durability of the end product. The Process Control Program not only defines the process and ensures final product performance, but is required to demonstrate compliance with existing federal and state environmental regulations associated with the operation of a mixed waste treatment facility. Once this Process Control Program is defined and accepted as part of an environmental permitting process, the inherent properties of the final glass waste form ensure protection of human health and the environment.

The Process Control Program requirements also include detail description of the sampling and analysis program. To ensure the glass' durability, DOE proposes to monitor the leach rates of several of the most leachable glass components. Two forms of leach tests, the Product Consistency Test (PCT) (ASTM-C1285-94) and TCLP have been proposed. The PCT test was developed for evaluating the performance of high-level waste glass and its durability as it relates to the release of radioactive components. Testing requirements for organic constituents identified in the vitrified waste stream are eliminated because organic wastes are thermally destroyed by the vitrification process, which typically operate in excess of 1000oC.

In summary, the DOE's proposal is based on the inherent characteristics of the vitrification process and stability of the waste form. Upon meeting specific Process Control Program requirements, the glass product would be exempt from RCRA Subtitle C control. Because the mixed waste vitrification process will be regulated under 40 CFR 264 Subpart X, the regulatory permitting agencies will be involved in the approval of the Process Control Program. This proposal provides a means to facilitate the use of a superior technology for responsible waste management while reducing costs, and maintaining full regulatory authority until an acceptable vitrified waste form is produced.

Contingent Management

While the proposals discussed above deal with specific waste forms, we believe they constitute examples of a broader concept which EPA has been considering. Both the 1992 PRM and the HWIR proposal discuss options whereby wastes that would otherwise be regulated under RCRA could exit the control of Subtitle C contingent upon subsequent management that would protect human health and the environment. In the most recent proposal, EPA detailed potential approaches to allow wastes to exit the Subtitle C system. These approaches fall into the following three broad categories:

1) Conditional exemptions based on unit type without additional management controls. Under this approach EPA discusses two possible options: a) constituent specific exit levels could be based on the second riskiest management scenario if there were a mechanism to ensure that the

riskiest management scenario would not occur; or b) set separate exit levels for each management scenario.
2) Setting conditional exemption levels for unit types with additional controls. Under this approach EPA would consider establishing less conservative exit levels at units applying specific design or operating controls to further minimize risk.
3) Conditional exit levels in states with qualified industrial non-hazardous waste programs. EPA discusses several options which would exempt some waste form Subtitle C and rely on state imposed requirements to ensure protectiveness.

DOE is currently investigating a variety of potential applications of the contingent management approach. As detailed earlier, these proposals may center on a specific waste stream or final waste form coupled with disposal. Proper management could also be demonstrated by evaluating specific waste disposal options alone. This could include a generic process, whereby Subtitle C exit levels are established contingent upon waste disposal at an AEA compliant site rather than an uncontrolled site; or a site-specific process whereby Subtitle C exit levels are established by considering detailed site-specific information and a multi-pathway exposure model. Regardless of the method, the validity of any contingent management scenario would be based on the ability to meet the goals of 10-6 and HQ=1.

Benefits Associated with DOE's Proposals

The following provides a discussion of the waste volumes that could potentially be impacted and the associated potential cost savings resulting from each of the three proposals. The volume estimates were obtained from DOE's Mixed Waste Inventory Report required by the Federal Facility Compliance Act of 1992.

Approximately 27,000 m3 of DOE's current inventory of mixed waste is debris and is a candidate for immobilization. This waste volume includes both heterogeneous and inorganic debris and accounts for roughly 4 percent of DOE's current mixed waste inventory. If the EPA, and subsequently the states, allow immobilized mixed waste debris to be disposed as low-level mixed waste, DOE could potentially save several million dollars, and possibly up to $1 billion, on disposal costs. This cost savings is based on comparing unit costs of disposing in a low-level waste landfill to a mixed waste landfill.

Approximately 360,000 m3 of DOE's current mixed waste inventory is high-level waste that can be vitrified. This accounts for roughly 60 percent of DOE's current mixed waste inventory. If EPA and the States except and implement the vitrification proposal, DOE could save over $1.5 to 1.6 billion on high-level waste disposal. This estimate is based on the assumption that a RCRA permit would not be required for the geologic repository receiving the vitrified high-level waste. DOE also has approximately 35,000 m3 of mixed low level waste that could be a candidate for vitrification. These waste streams include glass debris, wastewater treatment sludges, soil, acidic wastewaters, inorganic particulates, organic debris, ash, inorganic heterogeneous materials, and predominately inorganic materials. If EPA and the states accept and implement the vitrification proposal, DOE could save between $50 million to $100 million on disposal costs. This cost savings is based on comparing unit costs of disposing in a low-level waste landfill to a mixed waste landfill.

Because some of the individual waste streams may be covered by more than one proposal, such as debris waste, the totaling of the proposals may show a doubled cost savings. Therefore, the waste volumes and cost estimates for these proposals stand alone and cannot be combined to determine a total cost savings.

Future Plans and Proposals

DOE plans to continue the dialogue with EPA and provide information to support these and future proposals. DOE is optimistic that the basic tenets of the proposals will be accepted by the EPA and the States because they provide reasonable regulatory alternatives and substantial cost savings to the DOE without compromising protection of human health and the environment. If other viable alternatives for the regulatory scheme related to management of mixed wastes are identified and the technical data packages can be assembled, DOE will provide proposals to EPA for consideration.

An opportunity for continuation of the regulatory discussions with EPA will surface again in early 1996 when EPA proposes the second part of the HWIR rule for contaminated media generated from remediation of hazardous waste sites. The rule will exempt certain lower risk contaminated media from the traditional "prevention oriented" RCRA regulations and will set treatment standards for higher risk media that reflect the inherent differences between contaminated media (e.g., soils, groundwater) and newly generated wastes. EPA will set a "bright line" above which the wastes must meet full RCRA Subtitle C standards, and below which the requirements will be site-specific.

STREAMLINING THE MIXED WASTE TREATMENT CONFIGURATION - RESULTS OF THE DOE OPTIONS ANALYSIS TEAM

J. Sands
R.R. Aldridge
S.R. Ross
U.S. Department of Energy

ABSTRACT

The Federal Facility Compliance Act required that U.S. Department of Energy sites that generate and store mixed waste develop Site Treatment Plans describing how they intend to develop treatment capacities and technologies to treat mixed waste. Site Treatment Plans were developed by individual sites and eventually consolidated. Once combined, the resulting national configuration of treatment capabilities showed many redundancies and inefficiencies. The DOE Options Analysis Team (OAT) was chartered to analyze the national configuration and develop a "wise configuration" of treatment facilities. The OAT was able to optimize the use of existing and new facilities, minimize transportation, and minimize overall cost and schedule for completion of treatment, while addressing state equity and risk concerns. This paper presents the OAT approach, how configuration analyses were performed, how states' input was incorporated, how budget constraints were resolved, and the overall outcome of the OAT process.

INTRODUCTION

The Federal Facility Compliance Act (FFCAct) of 1992 added Section 3021(b) to the Resource Conservation and Recovery Act (RCRA) and required federal facilities which generate mixed waste (radioactive and hazardous waste) to develop Site Treatment Plans (STP) for treating currently

stored and future generated mixed waste. The FFCAct provided an unprecedented opportunity for the U.S. Department of Energy (DOE) to work with its regulators to resolve a long-standing issue - how to treat large amounts of mixed waste now being stored or generated at DOE sites. DOE sites completed these plans in three phases: conceptual, draft, and proposed. 49 site Draft STPs were completed in September 1994 which identified preferred treatment options and the selection processes used. Proposed STPs were completed in April 1995 and identified schedules for treatment options selected. Most sites entered into consent orders with their respective states by October 6, 1995, the date marking the end of sovereign immunity of the federal government from fines and penalties associated with violation of the storage prohibitions of RCRA. The individual site consent orders specify implementation requirements for the STPs.

Because the Draft STPs were prepared by the sites using a "bottoms up" approach, the resulting national treatment configuration contained many redundancies and inefficiencies. Thomas P. Grumbly, DOE Assistant Secretary for Environmental Management, requested that the STP Task Force develop a "wise configuration" by minimizing redundancy, reducing costs, yet fulfilling the needs of the complex by providing timely and efficient waste management. In developing the Proposed STPs, an assessment was performed to determine what accommodations were necessary to blend the "bottoms-up" Draft STPs into a more sensible national configuration of treatment systems. To facilitate this assessment, DOE established the Options Analysis Team (OAT), comprised of site representatives and members of the DOE Headquarters' FFCAct Task Force. The OAT coordinated their efforts with the states through the National Governors' Association (NGA) to ensure the national mixed waste configuration reflects both the states' and DOE's concerns. As part of this evaluation, the impacts of implementing the emerging DSTP configuration, as well as alternative configurations, were evaluated. The resulting national configuration is DOE's best attempt to balance competing DOE and stakeholder interests and decreasing government resources.

OAT CHARTER AND MEMBERSHIP

The OAT was formed to provide a diverse yet representative group that could overhaul the Draft STP configuration while reflecting site capabilities, needs, and regulator interests. This team was formed in June 1994 and was comprised of DOE site representatives and members of the FFCAct Task Force. Technical support was provided by site technical experts and technology development representatives. The site representatives offered the sites' perspectives and brought individual state and site issues to light, while the Headquarter's representatives offered insight from their dealings with policy issues and the "big picture." The technology development Mixed Waste Focus Area supported the OAT, and their goals were to identify technology development needs, assess benefits of using emerging technologies, and scope technology development programs that are responsive to sites' compliance requirements.

The OAT worked closely with the states through the NGA, which opened up communication at a key time in the development of individual STPs. The OAT and NGA met at least quarterly through development of the STPs, OAT process, and consent orders. State representatives were given the opportunity to interact with DOE as a whole -- both individual site representatives and policy makers from DOE Headquarters. It was also

valuable for the states to confer with one another about DOE site issues and approaches.

The OAT began analyzing the Draft STP configurations in August 1994 and completed the majority of the work by January 1995. The OAT, however, continued to work with the sites to refine treatment options through the completion of STPs (October 1996). The OAT dealt with the treatment configuration for mixed low-level waste (MLLW) only. Treatment for high-level waste and mixed transuranic waste are handled through other efforts. The results of the initial OAT analysis was shared with each of the sites and the state regulators, as well as DOE management. The following months were spent responding to state requests for additional analysis, incorporating ongoing site analysis, and responding to comments. Open communication and involvement by the states, as well as their influencing the outcome of the OAT process, were fundamental to the success of the overall STP process. This success is demonstrated by the achievement of signed consent orders for most sites by the October 6, 1995 target date.

TREATMENT CONFIGURATION EVALUATION

The integration of the 49 Draft STP configurations formed the baseline for the OAT analyses. A database was developed with key waste stream and treatment facility data and was the key tool in analyzing the STP configuration. Waste streams were divided by the types of treatment needed to show the baseline configuration and allow comparisons. Several different configurations were then analyzed based on criteria requested by the states, and the OAT selected their preferred configuration to present to the states and DOE management.

OAT Database

The OAT database tracks key information about STP facilities and waste streams. Facilities were tracked by unique identifying numbers which included a site code prefix and an ID number. Waste streams were also tracked by unique identification numbers used in the Mixed Waste Inventory Report, a database of mixed waste information used to develop the STPs. Waste streams were categorized by waste type (mixed low-level waste, mixed transuranic waste) and waste matrix (a code identifying physical and chemical characteristics of the waste). The resulting database was used to sort the data on various types of information and allowed scrutiny of the configuration against evaluation criteria defined by the states and DOE. Both mixed low-level waste and mixed transuranic waste were included in the database; however, only the mixed low-level waste configuration was analyzed. Mixed transuranic waste treatment options are being reviewed under a separate effort.

Treatment Types

Initial sorts of waste streams were performed using the treatment type required and the treatment option (specific facility and location). These sorts allowed analysis of the Draft STP configuration by showing which facilities were being under-utilized, over-utilized, or were duplicated. The breakdown of treatment types is as follows:

- Organic Destruction
- Deactivation
- Non-Aqueous Neutralization
- Stabilization
- Mercury Amalgamation
- Inorganic Debris Treatment
- Mercury Separation

Soil Washing
Alkali Metals Treatment
Waste Water Treatment

These treatment types generally describe the mixed waste treatment needs across the DOE complex.

Treatment Configurations Analyzed

With input from the NGA, the OAT evaluated the following MLLW treatment configurations for each treatment type. In all configurations, the OAT attempted to use existing treatment systems to the maximum extent possible.

DSTP Configuration - site-preferred treatment options presented to the States in the Draft STPs. This configuration was used as the baseline for developing the other configuration scenarios. The Draft STP is a "bottoms-up" configuration reflecting the States' preference for on-site treatment.

Quick-Start Configuration - a mixed waste treatment configuration that emphasizes use of existing treatment systems, including DOE and commercial facilities, and mobile treatment units.

Centralized Treatment Type Configuration - a regionalized configuration based on treatment type and waste volume. This configuration emphasizes consolidation of a large number of treatment systems located in geographically strategic areas, based on waste volume and sites generating the wastes.

The Quick Start and Centralized Treatment Type configurations were created to emphasize different key State and DOE concerns (relating primarily to schedule and cost) and as such, to serve as building blocks for creating the OAT Proposed configuration. To meet this objective, OAT members decided it was important to have flexibility in creating these two configurations for the individual treatment types. Because of this, the consideration of existing facilities in these two configurations may seem inconsistent among sites.

OAT Proposed Configuration - the mixed waste treatment configuration that attempts to take into account the advantages and disadvantages of the three original scenarios (DSTP, Quick Start, and Centralized). This configuration incorporated the comments from the sites and was presented to the States and DOE management as a basis for further discussion.

Modified Centralized Treatment Configuration - a revised version of the Centralized Treatment Type configuration (above). This configuration extends the logic of the Centralized Treatment Type configuration in order to provide a least-cost reference point. This configuration was developed after completion of the OAT Proposed configuration, and analysis of this configuration supported ongoing cost evaluations described later.

In addition to the above configurations, three other scenarios were added later and evaluated:

Nearest-Site Scenario - a revised version of the DSTP configuration in which wastes proposed for off-site treatment are redirected to the nearest off-site treatment system. This configuration was created at the States' request to evaluate the impact of a "minimal shipment" option on interstate transportation of mixed waste.

Compact Scenario - a configuration that would restrict waste shipments to established low-level waste compact regions. In most cases, OAT members recognized that this configuration was not feasible. Therefore, the OAT did not pursue further evaluation of this scenario.

Alpha-Contaminated Waste Scenario - the treatment of alpha-contaminated waste (10-100 nanocuries per gram transuranic alpha) was originally intended to be evaluated as a separate scenario. However, it proved very difficult to completely separate it from the rest of the MLLW and as such, was considered along with MLLW in all configurations evaluated.

Site OAT members were each assigned treatment types for configuration development and evaluation. Members used the baseline database extract reports showing all new and existing facilities which could treat each respective treatment type and all waste streams proposed to be sent to each facility. The site representatives then developed each of the above configurations by proposing which facilities could most likely be deleted or consolidated with others, and which waste streams could be treated commercially.

Six specific evaluation areas influenced the configuration development process. The evaluation areas are described below. Considering these evaluation areas in developing the configurations provided consistency and enhanced comparison and evaluation.

Evaluation Areas

Mixed waste treatment configurations were evaluated based on their relative ranking (high, medium, and low) with respect to the following six evaluation areas:

Use of existing treatment facilities: evaluation based on number of existing treatment systems to be used under a given configuration and volume of waste proposed for treatment in them.

Number of new treatment facilities: evaluation based on number of new treatment systems proposed under a given configuration. This evaluation area, in addition to addressing cost, also addresses construction risk. It was assumed that new treatment facilities would be designed or re-scoped to handle any waste stream changes proposed by the OAT.

Volume of waste transported across state lines: evaluation based on volume of waste proposed for shipment to another state under a given configuration. This evaluation area addresses equity issues, as well as transportation risk.

Cost: evaluation based on best available cost estimates and results from a cost estimating model under development at the time. This model provided a life cycle cost estimate based on key waste management activities, such as characterization, treatment, storage, disposal, shipping, etc. The cost model had not been validated by DOE at the time of this analysis; therefore, the results were only used for preliminary relative cost comparisons.

Time required to complete treatment: evaluation based on OAT members' experience in scheduling new facility design, construction, permitting, etc. and on assumption that commercial and mobile treatments can be implemented faster.

Use of alternative treatment technologies: evaluation based on the extent to which the use of future alternatives is feasible under a given configuration. Since the OAT did not select specific technologies for new facilities, all configurations were deemed equal in this regard. The maximum opportunity for using alternative technologies will be in the construction of new treatment facilities. All configurations analyzed assumed some new treatment facilities would be built.

For each configuration, representatives rated each evaluation area as high, medium, or low relative to the other configurations. The OAT met in October 1994 to review the OAT members' treatment type analysis and

further refine this process. The goal of this meeting was to develop the national OAT Proposed configuration. To do this, the team members discussed the results of their analyses, and it became clear that some alternatives were better than others. It was decided that the OAT Proposed configuration should combine the successful attributes of the different scenarios. The team reviewed each treatment type and which facilities the site representative recommended be eliminated or increased in scope. The team examined each treatment system, focusing on treatment type and volume of waste targeted to the system, and decided which would remain in the OAT Proposed configuration. Both site programmatic and technical representatives were present to discuss with the group why different systems were or were not justified. The team discussed the relative importance of the various evaluation areas and used the database to quantify results as the Proposed configuration was further refined. Once this was completed, the team reviewed the remaining treatment systems based on the evaluation areas to determine if the list was acceptable from a national perspective. The result of this process was an OAT Proposed configuration which was sent to the sites for review and comment. The team then met in November 1994 with additional site representatives to resolve site comments. In addition, the Modified Centralized treatment configuration was developed to provide a least-cost reference point. The results were provided to NGA and the states, and their issues and concerns were identified.

As costs and schedules were further refined at the site level, the OAT continued to meet and work towards an OAT Proposed configuration which would be the basis for the Proposed STPs. The costs derived from the cost model were merely used for comparison of configurations. Actual facility estimates generated by the sites, using consistent Headquarters guidance, became the basis for cost-

dependent decisions. The final OAT Proposed configuration was approved by DOE management in February 1995. This configuration became the basis for the site Proposed STPs and was thus the baseline for the STP process. Any changes resulting from sites' further review of both commercial and available treatment options had to be approved by the OAT team leader and FFCAct Task Force.

Assumptions

The proposed OAT configuration could only be valid if certain key assumptions were considered. These assumptions were as follows:

- States will agree to accept some treatment of out-of-state waste
- DOE will be able to operate existing incinerators
- DOE will be able to use off-site existing commercial treatment facilities
- Existing commercial and mobile treatment will be less expensive and will treat waste faster than construction of a new facility

The OAT, NGA, and DOE management agreed with application of these assumptions in the OAT process.

Mobile Treatment

In preparing the Draft STPs, the states asked DOE to evaluate on-site waste treatment to the extent possible. Accordingly, the states were very interested in evaluating the use of mobile treatment across the DOE complex. Mobile units offer a compromise between building expensive permanent treatment units at smaller sites and shipping waste off-site for treatment.

The Albuquerque Operations Office relied heavily on mobile treatment options when preparing their Draft STPs due to the mid-sized mixed waste volumes present at most of their sites. The rest of the sites were encouraged to evaluate use of mobile treatment in preparing their Draft STPs. The initial OAT Proposed configuration doubled the use of mobile treatment originally proposed in the Draft STPs. A more concentrated effort was then focused on maximizing the capabilities and use of the mobile units. This effort further increased the proposed use of DOE complex mobile units.

EVALUATION RESULTS

The results of the OAT evaluations of the initial three configurations (Draft STP Baseline, Quick Start, and Centralized) provided a starting point for developing the OAT Proposed configuration. Table I, below, shows how each of the initial five configurations evaluated by the OAT rank relative to one another in five evaluation areas. As noted earlier, the sixth evaluation area--"Use of Alternative Treatment Technologies"--was judged equivalent for all treatment configurations.

The high, medium, and low ratings are defined as follows:

HIGH Indicates the configuration was rated more favorably in this area than the other configurations.

MEDIUM Indicates the configuration was rated no better or worse in this area than other configurations.

LOW Indicates the configuration was rated less favorably in this area than the other configurations.

Table I

Comparing the ratings of the OAT Proposed configuration demonstrates how this alternative optimized the positive attributes of the other configurations. While the OAT attempted to maximize the use of existing facilities, no configuration rated "high" on Table I in this area because it appears there is still excess capacity available. The excess is due to a lack of waste currently available to support the existing types of treatment. The excess capacity is planned to be used to treat future environmental restoration and decontamination/ decommissioning mixed wastes.

In creating the OAT Proposed configuration, certain Draft STP treatment systems were eliminated. The main reasons for elimination of a treatment system are the following:

- There is excess capacity at existing DOE or commercial treatment systems
- mall volumes of waste were targeted for a different facility where other options were available
- More favorable treatment schedules were available at other existing or proposed treatment systems
- There is the potential for cost savings through use of another option
- Interstate transportation of large waste volumes could be minimized

For example, during development of the Proposed STPs, DOE Oak Ridge determined that developing their own mixed waste treatment capabilities was prohibitively expensive. They proposed to meet their mixed waste treatment needs through using both established and developing commercial processes using DOE mobile units. Later, after the Proposed STPs were submitted to the states, DOE Idaho also chose to replace their Idaho Waste Processing Facility (IWPF), consisting of 10 treatment trains, with a commercial option. These decisions significantly affected the overall cost and schedule of the final configuration.

Use of DOE mobile units was significantly increased through the OAT process. The Oak Ridge Mixed Waste Treatment Facility reactive metals treatment train was replaced with the Los Alamos National Laboratory Reactive Metals Skid mobile treatment unit. This change diverted treatment of 46 cubic meters of reactive solids to a mobile unit and avoided construction of this treatment system. A similar case was the replacement of the IWPF debris decontamination train and the Idaho WEDF macroencapsulation train with the Los Alamos Lead Decontamination Trailer and the Pantex Mobile Macroencapsulation Process, respectively. These two replacements diverted 400 cubic meters to mobile units that could be moved to Idaho and avoided construction of two new treatment trains and transportation of the waste off site.

These results from the OAT analyses, in addition to discussions with the sites, States, Environmental Protection Agency, and DOE management, led to the final STP configuration. Funding constraints led to further streamlining, which was mainly accomplished through privatization of some treatment options as previously described. Table II shows quantitatively how the final STP configuration (as of 10/95) measures up against the DSTP Baseline configuration in some key areas.

Table II

The overall "report card" for the STP process, as developed by the NGA from information requested by the states, shows the following.

States requested that DOE:

- Maximize use of on-site treatment
  - ...1.6% of MLLW is targeted out-of-state
- Evaluate use of mobile treatment units to minimize waste movement
  - ...10,725 m3 of waste is targeted to mobile units (9% of MLLW)
- Use existing facilities wherever possible
  - ...About 19% of MLLW is targeted to existing facilities
- Evaluate a nearest-site scenario for waste sent out-of-state
  - ...OAT evaluated nearest-site configuration
- Establish satisfactory schedules for waste treatment
  - ...Consent orders for treatment schedules signed for 29 of 35 STPs
- Address disposal of treated mixed waste

Disposal process is on-going

From DOE's standpoint, this report card shows a very successful effort on both the states' and DOE's part. DOE's cost saving initiatives, coupled with the equity and risk minimizing initiatives injected by the states, resulted in the best possible approach for mixed waste at the federal, state and stakeholder levels.

FUTURE EFFORTS OF THE OAT

Because many well-established technologies already exist in the hazardous waste industry, and are constantly improving, DOE would like to benefit from this expertise by working with commercial organizations to adapt or apply these technologies to mixed waste. In order to fully utilize this option and focus this effort, the OAT has evolved into the Commercial Options Analysis Team (COAT). The goal of this team is to continually improve our MLLW treatment alternatives, since many new facilities are not scheduled for several years and are not fully scoped. The goal of this team is to find ways to do things better, faster, and cheaper. The COAT is working with the technology development Mixed Waste Focus Area to identify existing partnerships with industry, demonstrations, and promising new technologies that can be applied to this MLLW effort. The COAT will continue to coordinate with the states and NGA, and sites will

notify the states of changes to STP treatment options according to the requirements of their FFCAct implementing orders.

DEVELOPING A NATIONAL TREATMENT CONFIGURATION FOR TRANSURANIC MIXED WASTE

Philip Altomare
Douglas Tonkay
USDOE
Environmental Management
Amber Clay
USDOE
Carlsbad Area Office

ABSTRACT

The Department of Energy (DOE) manages its transuranic (TRU) waste in a manner which protects human health and the environment and meets regulatory requirements. Waste managers continue to work with federal and state regulators to implement the Federal Facility Compliance Act (FFCA), since much of DOE's current inventory of TRU waste is suspected to contain hazardous constituents and is managed as mixed waste. Treatment of this waste is addressed in individual Site Treatment Plans (STPs) and consent or unilateral orders developed through the FFCA process.

Site Treatment Plans (STPs) were developed consistent with DOE's TRU waste management policy, which prescribes waste processing/treatment to meet waste acceptance criteria (WAC) for disposal at the Waste Isolation Pilot Plant (WIPP). The STPs describe each site's mixed waste treatment plans with associated cost and schedule, which in the case of TRU waste is generally waste characterization and any needed repackaging.

As the FFCA process proceeded, DOE determined a need to develop a national waste treatment configuration analysis for TRU waste and certain mixed low-level wastes (MLLW) excluded from prior configuration deliberations. The analysis, conducted with participation of effected states, will be completed to support future discussions with the regulators and possible revision to STPs. This analysis, when complete in fiscal year 1996, will formulate a national TRU waste treatment configuration that addresses options such as: aligning treatment schedules to WIPP operating schedules, using mobile waste characterization equipment in existing facilities as opposed to constructing new facilities; and using more robust treatment for commingled TRU waste/MLLW when found to be cost effective for the total waste management system.

The configuration analysis is part of the National TRU Waste Management Plan being developed by the DOE Carlsbad Area Office. A systems model developed for the TRU waste management system is one tool that is being used in the analysis. Acting on behalf of affected states, the National Governors' Association is peer reviewing the process, assumptions, and scenario input to ensure that the results will be valid.

INTRODUCTION

The Department of Energy and its predecessor agencies have generated waste with transuranic (TRU) radionuclides since the early 1940s primarily by weapons manufacturing, plutonium recovery operations, and research and development activities. More recently and in the future these wastes will result from environmental restoration, facility stabilization, and weapons dismantlement activities.

Transuranic Waste

Transuranic (TRU) waste is defined as, without regard to source or form, waste contaminated with transuranium radionuclides (atomic number greater than 92) with half lives greater than 20 years and concentrations greater than 100 nanocuries/gram at the time of assay.

A TRU waste definition has existed since 1970, although such wastes have been generated since the 1940's (Manhattan Project). The initial TRU waste definition had concentrations greater than 10 nanocuries/gram. The current definition, adopted in 1984, increased the level to 100 nanocuries per gram. Wastes generated since 1970 and classified as transuranic waste have been stored in a retrievable manner pending shipment to a deep geologic repository when disposal is available.

This category of waste is peculiar to the Department of Energy (DOE). Transuranic elements include isotopes of plutonium, neptunium, americium, curium, and californium. The primary contaminant being plutonium, due to the nature of waste generated from recovery of plutonium during research and development and weapons production activities by DOE and its predecessors.

The TRU waste management strategy has evolved over the years to reflect increased regulatory requirements and emphasis on protecting the environment and the safety and health of workers and the public. The strategy continues to evolve as stakeholders increase their participation in the process to set waste management priorities with limited resources available. The strategy for managing defense-related TRU waste is to retrievably store waste in regulatory compliant facilities for the near term prior to permanent disposal in a deep geologic repository, the Waste Isolation Pilot Plant (WIPP). Prior to transport and disposal at WIPP, TRU waste must be characterized, treated/processed (as necessary), and certified to meet the WIPP waste acceptance criteria (WAC).

Approximately 70,000 cubic meters of contact-handled transuranic (CHTRU) waste and 1,600 cubic meters of remote-handled transuranic (RHTRU) waste are retrievably stored at 10 major sites and numerous small quantity sites throughout the nation. Over 97 percent of the stored CHTRU waste by volume is located at 5 sites: Hanford Site, Idaho National Engineering Laboratory (INEL), Los Alamos National Laboratory (LANL), Rocky Flats Environmental Technology Site, and Savannah River Site. Much of this waste is stored on pads and covered with earth pending retrieval and characterization prior to shipment to WIPP for disposal. About 87 percent of the stored RHTRU is at the Oak Ridge National Laboratory.

As much as two-thirds of existing TRU waste in storage is managedas mixed waste, meaning that in addition to the radionuclides it contains hazardous wastes regulated in accordance with the Resource Conservation and Recovery Act (RCRA) and subject to provisions in the Federal Facility Compliance Act (FFCA).

TREATMENT - A TRU WASTE PERSPECTIVE

Treatment is defined as any method, technique, or process designed to change the physical or chemical character of the waste to render it less hazardous, safer to transport, store, or dispose. Treatment can range from repackaging or overpacking waste, to volume reduction, to destruction of hazardous constituents and solidification of residues. Numerous federal, state, and local regulations, DOE Orders, and agreements establish the legal and regulatory framework under which the Department must manage TRU wastes. Authority to manage TRU wastes is provided to the Department through the Atomic Energy Act of 1954 (AEA), as amended, for radioactive constituents. The Department's authority

under the AEA is formalized in DOE Order 5820.2A, "Radioactive Waste Management."

DOE Order 5820.2A Transuranic Waste Treatment Requirements

TRU waste shall be certified in compliance with Waste Isolation Pilot Plant Waste Acceptance Criteria (WIPP WAC)

Mixed TRU waste shall be treated, where feasible and practical, to destroy the hazardous waste component

Classified waste shall be treated to remove or destroy classified characteristics

As part of waste minimization efforts, waste volume reduction techniques, such as incineration, compaction, extrication, and shredding, shall be implemented, wherever cost effective and practical

Treatment facilities must be permitted by appropriate regulatory authority.

The Order clearly requires the waste generator to provide processing/treatment to minimize volumes, remove classified characteristics, and segregate TRU from other waste types. Waste characterization (and possibly some treatment) in order to obtain the WIPP WAC certification are necessary for WIPP disposal. The operative words on treatment requirements with regard to mixed waste are "where feasible and practical." The Order allows, but does not prevent or require, TRU waste from being treated to levels beyond WIPP WAC requirements. The Order is currently being revised and is expected to be issued later this year.

Regulatory authority for any hazardous constituents comes under the auspices of the U.S. Environmental Protection Agency (EPA) and states primarily through RCRA. Agreements have been established at many sites with local and state regulators that define specific waste management requirements.

The FFCA was enacted into law on October 6, 1992, to amend the Solid Waste Disposal Act, which was previously amended by RCRA. The FFCA required DOE to develop site treatment plans (STPs) which describe mixed waste treatment capacity and technology development, including schedules, for bringing each DOE mixed waste generator or treatment site into full compliance with RCRA. EPA or the effected state then negotiated legally enforceable compliance agreements with the Department to allow continued waste storage subject to RCRA.

The Department's policy is to dispose of defense-related mixed TRU waste in WIPP using a No-Migration Determination (NMD) as established in RCRA regulations, thus the FFCA process produced STPs that focus on mixed TRU waste treatment capability to meet requirements for WIPP disposal and not treatment to meet Land Disposal Restrictions (LDR) under RCRA. Disposal of mixed TRU waste at WIPP is regulated by both the EPA, for waste disposal regulations and NMD, and the State of New Mexico, for RCRA Part B permit.

Resource Conservation and Recovery Act (RCRA) of 1976

Title 40, Code of Federal Regulations, Parts 260-270

Applies to the treatment, storage, an disposal of mixed TRU waste (and waste that has the possibility of being mixed)

Requires all waste generation and storage sites to store any RCRA-controlled hazardous waste only for limited periods prior to shipping them to a regulated treatment or disposal facility

Regulates treatment, storage, and disposal facilities through permits issued by EPA or states with authority granted by EPA (Part 264)

Restricts what materials may be disposed through land disposal restrictions (LDR), thus necessitating treatment to remove or make innocuous hazardous constituents prior to disposal

Provides for a No Migration Determination for the disposal facility to exempt waste from treatment to LDR requirements (Part 268)

Waste Disposal Regulations

The WIPP Land Withdrawal Act, enacted in 1992, established a regulatory framework for WIPP

ERA regulations for governing the management of transuranic waste are promulgated in 40 CFR 191

Criteria for WIPP to meet the regulatory standard in 40 CFR 191 are promulgated in 40 CFR 194

The radioactive portion of waste disposed at WIPP is regulated by EPA under Environmental Radiation Protection Standards for Management and Disposal of Spent Nuclear Fuel, High-Level and Transuranic Wastes (40 CFR 191).

As the Department finalizes the No Migration Variance Petition and resolves issues associated with the Part B Permit, it may be necessary for the Department to add engineered barriers to the repository or alter the waste package or waste form, such as waste treatment, to comply with the disposal regulations.

Formal decisions on waste treatment will be made based on the disposal regulatory compliance requirements and within the National Environmental Policy Act (NEPA) process. A Draft Waste Management Programmatic Environmental Impact Statement (WMPEIS) has been prepared to support anticipated waste management system configuration decisions. The WMPEIS is examining a range of TRU waste treatment configuration alternatives ranging from the current (decentralized) approach to regional and centralized alternatives. Impacts of the level of waste treatment performed, e.g., WIPP WAC, are also being addressed with respect to impact on configuration.

In addition to the WMPEIS, the second supplement to the WIPP Environmental Impact Statement (SEIS-II) for disposal operations is currently being prepared. A record of decision regarding TRU waste treatment within the NEPA process will use the results of the WMPEIS and WIPP SEIS-II. The record of decision is scheduled for fiscal year 1997.

TRU WASTE CONSIDERATIONS IN THE FFCA PROCESS

During the development of the STPs, concerns were identified regarding system-wide decisions for all waste types. In particular for mixed-TRU waste, the plans were developed based on the start of WIPP disposal operations in 1998 under an NMD (and certification of compliance) from EPA. Within this strategy each site developed its STP assuming TRU waste would be characterized and treated only as necessary for shipment and disposal at WIPP. As the STPs matured, there was a need to ensure that the national TRU waste treatment and disposal strategy was comprehensive and consistent. In many instances resource constraints forced scheduling of TRU waste retrieval and characterization activities well into the future and in some instances beyond the projected end of WIPP disposal operations. There was a need to integrate complex-wide characterization and treatment schedules with the disposal schedule. The final STPs attempted to correct some of the schedule inconsistencies as certain sites re-evaluated their plans and schedules with a new forecast WIPP disposal operations schedule. The TRU waste treatment schedules in the STPs vary from site to site, but have operational schedules which now are

within the current WIPP disposal operations window. The current forecast for WIPP operations is to begin CHTRU waste receipts in 1998 on a limited basis taking several years to ramp up to full operations and begin RHTRU waste receipts in 2002 under the current forecast. Disposal at WIPP will continue through 2032, for a total operating period of 35 years.

One other TRU waste activity had a significant impact on the FFCA process. A decision was made by the Department to further study and begin procurement on the Advanced Mixed Waste Treatment Facility (AMWTF) at INEL for treatment of commingled mixed low-level waste (MLLW) and TRU waste.

Advanced Mixed Waste Treatment Facility

In January 1994, DOE's Idaho Operations Office issued a Request For Proposal for feasibility studies to obtain industry's best thinking for an approach to cost effectively treat large quantities of stored commingled TRU and mixed low-level waste (MLLW). The results of the feasibility studies indicated that at INEL it may be cost effective to treat their commingled MLLW and TRU waste to requirements of Land Disposal Restrictions (LDR) established in RCRA regulations.

This conclusion was a result of processing requirements for the large volumes of stored mixed TRU waste commingled with MLLW. The MLLW is generally the same physical and chemical form as the TRU waste at INEL, but it contains concentrations of a alpha-emitting radionuclides under the threshold in the TRU waste definition (100 nanocuries per gram). The MLLW must be treated to comply with LDR requirements prior to disposal in a permitted disposal facility. The proposed strategy treats the commingled waste as a single waste source, resulting in a concentrated waste product that meets the definition of TRU waste which can be disposed at WIPP.

Cost savings to the waste management system at INEL have been identified as a result of eliminated costs needed to characterize and segregate the MLLW from the TRU waste, reduced storage and transportation costs due to treated TRU waste volume reduction, and the use of a privatized facility. It is unknown at this time whether the unique waste management strategy being considered by the Idaho Operations Office is applicable to other sites.

The Department considered, in this case, more robust treatment of TRU waste than required for WIPP disposal, since initial feasibility studies indicated it to be cost effective from a total waste management systems perspective. Since the facility, when operational, may be able to treat similar waste from other sites, there is a need to systematically evaluate TRU waste treatment facility configuration for sites with similar commingled MLLW and TRU waste.

During STP discussions with certain states concerns were raised that WIPP may not open on schedule or that the NMD may not be issued. The Orders issued by the states under the FFCA, for the most part, reflect the Department's TRU treatment and disposal strategy in the STPs, but some went further to provide specific conditions to address these concerns. New Mexico issued a unilateral order which requires the Department to submit plans and schedules for treatment of TRU wastes at LANL and Sandia National Laboratories - New Mexico by 1999. The Department can request discussions with the State regarding treatment requirements if WIPP receives its NMD and opens.

CONFIGURATION ANALYSIS

As discussed above the FFCA process resulted in STPs with a configuration for TRU waste facilities that, in general, is consistent with the current WIPP disposal operations window. There was no attempt to optimize the configuration in the STPs, to address potential privatization, or look at the tradeoffs of new permanent facilities, or use of mobile capability for characterization and limited treatment. There was no attempt to fully analyze the proposed AMWTF at INEL with respect to the remainder of the TRU waste system. Since the STPs are revised annually, the opportunity exists for the States and the Department to modify plans in the future. The National Governors' Association (NGA) was briefed on a proposed configuration analysis as a first step.

The Department's National Transuranic Waste Program (NTP) team is currently developing a National TRU Waste Management Plan to detail a strategy that aligns the complex-wide TRU waste management activities with the WIPP disposal schedule. The NTP team is formulating a strategy that will optimize the amount of TRU waste available to support the disposal schedule. This Plan will consider existing site facilities, proposed new facilities, and mobile units to prepare, characterize, and certify waste for disposal at WIPP. The Plan will consider use of mobile units at sites where additional or expanded facilities are needed to characterize, re-package, or otherwise treat TRU waste to meet WIPP waste acceptance criteria. The use of mobile units or transportation to larger sites will be an important consideration for small quantity sites, where construction of permanent facilities is not practical. The National TRU Waste Management Plan will be complete in late fiscal year 1996.

The National Transuranic Waste Management Plan analysis examines the current configuration, the configuration proposed in the STPs, and various alternatives. The analysis will assess where commingled MLLW and TRU waste inventories exist, consider expanded use of the AMWTF, and/or consider other regional treatment centers for TRU waste. It was determined that the systems analysis and results could not be completed in time to support the initial STPs, but the studies could be completed and results available for future discussions with the states on annual updates of the STPs. These studies will also be linked to similar future activities planned in the MLLW area.

The NTP team is developing a model that simulates waste processing (characterization, treatment, certification) at the generator sites in a systems context. The model tracks in detail waste movements in each scenario analyzed and uses cost modules from the Systems Cost Model developed by the Idaho National Engineering Laboratory, which were utilized for the WMPEIS and the Baseline Environmental Management Report. The model results will allow multiple scenarios to be analyzed and help screen scenarios for further consideration.

National TRU Waste Management Plan

Input:

Waste characterization studies (mobile systems for NDA/NDE, active and passive neutron detection, headspace gas sampling, sample coring, etc.)

Waste certification quality assurance program plans

Waste information (TRU Waste Baseline Inventory Report)

INEL treatment studies (AMWTF)

Current site capacity for characterization and treatment with costs and schedules

Output:

Waste schedule for disposal integrated with generater site plans

More optimized system configuration for waste characterization and treatment

Prioritization of projects and activities

Waste removal plan for small quantity sites

Integration of commingled MLLW in TRU waste planning

The proposed plan was presented to the NGA and feedback has been positive. NGA and state representatives have visited WIPP and met with the NTP team to review the National TRU Waste Management Plan process. NGA and state participation in the process will continue throughout this year with regard to reviewing the process, assumptions and data, selecting scenarios to be analyzed, and peer reviewing tools and models. Through this participation, the results will be comprehensive, meeting the states' and DOE's needs.

NEXT STEPS

The results of the configuration analysis will be discussed with the NGA and states. Active involvement by NGA and states in the process will ensure success. The results will provide input on suggested changes to Site Treatment Plans that will provide an integrated and coordinated approach to TRU waste management. The Department will be able to utilize the information in its budget formulation process to impact decisions regarding its request for fiscal year 1998 and beyond. The cooperative FFCA process, successful to date, continues as the TRU waste treatment system configuration matures.

ACCELERATED ROCKY FLATS MIXED WASTE TREATMENT FOR FEDERAL FACILITIES COMPLIANCE ACT IMPLEMENTATION

Patrick M. Arnold

Andrew P. Power
Rocky Mountain Remediation Services, LLC

ABSTRACT

Rocky Flats Environmental Technology Site (RFETS) received a Compliance Order from the State of Colorado on October 3, 1995, approving with modifications the radioactively contaminated hazardous (mixed) waste strategies outlined in the RFETS Proposed Site Treatment Plan (STP) (1) and committing the Department of Energy (DOE) to actions that will achieve compliance with the land disposal restriction (LDR) regulations

covering the hazardous portion of mixed wastes presently stored at the site. The STP was submitted to the State of Colorado per the mandates of the Federal Facility Compliance Act of 1992 (FFC Act) and was the result of an iterative process between the DOE, the lead regulatory agency from the State of Colorado, and local stakeholders. The STP presents a baseline implementation approach for compliance with LDR standards given the strict federal budget constraints forecasted for future years. Accelerated treatment of the RFETS mixed waste inventory to meet LDR limits is required to satisfy several purposes. In order to support a proposed Accelerated Site Action Project (ASAP) that has the objective of accelerated deactivation and cleanup, treatment and disposal of the mixed waste inventory is necessary within the next ten year period (2). Accelerated treatment has other merits for its implementation including outyear storage cost avoidance, as portions of the mixed waste inventory are stabilized and disposed in such a manner that can facilitate future retreivability and offsite disposal, if economically feasible. This paper will discuss how the magnitude of the storage costs for maintaining the mixed waste inventory at RFETS has become an important economic driver for accelerated mixed waste treatment in light of continued limited resources available to the site. Options for accelerated waste treatment, with an emphasis of more accomplished with less resources, are being explored and include the use of regional treatment facilities, outsourcing of selected waste streams to commercially available treatment systems or accelerated construction and operation of treatment facilities through private sector initiatives. Accelerated mixed waste treatment has captured widespread interest within the DOE complex and the commercial industry as both institutions grapple with similar issues regarding conventional mixed waste management strategies. It is the intent of this paper to communicate the experiences gained at RFETS in evaluating and exploring accelerated treatment strategies, the implementation for these strategies at the site, and foster the active participation of all DOE or commercial interests engaged in the development of mixed waste treatment solutions as an answer to compliance under the FFC Act.

INTRODUCTION

The Rocky Flats Environmental Technology Site (RFETS) is a government-owned, contractor-operated facility which is a part of the nationwide Department of Energy (DOE) nuclear weapons production complex. Prior to 1989, the primary mission of site was the continual production of components for nuclear weapons. Production activities included metalworking, fabrication and component assembly, plutonium recovery and purification, and associated quality control functions ensuring the technical performance of the weapons' components. The plant was built in 1951 and began operations in 1952. In 1989, as a result of a changing international political climate, the decision was made by the United States government to discontinue production of components for nuclear weapons at Rocky Flats. Rocky Flats has undergone a transition from a weapons production facility to an environmental restoration and waste management site. The current mission of the site is to manage waste and material, clean up and convert RFETS to beneficial use in a manner that is safe, environmentally and socially responsible, physically secure, and cost-effective.

As a result of these activities of over forty years in production, RFETS has accumulated a significant quantity of mixed wastes subject to the regulation under the land disposal restriction (LDR) standards of the

Resource Conservation and Recovery Act (RCRA) (3). These waste streams include low level mixed waste and transuranic mixed waste, both subject to regulation primarily due to solvent and heavy metal contamination arising from RFETS heavily industrialized past. The LDR compliance issues are not unique to RFETS but are relevant to all DOE sites that manage mixed wastes given the recognized lack of existing treatment capacity and technology applications within the DOE complex for the treatment of LDR mixed wastes.

ISSUE DEFINITION/RESOLUTION

As required under the FFC Act, the DOE submitted the RFETS Proposed Site Treatment Plan (STP) in early April and received on October 3, 1995, a Compliance Order from the State of Colorado Department of Public Health and Environment (CDPHE). The Compliance Order approved with modifications the mixed waste management strategies outlined as the baseline implementation path in the STP. Five mixed waste management strategies comprise the framework for achieving compliance with the Order. Three of these strategies are focused on compliance for mixed low level (MLL) wastes with the remaining two strategies are oriented towards compliance with mixed transuranic (MTRU) wastes. For MLL wastes, the framework for compliance includes the use of a graded characterization program, evaluating the physical and chemical properties of the waste, to determine the specific applicability of LDR standards. The second MLL strategy in the STP baseline has identified treatability group matches for treatment offsite at existing or planned DOE or commercial facilities. The third MLL strategy proposes treatment of the mixed waste backlog through the implementation of three capital projects at the Site. The capital projects focus upon two primary treatment methods; separation of solvent contaminants from the physical waste matrices and immobilization of heavy metal constituents. The STP baseline represents an enforceable treatment-based effort spanning twenty five years and costing over $900 million dollars. Over $600 million dollars or an average of $24 million dollars per year, of this implementation cost is associated with the continual storage of backlog and newly generated MLL wastes while treatment technologies and capacities are developed and operated.

The dilemma of increasing costs to implement the cleanup of legacy wastes at RFETS is shared among other sites in the DOE Complex. In response to this challenge, DOE has formed task force working groups to identify privatization initiatives and change the fundamental way that DOE has conducted business in the past. DOE's goals for privatization include improving the quality of contractor performance and saving taxpayer dollars with no sacrifices made in DOE's commitment to protection of the environment, public health, or safety. Preliminary data gleaned from initial DOE ventures into privatization have generally demonstrated increased cost effectiveness, schedule efficiencies, and the development of new contractual relationships between DOE and vendor participants.

A strong economic incentive exists at RFETS for identification of alternatives to the STP baseline which can accelerate treatment schedules and generate significant cost savings in the storage and management of backlog wastes. A recent development at RFETS is the preparation of a draft conceptual vision by the new integrating management contractor team which took over day-to-day operations at the site in July 1995. The Accelerated Site Action Plan or ASAP focuses on accelerated cleanup, plutonium consolidation, physical plant conversion, and end land use. A

major premise underlying ASAP is that all stored plutonium and other special nuclear materials will have been removed from the site by the target date of 2015. In addition, no DOE-operated buildings will remain at the site. From this perspective, a new approach for compliance under the FFC Act, while integrating with the ASAP focus on faster and more cost-effective cleanup, is what is required. The issue facing RFETS is how to challenge conventional methodologies for onsite waste management, accelerate mixed waste treatment at the Site, and capture the cost savings that accompany avoiding the large operating budget outlays in storage costs and capital investment for on site treatment systems as projected by implementing the enforceable STP baseline.

Accelerated treatment of LDR wastes within the next ten years can be accomplished through initiatives with the private sector especially if certain barriers common to private sector contracting are resolved effectively. Such initiatives can be successful due to the expedited schedules possible by exiting the DOE funding cycle constraints and using private sector financing of treatment facilities and operation. Capital cost for development and construction of the treatment facility can be recovered through the use of fixed price or fixed price per unit output contracts. The private firm furnishes goods and services using their own equipment and gains the operating efficiencies developed in other commercial applications. During or after the contract performance, the private firm is able to seek new markets for the equipment outside of the existing contract, thereby further lowering unit price. The new integrating management contract implemented at RFETS is an example of innovative contracting with the objectives of accelerated schedules with greater cost efficiency and productivity.

Commercial enterprises exist that have the proven track record in hazardous and radioactive wastes and are willing to apply significant resources to provide mixed waste treatment capability. These enterprises have developed in support of industries and markets such as the commercial nuclear power industry, both domestic and foreign, the defense industry, and various commercial generators of hazardous waste. A survey of mixed waste treatment capabilities was performed to determine the availability of these systems for RFETS LDR waste by either transporting wastes off-site or bringing or constructing treatment systems on-site. Some important criteria necessary for system selection were that the systems are currently developed, available and ready for implementation in radioactively hot systems with minimal modification. The survey assessed matches between RFETS waste forms and vendor treatment capabilities. With continued research and development to treat RFETS LLM waste, existing, planned, or proposed vendor treatment option technologies will be capable of treating RFETS waste forms. Vendor treatment capabilities include:

- Stabilization/immobilization via the application of cementation, vitrification, or emerging polymer solidification
- Separation or decontamination technology applications through the use of thermal desorption, supercritical extraction, or steam stripping
- Organic destruction through the application of ultraviolet oxidation, non-thermal plasma, incineration, and emerging catalytic chemical oxidation.

Use of on-site high temperature thermal treatment systems has been previously discounted due to high cost and anticipated negative public reaction. Careful consideration of off-site treatment to comply with the

receiving facility waste acceptance criteria is needed to assure that the waste can be economically shipped and treated. Work is progressing on contracting with these facilities to treat some of the higher risk and difficult to treat LDR waste at the commercial facilities.

In September 1995, Rocky Mountain Remediation Services, LLC, (RMRS) prepared a feasibility study (4) that assessed a spectrum of on- and off-site privatization opportunities. Anticipating accelerated and cost-effective treatment of RFETS waste via privatization, the Study purposefully compared the cost, schedule, and risk of all feasible privatization options to the RFETS STP baseline. The Study selected four options for evaluation:

Option 1, the RFETS STP baseline

Option 2, treatment at the Idaho Alpha Low Level Mixed Waste (ALLMW) treatment facility

Option 3, a DOE-provided facility for location of vendor equipment

Option 4, a privately financed, designed, and constructed facility

Option 2 consisted of the Idaho Waste Processing Facility (IWPF)/Alpha Low Level Mixed Waste (ALLMW) Treatment Facility. This facility is a privatized facility proposed to treat TRU and alpha wastes which are stored either in boxes or drums at the Idaho National Engineering Laboratory (INEL). Option 3 conceptualized an on-site DOE-provided facility as the location for skid-mounted, specialized, or niche treatment units provided by commercial vendors. Commercial vendors with niche treatment experience would be selected using a systems approach to campaign RFETS waste forms appropriate to anticipated budget constraints. Option 4 developed the concept of an on-site, newly-constructed, privately financed, and operated facility to treat RFETS waste. This option provides an integrated treatment systems approach that could also make use of commercial vendor skid-mounted, modular technologies. Existing or planned off-site commercial treatment facilities were assessed and found to be of limited value in conforming to the RFETS ASAP timeline.

OPTIONS COMPARISON

Option 1, the RFETS STP Baseline, meets the compliance milestones in the STP Order through the use of resource intensive technology and treatment system development schedules. Financial risk to the DOE is extremely high from both the total life-cycle cost involved with extended storage and treatment schedules, and line-item funding process perspectives. Regulatory compliance, permitting, and transportation risk is perceived as relatively low, however.

Option 2, off-site treatment at the IWPF/ALLMWF, meets STP Order compliance milestones but does not integrate with the objective in ASAP of dispositioning all RFETS mixed wastes within the next ten years. Financial risk to the DOE appears to be relatively low due to private sector financing. The thermal treatment technology selected is robust and suitable for RFETS TRU and LLM waste but may have elevated technological, regulatory compliance, and permitting risk. Further, the need to pretreat wastes prior to shipment add to the costs of this option. Off-site transportation of RFETS waste to INEL may have greater relative risk as perceived by Denver metro area stakeholders (5). This option offers a potential cost and schedule savings, compared to Option 1, of approximately $450 million dollars and 8 years, respectively.

Option 3, on-site treatment in a DOE-provided facility, meets STP Order compliance milestones and supports the ASAP objectives for the Site. This

option's systems design approach offers the flexibility to campaign higher risk wastes in a more cost effective manner. Thus, RFETS will only pay for the treatment capacity required for the Site's needs. Lower technological risk is anticipated from the use of experienced commercial vendors. Minimal capital investment is required of the DOE for retrofitting an existing facility. Operational treatment system costs are expected to be lower due to vendor distribution of fixed investment costs over multiple customers via multiple site operations of skid-mounted systems. This option offers a potential cost and schedule savings, compared to Option 1, of approximately $660 million dollars and 11 years, respectively.

Option 4, on-site treatment in a newly-constructed facility, also meets STP Order compliance milestones and near-term waste management timelines within ASAP. This option requires full capital investment by a commercial vendor to supply a turn-key treatment and storage facility. Fixed capital investment must be fully recovered by processing only RFETS waste, resulting in greater per unit costs than with Option 3. Schedule implementation and operational readiness is anticipated to take longer than Option 3 due to inclusion of an entire entrained process utilizing multiple technologies. This option offers a potential cost and schedule savings, compared to Option 1, of approximately $620 million dollars and 11 years, respectively.

OPTIONS ANALYSIS CONCLUSIONS

The DOE Line Item funding process and constraints result in Option 1's extended schedule and higher life-cycle costs. Off-site treatment technologies and treatment systems (Option 2) offer little near-term treatment capabilities for RFETS waste. Off-site treatment and disposal carries technological, permitting, transportation, and stakeholder risk that does not integrate with the ASAP concept.

Privatization of facility construction (for both Options 3 and 4) and operation result in accelerated schedules, storage cost avoidance, and reduced capital expenditures and operating costs ultimately reducing DOE risk/liability. When risk is factored into the decision-making process, as well as cost and schedule elements, Options 3 and 4 are more viable than either Option 1 (higher cost, longer schedule, greater financial risk to DOE) or Option 2 (longer schedule, transportation/permitting risk).

The Privatization Feasibility Study recommends implementation of Option 3 due to achievable permitting, design, construction, and operational cost and schedule improvements beyond Option 4's capability. Option 3 leverages a vendor's treatment system design, development, and fabrication costs, and eliminates many infrastructure issues associated with siting a new facility at RFETS as presented with Option 4.

RECENT DEVELOPMENTS

An innovative solution for the treatment of LDR waste that allows storage in the waste management unit retrievable storage cell on-site at RFETS is the immobilization system being investigated as part of the Alternative Water Treatment System (AWTS). The AWTS is proposed to replace the aging process water treatment facility at RFETS and avoid the approximate $60-100 million upgrade of the facility for continued use. Treatment of LDR sludge can be initiated by 1998 on tank stored sludge as compared to 15 years later under the baseline site treatment plan. Due to the accelerated schedule and avoidance of capital upgrades, the AWTS life

cycle costs are projected to be approximately half of that required under the baseline approach.

CONCLUSIONS

Through the utilization of life cycle cost analysis as a basis for decision-making, it has become evident that privatization and commercial type contracting of RFETS waste treatment can result in accelerated schedules, significant storage cost avoidance, and reduced capital expenditures and operating costs. RMRS was able to complete a risk based and best management practice treatment prioritization of the stored inventory utilizing commercial expertise of personnel and numerous commercial vendors. From this approach, a solution for RFETS ultimately reducing DOE risk and liability is privatization. When cost, schedule, and risk elements are factored into the decision-making process, Options 3 and 4 are more viable than either Options 1 or 2. Option 3, however, offers the flexibility necessary to campaign waste by waste form, including those of "higher risk", such as liquids, oils, and semi-solids. Such waste treatment flexibility is paramount during DOE budgetary uncertainties.

In order to more effectively bring private sector resources to bear on managing LDR waste problems at RFETS and other DOE facilities, barriers must be resolved. Commercial type contracting reform is needed to allow DOE to enter long-term contracts without the Federal budget uncertainties that make private sector contracting with DOE a high risk prospect. Contract reform efforts with DOE's prime contractors such as the integrating management contract at RFETS should be considered as part of DOE's privatization initiatives. Labor unions throughout the DOE complex view privatization as a potential loss of jobs and wages. Worker and community transition is as important as the actual work and a team approach must be implemented by all affected parties.

To enhance the probability of successful privatization of waste treatment, commercial vendors typically require definition of 1) input waste feed material or waste stream and a guarantee of minimum quantities of feed material to allow fixed price bid proposals, 2) specification of all final product or service requirements including owner/operator penalties for failure to comply with those requirements, 3) investment framework resulting in a balanced risk-reward equation including clear division of responsibility and risk, and 4) regulatory framework clarifying oversight requirements and minimizing regulatory uncertainties (6).

Recent events point towards changing business conditions within the DOE complex that will impact future mixed waste management strategies. Accelerated treatment opportunities can incorporate the changing business climate into future realities by proposing innovative and affordable mixed waste treatment systems within the constrained DOE operating budget. Accelerated treatment at Rocky Flats will seek to become the driving mechanism for expediting compliance with the STP Compliance Order through cost advantages of commercial treatment systems, while balancing the environmental and safety objectives governing the site.

DOE/Idaho Operations Office

ABSTRACT

In conjunction with the affected States as part of their interactions required by the Federal Facilities Compliance Act, the Department of Energy has been developing a process for a disposal configuration for its mixed low-level waste (MLLW). This effort, spanning more than two years, has reduced the potential disposal sites from 49 to 15. The remaining 15 sites have been subjected to a performance evaluation to determine their strengths and weaknesses for disposal of MLLW. The process has included institutional and policy factors as well as strictly technical factors, with each highly dependent on the other: policy decisions must be supported by technical analyses, and technical analyses must be performed within a framework which includes some institutional considerations, with the institutional considerations selected for inclusion largely a matter of policy. While the disposal configuration process is yet to be completed, the experience to date offers a viable approach for solving some of these issues. Additionally, several factors remain to be addressed before an MLLW disposal configuration can be developed.

INTRODUCTION

The Federal Facility Compliance Act (FFCAct) of 1992 (1) requires the U.S. Department of Energy (DOE) to work with its regulators and with members of the public to establish plans for the treatment of DOE's mixed low-level waste (MLLW). Although the FFCAct does not specifically address disposal of treated MLLW, both DOE and the States recognize that disposal issues are an integral part of treatment discussions. The DOE established the FFCAct Disposal Workgroup (DWG) in June 1993 to work with the States in defining and developing a process for evaluating disposal options for treated MLLW. This joint DOE-State process has currently narrowed the DOE sites for further evaluation from 49 to 15.

Several technical, institutional, and policy factors have been used throughout this project. The overriding policy factor was to enable decisions that are supported by technical analyses, that incorporate

appropriate institutional factors, and that give the best value for the tax dollars spent. In this context, the technical analyses are following a phased approach in which 1) technically unacceptable candidate sites were screened from further consideration, 2) the remaining sites were subjected to a scoping analysis to identify their strengths and weaknesses for disposal of MLLW, and 3) results from the scoping analysis will be compared to actual waste streams to determine the ability of the sites to dispose of actual DOE MLLW. These and other technical analyses will provide the support to enable further policy decisions pertaining to the final disposal configuration for MLLW. The final configuration will also include consideration of institutional factors such as the existing disposal infrastructure, other on-going complex-wide assessments, and input from interested stakeholders.

SCREENING ANALYSES

The overriding policy of enabling decisions that are supported by technical analyses, incorporating appropriate institutional factors, and giving the best value for the tax dollars spent was first met by a screening analysis. This analysis eliminated obviously technically unacceptable candidate sites from further consideration so that resources could be focused on the more viable sites. Forty-nine sites that were identified in the first draft of the Mixed Waste Inventory Report (MWIR) (2) comprised the initial universe of potential candidates for MLLW disposal. After consultation with the States, the DWG initiated and implemented a tiered screening process to narrow the field of potential candidate sites from 49 to 15 in two phases (3). The results of this screening process, which were reviewed and agreed to by the affected states, are illustrated in Fig. 1.

Fig. 1

After combining five sites based on geographic proximity, the initial screening eliminated 18 of the most obviously poor candidate sites based on three objective criteria with regulatory or operational basis. The site

- must not be located within a 100-year flood plain (5),
- must not be located within 61 meters of an active fault (5), and
- must have sufficient area to accommodate a 100-meter buffer zone (6).

The second phase of the screening process was based on a more refined evaluation of the remaining 26 sites (7) using several criteria grouped into three board categories:

- technical considerations (e.g., hydrology, geology, topography, and volcanic and tectonic potential),
- potential receptor considerations (e.g., populations significant groundwater resources, and sensitive environments), and
- practical considerations (e.g., ownership, mission, MLLW storage and generation, and regulatory considerations).

Each category was evaluated for each site and assigned a ranking as either a major problem, moderate problem, or a minor problem (3). Baaed on this analysis, the States agreed to eliminate an additional 5 sites from further consideration and to assign a lower priority to another 6 sites. The lower priority sites were to continue to be considered for on-site disposal and would be considered for disposal of wastes from off-site only if a disposal configuration could not be defined with the remaining 15 sites.

SCOPING ANALYSES

A more technically detailed performance evaluation (PE) was conducted on the remaining 15 sites (Fig. 1) to estimate their strengths and weaknesses for disposal of MLLW (4). The PE evaluated the water and atmospheric transport pathways and inadvertent intruder scenarios for 58 radionuclides expected to be in DOE MLLW for trench and tumulus disposal facility types. The permissible radionuclide concentrations in grouted waste were estimated based on site-specific data and on performance objectives determined from DOE Order 5820.2A (8). These "permissible waste concentrations" (i.e., the radionuclide concentrations in waste in a disposal facility that do not exceed the performance criteria specified at the performance boundary) were estimated for each pathway and for each radionuclide. The smallest of these values represents the limiting concentration for each radionuclide at each site. The methodology and results of the PE were reviewed by both internal and external review panels as well as DOE Headquarters, the affected sites, and the States.
A summary of the results of the analysis are shown in Table I. This table presents the radionuclides that were limited by the water or atmospheric pathway for each of the 15 sites. Blank cells indicate that the radionuclide was limited by a human intrusion scenario at the site. Fourteen radionuclides were limited by intrusion at all sites, and an additional 27 radionuclides were limited by intrusion at 13 or 14 of the 15 sites. The results of the PE demonstrated that the intrusion scenarios selected for evaluation, which were based on performance assessments (PAs) of DOE low-level waste (LLW) disposal facilities (9, 10), provided the most limiting permissible waste concentrations for most radionuclides at most sites.

Table I

The water pathway limited several of the more environmentally mobile radionuclides at sites located primarily in the more humid region of the country (Table II). With the exception of C-14, each of these radionuclides is long-lived relative to the 10,000-year period of performance. All the radionuclides have high or medium environmental mobility (4), indicating that they would migrate to the 100-meter performance boundary within the 10,000-year period and, therefore, would not decay appreciably. The number of sites limited by the water pathway is an indication of the relative mobility and persistence of the radionuclides, with Tc-99 and I-129 being the most mobile and persistent of the radionuclides evaluated.

Table II

The atmospheric pathway was evaluated only for the volatile radionuclides tritium (as tritiated water) and carbon-14 (as carbon dioxide gas carrying the C-14 isotope). This analysis indicated that tritium would not be limited by the atmospheric pathway at any site and that C-14 would be limited by the water pathway at about half of the sites.
Although the purpose of the PE was not to eliminate sites from further consideration, the analysis indicated that several radionuclides can be disposed of at the more arid sites at higher permissible concentrations than at the more humid sites. The PE analysis revealed that engineered barriers offer no long-term advantages for the disposal of wastes containing long-lived radionuclides; their benefits are for containing shorter-lived radionuclides while they decay to insignificant levels. The analysis also identified key parameters characterizing both the sites and the wastes and identified several indicator radionuclides which can be used to represent the behavior of broad classes of radionuclides.

The permissible radio nuclide concentrations in waste estimated by the PE will be compared with estimates of radionuclide concentrations in treated MLLW streams to determine the ability of the 15 sites to dispose of actual DOE MLLW. The radionuclide concentrations in treated MLLW will be estimated by using existing waste stream and treatment train databases and process knowledge to estimate the concentration changes due to the various treatment processes. Other information that will be provided by this analysis includes the estimated volume of MLLW after treatment and the usefulness of the existing DOE MLLW databases.

Upon completion of this analysis, the technical capability of the 15 sites for disposal of DOE's MLLW will be presented to the States. Before further progress can be made in refining the MLLW disposal configuration, the incorporation of institutional and policy factors will be required.

Institutional and Policy Factors

The major institutional and policy factors that remain to be addressed before a final disposal configuration for MLLW can be proposed can be grouped into three categories: integration of MLLW into the larger picture of low-level waste disposal; the disposal facility infrastructure; and the evolving regulatory landscape. Each will require one or more supporting technical analyses.

Perhaps the most pressing complex-wide initiative for integration of MLLW disposal issues is DOE's response to the Defense Nuclear Facilities Safety Board's (DNFSB) Recommendation 94-2 (11) pertaining to the DOE's management of low-level waste. One of the most important recommendations of the DNFSB is that the effects of nearby source terms and existing contamination be considered when analyzing the impacts of operations of planned LLW (including MLLW) disposal facilities. Prior to this recommendation, each disposal facility was evaluated according to specific performance objectives independently of nearby facilities or contamination.

Incorporation of existing disposed waste and contamination is problematic in terms of technical issues as well as institutional issues. One of the main technical problems to be addressed is that the inventories of past disposal activities or accidental releases are generally poorly known. This lack of knowledge introduces uncertainty into the analysis that may overshadow the deleterious effects of the wastes to be disposed of. Until characterization of the existing in situ waste and contamination can be characterized, they must be treated in a conservative fashion that may tend to limit the capability of planned disposal facilities. Scoping-level technical analyses can aid formulation of a coherent policy that will in turn result in clear direction for more detailed technical analyses.

One of the important institutional problems this new approach introduces is the distinction between the PA methodology for LLW and MLLW and the risk assessment methodology specified under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) (12). The approaches to evaluating risk and performance, the timeframes of the analyses, and the endpoints for analyses are different for PAs and CERCLA risk assessments. These issues must be resolved before significant progress can be made. Again, scoping-level technical analyses, such as the process described above, can be used to help formulate policy for addressing these issues.

Another complex-wide initiative for integration of MLLW disposal activities is DOE's Programmatic Environmental Impact Statement (PEIS)

(13). A PEIS is required to provide National Environmental Policy Act (NEPA) coverage for major federal programmatic actions and includes a Record of Decision which is issued to support the selected alternative. As currently envisioned, the analyses used to support the planning process for MLLW disposal will be incorporated into the PEIS documentation so that NEPA coverage will be provided for the recommended configuration decision.

Integrating the MLLW disposal configuration process into the existing LLW disposal facility infrastructure is another important institutional factor and is interrelated with the 94-2 and PEIS considerations. Because the nearby existing source terms and contamination will now be considered in the performance assessments of disposal facilities, the future LLW and MLLW disposal volumes must compete for a finite disposal capacity at some sites. The estimates of treated MLLW volume are an important piece of technical data that will factor into the analyses; however, longer-term projections of expected waste volumes are difficult to justify with any accuracy, especially when considering highly uncertain environmental restoration waste volumes.

There are still several institutional issues the must be addressed. Some of the more important questions are the following: How will commercial disposal factor into the analysis? How will the input from the States and stakeholders influence the decision-making process? What changes in operating practices will be required for existing disposal facilities? What factors are the most important in selecting new disposal sites? Are the current disposal sites the most appropriate ones for continued disposal? Technical analyses will provide the basis for answering many of these questions, but some policy decision will also be required to provide direction to those technical analyses.

In addition to the resolution of the internal DOE policy issues mentioned above, at least one external regulatory change is expected to occur that will influence MLLW disposal: the Environmental Protection Agency's Hazardous Waste Identification Rule (HWIR) modifications to the Resource Conservation and Recovery Act (RCRA) (14). The HWIR is expected to establish "exit levels" for listed RCRA wastes that pass a test for leachability. The mixed wastes that pass this test are not required to be disposed of in a RCRA Subtitle C-type disposal facility, and therefore, these wastes can be disposed of in a LLW DOE disposal facility. Presently, listed RCRA wastes remain classified as hazardous even after they have been treated. The HWIR may have the effect of reclassifying some MLLW as strictly LLW in terms of disposal, but it will not reduce the total combined volume of MLLW and strictly LLW to be disposed of.

SUMMARY

Significant progress has been made toward developing a process for determining the disposal configuration for DOE's MLLW. The number of DOE sites being considered has been reduced from 49 to 15, performance evaluation of these 15 sites has been completed, and additional technical analyses are being conducted to determine the technical capabilities of the 15 sites for disposal of treated DOE MLLW. However, several institutional and policy factors must still be addressed. Some of these factors include 1) integrating MLLW disposal with other complex-wide assessments of LLW disposal practices, 2) MLLW and LLW competing for a finite disposal capacity, 3) evaluating the impact of potential changes in the regulations affecting MLLW disposal, and 4) developing a fair and equitable process for determining the MLLW disposal configuration. Each

of these factors has components that are technical in nature and that additional technical analyses can help solve. However, there will always be an intimate relationship between the policy guidance necessary for establishing appropriate technical analyses and the technical analyses that will be used to support policy.

Nez Perce Tribe

ABSTRACT

Indian tribes of the western United States, including the Nez Perce Tribe, the Confederated Tribes of the Umatilla India Reservation, and the Yakama Indian Nation, have entered into cooperative agreements with the U.S. Department of Energy to oversee the cleanup of the Hanford Reservation, in Washington state. These and other tribes considering involvement in nuclear waste management programs have been subjected to severe criticism from some Indians and non-Indians, accusing them of aiding and abetting the violation of Mother Earth by acquiescing in the contamination of lands by radioactive wastes. The authors suggest that this view of the Indian relationship to nature and the environment is too narrow. While the purpose of this article is not to suggest that Indian beliefs support the location of waste management facilities on Indian land, the authors describe aspects of Indian religion that support tribal involvement in radioactive waste management and environmental restoration, and participation in radioactive waste management decision making.

INTRODUCTION

Indian tribes of the western United States, including the Nez Perce Tribe, the Confederated Tribes of the Umatilla Indian Reservation, and the Yakama Indian Nation, have entered into cooperative agreements with the U.S. Department of Energy to oversee the cleanup of the Hanford Reservation, in Washington state. These and other tribes considering involvement in nuclear waste management programs have been subjected to severe criticism from some Indians and non-Indians, accusing them of aiding and abetting the violation of Mother Earth by acquiescing in the contamination of lands by radioactive wastes. The authors suggest that this view of the Indian relationship to nature and the environment is too narrow. While the purpose of this article is not to suggest that Indian beliefs support the location of waste management facilities on Indian lands, the authors will describe aspects of Indian religion and culture that support tribal involvement in radioactive waste management and environmental restoration, and participation in radioactive waste management decision making.

THE RELATIONSHIP OF THE INDIAN TO NATURE AND THE ENVIRONMENT

When Europeans arrived in the Western Hemisphere, they did not find an empty continent, a virgin land, an untouched landscape. North America was already home to millions of Native Americans. When whites first saw the eastern woodlands or the California coast, they found numerous parklands created by Indian burning techniques. These were not forests primeval, but habitats arranged by humans for the benefit of plants and animals necessary for human subsistence. In climates that permitted horticulture, whites discovered vast fields of crops of corn, beans, squash, and many other food products. Indians developed different species of corn and engineered and constructed huge, sophisticated irrigation projects, particularly in the southwestern United States. From the earliest times,

Indians used fire, stone tools, and other implements to modify their environment in order to survive and to enjoy the world.

American Indians loved nature, and nature granted them the food, fuel, fiber, and materials they needed to sustain life. Their environmental religions promoted both dimensions of human-nature relations. Their religions supported, apologized for, and justified subsistence activities. Their religions asserted both a separation from nature (because nature was the Indian's economic source of life) and a participation in nature (because nature was the Indian's spiritual source of life). Their religions recognized the lack of full human harmony with nature and sought to overcome it.

The buffalo story told by many tribes and the Nez Perce name-giving story are illustrative of this paradoxical cultural view of nature. As discussed below with regard to implications for the back end of the nuclear fuel cycle, these stories capture the essence of living in harmony with nature, balanced with the need for the responsible and respectful use of natural resources. Thus, as human use may alter the natural balance, responsible management actions are required to strike a new, albeit man-made balance.

THE BUFFALO STORY

The buffalo story illustrates the American Indian belief that nature is there to be used by humans, but with consideration and appreciation of the changes that our use effects:

Once, a long time ago, the humans were accustomed to killing and eating members of the Buffalo Nation. They did this all the time and thought nothing of it. So the Buffalo Nation held a big council, and after much debate and discussion the Buffalo Chief announced that the Buffalo Nation would no longer allow themselves to be used by the human beings for food, clothing, and all the things they require to live as humans because they did not appreciate the Buffalo Nation's generosity. The people were soon starving and their moccasins were worn, their clothes were wearing out, and they had no robes to keep them warm in the winter. The Buffalo Chief complained that for years the Buffalo Nation shared their bodies with the People for meat, robes, and homes, and never once did the People mourn the death of the Buffalo or smoke or pray for their return.

The Chief of the People recognized the wrong that the People had committed against the Buffalo Nation and agreed that they would sing and dance after killing the Buffalo so that the Buffalo could return and live again. They did so, and for a long time there was plenty for all.

THE NEZ PERCE NAME-GIVING STORY

The Nez Perce name-giving story carries forward the time-honored theme of respect for the complexity of nature while highlighting the ability and need to adapt to environmental perturbations. This maintains a balance in nature:

One day when Coyote was camped among his animal friends, he was called to the mountain by the Creator. "Coyote come here," the voice called. So Coyote went to the mountain to hear what the Creator had to say. "I want you to call all of the animals together tomorrow morning. The two-legged animal is soon to be here and I want to give the animals names or rename them so that they can be recognized."

All of this was happening when all that existed on this earth were the animals, birds, and fish. They had lived together since the great Creator put together Mother Earth. So Coyote went to all animal camps and told them to be at the mountain at sunup so that they might receive the names

of their choice. Coyote was excited, excited because perhaps he would be able to change his name to something more desirable. Coyote was a name recognized in the animal world as one being sly, crafty, and sometimes dishonorable. He wanted to be something else, more respected, more powerful and strong, like the grizzly bear, the eagle, or the salmon.
So Coyote decided that he would stay up all night so that he could be first in line to choose the name that he wanted. He went back to his tent and sat by his fire, preparing to stay up all night. But near dawn Coyote fell asleep. At dawn, all of the animals were lined up to receive their names while Coyote slept. When Coyote finally awoke, he went to the mountain to receive his chosen name. As he approached the Creator, he noticed that none of the other animals were around, and thinking that he was first, he was very happy. He greeted the Creator and said that he wanted the name of Grizzly Bear, the most powerful to rule the forests.
"Too late!" answered the Creator. "That name has already been taken."
"Then I want the name of Eagle, to rule the skies."
Again, "Too late!" cried the Creator.
"Then give me the name of Salmon," he said in a low and meek tone.
The Creator then told him that all of the names have been taken except for one and that is the name of Coyote. "No one wanted the name of Coyote, and that shall be your name."
Coyote, very dejected, went back down the mountain almost crying. The Creator, feeling sorry for Coyote, called him back. Coyote ran back up the mountain. "Yes, yes, what is it?"
The Creator reminded Coyote that the two-legged animal was coming soon, which is why he was doing the name-giving. "Someone has to prepare all of the animals for the coming of the two-legged animals. That will be your job. You will teach them to be alert, cunning, and evasive. The animals will provide for their subsistence, their food, clothing, and tools. But the two-legged ones must learn to respect the animals that provide this."

THE ROLE OF RELIGION

Indian environmental religions sought to overcome the tension between reverence for and exploitation of the world of nature. Note, however, that the method of overcoming, as in the buffalo story, was apologetic in a double sense. Indians apologized to the animals they killed; they begged their pardon. At the same time, Indians manipulated animals; they thanked them in order that they might kill them in the future. It was said of an Ojibwa cultural hero that "he called the birds, beasts, trees, flowers, and all he saw around him his relatives and friends, yet he was always trying to outwit them and use them as servants, and would maneuver to get them to do his bidding." In the same way, Indians both apologized to nature and created a body of apologist oral literature regarding their use of natural resources. A large corpus of Indian beliefs attempt to justify Indian use of the natural world, including the killing of animals. And Indians could cultivate and use corn because the corn spirit had given the food as a gift.

MUTUAL RESPONSIBILITIES

The relationship between hunter and prey parallels the relationship between any exploiter of natural resources and that resource. What are the mutual and reciprocal responsibilities between hunter and prey? The relationship is of an essentially spiritual nature. The interdependence of life finds expression in Chief Seattle's wisdom: "When you spit on the earth, you spit on yourself. What one does to the web of life, one does to oneself." The hunter seeks his prey. The prey offers itself to the

hunter. The hunter's first responsibility is to sing, dance, and pray to become a worthy recipient of the sacrifice of the hunted. His second responsibility is to sing, dance, and pray the willing sacrifice back to life, fulfilling the spiritual obligation. The third responsibility is to take as little as is required for physical and spiritual survival and to avoid wasting any part of the sacrifice. Wasted sacrifice is sacrilege, the transformation of the sacred to the profane. Therefore the failure of the hunt was not caused by mere misfortune, inferior stalking skills, or by poor marksmanship, but was viewed as a sign of inadequate spiritual preparation by the hunter. An animal would give itself up only to one who was spiritually prepared. Thus the great care with which so many of the Indians utilized every portion of the carcass of a hunted animal was an expression not of economic thrift but of courtesy and respect and an aspect of the religious relationship that exists between the hunter and the hunted.

The hunted's responsibility is to offer himself as a willing sacrifice to sustain the life of the hunter and his kind. In so doing, one validates his true relationship with the other and so maintains the balance and harmony of creation. The common good of the entire community of creation has primacy over individual self-interest.

The buffalo story reveals the responsibility of the hunter to his prey and the corresponding reciprocal responsibility of the prey to his hunter. That story and the Nez Perce name-giving story reveal the Indian social truth of reciprocal responsibility that characterizes Indian social interactionthat one cannot exist without the other. This mutuality of interests whereby one's very existence is dependent on respect, honor, and compassion for self and others (whether they be human or nonhuman, or animate or inanimate) produces a very different model for human social imagination from which to fashion social structures and practices. If a hunter and his prey are unified rather than polarized, then creation itself represents a universal community. The individual responsibility is to assure the continuity of life and, by implication, the well-being of the people. This does not violate the right of any individual, but instead places individual rights in balance with the responsibility for continuity of community life.

THE IMPLICATIONS FOR THE BACK END OF THE FUEL CYCLE

Historically, Indians did not exist in unending harmony with nature, the source of their life. Instead, they cared about and recognized the tensions in their relation with nature, and they tried to reckon with them, make them livable, without doing away with the question of an ethical response to the world. Indians were uneasy about the apparent paradox of being part of the world and also using its resources. Their religions revealed that uneasiness and sought to resolve its tensions, not by denying either the "economic" or participatory dimensions, but rather by affirming them simultaneously.

The experience of Indian tribes with the front end of the fuel cycle, primarily mining and milling, illustrates that paradox. Uranium mining had been at once profitable and devastating to Indian tribes. The lands of the Navajo Nation and the Spokane Tribe are dotted with abandoned uranium mines that pose risks to human health and the environment. Many of the Navajo and other miners who toiled in unventilated underground uranium mines are dead or dying of cancer. The experience of these tribes and the current inability of American society to deal with radioactive waste disposal and environmental issues has led the Council of Energy

Resource Tribes (CERT) to promulgate a policy calling for the phase-out of nuclear power in the United States. At this time, CERT sees a need for further research into reactor and disposal technologies that would lessen the environmental impacts of using nuclear power. The CERT policy also acknowledges the mutual and reciprocal responsibilities of tribes to participate in the safe and environmentally sound management of radioactive wastes.

Ultimately, Indian beliefs do not provide the answers regarding the back end of the fuel cycle. However, they do provide a framework for expanding the scope of the dialogue. For example, we ask whether reprocessing should be viewed as a way of using all of the resource, as a way of avoiding further injury to the Earth, as a way of avoiding further uranium mining and the consequential destruction of the lands of indigenous peoples. Does reprocessing prevent the sacrilegious waste of the resource? Is reprocessing a way of honoring the efforts of those workers whose health was destroyed by mining and milling uranium and fabricating the fuel? Conversely, does the once-through cycle dishonor their sacrifices?

The Indian view of the Earth as Mother also leads to the question of whether the construction of deep repositories is wise. Is the disposal of spent fuel in deep underground repositories with no provision for retrieval tantamount to the entombment of something alive and useful? More importantly, we ask why these decisions should be made without the participation and the point of view of those who have paid some of the highest costs for the United States' entry into the nuclear era, namely, the Indian tribes.

It may be that the involvement of Indian tribes in waste management and environmental restoration is entirely consistent with their religious tenets. Certainly, the Nez Perce Tribe would not undertake any activity or endorse any action that would be inconsistent with its core beliefs. If tribes such as the Mescalero Apaches are willing to assume the responsibility to assure the safety and security of spent nuclear fuel, it may be not only for the monetary benefits but also to help protect the well-being of the people and of future generations. Even if tribal involvement in radioactive waste management is construed by others to be contrary to their teachings and detrimental to their environment, ultimately it is for the individual tribe to decide, based on their teachings, whether these actions comport with their views of their responsibility to Mother Earth. For the Nez Perce Tribe, like the many of the Indians, the world does not consist of inanimate materials to be used and of animals to be butchered and eaten. It is alive, and everything in it is alive and could help or harm people. Such was a basic premise of Indian existence: the world and everything in it is alive and powerful and personally significant. The debate over the back end of the fuel cycle would do well to include these views.

21-2

A LIMITED SAMPLE OF CONCERNS OF THE CONFEDERATED TRIBES OF THE UMATILLA INDIAN RESERVATION COMMUNITY ON USING THE APPROPRIATELY DEFINED RISK ASSESSMENT MODEL

S.G. Harris
Confederated Tribes of the Umatilla Indian Reservation
Department of Natural Resources
P.O. Box 638

Pendleton, Oregon 97801
ABSTRACT
Risk assessment methodologies for traditional American Indian lifestyles are inadequate, and have gone unnoticed in classical risk assessments that typically focus on suburban lifestyles. A potential risk from nuclear or hazardous waste that affects one member of the Confederated Tribes of the Umatilla Indian Reservation (CTUIR) may affect all of the tribal members and may have lasting impacts throughout the entire indigenous community. In order to encompass the wide range of factors directly tied to the culture of the traditional American Indians of the CTUIR, current human health risk assessments must implement a re-structured risk assessment process. These processes must address the overwhelming problems including but not limited to: 1) lack of breadth of coverage, 2) lack of integration, 3) deficiencies related to ignoring or inadequately addressing the CTUIR traditional American Indians' quality of life, 4) the interrelated and inseparable eco-culture, and 5) the unique exposure parameters and pathways. The need for understanding the pathways and associated exposures that directly involve the CTUIR traditional American Indian cannot be understated. The traditional CTUIR American Indian ties to the environment are overwhelmingly more significant and complex than is currently understood by contemporary risk assessors. These ties if holistically accounted for, will play a very important role in determining how future risk assessment methodology is produced. The effectiveness of risk management will be dependent on identifying these cultural unknowns. The issues of environmental racism, environmental justice, and the right to a healthy environment, further highlight a need to formally incorporate affected tribal input.
INTRODUCTION
The Umatilla Indian Reservation located near Pendleton, Oregon is occupied by descendants of three Columbia Plateau Tribes, the Cayuse, the Walla Walla, and the Umatilla (Tribes). The Tribal Government is referred to as the Confederated Tribes of the Umatilla Indian Reservation (CTUIR). As a full service government, the CTUIR Board of Trustees (BOT), makes the decisions on providing detailed information regarding culturally sensitive information.
Under these Tribes' Treaty of 1855 [12 Stat. 945], the Tribes ceded lands to the United States. The lands comprising the eastern portion of the U. S. Department of Energy's (DOE) Hanford Site is among the lands ceded by the Tribes. Under the treaty the Tribes retained rights to perform many activities on those lands, including but not limited to fishing, hunting, gathering roots, berries, and pasturing livestock.
Long standing U.S. Supreme Court precedent holds that the federal government (including its executive agencies) has a trust responsibility to Indian Tribes. This means that the U.S. has a fiduciary responsibility to protect the rights of Indian tribes, including tribes' property and treaty rights. Additionally, a succession of U.S. Presidents beginning with President Nixon, have affirmed a federal policy of upholding tribal sovereignty and dealing with tribal governments on a "government to government" basis. Furthermore, there are federal laws to protect tribes' cultural, religious, and archeological sites, access to, and exclusive use, of those sites, and of traditions, activities, and practices associated with those sites as well as Hanford as a whole. Finally, environmental laws also confer rights upon the tribes. For example, the

CTUIR is a Trustee for Natural Resources under the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA).

CTUIR - AN INTERDEPENDENT CULTURE AND ENVIRONMENT

The CTUIR is a sovereign government, that has legal interest in the natural resources upon which the CTUIR's Treaty rights are based, including lands of the Hanford Site. Effective exercise of these treaty rights depends on the health of the natural resources. The CTUIR does not want the people exercising their treaty rights to be placed at risk.

A risk from nuclear or hazardous waste that potentially affects one person of the CTUIR community may have lasting impacts throughout all of the community. In other words, a wave of risk can ripple outwards affecting all of the individuals in our culture, just like a wave generated and propagated in a tapestry. The unique CTUIR culture can be irrevocably changed or extinguished if enough of the environment and the natural resources on which the CTUIR treaty rights are based are irreparably harmed. Without the natural resources, the cultural values of critical significance to the traditional CTUIR American Indian, and her/his community would be lost. If a culture dies, the only remnant is the material culture. In the event of the unthinkable happening, a continuously sustainable natural resource based material culture, such as the CTUIR would rapidly disperse into the natural environment leaving no trace of the living CTUIR culture.

The people of the CTUIR are a unique culture, that has long been complexly intertwined with the environment through their cultural, familial ties, (e.g., marriage, gender, extended families), and relationships with other tribes. The CTUIR people have enjoyed since time immemorial, many types of native foods and artistically constructed items of material culture (e.g., cookware, clothing, etc.). Individual members are an inextricable part of the environment. These members, their community and the environment are essentially one in the same.

The CTUIR culture, which has co-evolved with nature and through thousands of years of ecological education, has provided its' people with their unique and valid version of holistic environmental management. The traditional CTUIR American Indian is aware from cultural teachings that the appropriate behavior leads to continuous sustainable success in gathering food and material. Traditional education regarding food or raw material gathering practices are passed on from one generation to the next, and is done to ensure food for the next season or generation. The knowledge of the many gathering seasons and areas the traditional CTUIR American Indians get to utilize during the year has been handed down from generation to generation. Some CTUIR families teach cultural knowledge in complete secrecy on the maternal or paternal side of the family/tribal unit in order to protect tribal cultural/spiritual knowledge from exploitation from the non-American Indian societies and governments. Within the traditional lifestyle or culture, it simply is not enough to know that there are supposed to be salmon runs at certain times of the year. To sustain the tribes during the remaining interim periods when salmon are not returning to spawn and other foods are available, there has to be knowledge about other interrelated food chain cycles, gathering techniques, preparation, and cultural/spiritual relationships about what is needed for sustenance. This interdependency of the collective knowledge about the seasonal foods not only affects traditional individuals, but affects the whole tribe as a culture. One person can not be expected to know all things. In practical terms, if a tribe depended

on one critical individual, the loss of that one "all knowing" person would effectively end or severely disrupt subsistence existence for the rest of the cultural unit. The same is true of oral tribal history, songs, heritable religious practices and numerous other cultural practices Continuity may depend on specialized knowledge in each generation.

The natural world in the Northern temperate zone operates on a seasonal clock. Traditional American Indians of the CTUIR are influenced by this clock, and expectantly look forward to the next cyclic event. These events include not only birth and death but change in general. Throughout the year, when the CTUIR traditional American Indian participates in activities, (e.g. hunting and gathering for foods, medicines, ceremonial, and/or subsistence), the associated activities are as important as the end product. In the Judeo-Christian tradition, an analogy would be "kosher" dietary practices. In the exercise of these activities, the traditional CTUIR American Indian may cover hundreds of square miles, thousands of feet of relative elevation, and cross numerous types of physiographic provinces. All of the country crossed in the search for food has special meaning to the traditional American Indian and each area demands special effort and behavior. This traditional activity is a key to the hunting of, and gathering of, traditional American Indian foods and culturally significant materials.

All the foods and implements gathered and manufactured by the traditional American Indian are interconnected in at least one, but more often in many ways. For example, trade made up for what could not be physically gathered by one person in one time period. Salmon caught on the Columbia River are often traded for roots, other produce, or material culture. This trade creates a web of interaction and interdependence cutting across families, bands, and tribes. These objects of life are as important to the traditional American Indian as the materials that comprise them.

The people of the CTUIR community follow cultural teachings or lessons brought down through history from the elders. The goal of these teachings is to foster community cohesion and interdependence. Emphasis is placed upon cooperation and helping others in the community, cultivating close community interactions. This is an ancient oral tradition of cultural norms. The material or fabric of this tradition is unique, and is woven into a single tapestry that extends from the past into the future.

RISK ASSESSMENT PATHWAYS

The methodologies used in classical risk assessments are being critically considered by the CTUIR. The classical risk assessment has many deficiencies, including a limited breadth of coverage and lack of integration. Through a pseudo-scientific methodology, the classic risk assessment: 1) ignores time, 2) extrapolates from the lab into the field, 3) contains biotoxicological effects that are not fully understood, 4) ignores multiple pathways and complex contaminants, 5) contains enormous uncertainties, 6) ignores long term impacts, effects to health, environment, workers and society, 7) prejudices future options, 8) loses the big picture by ignoring cumulative effects related to assessing only one chemical/one path/one site assessment at a time, 9)ignores eco-cultural sustainability, and 10)is based on a suburban lifestyle. The holistic environmental management strategies outlined in the Blacksburg Forum (1) or Toward the 21st Century: Planning for the Protection of California's Environment (2) highlight these major problems.

In order to encompass the wide range of factors directly tied to the traditional American Indians of the CTUIR, a risk assessment has to be scaled appropriately. In effect, a re-structuring of the risk assessment process must occur in order to address the overwhelming problems including but not limited to, lack of breadth of coverage, lack of integration and deficiencies related to not addressing the CTUIR traditional American Indians' quality of life, the interrelated eco-culture and their unique exposure parameters and pathways. Other deficiencies include the failure to address the role of time to adequately assess risks to future generations of CTUIR members. The process of American Indian Tribes supplying cultural conversion metrics for risk assessments is, at best, subject to the legislative processes of the various sovereign Tribal governments. Unfortunately for the risk assessor there are few traditional American Indians willing and able to supply the appropriate pathway information, and to say they can speak for any one but themselves. A risk assessor in search of identifying American Indian data gaps has to identify the affected tribe(s) and approach the subject of lifestyles tentatively identified with a potential risk through the proper protocol of the individual tribal government. Until that information is obtained, the results of the classic risk assessment in no way suggest the potential pathways or exposure routes that fall within the breadth, depth, and richness of the CTUIRs' culture. Unfortunately, the processes, the approach and even the necessity to account for traditional American Indian lifestyles have gone unnoticed in classical risk assessments that typically focus on suburban lifestyles. The potential exposure pathways specifically oriented towards the traditional American Indian lifestyles need further identification to ensure protection of the CTUIR and the resources on which CTUIR culture is based. This must be done to provide risk assessors with the most accurate information possible. The principal concerns that affect the CTUIR traditional American Indian relate to a lack of identification of the critical pathways. In addition some risk assessments identify these pathways, "consider" them, and then ignore them, or label them as "insignificant." These multiple potential pathways to exposure are not included in typical suburban exposure pathway model, which has a seriously deficient relationship to the lifestyle of the traditional CTUIR American Indian. Each path stems from unique and multiple uses of the resources for food, ceremonial, cultural, or religious practices. Just as important to the people of the CTUIR are the more intangible considerations such as: aesthetics;physical, economic, community, future well-being, and equity; peace of mind; and sustainability.

A risk assessment covering only mechanistic exposure routes linking a single toxicological component to simple one celled organisms, to mega fauna, then to humans, without accounting for the time involved, does little to express the complexity of the interrelationships between the traditional American Indian, their lifestyles, their relationship with the earth and the natural resources. Anyone attempting to derive and plot on a chart the life cycles of all the native plants, animals, as well as the methods of storage, preparation, and all the unique interrelationships that stem from the area of concern, in order to deduce the complete functional pathways for exposure, will find that the process is probably beyond our capabilities and is expensive. Charting whole ecosystems is certainty not in the realm of this paper, moreover, the thought of placing a value on each and every organism for the purposes of

producing a number, does not convey what is a traditional American Indian entity. Even if a number could be produced, this does not take into account the traditional American Indian values, let alone uptake rates, absorption rates, mutation rates, bioaccumulation rates, and other food chain data needed to make a decision on what is important and what may affect the CTUIR traditional American Indian.

There are some common food plants such as the common cattail, the tule, the willow, and the nettle, that serve dual or more purposes. These could be considered by risk assessors, if nothing less than to point out the enormous data gaps involved. The traditional tribal communities often constitute critical segments of populations whose cultural lifestyles result in disproportionately greater than average exposure potential. Gathering, cleaning, eating, and using these plants may potentially expose many traditional American Indians multiple times, and may subject critical CTUIR population groups to unneeded exposure. The life of the cultural items made from potentially contaminated plants may last years; exposure may occur daily or more, over multiple generations.

Traditional American Indians of the CTUIR have to bear a disproportionate amount of risk in relation to the longevity of radionuclide contaminated groundwater. Take, for example, the common cattail: in the spring the shoots are eaten, the roots are consumed, and the fibrous stalks and leaves are split, woven or twisted. Later in the year the pollen is used in breads, and the stalks are used. The woven products may include food storage bags, food storage baskets, cook hole layers, cooking baskets, mats for the floor, mats for the sweat lodge, or mats for the funerary. Each of these activities necessitates a behavior pattern that encompasses: traveling to the plants, selection, gathering, sorting, cleaning, stripping, peeling, splitting, chewing, and forming of the plant materials. This is just for one type of plant among the hundreds of plants and animals that are used by traditional CTUIR American Indians.

CRITICAL SUB-POPULATIONS OF THE CTUIR

Even during the quest for some food, a typical CTUIR member may potentially be exposed through a variety of pathways. The riverbank walk towards the spring where the plant of interest grows may contain discreet particles of radioactive material, such as Co60. This affects certain subgroups within the CTUIR population more than expected, such as the women and the children. The classic risk assessment focuses on a healthy suburban male of average mass. In comparison the women and children as a result of their smaller mass and shorter stature will receive a higher dose (3). The mud surrounding some Hanford springs may potentially contain Cr [+6], Sr90, or H3.

During the assessment of the quality of the plants (i.e., which ones to select for gathering), a process that demands time standing in spring water, or in spring water saturated mud, could result in absorption of H3 through the skin (4). The women and children, due to their physical characteristics and their culture, may receive greater exposure. Children in particular may be at much higher risk of radionuclide contamination of the environment than adults. Children have a much shorter stature and less body mass than adults, meaning that they have less natural shielding and are closer to source materials.

The gathering process involves not only continued immersion in the spring water, but immersing the hands and compacting mud under and around the fingernails as well. Sorting the plants afterwards, either at the site or elsewhere involves more handling and washing. The bulbs or root of the

food plant may have special cleaning needs. Roots may not be uniformly smooth as carrots or potatoes but undulated, having places where the earth can not be washed out, and if eaten, creates an ingestion pathway for potential exposure. The skin of the root may need to be peeled. Peeling roots is a difficult and time consuming chore involving not only the hands but in many cases a knife and the teeth. Splitting the leaves involves a lot of handling and the experience comes with cuts and abrasions, and more soil accumulation under the nails. If the food is to be eaten and not stored, another potential pathway for contamination is revealed through traditional cooking methods. Local rocks are gathered and heated with local wood. A hole is dug. The heated rocks are dumped in the hole. The rocks are covered with the cattail leaves. The cleaned, peeled, roots are placed on the leaves, and covered with more leaves. This is covered with soil, and a fire is built over the covered cook pit. The result is tasty, but in certain places this type of unique cultural activity could increase exposure. Thus, traditional CTUIR American Indians can be exposed to radionuclides through digging, breathing smoke, breathing dust, breathing steam, eating dust and soil, storing vegetables underground, and eating steamed vegetables.

This risk scenario is but one of many that can be played out for one food, at one site, during one time of the year. The complexities involved with hunting and gathering foods are extremely time consuming and involve at a very primary level many traditional American Indians and the environment. Other significant factors include higher intake rates per body mass for children than adults, the fact that primary gathers are likely to be women of childbearing age, variations in metabolic parameters, and increased risk to CTUIR elders with age-dependent decreased physiological resistance or underlying health problems. Because the CTUIR is unique, risk assessors must realize and accept that the threat to the whole living CTUIR culture begins with two reasons for increased risk: increased exposure and increased sensitivity

The Columbia River continues to be very important to the traditional American Indians that live around it. The river provides a link to the past and a path [for] the future of their children. Understanding the ecosystem and how the traditional American Indian is associated with it is critical for these people and their survival. The health of the river is dependent on the health of the groundwater; the peoples' health is dependent on the river and all that comes from it (5).

The need for understanding the pathways that directly involve the traditional American Indian cannot be understated. The ties to the environment are much more fixed than is currently understood. These ties will play a very important role in determining how risk assessment methodology is produced and how effective risk management will be. The issues of environmental racism, environmental justice, and the right to a healthy environment, highlight a need to formally incorporate affected tribal input.

ABSTRACT

Federal agency personnel and contractors who find themselves working on projects and in programs that require consultation with American Indian tribal governments and their representatives often find these interactions less satisfactory and useful than they could be. Federal personnel and contractors often find themselves wishing for:

a more practical understanding of the political concepts that have determined the unique relationships that exist between the United States government and tribal governments,

more information about appropriate approaches and methods for interactions with tribes, and

ways to avoid the all-too-frequent political and institutional barriers that impede communication and hinder the building of trust.

This paper explains the key political concepts and federal policies that have defined the federal/tribal relationship. It outlines a style of approach and methods for effective, culturally appropriate interactions with tribal governments and their representatives. The paper also examines obstacles to trusting, effective communication between the federal government and tribal governments; these include conflicting values within tribes as well as political and institutional barriers within agencies. the paper makes these points in part by examining the case of a recent environmental risk evaluation in which JK Research Associates was responsible for coordinating tribal involvement. The paper concludes with recommendations for changes in institutional practices and policy-making that will facilitate greater inclusion of tribes in policy decisions.

INTRODUCTION

Federal agency personnel and contractors and American Indian tribal government representatives who find themselves working on projects and in programs that require consultation, often find these interactions less satisfactory and useful than they could be. Federal personnel and contractors often find themselves wishing for a more practical understanding of the political concepts, treaties, and policies that have determined the unique relationship that exists between the United States government and tribal governments and how the federal/tribal relationship

should be fulfilled within their work. Tribal government representatives and tribal personnel often find themselves wishing that federal agencies would take seriously commitments to consult with tribal governments, consider tribal rights, needs and values, and incorporate tribal information when making policy decisions. Both federal and tribal personnel have found themselves discouraged and wondering how it is possible to work through the all-too-frequent political, institutional, and cultural barriers that impede communication and collaboration and hinder the building of trust between tribes and federal agencies.

This paper explains the political concepts and federal policies that have defined the federal/tribal relationship. The paper examines barriers that hinder the building of a cooperative relationship. These include conflicting and/or misunderstood values, underdeveloped communication strategies, and the absence of guidance to direct federal personnel in how to fulfill the requirements of the federal/tribal relationship within their program responsibilities. The paper examines such barriers by discussing the case of a recent environmental risk evaluation in which the author was involved in coordinating tribal involvement. The paper also discusses two other cases in which the U.S. Department of Energy (DOE) and the U.S. Environmental Protection Agency (EPA) made policy and/or regulatory decisions that would impact tribal lands and tribal health. However, the tribes affected by those decisions viewed tribal input to those decisions as non-existent or not very meaningful. The paper concludes with a discussion of strategies that tribes and federal agencies might consider in order to facilitate meaningful tribal involvement in program and policy decisions that affect tribes and their interests.

THE FEDERAL/TRIBAL RELATIONSHIP

DOE and EPA, as arms of the federal government, are directed to uphold federal commitments within the federal/tribal relationship. In order to fulfill this relationship, federal personnel should understand federal responsibilities to tribes and how they apply as federal personnel carry out their program activities and implement policies that affect tribes. Federal responsibilities to tribes were determined by political concepts, policies, treaties and other laws. These concepts and policies include tribal sovereignty, tribal self-determination, the government-to-government relationship and the federal/tribal trust relationship (1,2,3,4). In addition, some of the tribes near DOE installations have treaty-protected rights to access cultural and natural resources within portions of these installations (5).

Tribal Sovereignty

Sovereignty is a concept that is difficult to define and understand. However, the powers held by sovereign nations illustrate more clearly, the concept of sovereignty. They include lawmaking and enforcement, defining territory, determining citizenship, regulating trade and property, and forming alliances with other nations through treaties, and other agreements. The Indian nations of North America exercised the powers of sovereign national and recognized the sovereignty of one another by making treaties and trade agreements and by forming political and military alliances with other tribal nations. The colonial governments and later the United States recognized the sovereignty of Indian nations by entering into over 800 treaties with tribes. In Worcester v. Georgia (1832), the U.S. Supreme Court said:

. . .the very fact of repeated treaties with [tribes] recognizes [the Indians' right to self-government] and the
. . .doctrine of the law of nations is that a weaker power does not surrender its independence--it's right to self-government by associating with a stronger and taking its protection.

The U.S. Constitution also recognizes tribal sovereignty by directing the federal government, rather than the states, to conduct official relations with Indian nations (2).

Tribal Self-determination and the Federal/Tribal Government-to-government Relationship

In 1934 Congress passed the Indian Reorganization Act (IRA). The IRA recognized tribal governments, reaffirmed federal recognition of the sovereignty of tribal nations, restricted the power of the federal government over Indians, and established economic development programs to assist tribes. IRA has contributed substantially to the present definition of self-government and self-determination that tribes use as a basis for seeking to be involved nfederal policy decisions. Since the 1960s, beginning with the Johnson administration, administrative policy has also reaffirmed the federal government's recognition of tribal self-determination. Such recognition of tribal sovereignty was formalized with the passage of the Indian Self-Determination and Education Assistance Act in 1973 and is illustrated by the government-to-government relationship held between the federal government and tribal governments. Within this relationship, the federal government pledges to work directly with tribes as separate governments and not as political subdivisions of states or other governmental units (1,3).

Since Johnson, succeeding presidents have also expressed support for tribal self-determination and the government-to-government relationship. President Johnson covered tribal self-determination in his 1968 congressional message. President Nixon followed in 1970. In 1983 the Reagan Administration expressed support for tribal self-determination and a government-to-government relationship. In April 1994, President Clinton issued a memorandum to the heads of executive departments and agencies that outlined the principles that define the federal government's responsibility to operate within a government-to-government relationship with federally recognized tribal governments (4,6).

The Federal/Tribal Trust Relationship

Characteristic of the unique federal/tribal relationship is the concept of "federal trust" responsibility to tribes. The U.S. Supreme Court ruled in Cherokee Nation v. Georgia (1831) and in Worcester v. Georgia (1832) that the federal government's trust responsibility is to ensure "the continued survival of Indian tribes as self-governing peoples." From this ruling, the original definition of federal trust responsibility emerged:

The United States Trust responsibility toward American Indians is the unique legal and moral duty of the United States to assist Indians in the protection of their property and rights.

Other definitions of the federal trust responsibility have been used. The Department of Interior defines the federal responsibility as the legal obligation of the U.S. government to protect "valuable Indian lands, water, minerals, and other natural resources." However, this definition is incomplete as it mentions only physical properties. In 1977 the American Indian Policy Review Commission defined the trust responsibility as "an established legal obligation which requires the United States to protect and enhance Indian trust resources and tribal

self-government and to provide economic and social programs necessary to raise the standard of living and social well-being of the Indian people to a level comparable to the non-Indian society." Despite differing interpretations of the federal trust obligation to tribes, the original purpose of federal-tribal trust has appeared in treaties and agreements, court decisions, tribal statements, and Congressional acts. This definition is most often cited despite many examples of federal actions which are inconsistent with intent of the Supreme Court (3,7).

Tribal Treaty Rights

One of the most misunderstood areas of federal Indian law are the treaties that have been negotiated between the United States and Tribal nations. Under treaties, tribes ceded certain lands to the United States, but reserved other lands and retained perpetual rights to perform certain activities on certain lands ceded to the U.S. In order to fully understand the rights of tribal governments and Indian people, one must understand how treaties have recognized the distinct identity of tribal governments. Many Americans, unfamiliar with Indian history and Indian law, oppose the treaty rights of tribes. Many people mistakenly believe that a violation of the treaty by the United States has nullified those treaties. However, Congress must repeal a treaty legislatively in order to invalidate the treaty (1,2).

There are several tribes that have rights to access natural and other cultural resources found within several DOE nuclear installations. Tribal rights to hunt, gather, fish, and engage in other traditional activities are protected by treaties that the tribes signed with the federal government. In these treaties, tribes retained access to resources within land areas that now host several DOE nuclear installations. For example, in the Treaty of 1855, the Walla Walla, Cayuse and Umatilla Tribes (now the Confederated Tribes of the Umatilla Indian Reservation or CTUIR) ceded lands to the U.S. that included what is now the eastern third of the Hanford Nuclear Reservation. As a result, CTUIR's rights regarding lands and resources within the Hanford reservation were retained under the 1855 treaty. Under the treaty, the Tribes retained the exclusive right to take fish from the streams running through and bordering the Tribes' reservation and retained the privileges of hunting, gathering roots and berries, and pasturing their stock on unclaimed lands that include the portion of Hanford that falls within the Tribes' traditional lands (5,8,9). The Yakama Indian Nation and the Nez Perce Tribe also have treaty-reserved rights to access resources within portions of the Hanford installation. In 1855, the Yakama Indian Nation ceded 10.8 million acres to the U.S. government in exchange for their present reservation and retained rights to hunt, fish, gather, and pasture stock on portions of their ceded lands, some of which are within the Hanford site. In 1855, the Nez Perce also signed a treaty with the U.S. in which they retained similar rights of access to portions of their ceded lands (5,10).

The Shoshone-Bannock Tribes of Fort Hall, Idaho are yet another example of a tribe that possesses treaty-protected rights to use resources within a DOE installation. The Idaho National Engineering Laboratory (INEL) lies on the aboriginal territory of the Shoshone and Bannock people. Before Whites settled in the area the Tribes used the lands and waters within the area that now hosts the INEL for fishing, hunting, gathering plants for food and medicine, and for other cultural purposes. In 1868 the Tribes signed the Treaty of Fort Bridger with the U.S. government which protected tribal rights to perform traditional activities on unoccupied

lands of the federal government, some of which include the area that the INEL occupies today (11,12,13,14).

Finally, for tribes to safely and effectively exercise their treaty rights to hunt, fish, and gather on these lands, the natural resources upon which these rights are based must be safe toconsume. However, activities undertaken by DOE, other governmental entities, and private parties, have harmed natural and cultural resources that are important to many tribes across the country.

The DOE and EPA Indian Policies

The U.S. Department of Energy and the U.S. Environmental Protection Agency, as well as other agencies and departments, have developed Indian policies that outline their responsibilities, as they interpret them, to American Indian Tribal governments. In 1984 the "EPA Policy For the Administration of Environmental Programs on Indian Reservations" was signed. EPA's Indian Policy recognizes tribal self-government and the federal/tribal government-to-government relationship. The EPA policy outlines nine general principles to guide the agency in managing and regulating environmental problems on tribal lands. EPA has stated that it will involve tribes in decision-making and program management that affect tribal lands and that tribes should be included as partners in environmental management in much the same way as states are involved in policy decisions that affect state lands. Five of the nine EPA Indian Policy principles address tribal government involvement in EPA decision-making. Two principles stress that state, local, and the federal government and its agencies should work cooperatively with tribal governments to aid tribes in assuming environmental protection responsibilities for reservations. The EPA policy is primarily emphasizes EPA's recognition and respect of the rights of tribal governments to protect the reservation environment and the reservation populace. However, the EPA policy is without implementation guidance that would explain to agency personnel how the policy principles apply to their work (15). Like the EPA Indian Policy, the "DOE American Indian Tribal Government Policy," released in December 1991, recognizes tribal sovereignty, the government-to-government relationship, tribal self-determination, the federal/tribal trust relationship, federal responsibilities to tribes determined by tribal political status, treaties, and federal law (16).

THREE CASES

Following, are brief descriptions of three processes in which DOE or EPA were implementing programs and determining policy and regulations. In all three processes, tribes would be affected by the decisions made by DOE and EPA, and their contractors. In all three processes there was a breakdown in communication and understanding between federal personnel and tribal representatives. In addition, in all three cases there was cultural information that was either not accessible to federal personnel or was not fully considered in federal decision-making.

DOE Consortium for Environmental Risk Evaluation

The Tulane/Xavier Consortium for Environmental Risk Evaluation (CERE) consisted of academic institutions and corporations with risk analysis and public involvement expertise. The U.S. Department of Energy (DOE) retained CERE under a cooperative agreement toperform "an independent qualitative evaluation of risks to the public and tribal health, to worker health and to the environment" arising from DOE's environmental management activities (17).

Conventional risk assessment methods do not generally evaluate exposure resulting from tribal lifestyles. For example, assumptions regarding food consumption are based on average consumption practices which may differ significantly from tribal practices. Conventional risk assessment also does not evaluate risks that are difficult to quantify, such as risks to cultural resources. Partly because of these limitations and because existing risk documents had obviously not assessed some of the crucial risks to tribes, the CERE team was not equipped to evaluate risks to tribal cultural resources. However, in the tribes' view, a legitimate evaluation of risks to tribal health was not possible without evaluating the risks to natural and other cultural resources, particularly from the transportation of radioactive and hazardous materials across tribal lands.

The evaluation of culturally-specific risks is a still emerging practice in risk assessment. Unfortunately, none of the members of the CERE risk evaluation team had experience with incorporating tribal values into a traditional risk evaluation framework. CERE focused primarily on documenting direct risks to human health. In addition, CERE was charged with performing a qualitative, rather than a quantitative evaluation, that was based on existing risk information, which did not include information on risks to cultural resources. During discussions held at CERE workshops and in a separate report prepared by Confederated Tribes of the Umatilla Indian Reservation (CTUIR), the tribes involved in the program made it clear that they considered the absence of an evaluation of culturally-specific risks to seriously limit the value of CERE's report (9).

Tribal representatives involved in the CERE program were also dissatisfied with how CERE communicated with tribes. The tribes do not believe that interactions with tribes were a priority for the CERE risk team, which they also believe had little understanding about the nature of the federal/tribal relationship. In addition to staff level communications which did not occur regularly (thereby hindering the gathering of existing tribal risk information), formal communications between CERE and the tribal governments did not occur (11,9). The CERE public involvement team did distribute a paper to its team members outlining the key political concepts and federal/tribal policies that have determined the nature of the federal/tribal relationship. This effort was recognized by the tribes as a positive step by CERE to educate its team members, but did not fulfill the need for CERE decision-makers to act as official points of contact to open up direct lines of communication between tribal government leaders and contractor decision-makers. However, the CERE risk evaluation team should not be held entirely at fault for not understanding the nature of the federal/tribal relationship and the proper protocol for dealing with tribal governments. DOE and other federal agency personnel also do not seem to understand how federal responsibilities to tribes apply to their work and the decisions they must make.

The Penobscot Nation of Maine and EPA Regulation of Dioxin Discharge

The Penobscot Nation Reservation comprises approximately 200 islands in Maine's Penobscot River, including Indian Island, the main island of residence for the tribe. Historically, and still today, tribal members use the river for subsistence fishing, hunting, trapping, and to gather fiddlehead ferns which are either consumed or sold to grocery stores. Because the reservation includes waters of the Penobscot River, and

because the river is vital to maintaining tribal traditions, the preservation and enhancement of the river and its resources are of the utmost concern to the Nation. Unfortunately, the river has suffered degradation from sawmills, textile mills, leather tanneries, and pulp and paper mills. Though water quality has improved since the late 1960's with the passage of environmental protection laws, the water quality of the river is still not sufficient for tribal members to safely consume fish at subsistence levels from its waters (18,19).

Dioxin that is present in the river and in fish tissue is one of the greatest issues of environmental concern to the tribe. Dioxin, a likely human carcinogen, is produced as a byproduct of the chlorine bleach process used to produce high quality white paper (New England Journal of Medicine, 1991). The Penobscot Nation has consistently stated that their right to fish at subsistence levels, which is guaranteed in treaties, has been impinged upon by paper mills that discharge dioxin laden effluent into the river and by the State of Maine, which allows such practices. In 1992, Lincoln Pulp and Paper, located 35 miles upstream from Indian Island, applied to EPA Region I for renewal of a five-year permit that allows the mill to discharge dioxin laden effluent into the Penobscot River at a specific concentration. Because the State of Maine did not have permitting authority under the Clean Water Act, EPA was responsible for issuing the permit using EPA's recommended dioxin standard. The State of Maine, as a "primary affected party," received special consideration as a primary commenter on the permit and was notified of Lincoln Pulp and Paper's application for renewal of the discharge permit. However, the Penobscot Nation was not viewed as a primary affected party, nor was it given the same early opportunity to comment on the permit. EPA Water Quality staff, in an interview, admitted that this oversight was due to the lack of awareness by staff of the location of the reservation, and of the traditional fishing practices of tribal members (21). Given the reservation location and tribal fishing and gathering practices, tribal members are more directly affected by dioxin contamination in the river. The fishing rights of the Penobscot Nation have been acknowledged by treaties and reaffirmed by the Maine Indian Claims Settlement Act of 1980. The Penobscot Nation should have received special consideration as a primary party and commenter on the permit. In comments submitted to EPA, Region I and to EPA Administrator, Carol Browner, the Penobscot Nation pushed EPA to uphold its trust responsibilities to the Penobscot Nation by protecting the Penobscot River from environmental degradation.

DOE's Development of Site Treatment Plans for Mixed Waste

Under the 1992 Federal Facility Compliance Act (FFCA), which amends the Resource Conservation and Recovery Act (RCRA), the U.S. DOE was required to develop andimplement Site Treatment Plans (STPs) for the treatment, transportation, and storage of mixed waste at 38 DOE sites (NGA, 1994). Several of the DOE sites occupy land areas that were ceded by tribes in treaties with the U.S. government. These tribes still have treaty-guaranteed rights to access natural and cultural resources within these sites. In meeting the requirements of the FFCA, DOE will transport wastes between sites for treatment and will transport waste treatment residuals back to their sites of origin. Many of these waste shipments will cross reservation lands. Tribes near DOE installations are concerned that DOE waste treatment activities will pose risks to tribal health and resources and tribal sovereignty (23,24).

From October 6, 1992, when the FFCA was passed, until October 6, 1995, when DOE was required to gain approval of STPs from the regulating states and EPA, DOE worked with the states and EPA to develop the plans (22). Although the FFCA did not require state involvement, DOE recognized that states should be involved because ultimately, they would approve the completed plans. The states recommended that the National Governors' Association (NGA) coordinate the states' role in STP development. DOE agreed and negotiated a cooperative agreement with the NGA. During the three years after FFCA was enacted, the NGA coordinated state involvement in the development of STPs by providing forums primarily for state, EPA, and DOE representatives to discuss technical, policy, and implementation issues related to the STPs.

However, because tribes did not possess regulatory authority under RCRA for hazardous waste, the FFCA did not require tribal government approval of STPs as it required approval by regulating states. Therefore, DOE did not have the impetus to prioritize tribal consultation in the same way as it prioritized state consultation. Consequently, tribes have expressed dissatisfaction with how they were involved in developing STPs. The tribes state that they did not have sufficient opportunity to engage in government-to-government discussions with DOE and to provide information about risks to tribal communities to be incorporated into the transportation, treatment and storage decisions reflected in the plans. During STP development, tribes were invited to attend meetings that primarily reflected the agendas and concerns of state regulators including a national FFCA meeting and NGA meetings (25). While some tribal representatives attended some of these meetings, those tribal representatives note that such meetings did not fulfill DOE's responsibility to interact with tribes on a government-to-government level. The NGA exists as a forum to bring together representatives of states. Its primary goal in the STP development process must be to facilitate effective discussion between states and DOE and to promote state influence in the STP process. While inviting tribes to participate in the NGA meetings does not in itself contradict DOE's government-to-government relationship with tribes, tribal representatives point out that in order to fulfill the responsibilities of the relationship, similar meeting should have been held between DOE's tribal governments throughout the STP development process. Such meetings would have provided tribes with opportunities to talk at length with DOE about mixed waste activities and their potential impacts on tribal communities and resources in order to influence STP decisions about how to treat, transport, and store mixed waste. Because such meetings did not occur, the tribes have view their involvement in STP development as minimal (25).

INSTITUTIONAL AND CULTURAL BARRIERS THAT HINDER COMMUNICATION BETWEEN FEDERAL AGENCIES AND TRIBAL GOVERNMENTS

Relations between tribes and DOE and EPA have improved, becoming more consistent as tribal environmental programs have emerged to work with DOE and EPA on a daily basis. However, tribal representatives continue to express frustration with federal agency actions that seem to be inconsistent with federal trust and treaty responsibilities. Tribal representatives remark that program and policy decisions are still being made and implemented without consideration of federal commitments to tribes and without incorporating tribal cultural information into these decisions that affect reservation lands.

In examining the three cases, two types of barriers emerge that hinder communication and cooperation between tribal governments and the federal government. These are institutional barriers such as an organizational infrastructure that has not developed decision criteria to guide agency staff (and contractors) in incorporating tribal values and information into technical and policy decisions. Such criteria should be based on the federal/tribal relationship and tribal treaty rights, but should also consider the needs and restrictions of tribal governments and federal agency programs. Barriers to cultural understanding also hinder communication and collaboration. These include an incomplete understanding by federal agency personnel and tribal representatives about the resource restrictions, knowledge base, and cultural tenets that determine the priorities and capabilities of each party.

Tribal representatives noted the CERE team did not communicate regularly with tribal representatives, did not communicate on a staff level, and did not communicate formally with tribal government leaders. The tribes determined that CERE did not communicate well with tribes because the team did not truly understand how federal responsibilities to tribes applied to their evaluation of risks. The CERE team was largely untrained in tribal rights, values, and government-to-government protocol. Consequently, an unfortunate, yet common pattern emerged in the CERE teams' relationship with the involved tribes. Because the team did not seem to understand how to fulfill its responsibilities to tribes, communication with tribal representatives was, for the most part, "ghettoized." This means that tribal "involvement" responsibilities were thought to rest on the shoulders of the public involvement team that was working with the risk evaluation team. However, meaningful tribal consultation on a technical level could only have been carried out by the risk evaluators. Rather, it was left to the public involvement team to write a brief section within the risk evaluation report about the risks to tribal cultural resources. This section was based on non-technical information the public involvement team had gathered from the tribes. The risk assessment community has not yet figured out how to quantify risks to tribal members resulting from exposure through traditional activities. It is likely that these risks cannot be quantitatively evaluated. Therefore, the CERE team members were handicapped in their evaluation of the risks to tribes by more then the fact that they did not understand tribal rights and values. The team also did not consist of any members with experience in considering the risks to tribes from exposure through traditional lifestyles. In addition, the team was not provided with training in the government-to-government relationship, the treaty rights of the tribes they would be working with, and they were not equipped to evaluate risks from culturally unique activities.

EPA, Region I, in issuing a dioxin permit to Lincoln Pulp and Paper, faced similar institutional barriers. EPA Water Quality staff responsible for issuing the permit, did not understand how the federal/tribal relationship determined their responsibilities to tribes. They also were not aware of basic information about the Penobscot Nation, such as the reservation location or the tribe's treaty rights regarding traditional usage of Penobscot River resources. Had EPA Water Quality staff understood the federal/tribal relationship and Penobscot Nations treaty rights, they would have designated the tribe as a primary commenter on the permit. Once they were informed of the tribal situation EPA Water Quality staff seemed very willing to use information regarding tribal

member exposure to calculate the dioxin standard for the final permit. However, the Penobscot Nation had received several grants for their activities related to monitoring the river. Therefore, it follows that pertinent tribal information was already available within the Water Quality section. However, it was obviously not used to train staff in tribal issues relevant to their work.

During the development of the Site Treatment Plans for mixed waste, DOE and the affected tribes encountered additional barriers to working collaboratively. While DOE staff may have had a general understanding of the federal/tribal relationship, they did not seem to understand how this relationship was affected by the FFCA. Although the FFCA did not mention the role of tribes (because tribes were not regulators under RCRA), this did not release DOE from its government-to-government relationship or its trust responsibilities to tribes. Although tribal governments would not officially approve the plans, tribal consultation should have remained a high priority during STP development because of the government-to-government relationship and because many waste shipments will cross reservation lands. In addition, tribes have certain regulatory rights under the Hazardous Materials Transportation Uniform Safety Act.

CONCLUSION

In all three cases, federal personnel and tribal representatives encountered barriers that resulted from differing priorities, and from their inability to communicate with each other and to share their expertise. EPA and DOE almost always have priorities that differ from the priorities of tribes. Federal personnel and tribal representatives operate within very different cultures. They are subject to the demands of constituencies that have often conflicting interests, values, and needs. Although federal agencies and departments are bound to fulfillthe federal/tribal relationship, their priorities and budgets are significantly determined by a Congress and Administration that are heavily influenced by the priorities of states and other interests that are able to exercise greater power than tribes are able to exercise.

In addition, EPA and DOE program staff and their contractors often have different areas of expertise than tribal staff and tribal government leaders. While DOE and EPA each have a cadre of staff with technical expertise in specific areas, tribes have much more limited resources and thus often hire one person to operate and entire tribal environmental program. Sometimes tribes hire several staff that possess technical expertise in specific areas. However, tribes still rely on the wealth of technical expertise held within EPA and DOE to supplement their capabilities. On the other hand, tribal staff, tribal leaders, and tribal members possess a wealth of knowledge about tribal cultural resources. Tribal staff and members know where to find these resources and how the resources are used. Therefore, they know how tribal members might be exposed to contamination. Tribal staff and tribal members know why these resources are so important for maintaining traditions and they understand the implications for the tribe if such resources were to be damaged or completely lost. DOE and EPA must rely on this expertise to supplement their understanding of the risks to tribes and tribal resources from federal activities.

While tribes have had little input to federal agency priorities, this situation does not have to continue. Tribes are working diligently to develop environmental program capacity. In doing so, they are developing technical and policy expertise and are gaining regulatory and political

experience that will enable tribal environmental protection specialists and tribal policy experts to wield greater influence over policy and regulatory decisions so that tribal interests are protected.

DEVELOPING NEZ PERCE TECHNICAL EXPERTISE IN WASTE MANAGEMENT AND ENVIRONMENTAL RESTORATION ACTIVITIES

Rico O. Cruz
Daniel S. Landeen
David Conrad
Stanley M. Sobczyk
Nez Perce Tribe

ABSTRACT

Since the inception of the Nez Perce relationship with the U.S. Department of Energy, and its regulating counterparts, the U.S. Environmental Protection Agency and the Washington State Department of Ecology (the signatories to the Tri-Party Agreement), the Nez Perce Department of Environmental Restoration and Waste Management (ERWM) has been building its technical expertise. The ERWM Department experienced the immediate need to develop this expertise when confronted with massive technical studies of impacts, and plans for remediation and restoration, of those impacts to areas considered critical to Nez Perce Treaty rights (Treaty of 1855). The Nez Perce Tribe has recognized, however, that maintaining this level of technical effort depends upon a sustained level of political support. The brief history of the Nez Perce/Federal relationship (and the Federal/Tribal relationship in general) leads the Nez Perce leadership to seek to strengthen political support, highlight economic justification, and market its technical excellence. The Nez Perce Tribe is aggressively pursuing contracts in areas critical to protection of Nez Perce Treaty rights at the Hanford site. Within the two years that the Nez Perce ERWM Department has been funded under the cooperative agreement with the Department of Energy, it has built a technically credible team, is seeking contracting opportunities in the global arena, has just graduated its first engineering student/intern,

and is seeking ways to improve environmental management decision-making based on the Nez Perce traditional worldview and practices.

INTRODUCTION

The Nez Perce Tribe is involved with the U.S. Department of Energy and its environmental management activities at the Hanford Site in south-central Washington through the legal doctrine of trust responsibility by virtue of the Treaty of 1855, signed by the Nez Perce Tribe and the federal government. Under a cooperative agreement between the U.S. Department of Energy and the Nez Perce Tribe, the Tribe is actively participating in issues regarding the clean up of radioactive and chemical contaminants that were a result of nuclear weapons production since the 1940's.

What follows is a brief history of Nez Perce involvement at Hanford,on the technical front. Where this paper leaves off is the beginning for our second paper on translating the traditional Nez Perce worldview into environmental management strategies.

The Nez Perce Tribe specifically retained customary usage rights to the Columbia River when the Tribe ceded over 11 million acres to the Federal Government in the Treaty of 1855. By entering into The Treaty of 1855 and subsequent treaties, the Federal Government has acknowledged that our Tribal Rights preceded the U.S. Constitution and are retained with regard to the Columbia River. The disposition of more than 100 million curies of radioactivity into the Columbia River, since Hanford operations began, has diminished the value of our retained rights without consultation or compensation.

TECHNICAL INVOLVEMENT

The Nez Perce Tribe's Department of Environmental Restoration and Waste Management (ERWM), formed in 1992, is involved in reviewing regulatory documents and suggesting implementation strategies in a number of areas under various regulatory authorities and Departmental orders. This involvement in Hanford cleanup activities is a way for the Tribe to keep tribal members informed and to build technical expertise in remediation and restoration procedures. Nez Perce involvement at Hanford is also the way by which treaty rights and cultural and natural resources are protected. The Tribe's primary focus is stopping further contamination to the groundwater and the Columbia River. The Tribe is also concerned about protecting native shrub-steppe habitat.

There are over 1,500 contaminated sites at Hanford that have been grouped into 78 operable units according to contaminants and location. Cleanup procedures are guided by three regulatory programs: National Environmental Protection Act (NEPA), Comprehensive Environmental Response Compensation and Liability Act (CERCLA), and the Resource Conservation and Recovery Act (RCRA). The guidelines indicated by NEPA, CERCLA, and RCRA set the framework for clean-up procedures and include similar stages such as data gathering for risk characterization, remedial action and design plans, and monitoring and surveillance activities. DOE's federal trust responsibilities require that the Nez Perce Tribe is included in all aspects of this work before comments about remedial actions are accepted from the public.

The Tribe's monitoring of and participation in clean-up activities centers on six primary areas: 1) Waste Management and Environmental Restoration, 2) Cultural Resources, 3) Human Resource Development, 4) Technology Development, 5) Public Education and Information, and 6) Health and Emergency Response. The ERWM has a technical staff with

expertise in policy analysis, geology, hydrogeology, biology, agricultural engineering, cultural and natural resources, communications, health, and pollution prevention. The technical staff are active participants on several DOE and Hanford related advisory committees including the Hanford Health Information Network, Hanford Advisory Board, Columbia River Impact Assessment Workshops, Community Leaders Workshop Forum, and Natural Resource Trustee Council.

In addition to the technical staff, the Nez Perce Tribe has an active internship program which provides Nez Perce students with educational opportunities and access to job training. Student interns have helped conduct research on DOE policies, proposal development, health issues, botanical collecting and revegetation, and cultural resources issues.

What follows is a select list of projects the Nez Perce ERWM Department is currently involved in. The select list was chosen to reflect a combination of priorities, demonstrable expertise, and practical solutions. To this end, the Tribe reviews Hanford Operations which directly and indirectly affect ground water and the Columbia River.

The U.S. Government operated eight "single-pass" (open-coolant) reactors along the Columbia River from 1944 to 1971. During this time period, the Hanford Site released more than 100 million curies of radioactivity into the Columbia River and large quantities of chemicals into the soil column surrounding its reactors and spent nuclear fuel reprocessing plants. Additionally, fuel slug ruptures, chemicals added to the cooling water, and neutron activated particles and debris from reactor purging(cleansing) operations entered the river. Riverbed sediments and floodplain soils of the Hanford Reach constitute a sink for many of the pollutants released to the environment by Hanford's operations.

WASTE MANAGEMENT AND ENVIRONMENTAL RESTORATION (EM)

What has been the fate of the 100 million curies discharged to the Columbia River? Most of that radioactivity was very short lived and rapidly decayed away. Studies based on random sampling of locations along the Columbia River from Hanford to the coast are cited by DOE-RL to indicate that radionuclides do not pose a significant human health risk. However, random sampling of locations along the river ignores hydrodynamic characteristics of the river and the particle size of radionuclides discharged into the Columbia River. There are areas along the river where radionuclides will preferentially settle out. Declassified documents suggest, that during Hanford Operations, 98% of particles associated with fuel rod ruptures were less than 30 microns in size. Water velocity, river bottom roughness, particle density, shape, and size dictate sediment deposition. This suggests that radionuclides could preferentially concentrate in sediment deposits in the silt-size range.

Any shoreline activities which effect the flow of the Columbia River risk the remobilization of contaminants entombed within river sediments. For example, erosion is now occurring on Locke Island caused by a change of flow within the river. This change may be due to landslides in the White Bluffs, which result from irrigation tail-water. Even today, it is possible for the public to come into direct contact with neutron activated particles (cobalt-60) in the river sediment. On June 7, 1995, employees of the U.S. Department of Energy and its contractors, EPA, Washington State Departments of Health and Ecology met to decide on protocol to determine the risk associated with cobalt-60 particles known to be on D Island in the river. The Nez Perce Tribe is concerned that

contaminants left in place at depth in the soil column after the Hanford Site's remediation will result in further degradation of the Columbia River. If irrigation occurs on lands north of Gable Mountain and Gable Butte, the subsequent rise of the water table under the 100 areas could potentially remobilize contaminants and provide a pathway for contaminants to reach the Columbia River. A "Wild and Scenic Designation" of the Hanford Reach will help to protect public health and the environment by preventing the remobilization of contaminants entombed within the river's sediment and the shoreline's soil column.
Chromium polluted ground water at levels toxic (greater than 11 ppb of hexavalent chromium) to salmon redds (salmon nests) is entering the Columbia River. The pore-water sampling program confirms that hexavalent chromium is present in the gravel beneath the Columbia River. Salmon redds are present in these gravel areas. Sediments in areas near D reactor and H reactor have been sampled and have been shown to contain levels greater than 11 ppb of hexavalent chromium. The Nez Perce Tribe ERWM has proposed that DOE consider pumping ground water from the areas of highest hexavalent chromium concentration, treating this ground water, and then injecting this treated ground water in well bores along the bank of the Columbia where toxic ground water is entering the river. The injection of treated groundwater in the bank of the river could create a hydraulic barrier which would prevent concentrated ground water from reaching the Columbia River. Nez Perce ERWM staff also is concerned about the chromium plume associated with N reactor.

Cultural Resources

Another Hanford restoration project where the Nez Perce have been active participants concerns the restoration and revegetation of the former Environmental and Molecular Sciences Laboratory (EMSL) site. Human remains which were believed to be those of Indians were discovered during preliminary construction activities in 1994. As required by law, all construction on the project was postponed for 30 days during which time representatives from the four affected tribes developed recommendations on how to proceed. The Nez Perce Tribe ERWM agreed with the other tribes that the tribal members should be left where they were originally interred. As a result of these findings the EMSL site was moved to another location. The former EMSL site was recontoured and a native revegetation effort was undertaken. With funding from DOE, the four affected tribes established a native locally-adapted seed bank and nursery in 1993. Native plants such as sagebrush, rabbitbrush, buckwheat, Indian rice grass, and needle and thread grass have been successfully reintroduced on some areas of the EMSL site. These revegetation activities are planned to continue until 1998.

Technology Development

The Nez Perce ERWM have recently reviewed a sonic drilling method which is a relatively new technology used in FY 95. Wells drilled in FY95 used this method but the technology failed to meet the design criteria as substantial formation damage occurred during drilling and/or completion. The following problems were encountered when using this method:

1) Formation damage.
2) Inability to collect samples with a representative grain-size distribution.
3) Inability to collect undisturbed cores.
4) Possible formation damage increase with increasing hole-size.

5) The drilling method may not produce waste minimization a valid claim beneath the water table.

Mitigation

The Nez Perce advocate including the costs and plans for habitat restoration in the budgeted cleanup activities. Restoration activities include site characterization, revegetation, mitigation, and monitoring plans. The Nez Perce Tribe and other affected tribes have had direct involvement in restoration activities of the Environmental Restoration Disposal Facility (ERDF), a Hanford project. The ERDF is an inland disposal facility that will eventually be filled with contaminated material that is being removed from waste sites along the Columbia River. Native plants were salvaged prior to construction of the ERDF and transplanted to areas on the north slope of the Columbia River that had been disturbed as a result of cleanup activities. Since the ERDF site was constructed on undisturbed sagebrush habitat, the Nez Perce Tribe is also actively involved in providing input to the ERDF Mitigation Action Plan. The Nez Perce Tribe is also actively participating in other Hanford related issues which includes land use planning, protection of state and federal plant and animal candidate species, participation in cultural and ecological surveys, Columbia River impact assessment concerns, groundwater contamination, and review of focused feasibility studies and proposed plans.

As a result of these actions, the Nez Perce Tribe can claim that it is one of the key players that help DOE-RL save millions of taxpayers dollars. Although the Nez Perce Tribe has not always been properly consulted with, the Tribe is proud to say that it has played an important role.

The benefits of these efforts will help the Nez Perce Tribe in forming and promoting a tribal environmental restoration team that could be developed as a private enterprise for future Hanford remedial activities. This example of combining environmental justice with environmental restoration technology transfer could be a positive example that can be replicated at sites across the nation.

Public Education and Information

In 1983, the Nez Perce Tribe was found to be "affected," as defined by the 1982 Nuclear Waste Policy Act. A year later, the Tribe was funded to start the negotiation under the Consultation and Cooperative Agreement. The negotiation occurred in May 1987 and the Tribe was involved with the Basalt Waste Isolation Project (BWIP), in Hanford, a deep geologic repository project. Along with the stoppage of BWIP, funding for the Nez Perce also ceased. DOE created Environmental Restoration and Waste Management (ERWM, later changed to EM) in 1990, and the affected status of the Nez Perce Tribe was re-affirmed a year later. In 1991, the Nez Perce Tribe applied for a planning participation grant, which was funded in 1992, thus creating its ERWM Department. Since then, ERWM staff and its technical consultants provided technical and cultural comments and recommendations to many documents and activities that have been requested by DOE-RL. Concerns and issues of the Nez Perce Tribe include regulatory status, cultural or natural resources management, transportation emergency responses, risk assessment, Tribal religious freedom, technical/management capabilities, and others. On technical related issues at DOE-RL, the Nez Perce Tribe is a member of the Hanford Advisory Board (HAB), the Hanford Natural Resources Trustee Council (NRTC), and the Site Technology Coordination Group (STCG). On the regional and

national level, the Nez Perce ERWM is a member of groups such as DOE-HQ's Community Leaders Network (CLN), Stakeholders Working Group (SWG), and the Interstate and Regulatory Technology Working Group (IRTWG), and the State and Tribal Government Working Group (STGWG). The Nez Perce Tribe has regularly and consistently sent its technical representatives to meetings, conferences, and workshops which are sponsored by DOE, American Nuclear Society (ANS), Weapons Complex, US Environmental Protection Agency (EPA) Western and National Governors Association (WGA/NGA) and private agencies. It has also sent representatives overseas to visit a nuclear facility in Sellafield, England, and attended the 5th International Conference on Radioactive Waste Management and Environmental Remediation (ICEM) in Berlin, Germany and Global '95 in Versailles, France. Nez Perce ERWM have presented papers in WM'94 and WM'95, and Global '95. Currently, ERWM staff expertise encompasses geophysics, geology, bioresource engineering, statistics, wildlife biology and environmental science. With this expertise, the Nez Perce Tribe plans to contract cleanup related activities which will further its goals of building a scientific/technical infrastructure while protecting its treaty retained rights.

CONCLUSION

In the few short years that the Nez Perce Tribe has been officially involved at the Hanford site, the U.S. Department of Energy funding has allowed tribal participation to reach the necessary level of technical and program sophistication that is currently producing cost savings and building a stronger regional economy. The Nez Perce Tribe is aware of the possible funding shortfalls and makes no mystery of the fact that the Nez Perce ERWM Department is moving into the contracting arena. The Nez Perce ERWM Department is adding value to every federal dollar spent by transitioning some of its functions into the marketplace, by building an educated and technically capable workforce, by improving coordination of efforts on site, by piloting an effective tribal participation core program, and by offering new insights to environmental management practices and strategies.

21-5

TRANSLATING THE NEZ PERCE WORLDVIEW INTO ENVIRONMENTAL MANAGEMENT STRATEGIES

by
J. Herman Reuben
David F. Conrad
Barbara Harper
Nez Perce Tribe

ABSTRACT

The Nez Perce Tribe has developed the technical, scientific, and management expertise to offer input, in close government-to-government consultation, recognizing the federal trust responsibility to indian tribes, on many different levels of a national nuclear weapons contamination cleanup program, After a few short years of digesting the ongoing environmental management practices of the U.S. Department of Energy and its contractors, the U.S. Environmental Protection Agency, and the Washington Department of Ecology, the Nez Perce Tribe Department of Environmental Restoration and Waste Management is ready to offer its perspective on developing strategic directions and goals for the cleanup of the Hartford reservation in eastern Washington. The paper introduces the Nez Perce worldview and moves on to develop a concrete example of how

that worldview can be incorporated in setting cleanup goals and endstates. This paper examines the efficacy of developing values-based mission statements and performance measures to provide for cleanup, protection of Nez Perce treaty rights, continued practice of traditional Nez Perce activities, and multiple uses for the local non-Indian population, The paper concludes by showing the benefits of taking a landscape approach, in close consultation with the Nez Perce Tribe, to site-wide integration of remedial actions.

INTRODUCTION

The Nez Perce Tribe has been involved in nuclear waste issues since 1987 and the Basalt Waste Isolation Project (BWIP). Nez Perce involvement has always been somewhat constrained by the level of funding and the enormous task of wading through Department of Energy documents. Since 1992, however, the Nez Perce Department of Environmental Restoration and Waste Management (ERWM) has been attempting to define its own agenda. We are moving beyond document review, and into shaping strategic policy directions. One such strategic policy direction is incorporating a Nez Perce worldview into environmental management practices, from risk assessments to technology development. This paper will introduce the Nez Perce worldview and how that worldview and accompanying values shape the Tribe's environmental management decisions. We will also touch on how the value-adding practice of incorporating this worldview might help others' making environmental management decisions.

Today, as the Nez Perce ERWM Department matures, we are defining our own path in Nez Perce terms that others can understand. This path follows the same direction as those of the Tribe's traditional past, however we are using radically different technologies to help us along this different new path. We feel pressure to develop this new path from internal sources as a way of incorporating new, and necessary, technologies into our lives in a way that minimizes the cultural impacts. We are also developing this new path for external consumption. People and governments are making decisions that affect our lives. We are developing processes to inform strategic directions in environmental management that incorporate Nez Perce values, in the hope that such processes and directions will find greater acceptance. This education through process development has the added benefit of introducing Nez Perce values, making them less "mystical," doomed to be forever too "ethereal" to be the basis for any serious decision making.

We cannot expect anyone to understand Nez Perce values and interests as the Nez Perce do, however, we can translate, or transliterate, these concerns into the larger society's lingua franca to ensure we are not marginalized. But more importantly, we must transliterate this worldview for the larger society, because with our help, we believe that the United States, and the world, can achieve more fundamental environmental protection with less red-tape in a shorter period of time.

VALUES, RIGHTS, AND CONCERNS

The Nez Perce people have been here since time immemorial and think about the consequences of their actions in terms of hundreds if not thousands of years. While planning that far in advance may seem impossible, it reveals a culturally conservative worldview, one that attempts to implement a survival plan based on thousands of years of collective wisdom. This wisdom is passed down from generation to generation in a context that brings the past alive and encourages thoughtfulness for generations to come.

Before a child could walk, he was taught cultural and traditional values, the parents knowing that experience was the greatest teacher began teaching their children to honor and respect the properties of Mother Earth, as provided by the Creator. The children were taught that these properties of Mother Earth, the land, animals, plants and forests were never owned, but to be borrowed and used for their subsistence and they were to give thanks for their use. Nez Perce children were taught to always leave/give something in return to replace what had been taken. For centuries, each year the bands, families, friends and neighboring tribes gathered in the springtime for a thanksgiving feast called, "Ka-oo-yet." Giving thanks meant sharing salmon, roots, and traditional foods as a tribute to Mother Earth and the Creator. Thanks was again given in Autumn for the harvest of traditional foods. This practice continues today, however the salmon are endangered, traditional foods and berries are becoming scarce, and access to traditional use areas are increasingly limited. Maintenance of these traditions and values ensures the protection of resources through reverence for life and humility before creation. This reverence for life and humility, for the Indian, is inseparable from the identity of individuals, families, bands, and tribes.

The contrasting view of environmental protection found in the non-Indian world of the United States frustrates many Indian people because it is media specific, contaminant specific, and divided into human and ecological risks, administered through "stove-piped" programs and funding. The contrasting, reductionistic view of problems and solutions is evidence of a different worldview, a worldview that does not necessarily lend itself to environmental protection easily. The Nez Perce worldview translates into practice through time consuming, and often contentious dialogue. This dialogue is conducted within a set of given cultural parameters. The introduction of new ways of understanding threats and solutions (risks and technology developments) in the arena of nuclear weapons cleanup is both a cultural and democratic challenge.

OPEN DECISION PROCESS

How questions are asked is sometimes almost as important as the questions themselves. A tribal dialogue on plutonium disposition, for example, cannot take place without presenting the technical and political considerations against the array of tribal legal, cultural, political, and natural resource considerations. Developing this complex matrix of concerns to arrive at an answer can be a daunting task, but questions such as plutonium disposition must be considered by the Tribe. Crafting an answer might be a time consuming process, but the longer it is discussed, the more it is related to other daily tribal concerns, the more it will become part of Nez Perce reality. The long-lived nature of plutonium and other radioisotopes requires the Tribe to incorporate these concerns into the collective Tribal experience. Lessons learned from this question and answer exercise can be transferred to non-tribal society as an example of establishing low-tech longevity of information within a society.

The first step to opening this dialogue must be based in the traditional Nez Perce value practice of seeking an answer respectfully and with a commitment to honor the answer. We must carefully ask the whole question of plutonium disposition in a way that shows respect that we have for those we are asking. A carefully asked question will hopefully elicit a carefully considered answer. Perhaps the Tribe will not be willing to

share the whole answer(s), or may not give the answer the U.S. wants to hear, or may even give an ambiguous answer(s) that can stimulate further dialogue that can lead the U.S. to a better solution. In any case, it is a question we must ask of our Tribal public, and one that will prove to be useful, not only for the example of incorporating tribal values into decision-making processes, but also in how tribes create and sustain open and democratic processes.

For the Nez Perce Tribe formal decisions are made within a constitutional structure; however, there is more to forming that opinion than the simple voting at General Council, or by resolution from the Nez Perce tribal Executive Committee (NPTEC). The way decisions are made, through the various formal and informal mechanisms, constitutes the Nez Perce decision making process. The scope of the decision making process varies from decision to decision; however, in attempting to answer a question such as plutonium disposition the Nez Perce ERWM Department is not only looking for the answer. It is also attempting to give the process greater transparency for the benefit of the Nez Perce people, and for the benefit of our partners in the field of environmental management.

The formal structure of the Nez Perce decision making process is found in the 1961 Constitution, as revised. The Nez Perce tribe has an elected body consisting of nine members called the Nez Perce Tribal Executive Committee (NPTEC). This governing executive committee is responsible for the protection of Tribal sovereignty, including protection of Tribal rights in Nez Perce ceded territory and areas over which the Nez Perce exercise off-reservation treaty rights, and promotes the health, education and welfare of the Tribe. The NPTEC members are elected from the Tribal membership by the Nez Perce General Council, which includes all eligible voting Tribal members. Both the General Council and the NPTEC are governed by the Revised Constitution and Bylaws of the Nez Perce Tribe. The Constitution and Bylaws describe the duties and responsibilities of the NPTEC and General Council. Any enrolled Nez Perce Tribal member may address any issue before the NPTEC or the General Council.

Prior to the adoption of the Constitution and formation of the Tribal Council, all issues were discussed before a Tribal General Council meeting, called for that specific purpose. The General Council Chairman, Vice-Chairman, and Secretary were elected by special election. The meeting, called by the Chairman, lasted no more than two days to discuss the issue at hand. This early General Council system resembled a council of elders, as they discussed Treaty rights, traditional practices, and cultural impacts before making a decision. Today, the General Council is attended by both young and old, but special committees are usually reserved for elders to research issues and evaluate impacts to culture, traditional practices, and treaty rights. These special committees make recommendations to the General Council and these are then often forwarded to the NPTEC for final resolution. This process ensures direct democracy, and several cultural and political screens that will make a decision "Nez Perce."

SOVEREIGNTY: DUTY TO NEZ PERCE COMMUNITIES

In conjunction with the Nez Perce duty to protect its treaty rights, the environment, culture, and welfare, is the duty to educate its members and neighboring public to its activities. The Nez Perce Tribe assumes many different roles and therefore has the responsibility to protect and enhance these relationships in a uniquely Nez Perce way.

The Nez Perce Tribal is a governmental entity with certain powers and authorities derived from its inherent sovereignty, status as land owner, and delegations from the Federal government. The Nez Perce Tribe exercises its powers and authorities to serve its members and to regulate activities occurring on the reservation. The Nez Perce Tribe is a cultural entity, accordingly charged with the responsibility of protecting and transmitting that culture which is uniquely Nez Perce; the Nez Perce tribe is also the beneficiary within the context of federal trust relationship, and consequently has obligations to other Indian Tribes.

The U.S. Department of Energy planning activities touch, in some way or other, each of these roles of the Nez Perce Tribe--and particularly so when the Tribe acts in its cultural, treaty, and trustee roles. The understanding iterated in this paper reflects the diverse interests and responsibilities of the Nez Perce Tribe.

Nez Perce vis--vis the Department of Energy

The relationship between the Nez Perce Tribe and DOE around the planning issues is defined by the trust relationship that exists between the federal government and the Tribe, by the DOE American Indian policy, and by the mutual and generally convergent interests of the parties in the efficient and expeditious cleanup of the Hanford site and other areas. For example, the Nez Perce Tribe sees itself not only as an advisor to DOE, but also as a previously untapped human resource pool of scientific and engineering personnel that will be available to assist the Department in the 21st Century. The Nez Perce Tribe also sees its members as a pool of technically trained and certified labor force for environmental restoration and decontamination and decommissioning work. The cooperative agreement between the Nez Perce Tribe and the U.S. Department of Energy outlines an approach that will integrate these and other roles into a comprehensive Nez Perce-DOE program.

Relationships with Tribal Members and the Reservation Community

The Nez Perce Tribe views its primary responsibility toward its members as protection of Tribal treaty rights. However expansive that responsibility may be, Tribal leadership would be remiss if that were the only focus of the proposed relationship between the Nez Perce Tribe and DOE. The Nez Perce Tribe also has an obligation to educate its members and the reservations community of its and DOE's activities at Hanford. This will mean reaching into the Headstart Program; elementary and secondary schools; and the Tribal reservation communities and general public. The Tribe also must examine the employment and economic and business development opportunities presented by the cleanup at Hanford and must create programs that will enable Tribal members to realize these opportunities.

Relationship with Non-Human Community Members

Native American healing practices have been historically misrepresented, either through ignorance or with exploitative intentions, however, as an aspect of the Nez Perce duty to our non-human community it seems necessary to explain, at least partially, what this relationship is. For centuries the Indian has used natural resources and borrowed from the land for his subsistence, taking roots, berries, and herbs for foods and medicines. The animals, birds, and fish were his clothing and food. His knowledge of the land and the resources it provided gave him the power and control of traditions, culture, and religion of his choosing. He was taught by his elders and parents from early childhood and eventually

became superlative in the use, knowledge, and care of natural/cultural resources. These powers were enhanced when and if an individual received a vision, or "wa-ya-kin," thus gaining knowledge and spiritual support from an animal or thing. These special powers were recognized by his people throughout his lifetime, usually by taking the name of the animal or a piece of the animal that he wore as part of his apparel (i.e. "rabbit-skin leggings"). In addition to the spiritual knowledgeof the special animal, the individual became versed in the different types of herbs, roots, barks, leaves, and berries to be used as medicines that could be taken by eating, drinking, smoking, application to wounds or the skin, or by other means. Application of the medicines was usually accompanied by chanting, singing, rattles, and sometimes dancing, which actions were requests for assistance from the spirits of the special plants and animals.

Relationships with Other Indian Tribes and Tribal Organizations

The Nez Perce Tribe views its role within the DOE planning context as operating on two levels. The first, and most important, is obviously the Tribe's role as advisor to the site-specific cleanup of the Hanford site. However, the Tribe realizes that its consultation with DOE will be viewed by both the Department of Energy and other Indian Tribes whose interest in the DOE environmental management planning process are not as compelling, as representatives of American Indian Tribes in general. This is not an unrealistic concept. The fact is that the Tribe must prepare and act on these two levels. It must carry out the oversight, monitoring, and analysis necessary to be a strong advocate for Tribal rights at the Hanford site and must be able to extrapolate from the site-specific analysis the generalized concerns that are relevant to American Indian Tribes across the country. We believe, the transportation issues and planning for human resource development fit into this category. The Nez Perce tribe believes that it can and must operate on these various levels to act as a credible representative of general Tribal interests in environmental management decisions.

With this introduction to the values, decision making process, and responsibilities to the various communities of the Nez Perce Tribe we move on to a discussion of basing environmental management decisions on more project-specific information.

DEVELOPING VALUES-BASED MISSION STATEMENTS AND PERFORMANCE MEASURES

The current Hanford mission statement ("cleanup Hanford") is really a "means" goal rather than an "ends" goal. Hanford is being remediated for reasons in addition to the fact that cleanup is good. However, site-wide target endstates have not been defined, and therefore performance measures that apply during remediation have not been clearly defined. The dangers of beginning massive cleanup before endstate goals have been defined should be readily apparent. For example, proceeding with excavation before defining the target endstate could result in permanent loss of habitat, whereas initially setting an environmental management goals might result in the selection of remedial technologies that are less intrusive. It is not sufficient to begin excavation on the assumption that eventually it will become clear when to stop, and that appropriate restoration measures can be designed at some time in the future when endstate land uses have been clarified. Similarly, a temporally phased cleanup might result in initial cleanup to brownfield standards, thus allowing industrial development in an area later targeted for ecological preservation. Both of these examples violate the decision

principle of preserving future options for natural resource management and multiple land uses.

If a higher site-wide goal, such as "preserve the eco-cultural landscape," is articulated early in the decision process, then several things happen. First, agreement about higher-level goals may reveal commonalties among the Nez Perce Tribe and other potential endstate "user groups" that were formerly unrecognized. Second, the list of technical options could likely increase. Third, conflicts about each isolated action may diminish if site-wide, holistic, values-based goals are developed and enforced. Fourth, both external groups and internal program managers will be able to relate individual actions to real progress.

Scope of Analysis Required to Support Broad Management Goals

Strategic planning efforts frequently fail to recognize that the choice of a strategy can significantly influence the endstate. For instance, a narrowly defined risk reduction strategy automatically relies on certain types of information and excludes other types. Conventional environmental safety and health (ES&H) strategies typically focus solely on reducing human exposure, with only minimum attention to environmental and ecological goals, and no attention to cultural values-based goals (Fig. 1). If reducing (or avoiding) human exposure is the sole risk performance measure, then other types of risk (accident probabilities, probability of ecological impacts, probability of cultural impacts, and so on) may not receive adequate attention of budget. Programmatic risk may actually increase if performance measures are too narrowly defined and if the decision logic fails to identify uncertainties in the path forward. Decisions are more stable (i.e. technically defensible and politically acceptable) if they are linked to broad management goals; this in turn requires a broader (but not necessarily data intensive) information base. There is much more to health than just the absence of exposure, and the Nez Perce identify at least three types of health: physical, spiritual, and emotional. Further, there is more to risk reduction than just reducing the probability of adverse human health effects. One approach that is inherently more suited to indigenous values and holistic perspectives is Comparative Risk (Fig. 2). Comparative Risk (7,8) is clearly more comprehensive than human exposure-based assessments. It also captures Quality-of-life concerns, which we have termed "Culture" to include concepts about Nez Perce culture and the ability to practice traditional activities. The three types of impacts (health, environment, and culture) together give an indication of the impacts to, or health of, holistic Circle of Life. The Circle of Life, reflects the culmination of indirect health effects, the conclusions of community-based knowledge on how contaminants affect the community's cultural identity, knowledge of elders about what natural resources really mean to Nez Perce people, and inherent rights of all species (modified from Cole, (2)). In Nez Perce reality, the Circle of Life also reflects the concept that there is a single "essence" that extends to the bounds of the Earth, that every natural thing originating from the Earth represents a local or mobile manifestation of that essence, that each thing is connected to every other thing through the shared essence, that therefore harm to any of those components also harms the whole.

Fig. 1

Fig. 2

When assessing risks in practices, a tribal risk model might incorporate information about culture-specific foods, medicines and other materials

obtained from the study area, provided that the assessment is designed to avoid the necessity of revealing confidential information. In fact, most standard exposure equations cannot truly use this information in the first place, because species-specific uptake factors are usually unavailable. Therefore, careful assessment design can adequately reflect exposures that might reflect exposures that might occur during a set of traditional activities without compromising confidentiality. Similarly, ecological species of particular cultural importance will likely be different from threatened and endangered species, but artificial (computer) foodweb models that list multiple species but lack species-specific contaminant transfer factors will limit the usefulness of gathering sensitive or confidential information.

The importance of including the full list of stressors in the evaluation cannot be overemphasized. Because decisions about environmental remediation or waste management are usually focused on chemicals and radionuclides and the environmental media or facilities that contain them, other stressors may be excluded from the decision process. For example, Hanford habitats and treaty-reserved rights are at just as much risk from political (zoning, boundary creep, reduced budgets), legal (denial that treaty rights exist, adverse land use designations), institutional (closed decision processes, denial of access to traditional lands and resources), physical (expanding infrastructure, habitat fragmentation, clean fill mining) and aesthetic (noise, visual impacts, shrinking buffer zones around sacred sites) impacts as they are from contamination. If this is recognized early in the decision process, it is more likely that values-based mission statements will adequately reflect Nez Perce concerns. If it is not recognized, then decisions typically become technical problem statements that lose direct links to values and may ultimately be rejected or cause costly mid-course project corrections.

TRANSLATING TO ENVIRONMENTAL MANAGEMENT STRATEGIES

The last step in the planning process is to evaluate alternative means of achieving each target land use; since the target endstates were clearly defined in the previous step, alternative solutions can be more precisely selected. In addition, cost, schedule and worker exposure during remediation are modifying factors in project implementation rather than insurmountable obstacles that might automatically preclude further consideration of the preferred endstate.

At Hanford, a common misperception is that traditional indigenous land uses, habitat preservation and general recreational uses (e.g. bird watching, fishing, hunting) are entirely different endstate designations that are mutually incompatible. A related misperception is the "pristine or nothing" label applied to tribes when they push for maximum remediation and restoration. Ultimately, the Nez Perce Tribe has a trust duty to their members to protect treaty rights, human health and natural resources. However, once this is acknowledged as the ultimate goal for the site, then a wide range of mutually-compatible activities is possible during interim phases of cleanup.

CONCLUSION

The nuclear waste cleanup experience gained by the Nez Perce tribe continues to grow and gain technical sophistication. The Nez Perce Environmental restoration and Waste Management Department is involved in a number of remediation, environmental restoration, technology development, and waste management activities. After a few short years of

digesting the current processes and schools of thought involved in these various activities, the Nez Perce Tribe is attempting to synthesize these "technologies" with its values, offering an alternative way of conceptualizing one path to holistic environmental management goals. The Nez Perce Tribe subscribes to the theory that close consultation is an educational tool for everyone involved. Through this educational process the Nez Perce Tribe offers to share its collective wisdom and practical advice, obtained through thousands of years of trial and error, and maintained by culturally conservative practices. The Nez Perce Tribe has a duty to contribute to solutions for the problem encountered in the filed of environmental management. In return, the Nez Perce Tribe expects that through this educational process of consultation others will begin to grasp the full scope of humankind's duty to the environment.

ABSTRACT

The WERC/FAST Initiative embodies the merits of two successful programsthe Waste-Management Education and Research Consortium (WERC) and the Fast-track Advancement of Significant Technologies (FAST). In the accomplishment of its mission, WERC hosts an annual environmental design contest, the only environmental process design competition of its kind in the United States that provides university participants with design, as well as practical, experience on real environmental problems. The intent of FAST is to leverage a small amount of funding from the U.S. Department of Energy (DOE) to make potential users at DOE sites more comfortable with existing technologies to solve specific problems by providing quality treatability testing to document performance. This synergistic relationship of the two programs concentrates on moving promising technologies selected during the WERC environmental design contest to a field-ready level. DOE, through the Office of Environmental Restoration, has tasked the FAST Program to provide financial support to the universities selected in the WERC competition to perform treatability studies and performance testing. This testing is conducted in cooperation with WERC and the DOE site sponsors of the problems.

INTRODUCTION

Many mechanisms exist for the promotion of environmental technology, particularly those that are considered to be "innovative." The U.S. Environmental Protection Agency (EPA) has its SITE (Superfund Innovative Technology Evaluation) program, the VISITT (Vendor Information System for Innovative Treatment Technologies) database, and numerous publications to spread the word about environmental technologies. The U.S. Department of Defense (DOD) has prepared technology screening matrices, publications on technology demonstrations, and environmental management "good news" stories. The U.S. Department of Energy's (DOE's) technology development program issues programmatic and site-specific summaries of technology demonstrates and related projects, has conducted workshops to promote technology transfer, and has distributed technology information in a "baseball card" format. Despite all these efforts, technology vendors and providers continue to complain that their technologies are not used and environmental restoration problem holders continue to complain that existing technologies are inadequate to fulfill their needs.

Some of the barriers that hamper technology use include the following factors:

Sources of technology information, such as publications and databases, are not always reliable because much of the information is supplied by the technology vendors and providers to promote their products or services and often do not include adequate data on performance and cost.

The belief that just because a technology worked at one site, it won't necessarily work at another (i.e., the "my-side-is-different" syndrome).

DOE sites, used to doing everything in-house, sometimes suffer from the "not-invented-here" mentality.

Decisions to use a particular technology are often made by committee (e.g., EPA, State, community, and responsible party) or require adherence to a stringent permitting process. These conditional factors can contribute to second guessing about the acceptability of a technology.

Those responsible for cleanup of environmental problems often want a "risk-free" solution.

The agencies tasked with the lion's share of the nation's cleanup effortsEPA, DOD, and DOEhave several efforts under way that focus on removing barriers to technology use. The Federal Remediation Technologies Roundtable and the Western Governors' Association DOIT (Develop on-Site Innovative Technologies) committee are among the multiagency organizations that are working on these issues. DOE has established the National Environmental Technology Applications Center to promote the commercialization of technologies by assisting them through the so-called "valley of death" where technologies languish for lack of a champion. Environmental centers have also been established at other DOE sites (e.g., Oak Ridge National Laboratory, Lawrence Livermore National Laboratory, Rocky Flats Environmental Technology Site), and programs (e.g., Technology Connection Program) and hot lines have been started that focus on dissemination of technology information. DOD has aggressively pursued the use of new technology in its cleanup of McClellan Air Force Base in California and through its Air Force Center for Environmental Excellence. In addition, the State of California's EPA has established a program to certify environmental technologies that have proved successful in remediating sites. However, many of these endeavors are in their infancy and some are still trying to formulate their strategies for promoting environmental technologies.

For individuals in the field who are responsible for the cleanup of an environmental problem in the very near future, is there a more expedient way for them to understand and accept the inherent risk of using an innovative technology? We believe there is, and it's known as the WERC/FAST Initiative.

BACKGROUND

The WERC/FAST Initiative consists of two separate programs, established for two different objective. In combination, these programs provide a unique opportunity for problem holders to identify and to become comfortable with innovative solutions. The term "comfortable" is used to convey the psychological state that decision makers have when they are willing to accept the risks of using an innovative approach. WERC is the Waste-management Education and Research Consortium, which is a nonprofit collaborative program whose members include universities, colleges, and national DOE laboratories located in New Mexico. The mission of WERC is to expand the nation's capability to address issues related to the management of all forms of waste through education, technology development, and information transfer. As part of its mission, WERC hosts an annual Environmental Design Contestthe only environmental process design contest of its kind in the United States that provides university participants with design, as well as practical, experience on a real environmental restoration (ER) or waste management (WM) issues. Many of the design problems are actual DOE ER and WM projects sponsored by sites that are actively seeking solutions.

FAST is the Fast-track Advancement of Significant Technologies, which was initiated in 1995 by DOE's Office of Environmental Restoration and leverages a small amount of funding to make potential users at DOE sites more comfortable with existing technologies. This reassurance is primarily accomplished by providing high-quality treatability studies to document performance. The intent of FAST is to be fast and independent, to provide head-to-head testing with baseline technologies to benefit

technology owners that cannot afford quality testing, and to allow these technology owners to retain all proprietary rights. Because the FAST Program directly involves DOE sites in the selection of technologies, it fosters a working relationship between industry and the users at the DOE sites.

The synergistic relationship in both WERC and FAST Program provides an opportunity to develop an approach that embodies the strengths of each program and enhances their respective capabilities. This relationship, known as the WERC/FAST Initiative, concentrates on moving promising technologies selected by the sponsoring sites during the WERC environmental competition to a more field-ready level. DOE, through the Office of Environmental Restoration, has tasked the FAST Program to provide financial support to the universities selected at the environmental design contest. The universities, through cooperation with WERC and the problem sponsors, conduct treatability studies and performance testing.

FAST PROMOTES OWNERSHIP

At the heart of the FAST program is the "blood, sweat, and tears" approach. When an individual or organization strongly supports a position, it typically is not because someone else has said that "this position is good for you;" rather, it is because the individual or organization has put its own efforts into the realization of that position. When we invest our own blood, sweat, and tears into a position, we are likely to support it and take the risk associated with implementing that position. An excellent example of this sociologic trait is the Habitat for Humanity program. Under this program, the recipients of housing upgrades participate in the rehabilitation or construction of a structure and, therefore, invest "sweat equity" to gain ownership. As a result, they develop pride in a home that does not generally occur when the work is provided solely by others.

Table I presents a comparison of the basic goals and principles of the Habitat for Humanity program and how the FAST mission emulates this program.

Table I

FAST implements this approach through site involvement in the identification of existing technologies that have potential benefit to solve their environmental problems but lack sufficient performance testing to receive their acceptance. To acquire this important performance test data, the FAST Program provides fundingbut only if the sites interested in the technology agree 1) to leverage site funding and/or provide in-kind support (e.g., engineering, laboratory analyses, health and safety) to perform the performance testing; 2) to work with the FAST Program to identify the performance objectives and the test plan for the technology; and 3) to seriously consider using the technology if performance testing indicates its acceptability. By directly involving DOE sites in the selection of technologies, a working relationship is promoted between industry and the users at the DOE sites.

THE VALUE OF THE WERC ENVIRONMENTAL DESIGN CONTEST

The value of the WERC Environmental Design Contest to a DOE site can be expressed best by the enthusiastic sentiment that one 1995 sponsoring site, the Hanford Site, had for the competition. Hanford personnel stated, they "... would recommend participation [in sponsoring a problem] to any organization seeking novel solutions to technical problems for a relatively low investment. The research and testing that took place would

have cost between 1 and 2 orders of magnitude to duplicate. It is unlikely that much, if any, of the work would have been approved for in-house development owing to the uncertainties of results versus cost...."

WERC estimates that for every problem sponsored by a site, the participating universities provide a combined 40,000 hours of research labor. The return on investment for each site that sponsors a problem is conservatively estimated to be 20 to 1. Each graduate and undergraduate university team prepares a technical paper on its technology, presents oral and poster presentations, and performs benchscale demonstrations.

For the 1995 competition the DOE site sponsors were Rocky Flats (treatment of solar pond sludges), and Hanford (retrieval of salt cake from high-level waste tanks). More than 20 universities accepted the challenge of developing practical solutions for each of these problems.

FASTHOW IT LEVERAGES WITH WERC

The common thread between WERC and the FAST Program is the insistence that problem holders invest their resources (money and expertise) into the process of identifying and testing potential solutions. This investment of sweat equity furthers the likelihood that the problem holders will assume ownership of the technologies and actively pursue their implementation. This common thread strengthens the synergism between the FAST Program and WERC.

THE 1995 WERC/FAST INITIATIVE

During the 1995 WERC Environmental Design Contest, the judges identified five entries with promising solutions for the two specific DOE problems being used in the competition: treatment of solar pond sludges (Rocky Flats) and retrieval of salt cake from high-level waste tanks (Hanford Site). Criteria used to select the technologies for FAST sponsorship were developed with site participation. Approximately 25 individuals representing DOE, DOE contractors, EPA, State regulators, engineering consultants, industry, and academia judged the WERC competition. The two DOE sites reviewed the recommendations of the judges and concurred that three of the solutions had sufficient interest to the sites to warrant further refinement of those technologies to a more field-ready level. Through FAST, WERC supported students during the 1995 summer months to refine the technologies. The selected universities and their technologies are

University of Oklahoma, Norman: modified borehole mining system for material removal (for Hanford Site problem).

University of Alabama at Huntsville: a removal system that uses a pneumatic steel-pellet blaster device with magnetic retrieval (for Hanford Site problem).

University of Idaho, Moscow: use of naturally occurring apatite to immobilize heavy metals in solar pond sludges (for Rocky Flats problem).

Each university was assigned specific objectives to achieve for its technology. The University of Oklahoma needed to perform some initial scoping tests to determine a good water temperature and jet-cutter nozzle design for the bench-scale tests of its borehole mining system. Additional quantitative data were required to identify parameters and values that are most critical to material removal: salt removal rate versus water temperature, nozzle orifice design, water pressure and velocity, water flow rate, and distance between nozzle and the salt for a range of the parameters.

The University of Alabama at Huntsville approach uses a steel-shot blasting technique that is similar to sand blasting with the advantage of

magnetic recovery of the shot from the waste stream. Tasks included obtaining a suitable air blast gun from a commercial vendor and conducting quantitative tests to compare its performance to salt cake removal with sand blasting. Other activities consisted of determining optimum air pressures and airflow and selecting steel shot and nozzle sizes to assess the potential of this technique for cleaning the walls of tanks at the Hanford site.

The University of Idaho needed to determine if the naturally occurring mineral apatite would be an appropriate admixture to stabilization mixes for immobilizing heavy metals in solar pond sludges at Rocky Flats. This technique has been used at Superfund abandoned-mine sites and has been investigated by Pacific Northwest Laboratory. Team assignments included tests to identify the performance range of various types of apatite at different ratios of salts, water, and pozzolan to determine an optimized formulation for immobilization of heavy metals while maintaining structural integrity of the final waste form.

General objectives for each technology consisted of 1) identifying outstanding issues relative to each technology that need resolution before full-scale implementation can occur, 2) preparing a fact sheet about each technology, and 3) demonstrating each technology at either the Hanford Site or Rocky Flats and giving an oral presentation of the findings to DOE and the sites' operating contractors.

Kick-off meetings were held at Hanford and Rocky Flats in July with all the parties involved in the 1995 WERC/FAST Initiative, including students and site representatives. Students were able to tour the sites and see the problems that their technologies address. Basically, they were afforded the opportunity to "kick the tires" of the problem. Guidelines were developed for the testing to be performed by the students during the summer and were agreed upon by the sites. All the students' activities have not been completed.

The University of Idaho presented the findings of its chemical engineering students to representatives of Rocky Flats, WERC and FAST. Test results indicate that the use of apatite in the proposed grout formulation could stabilize the process sludge to meet waste acceptance criteria. The best apatite material seems to be commercially available fish bones rather than mineralized apatite. Rocky Flats representatives will now use this information to assess the use of apatite on actual radioactively contaminated sludges. The use of apatite as a geochemical barrier for a mixed-waste repository at the site is also being considered.

Presentations to Hanford Site personnel by teams from the University of Oklahoma and the University of Alabama at Huntsville also offered solutions to problems. Results achieved with Oklahoma's water-jet device (34.5 megapascals [5,000 pounds per square inch] unconfined compressive strength) on hard salt cake had a fivefold to sixtyfold increase in removal rate with 66C water in comparison with 16C water. Alabama's pneumatic steel-pellet blaster retrieved salt cake at a rate of 10 cubic inches per minute. While that rate probably is not fast enough for bulk retrieval, this method could be used for cleaning tank walls or internal portions of structures. The Hanford sponsors noted that "...this is the only entirely dry waste retrieval method to have even limited success on material this hard." The management of the High-Level Waste Retrieval program exemplified the site's interest with a request to the two universities, in cooperation with WERC, to support the refinement of

their technologies for use with the robotic manipulator arm being perfected at the Hanford Site.

IS THE WERC/FAST INITIATIVE SUCCESSFUL?

One sign of success is the commitments by the problem holders at the sponsoring sites to advance the technologies to the next step in readiness for field use. Both Rocky Flats and Hanford affirmed their intents to use these technologies. This step of embracing the technologies the students developed in the WERC environmental design contest, enhancing the technologies by leveraging funds from FAST and in-kind support from the problem holders, and actually moving toward field-ready applications of the technologies demonstrates the success of the WERC/FAST relationship.

Another sign of the success of a WERC/FAST Initiative is the desire of other sites to participate and to allocate their resources into sponsorships. Although this is the first year for the WERC/FAST Initiative, three sites have agreed to fund the sponsorship of problems for the 1996 WERC Environmental Design Contest. The Idaho National Engineering Laboratory problem involves the remediation of a series of 1,900- to 190,000 liter (500- to 50,000 gallon) underground mixed-waste storage tanks and surrounding soil. Savannah River Site's problem is the remediation of radioactively contaminated vegetation with a method other than incineration. The third problem is a waste management issue at Rocky Flats involving the treatment of industrial machining filters contaminated with a hazardous solvent and plutonium particles. These sites will provide additional support in the form of in-kind services to develop test plans under the FAST portion of the initiative and will offer consultation and mentorship to the universities selected to further the field implementation of their solutions.

THE WERC/FAST INITIATIVE MEETS DOE'S NEEDS

The WERC/FAST Initiative stands up to DOE's tough demands for strategies that are customer driven, practical, cheap, and flexible. One of the criteria for acceptance into the WERC/FAST Initiative is needthe technology must meet the needs of DOE sites, regulators, and stakeholders. Because the students who compete in the WERC Environmental Design Contest must use technologies that they are confident will work, existing technologies are selected and are often innovatively adapted. This use of existing technologies avoids long-term research and development efforts and benefits DOE sites by furnishing more performance data for site-specific applications. Small investments in performance testing that are leveraged through both WERC and FAST produce large results for the DOE complexproven technologies. The inherent flexibility of FAST allows adaptability, such as the WERC/FAST Initiative, to meet changing real-world needs and offers opportunities with solutions to environmental problems.

ACKNOWLEDGMENTS

This work was performed under DOE Contract No. DE-AC04-94AL96907 for the U.S. Department of Energy; Daniel Varhus is the DOE Grand Junction Projects Office project manager. This program would not be possible without the support of our DOE Headquarters sponsor, Lawnie Taylor, Office of Program Integration. Abbas Ghassemi of the University of New Mexico, Albuquerque, was instrumental in the development of the WERC/FAST Initiative; that aspect of FAST was possible because of his backing.

STUDENT DESIGN PROPOSAL FOR MECHANICAL MOBILIZATION AND RETRIEVAL OF RADIOACTIVE WASTE FROM UNDERGROUND STORAGE TANKS

ABSTRACT

A student design team produced a conceptual design and planned a project for safe and cost effective removal of radioactive waste from underground storage tanks. The proposed design concept differed from baseline sluicing and remotely controlled manipulator arm technologies. Advantages of the design concept were identified as simplicity in deployment, operation, automation and maintenance, as well as potential for improved reliability over the manipulator arm technologies. Little or no additional radioactive waste would be generated. Legal and regulatory requirements, and health and safety considerations were taken into account in the project planning. All applicable legal and regulatory requirements were reviewed and actions were identified for compliance with these requirements. Legal and regulatory requirements included compliance with general radiation protection standards, standards for packaging and transport of radioactive waste, environmental regulations, procedures for decommissioning and decontamination of equipment and community right-to-know laws. A health and safety plan was produced which included monitoring of radiation levels, administrative and engineering controls and an emergency action plan. A plan for ensuring good community relations was identified which included public information meetings and information brochures describing the reasons for and the risks associated with the proposed project. A business plan and economic assessment indicated the viability and cost effectiveness of the proposed approach, based on present value project costs for waste removal from two tanks in a 34 month period.

INTRODUCTION

A group of eight students, five mechanical engineering seniors, one chemical engineering senior, one industrial hygiene senior and one MBA student produced a conceptual design for a mechanical system capable of mobilizing and retrieving radioactive wastes from underground storage tanks. The waste composition, storage tank specifications and other design requirements were those issued by the Waste-Management Education and Research Consortium (WERC) for the 1995 International Environmental Design Contest (1). The storage tanks were assumed to be located in Las Cruces, New Mexico, according to the contest rules. The single-shelled, underground storage tanks specified in the competition rules contain high level radioactive waste, varying in consistency from hard saltcake to sludge. Access to the interior of the tanks and,therefore to any equipment operating inside of the tanks, is severely restricted due to radiation levels. Because of this, any proposed waste retrieval system should be very reliable, simple to maintain and must be easily automated. The proposed concept met these requirements and avoids past practice sluicing which creates additional radioactive waste, and is significantly simpler than multi-degree-of-freedom manipulator arms, the other baseline technology.

RETRIEVAL SYSTEM DESIGN CONCEPT

After an extensive design tradeoff study, a rotating cutting device to mobilize the saltcake supplemented by an air conveyance system to remove the waste from the tanks was chosen for further consideration. The contest mailings (1) stipulated that the baseline, multi-degree-of-freedom manipulator arm technology and past-practice sluicing should be precluded from the proposed solutions. Several other alternative concepts were also considered but were determined to be inferior to the chosen one based on a sum of weighted attributes criterion or Pugh chart (2) analysis. This evaluation, however, did not include detailed design considerations or a detailed cost analysis because of time constraints.

Fig.1

Preliminary testing using a recipe for simulated saltcake supplied with the contest mailings revealed that typical cutting tools alone would not be likely to break up the hard saltcake to a form suitable for air conveyance, at least not in a time and energy efficient manner. However, it was hypothesized that, because of the brittle nature of the saltcake, its resistance to fracture could be significantly reduced by first "scoring" it (i.e. cutting a series of parallel grooves in it). Breakup of the material could then be accomplished by subsequent cutting with a high speed cutting wheel perpendicular to the grooves. Experiments with the simulated saltcake validated this approach. The contest mailings stipulated that an existing air-conveyance system was available for use with the retrieval system design.

To deploy the aforementioned scoring and cutting mechanism, it was proposed to use a telescoping arm with a central support, as illustrated in Fig. 1. A cutting head unit consisting of high speed abrasive scoring wheels with counter-rotating breakoff disks at right angles (shown schematically in Fig. 2) was to be mounted at the end of the telescoping arm. The arm could be folded into the central support so that the entire unit could be lowered into the tanks through existing central risers. The telescoping nature of the arm allowed the full range of the tank diameter to be accessed by the cutting head. The machinery would be powered with hydraulic motors because of their reliability and favorable torque-speed characteristics with relatively low weight, as compared to electric motors (3).

Fig. 2

The sludge material in the tanks was described as having a varying consistency but similar to that of peanut butter. In addition to breaking up the hard saltcake to a form suitable for air conveyance, this sludge would also need to directed into the air conveyance ducts. Thus,impellers would also be mounted on the cutting head unit to impart momentum to the sludge, forcing it into the air conveyance system.

The student design team believed that this conceptual design offered advantages over the baseline technologies. Because of the relative simplicity of the deployment mechanism in comparison to multi-degree-of-freedom manipulator arms, operation of such a system could be easily automated. Further, automation would be significantly less expensive than for manipulator arms and the reliability of such a system would be significantly improved over remotely controlled manipulator arms, again owing to the relative simplicity. Finally, the proposed system would create little or no additional radioactive waste, though it might be necessary to cool the cutting blades so that some coolant fluid would be

introduced into the radioactive waste stream and a heat exchange and recirculation system would be required for the coolant.

HEALTH, SAFETY, REGULATORY AND COMMUNITY RELATIONS ISSUES

In conjunction with the conceptual design, regulatory requirements, health and safety considerations and community relations issues were reviewed. In order to complete a waste retrieval project using the proposed technology, licensing requirements, radiation protection standards, packaging and transport regulations, environmental regulations, equipment decommissioning regulations and community right-to-know laws must be complied with (4-7). These were thoroughly reviewed and required actions for compliance were identified based on a New Mexico project site. A health and safety plan involving personal protection equipment and monitoring of workers for radiation exposure, employee training, engineering control of radiation levels and an emergency action plan was produced. A community relations plan including public meetings was also proposed.

General Radiation Protection Standards

The New Mexico Radiation Protection Standards (5) require everyone who receives, uses, transfers, possesses, or acquires a minimum amount of specific radioactive materials to hold a license (5). Therefore, licensing by the NRC would be required to perform the waste retrieval. Radiation exposure, regulated by OSHA and the NRC, should also be kept to levels that are As Low As Reasonably Achievable ("ALARA"), taking into account current technology and the benefits of public health and safety.

Decontamination

Decontamination is essential for maintaining the "ALARA" standards for the reuse, repair, and decommissioning of equipment used in the retrieval system. Decontamination removes a high percentage of the radioactive particles that adhere to the equipment, allowing for safer transport and maintenance. The chemical agent formerly used for decontamination of radioactive equipment was CFC-113. However, the Clean Air Act of 1990 bans the production of all known sources of atmospheric chlorine, including CFC-113. As a result, an alternate cleaning agent such as perfluorinated hydrocarbon surfactant solution would be required (6). It would be necessary to provide a decontamination area inside the above-tank facility, and decontamination could be performed through the use of high-pressure sprays.

Packaging and Transport

The packaging and transport of radioactive materials is governed by the NRC, 10 CFR 71; the DOT, 49 CFR 170-1891 (4); and the New Mexico Radiation Protection Regulations 3-700 & 4-260 (5). These laws pertain to the transport of licensed radioactive material outside the confines of the plant or place of use. Licenses for packaging and transportation would have to be obtained from the NRC, the DOT, and the NMED (New Mexico Environmental Department). Licensing would be required to transport samples of the tank waste off-site to be analyzed, since the tank contents must be analyzed before any retrieval begins.

The proper packaging requirements would have to be observed in accordance with the waste classification status (10 CFR 71 sub-part D, 49 CFR 173 sub-parts A and B and 49 CFR 178 sub-part K) (4). The packaging to be used to transport samples would have to be approved by the NRC. An application for package approval submitted to the NRC must include a detailed package description, a package evaluation, details of a quality assurance program, and the identification of the proposed fissile class.

The application requirements are described in full detail under 10 CFR 71 sub-part D (4).

Environmental Regulations

The Council on Environmental Quality (CEQ) has several requirements that must be met as mandated by the National Environmental Policy Act (NEPA). Environmental information documents (EIDs) would have to be prepared and submitted to the EPA for any proposed action that could have a potential impact on the environment. An environmental review process is required. The EPA will provide an environmental assessment to determine whether or not there is an impact significant enough to warrant the requirement of an Environmental Impact Statement (EIS). A record of the decision must be made available to the public. Further information on the procedures for implementing the requirements of the CEQ is located 40 CFR 6 (4).

Decommissioning

Decommissioning of the facilities and the equipment used is regulated by the EPA, the NMED, and the NRC. At the present time, there are no set standards. Each case is assessed individually, and a decommissioning procedure must be approved by all three agencies. The current practice is to reduce risk to below 10-4 to 10-6 and to reduce radiation levels to below external radiation standards set by the NRC (6). Retrieval equipment would need to be decommissioned in compliance with all regulatory decisions.

Emergency Planning and Community Right-To-Know

The Emergency Planning and Community Right-To-Know Act of 1986 (EPCRA), Title III of the Superfund Amendments and Reauthorization Act (SARA), requires that the public have access to information regarding the presence of hazardous substances in their communities. State and Local Emergency Planning Committees (SEPCs and LEPCs) must be notified when there is a release of reportable quantities (RQ) of a hazardous substances that may adversely affect the community. Reports must be made available to the public providing interested parties with names and quantities of the hazardous chemicals released. In the event of a release of an RQ, compliance with notification requirements as detailed in 40 CFR 302 (4) would be necessary.

Health and Safety Plan

All activities related to the operation of the waste retrieval system would be conducted in compliance with federal and state regulations for safe work practices as well as a proposed health and safety program. Federal health and safety regulations that must be followed include subparts of OSHA's general industry standards (29 CFR 1910.96) and subparts of the NRC's standards (10 CFR 20) for protection against radiation (4).

The proposed health and safety plan possessed the following components: monitoring and surveying to identify and quantify potential hazards, administrative controls and engineering controls to minimize those hazards, and an emergency action plan. This written health and safety plan was intended to be made available to all employees as well as all federal, state, and local authorities.

The main health and safety concerns associated with the waste retrieval are centered around the presence of alpha, beta, and gamma radiation within the single-shelled tanks. These types of radiation are caused by the presence of radioactive materials within the tanks, specifically 137Cs, 90Sr, 90Y, 238U, 239Pu, and 241Am (1). The health and safety program emphasized these concerns, but also addressed all other health

and safety concerns associated with the proposed project. The following discussion illustrates major components of the proposed health and safety program.

Monitoring

Continuous monitoring of radiation levels and airborne radiation levels in the repair unit, the control center, and the support center would be monitored to ensure a safe work site for employees and compliance with all appropriate regulations. All employees would wear film badges (to provide a legal record) and dosimeters (to provide an immediate reading) during their shifts. Monitoring would also aid in the selection of personal protective equipment (PPE) as it became necessary.

Administrative Controls

Employee training was a major element of proposed administrative controls. All site workers involved with the retrieval would be required to take a 40 hour training course and be certified to handle and remediate hazardous waste (29 CFR 1910.120) (4). Employee training would also be developed to address such areas as hazard awareness, hazard avoidance, proper use of PPE and limitations of that PPE (when applicable), evacuation procedures, the purpose of controlled work areas, Right-to-Know issues, the use of Material Safety Data Sheets (MSDS), and confined space entry. A medical surveillance program would be implemented to ensure employee health prior to and during employment. PPE is an administrative control that would be used as a last resort, but PPE would be readily accessible to employees for emergencies. The PPE would include gloves and clothing to minimize contamination during maintenance procedures. Employees would be required to go through a decontamination process after performing maintenance tasks that require contact with the waste. Decontamination facilities would be provided, and monitoring would be performed to verify adequacy of decontamination. Safety glasses would be worn by all employees. Respirators could be used if they were determined to be necessary during exposure monitoring, and if used, a Respiratory Protection Program would be implemented. Controlled work areas would be posted according to OSHA and NRC regulations to further ensure employee safety and site security, and audible warnings would be installed to alert employees entering high radiation areas. An industrial hygienist would be available during all retrieval operations to ensure compliance with the site health and safety program.

Engineering Controls

In the case of exposure to radiation, the controls would be primarily the automation of the retrieval system and the reduction of employees' time spent near the waste. Other forms of control such as shielding might be necessary to reduce employee exposure to "ALARA" levels, and the specifications of necessary shielding could be calculated once the radioactive content of the waste was known. The retrieval method was designed to minimize employee contact with the retrieval equipment, the amount of time that employees are in high radiation areas, and thus the employees' proximity to the waste. The retrieval system would be entirely automated, including the handling of the waste once it is out of the tanks and is being pumped into the waste transportation vehicles for subsequent transport to the waste retrieval facility. Employees would not be inside the above tank facilities (except in isolated areas) when waste was being pumped out of the single-shelled tanks and into the vehicles. Employees might have to enter the facility for tasks associated with moving vehicles out of the secondary structure when they are full and

when maintenance tasks are required. Again, when employees were engaged in these tasks, waste would not be pumped from the tanks, thus reducing potential exposure. The waste transportation vehicles would be designed so that employees working in the repair unit would not be exposed to levels above 0.2 mrem/hr (1). The above ground facility would provide general ventilation (as well as exhaust ventilation if air monitoring proves it to be necessary) to reduce the potential for airborne radiation.

It was determined to be imperative that the contents of the single-shelled tanks be analyzed before any retrieval could begin. This analysis would allow shielding requirements for the process to be calculated. Analysis results would also be used to determine the design of the waste transportation vehicles according to the appropriate regulations. The design of the above-ground facility and secondary structure would also be checked against the analysis results to determine if they adequately provide secondary containment to ensure that radiation was not released to the environment.

Emergency Action Plan

An immediate evacuation warning signal would be installed in the interim retrieval facility, in compliance with the regulations in 10 CFR 20 (4). The emergency action plan would include procedures for dealing with emergencies, as well as names of the local emergency agencies and federal and state regulatory agencies to be contacted in the event of an accident. Designated areas for first aid kits would be identified. MSDSs would be used to determine first aid procedures in the event that medical attention were necessary.

Community Relations

Good public relations would be imperative for success of the proposed project. A well informed community would help the project gain the support of regulatory agencies, help insure funding, and allow the project to proceed quickly since it would be clear that the rights, health, and environmental security of the local community would be protected. The statutory and regulatory requirements have been established in CERCLA as amended by SARA (40 CFR 300), and NEPA (40 CFR 1502-1503, 1506) (4). At sites where CERCLA response actions are taken, there are community relations requirements and procedures for specific situations in which public participation must occur. The community relations program would comply with these regulations.

It would be important to keep the community informed both before the project begins and as it progressed. Public information meetings would be held on a regular basis. These meetings would inform the community of the project's status as well as any changes in proposed actions.

Brochures would be distributed which outline the reasons and methods for retrieval, risk associated with the project, and emergency procedures that are in place for potential accidents. Possible questions and concerns the public may have would be anticipated, addressed, and responded to in these brochures. A telephone hotline would also be set up so that community residents could receive information about the project.

Another approach proposed to gain community trust was to create public participation programs where members of the public would be directly involved in the initial stages of planning. These participation groups would then oversee the project until completion.

BUSINESS PLAN AND ECONOMIC ASSESSMENT

A general description of project costs is given in Table I. The Gantt chart method for project planning was used to estimate the duration of the project and project scheduling. The proposed project allowed for retrieval of waste from two tanks within a 34 month period. the major phases of the project would be equipment design and construction and testing, facilities construction and retrieval from two tanks and equipment decommissioning. The total cost of equipment, required tank access hole enlargements and facilities construction was estimated to be $9.61 million, representing 65% of the total project cost. Costs associated with licensing requirements were omitted because they would be the same for any proposed retrieval method.

Table I

Economic Assessment

The assessment summarized in Table I was based on assumptions which produced the most conservative (i.e. the highest) estimates of project costs. A discount rate of 5% was used to compute present values and this was based on conservative estimates suggested by the EPA (21). This discount rate is used for CERCLA hazardous waste projects which have similar risks to the one described here. Tax and depreciation costs were omitted in order to make a cost comparison between baseline technologies and the proposed technology. The total estimated tax benefit based on the assumption of no salvage value for the equipment was $4,125,200.

CONCLUSIONS

A student design team proposed a mechanical removal method and planned a project which could safely and effectively remove radioactive saltcake and sludge from underground storage tanks. The mobilization and retrieval system differs from the baseline sluicing and remotely controlled manipulator arm technologies. The design concept utilized a rotating cutting head to break up the hard saltcake and this would be deployed by a telescoping arm and central support structure as an integrated system. This design was seen to offer several advantages. These advantages included the facts that it does not create significant additional radioactive waste, it offered simplicity in automation potential, deployment, and maintenance functions, and it offered significant potential for enhanced reliability compared to the use of a remotely controlled, multi-degree-of-freedom manipulator arm.

All applicable legal and regulatory requirements associated with the proposed project were reviewed and the actions which would have to be taken to comply with these regulations were identified. A health and safety plan which would ensure compliance with OSHA regulations and guarantee employee exposure to as low as reasonably achievable ("ALARA") levels was discussed and planned. An emergency action plan was also outlined.

A business plan was developed to assess project costs and scheduling requirements for a 34 month project duration. This business plan and an economic assessment indicated the cost effectiveness and viability of the proposed project. Costs comparable to the baseline, remotely controlled manipulator arm technology can be achieved, and the student design team believed that there was considerable potential for cost savings.

STUDENT-DESIGNED HIGH LEVEL IN-TANK WASTE RETRIEVAL SYSTEM AND MIXED WASTE REMEDIATION SYSTEM

Chris Kaiser
Shannon Wilson
Montana Tech

ABSTRACT
The Waste-management Education and Research Consortium (WERC) had requested designs for a high level radioactive waste mobilization and retrieval system for underground storage tanks and for a sludge

remediation process. The Montana Tech Environmental Design Team (MTEDT) designed creative, cost-effective methods for the given problems. One group within the team designed an In-tank waste Removal Integrated System (IRIS). WERC had requested that the waste be removed from the underground tanks within a six month time frame, and restricted the design from using a robotic arm or from sluicing. IRIS is a mobile system, relatively simple in design. Design parameters will allow removal of waste from a 0.75 Mgal tank in 5.8 months. The two major systems involved with IRIS are the pneumatic fracturing system and the air system. Other components include liquid/slurry retrieval pumps. The in-tank components are handled by a hydraulic cylinder system, with telescoping trusses. Air system components above ground handle collection of particulate, warming/dehumidifying the air stream, and elimination of dust emissions. The projected costs and operation/maintenance on IRIS, for waste removal from eight tanks, has been estimated to be $15.7 million. Another group within the team designed a two-step, low maintenance, semicontinuous Solvent Extraction and Contaminant Recovery Technology (SECRT), which is designed to be flexible for various contaminant levels and transportable. WERC had restricted the design from utilizing cementation or vitrification. SECRT's first step involves a liquid/solids separation and counter-current extraction of radionuclides, organics, and metals using a chelating agent and surfactant mixture. The second step involves sending liquid through the heating chamber of a two-stage, forced-circulation evaporator/crystallizer, where 70% of the contaminated liquid stream is flash-vaporized. The residual liquid is cooled and sent to a solvent/water separator, where the solvents are collected and marketed as either an industrial solvent or incinerator fuel. The water is further filtered to dischargeable levels. SECRT is designed to handle 7200 gallons per day (gpd) in contaminated liquid and 1800 gpd in pond sludge. The projected cost of treatment of the pond sludge is $4.66 million, or $3.88 per kilogram of sludge. MTEDT's plans also address legal issues, health and safety concerns, and community involvement.

PROCESS DESIGN FOR HIGH LEVEL IN-TANK WASTE RETRIEVAL SYSTEM

Preliminary Activities

A complete characterization of the tank interior will be conducted prior to starting waste retrieval operations. Characterization will include sampling for explosive chemicals such as hydrogen, ferrocyanide, and organic compounds, as well as depth profiling of waste moisture content. Water content data will be gathered with a modified neutron probe. The Montana Tech Environmental Design Team (MTEDT) has assumed that pumpable liquids will be removed from the tank. If a tank has less than three risers excluding the central riser, additional risers will be installed to accommodate monitoring and air circulation equipment. Also, nonessential in-tank hardware will be removed and decontaminated. A 20 foot by 50 foot concrete, load-bearing pad will be constructed adjacent to the tank. Mobile units containing air treatment equipment, a boom hoist, the decontamination chamber, and a containment unit will be assembled on the bearing pad.

Removal Process

An In-tank waste Removal Integrated System (IRIS) will be employed to mobilize and retrieve waste from the single shell tanks (SST's). IRIS consists of dual telescoping hydraulic booms with an integrated Waste Mobilization and Retrieval Module (WMRM) located at the end of each boom.

The WMRM is capable of solids fracturing, air conveyance, and liquid/slurry removal.

To mobilize and retrieve a full tank of waste, two sets of dual telescoping booms with identical technology (IRIS Jr. and IRIS Sr.) will be used. IRIS Jr. is a smaller version of IRIS Sr. and is necessary to enter a full tank of waste; however, for tanks having a minimum of 18.5 ft of clearance between the tank dome and the waste, only IRIS Sr. will be used.

Figure 1 illustrates IRIS's six major components: the IRIS deployment hoist, Vertical and Rotational Support System (VRSS), Support Column, Telescoping Boom, Angular Displacement Cylinder (ADC), and the WMRM, in addition to the air conveyance system. IRIS will initially be lowered into the tank through a 36 inch central riser and will be locked into the VRSS. Utilizing the VRSS, Telescoping Boom, and the ADC, a Programmable Logic Controller (PLC) will allow IRIS to maneuver within the tank.

Fig. 1

A pneumatic fracturing device located on each WMRM utilizes eight reciprocating air cylinders with chisel attachments to fracture the waste into sizes easily handled by the air conveyance system (see Fig. 2.). The PLC will operate the Intermittent Step and Repeat Removal Process (ISRRP) for solids fracturing. The ISRRP is similar to the procedures used in computer controlled milling applications and incorporates removing a layer of material in one plane, lowering the WMRM a prescribed depth, and removing another layer of material. To begin the ISRRP, IRIS will be lowered to it's set position in the tank. The ADC will then retract, moving the WMRM upward and outward, and the telescoping boom will be fully extended (IRIS Jr. can extend 30 ft, and IRIS SR. can extend to the interior tank wall.). Once in position, the telescoping boom will force the pneumatic fracturing device into the waste until a two inch depth is reached. The telescoping boom will then retract until clear of the waste, rotate through an angle along the circumference which allows a slight overlap of the previous position, and will again be extended into the waste. This process will be repeated until an annulus of waste around the perimeter is completely removed. The telescoping boom will then retract as the ADC extends, moving the WMRM radially inward, so that the fracturing of the next inner annulus can be completed. This step will be repeated until the WMRM reaches the center of the tank. At this time, the aforementioned process will be repeated for the next layer.

Fig. 2

As the waste is fractured, it will simultaneously be removed from the tank by an air conveyance system. Once outside of the tank, the waste will enter a pulsed-jet baghouse and will then be temporarily collected in a Collection, Storage, and Transfer (CST) station. From the CST, the waste will be transported to a Waste Retrieval Facility (WRF).

When liquids or slurries are encountered, the ISRRP will be interrupted. IRIS will be removed from the tank, and a submersible pump will be attached to the WMRM. IRIS will then be returned to the tank and directed to the liquid/slurry through manual operator control. Once the liquids/slurries are pumped, IRIS will be withdrawn from the tank and the pump will be removed. IRIS will then be redeployed, and the Step and Repeat process will again be enacted. Once the waste is removed, it will be temporarily placed in the CST station until it is transported to a WRF.

Wet or damp waste that cannot be pumped will be dried by hot, dry air convection and will then be pneumatically fractured and removed as a solid.

After IRIS has removed the bulk of the waste, an abrasive wire brush assembly will be attached to the WMRM to dislodge residual waste from the tank walls. This step will guarantee removal of greater than 99% of the waste.

Post-Retrieval

When retrieval at one tank is completed, the system will be transported to the next tank. IRIS Jr., if required, can be deployed at the next tank while IRIS Sr. finishes operations at the first tank. This practice significantly reduces total project time. As IRIS is removed from the tank it will be decontaminated by remote CO_2 blasting in the decontamination chamber (1). After decontamination, retractable shielding on the deployment hoist will enclose the booms to limit exposure until the system is redeployed at the next tank. Decommissioning will include the recycling of steel and the entombment of non-recyclable materials (2).

Project Time Requirements

The IRIS system will completely retrieve waste from a 0.75 Mgal tank in 5.8 months. This estimate is based upon retrieval of the contents of Hanford tank SX-105 (3), and laboratory retrieval rates of various waste types. Emptying a 0.5 Mgal tank requires 4.1 months and emptying a 1.0 Mgal tank requires 7.4 months. The total time required to retrieve waste from eight tanks (assuming four 0.5 Mgal and four 0.75 Mgal tanks) is 46 months. If IRIS Jr. and IRIS Sr. retrieve waste from two separate tanks concurrently, the total retrieval time will be reduced to 28 months.

PROCESS DESIGN FOR SLUDGE REMEDIATION

Waste Characterization

Analyses of the pond water and the pond sludge were provided by WERC for each of the three ponds. These data describe a chemically complicated hazardous waste which is characterized by broad ranges of nitrate, salts, metals, radioactivity, and total organic carbon (TOC). The complexity of the waste contaminates restricts the available remediation technologies; WERC further restricted treatment options by stating that vitrification and cementation methods were unacceptable. MTEDT developed a two-step, low maintenance, semicontinuous Solvent Extraction and Contaminant Recovery Technology (SECRT) which is designed to be flexible for various contaminant levels and transportable for use at future sites.

Step One of SECRT

Supernatant water is initially separated from the settled sludge. This water is then pumped from the covered storage tank, illustrated in Fig. 3, and sent to the contaminated liquid stream (CLS). The CLS is treated in Step Two. Recycled heated water (RHW) from Step Two is used to remove additional salts and to slurry the remaining solids from the original tank into hydrocyclone A; make-up water may be added if necessary to achieve proper slurry consistency. Mixing the RHW and the sludge results in the transfer of water-soluble contaminates from the sludge into the aqueous phase. After passing through hydrocyclone A, the liquid stream is sent to the CLS, and the sediment slurry travels to the first contaminate extraction mixer (CEM) in the counter-current extraction system.

Fig. 3

The first and second CEMs operate counter-currently using a chelating agent and surfactant mixture to remove radionuclides, organics, and

metals from the soil matrix. In the first CEM, sediment mixes with the recycled extractant liquor from the second CEM. Hydrocyclone B separates the slurry from the first CEM into a spent liquor stream which travels to the CLS and a sediment stream which travels to the second CEM. Fresh chelating/surfactant solution is added to the second CEM, and the liquor stream recovered from hydrocyclone C is sent to the first CEM while the sediment travels to the final water wash.

The counter-current system utilizes the extractant most efficiently by precleaning the most contaminated sediment with the liquor stream the second CEM and then contacting fresh extractant solution with the precleaned sediment. The second CEM mixes the cleanest extractant with the cleanest sediment, thus maximizing the difference in pollutant concentration and promoting dissolution of contaminates.

After hydrocyclone D, a high-efficiency centrifuge separates the sediment from the wash water, and dewaters the sediment to approximately 80% solids by weight (4). Liquid collected from the centrifuge travels to the CLS, and the solids are tested to determine proper disposal options. Disposal alternatives for delisted sediment include land application and possible marketing. If low-level radioactivity is present, shallow trench burial is a disposal option, or the sediment may be transported to a radioactive waste facility in Salt Lake City, Utah (5). High-level radioactive waste (HLW) may be disposed of at DOE facilitated sites.

Step Two of SECRT

The CLS travels through the heating chamber of the two-stage, forced-circulation evaporator/crystallizer (EC) where the waste stream temperature is raised under pressure. This process allows the liquid to reach boiling temperatures without actually volatilizing, thereby preventing scaling inside the chamber. The heated stream then travels to the low-pressure portion of the EC where the waste is concentrated and 70% of the CLS is flash-vaporized (6). The vapor stream, comprised of water and volatile organic compounds (VOCs), travels to the condenser while a brine waste containing metals, salts, radionuclides, and nonvolatilized organics exits at the bottom of the EC. A slip stream of the exiting brine waste slurry is recycled into the heating chamber. The recycling rate of the slip stream controls the CLS retention time in the EC and consequently determines the solid crystal content of the ultimate waste product. Depending on the radioactivity levels, the waste is dealt with accordingly, as mentioned in the previous section.

The vapor stream exiting the EC travels through a pipe coiled around the CLS input stream. This heat exchange process serves to preheat the CLS and to precool the vapor before it reaches the condenser. The condenser cools vaporized organics and water vapor to a liquid phase. Residual vapors leaving the condenser flow through an activated coconut-shell carbon unit to remove remaining organics and then flow through a High Efficiency Particulate Air (HEPA) filter to remove any potentially entrained radioactive particles (5). Condensate travels to a solvent/water separator where solvents will be collected and marketed as either an industrial solvent or incinerator fuel. The condensed water travels through a granulated, activated carbon filter where any remaining organics are adsorbed to produce dischargable water. A portion of the condensed water is recycled to the storage tank and the final wash portions of Step One via the RHW stream.

RESULTS OF TECHNICAL ASSESSMENT

In-tank waste Removal Integrated System

The Telescoping Boom consists of a double-acting telescoping hydraulic cylinder and two telescoping trusses. The double-acting telescoping hydraulic cylinder controls the length of the boom. The telescoping truss provides bending and torsional support for the boom and provides housing for the air conveyance lines, hydraulic lines, pneumatic lines, and the pump lines. A 55 gpm hydraulic fluid pump with a maximum operating pressure of 1500 psi will be used to maneuver the cylinders and the trusses. The ADC controls the angle at which the telescoping boom is maintained relative to the support column and will be operated by a 10 gpm hydraulic fluid pump with a maximum operating pressure of 3,000 psi. The ADC will apply a maximum force of 12,000 pounds.

The WMRM performs three separate tasks: 1) Pneumatic Fracturing: The pneumatic fracturing device uses four levels of chisels to mobilize the solid waste into sizes easily handled by the air conveyance system. Since one WMRM is located on each boom, a total of 16 chisels will be used. A 64 cfm airstream at 90 psi will be used to drive the 16 chisels. 2) Air Conveyance: Fractured waste will be captured and removed from the tank in a high velocity air stream utilizing a duct velocity of 7200 fpm. 3) Liquid/Slurry Removal: The liquid/slurry retrieval pump will be placed in the WMRM and submersed into any pockets of liquid and/or slurry encountered during the removal process. The pump will be capable of handling 70 ft of head and 75% solids by volume. The telescoping booms will be capable of fracturing the waste at a rate of 1.34 cfm. Dry material will be removed at a maximum rate of 5.34 cfm by the pneumatic conveyance system (2.67 cfm from each telescoping boom). A submersible pump will remove the liquid/slurry at a maximum rate of 50 gpm.

The pneumatic conveyance and drying system incorporates a closed air movement system to contain radioactive particulate. The air conveyance system is capable of conveying the mobilized waste to the surface at a rate of 500 pounds per minute. Each of the two waste removal pipes will convey the particles into cyclones mounted with the turbo blowers. From the two blower systems, the airstream will be joined by an additional exhaust ventilation line from the tank. Flow will then be directed to a pulsed-jet baghouse, which is currently the best available technology for particulate removal (7). The particles will be collected in a hopper at the bottom of the baghouse. Here, another conveyance system will interface with the CST. The airstream then passes through parallel desiccant dehumidifiers/preheaters and is returned to the tank. Exhaust from within the secondary containment will be vented through a double HEPA filter bank. Three lines are utilized to exhaust air and/or particles at a total rate of 7,200 cfm. Two lines return hot, dry air to the tank at a total rate of 7,000 cfm, maintaining a slight vacuum in the tank. Airflow is directed downward and deflected out to ensure uniformity of air distribution.

Solvent Extraction and Contaminate Recovery Technology

SECRT is designed to process up to 7,200 gallons per day (gpd) of contaminated liquids and 1,800 gpd of pond sludge. All water and slurry lines are constructed of stainless steel to resist corrosion. MTEDT performed laboratory settling experiments to estimate the ratio of supernatant liquid to sludge volume. Based on these experiments, MTEDT determined that approximately 5,500 gallons of supernatant liquid shall be pumped from each storage tank at a rate of five gallons per minute (gpm) and sent to the CLS. Recycled heated water (RHW) is used to dilute the remaining sludge to a slurry containing approximately 30% solids by

weight for easier pumping. This slurry is pumped through a hydrocyclone at a rate of 3000 gallons per hour (gph). All hydrocyclones used in SECRT were designed using on estimated dry particulate specific gravity of 2.0 with the following size distribution: 100% finer than 4.75 mm, 70% finer than 75 um, 20% finer than 40 um, and 5% finer than 20 um (8). The slurry exiting the hydrocyclone through the one-inch diameter outlet pipe will contain 60-65% solids (9). The slurry is transferred into a covered, 500-gallon polyethylene tank and mixed by means of a 3/4-horsepower shaft mixer operating at 420 revolutions per minute (rpm). An extract solution of EDTA and a proprietary surfactant is added to the slurry to achieve an approximate volume ratio of 3:1 liquids to solids (10). To ensure thorough contact of extractant with particulate, the solution is mixed for 15 minutes--the optimum agitation time as determined by MTEDT lab experiments. This process is repeated in two additional mixing tanks--one using fresh extractant solution and the other using RHW. Finally, an industrial, high-efficiency centrifuge dewaters the cleaned sludge to approximately 80% solids (4).

Supernatant from the storage tank, liquids from each hydrocyclone, and liquids from each centrifuge process are pumped through the forced-circulation EC at a rate of five gpm. A full-scale treatability study shall be conducted to determine the flow rate of the EC slip stream necessary to achieve maximum crystal content in the waste product. A high crystal content (due to increased water evaporation) minimizes the volume of hazardous waste product produced. The condenser discharges condensate at a temperature of approximately 125F(11). Condensate is directed through a separation unit where organic solvents are removed from the water. Excess vapors and the condensed water are routed through two separate activated carbon units to complete the remediation process. A portion of the pure water is recirculated via the RHW to be utilized as an extracting solvent.

METHODS FOR TESTING UNIT OPERATIONS/PROCESSES

Methods for IRIS

The fracturing rate for both saltcake and sludge was determined experimentally by measuring the time required to fracture a known volume of material with a single pneumatic chisel. A particle size distribution after fracturing for both saltcake and sludge was determined by sieve analysis. Bench scale waste removal rate was determined by measuring the time required to vacuum a known volume of material. Both the sludge drying rate and the critical moisture content at which the sludge can be fractured were determined by measuring the drying time of a known amount of sludge in a 104C oven. A desiccant was placed in the oven to reduce the moisture content of the drying air to simulate full scale conditions. The critical moisture content of saltcake was determined by mixing simulants of varying percentages of moisture and recording the highest percent of moisture content at which a fracturable solid could be attained.

Methods for SECRT

Using 0.2 M and 0.4 M EDTA, 1.00 M acetic acid, and 1.00 M citric acid, MTEDT conducted experiments on 22 test samples containing various metals, metal-salts, and pulverized kaolin. Supernatant water decanted from each of the test samples, and immersion solvent extraction was performed on the remaining clay. The decanted water, extraction solvent, and cleaned clay were first filtered, then digested, and finally analyzed using an Inductively Coupled Plasma (ICP) analysis.

A series of five immersion extractions were conducted on triplicate surrogate samples using a deionized water (DI) wash for the initial extraction, 0.1 M EDTA with 0.5 M Na2HCO3 (sodium bicarbonate) solutions for the next three washes, and a final DI water wash. Each solvent was mixed with the surrogate sludge and the resulting slurry was centrifuged. The liquor was collected, digested, and filtered for ICP analyses to determine the metals removal efficiency of each wash. In addition, residual contaminant quantities from the extractant solutions were approximated by evaporating a known quantity of extract liquor from each wash.

LAB RESULTS

IRIS Lab Test Results

Table I lists the results of the lab tests conducted. A single pneumatic chisel was used for the fracturing tests; therefore, all values listed are for bench scale unless otherwise noted (F = full scale, B = bench scale).

Table I

SECRT Lab Test Results

Although water removes a significant portion of adsorbed metals from course soil fractions, the addition of a chelating agent enhances the metals removal from the fine soil fractions. Both EDTA solutions in Experiment One exhibited consistently high removal efficiencies for the added metals without removing the metals associated with the pulverized kaolin. Therefore. EDTA was selected on the basis of economics, safety issues (i.e. concerns associated with acid extractant), and the lack of performance differences among the four acidic solutions tested. Based on literature searches (12), previous knowledge, and lab results, 0.1 M EDTA combined with a 0.5 M Na2HCO3 buffer solution was chosen for use in the bench scale and Experiment Two. Also, an oxidizing agent is not included in the extractant solution because it will not improve the removal efficiency of cadmium chromium, and nickel (13)--which are the only metals present in the WERC surrogate. At the beginning of Experiment Two, the optimum centrifuge rate was determined to be 2,000 rpm for a spin time of 15 minutes which reduced the sludge to 65% solids by weight. Experiment Two resulted in high removal efficiencies for calcium, chromium, and nickel, which are predominately extracted in the EDTA washes, as shown in Fig. 4.

ECONOMIC ASSESSMENT AND BUSINESS PLAN CONSIDERATIONS

All of the projected costs and operations/maintenance on IRIS are shown in Table II.

Fig. 4

Table II

If additional risers are necessary for a particular tank, a charge of $4 million would be added for each additional riser required.

The business plan and assumptions include the following to meet project goals:

Three shifts of four people would be required for operations, including a Health Physics Technician and supervisor per day.

All equipment is shipped FOB to the WERC site.

Labor costs associated with major equipment replacement or repairs are not included.

Utility costs are per New Mexico Public Utility Commission mandated rates.

All necessary risers are assumed to be in place.

Research and Development costs include setup of pilot operation.

All of the projected costs and operations/maintenance on SECRT are shown in Table III.

Table III

The cost of treatment per kg is $3.88, which includes $1.08/kg for capital costs, $0.53/kg for chemical costs, $0.06/kg for research and development, and $2.22 for operation and maintenance costs. There is also a potential that may be realized for a small amount of revenue, since the recovered solvents may be marketable.

The following is a list of process and cost assumptions:

75 gal/hr sludge feed rate from original tank.

Mobilization & set up: 20 days; demobilization: 10 days.

50 days of operation with 10% downtime.

24 hrs/day, 7-day workweek.

178,357 gal of sludge to remediate;

Personnel per shift to include 1 supervisor, 3 technicians, 2 maintenance personnel (on call)

Labor costs associated with major equipment replacement or repairs are not included.

Utility costs are per New Mexico Public Utility Commission mandated rates.

Due to unknown speciation of TOC, exact quantity of surfactant required is unknown--listed quantity is a reasonable estimate.

LEGAL, HEALTH, AND REGULATORY CONSIDERATIONS

A comprehensive site safety and health plan (SSHP) to ensure compliance with all legal, health, safety, and environmental regulations is an integral part of the overall design of IRIS and SECRT. The intent of this plan is to protect all life forms from the potential risks associated with exposure to ionizing radiation. Therefore, it includes all necessary criteria to keep exposures "as low as is reasonably achievable" (ALARA). These criteria are divided into safety and health, environmental, contingency planning, and legal considerations.

Safety and Health

For the duration of the mobilization, retrieval, or remediation of the waste, 29 CFR 1910.96 and 29 CFR1910.120 regulations will be adhered to. All applicable Nuclear Regulatory Commission (NRC) requirements (including 10 CFR part 20, subparts A through O, and appendices) will be followed as well. To achieve compliance with all regulations, a site-specific characterization, safety and health survey will be done to establish baseline contaminant levels compared to normal background levels. Ionizing radiation will be continuously monitored through the use of personal monitors, and area sampling as set forth in 10 CFR 20.1501. Based on sampling data, an exclusion zone (EZ) will be determined. Limited access to the zone will be granted to perform initial equipment setup and routine maintenance. A contamination reduction zone (CRZ) will be established in which a personnel decontamination station and auxiliary and emergency equipment will be located. The area outside the CRZ is the support zone and should be considered clean with no more than 0.002 mrem/hr of exposure. The support zone will contain the OCMS located up to 1300 feet from the tank undergoing retrieval operations. To ensure controlled access, the EZ will be fenced. The fence will be supplemented with visual monitors and alarms. All personnel entering the EZ shall wear the following personal protective equipment (PPE): Tyvek coveralls with hood, Tyvek gloves and boot covers, and full face air purifying

respirators with radionuclide cartridges. In addition to the PPE, all personnel working at the site shall wear appropriate dosimeters such as thermoluminescent dosimeters (TLD) and film badges. All personnel will be admitted into a radiation health and protection program to monitor exposures to ionizing radiation. At no time shall anyone receive a dose greater than 0.2 mrem/hr or a cumulative annual dose of 500 mrem, nor shall any organ or tissue receive 50 rem cumulative dose. The maximum dose for the eye is 15 rem. If at any time these doses are exceeded, further abatement measures shall be implemented immediately.

Environmental

All piping, duct work, and system components containing waste shall be double walled and shielded with a high density material with a half value layer adequate to protect personnel and the environment from gamma radiation. Alpha and beta radiation can be absorbed or shielded with normal construction materials to prevent them from being released into the environment. If a controlled release of air should be required, it will pass through a pollution control system to catch radioactive particulate. Controlled releases will be monitored to ensure regulatory compliance.

Contingency Planning

If an accident occurs and results in either a severe injury or a release of waste into the environment, emergency procedures will be immediately initiated to control the accident. The procedures shall be based on a worse case scenario at full operational conditions. A coordinated abatement effort between local health and emergency personnel will be implemented to minimize any adverse effects.

Legal Considerations

The Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) governs the remedial activity on a hazardous waste site. The immobilization and retrieval design process was developed to comply with the criteria established in the National Contingency Plan (NCP):

Threshold Criteria: Overall protection of human health and environment; and compliance with Applicable or Relevant and Appropriate Requirements (ARARs).

Primary Balancing Criteria: Long term effectiveness and permanence; reduction of toxicity, mobility, or volume through treatment; short-term effectiveness; implementability; and cost.

Modifying Criteria: State acceptance and community acceptance.

ARARs are regulations that pertain to the environmental work at a CERCLA hazardous waste site. ARARs for this project can be obtained from the following legislation: National Environmental Policy Act (NEPA); Atomic Energy Act of 1954; Resource Conservation and Recovery Act (RCRA); Clean Air Act; Clean Water Act; and from Emergency Planning and Community Right to Know Act.

PLAN TO ESTABLISH COMMUNITY RELATIONS

The community involvement plan has two primary purposes: 1) develop an understanding of public concerns and respond to such concerns; and 2) nurture positive community relations. In order to achieve these goals, the public involvement plan will include the following features:

1) Community input interviews. The initial phase of the community involvement plan will consist of thirty interviews conducted with a broad

cross-section of subjects. The goal of this activity is to identify the spectrum of community concerns. The IRIS project must remain flexible and responsive to concerns raised in this portion of the plan.

2) Availability of information. WERC must take the initiative in disseminating information in order to assure that the public is well informed. Furthermore, this information must be presented in a non-technical format which is accessible to the general public. Information presented here will include progress reports, press releases, fact sheets, explanation of concerns as WERC perceives them, explanations of how WERC arrived at certain decisions, and any other requirements under Superfund Amendment and Reauthorization Act, Title III.

3) Public meetings. Public meetings will be used as a forum for WERC to provide information and for the public to voice its concerns. Public meetings shall involve concerned individuals as well as citizen groups.

4) Central public information contact. The WERC employee overseeing press releases shall also act as a point of contact for the public. This individual will provide the public with personal contact and will allow the company to track public response to the IRIS project.

CONCLUSION

WERC has explored two main waste removal systems for the underground tanks: sluicing and a robotic arm. IRIS is a much more attractive system than sluicing for the primary reason that IRIS creates no additional waste. IRIS will also offer a significant improvement over existing robotic arms because of IRIS's mechanical simplicity. Past arm-based systems have not been cost-effective due to high maintenance requirements and a low degree of mechanical availability. The MTEDT strongly believes that this is not an inherent problem with arm based systems, but rather that it is symptomatic of a design that is overly complex for the task at hand. We believe that IRIS will represent a significant improvement over past arm-based systems in the areas of cost-effectiveness and mechanical dependability, because of the inherent simplicity of its design. The major structural components of the system are simple hydraulic cylinders. Because IRIS has a relatively simple design, we believe it will retrieve waste at a significantly lower cost. We estimate typical retrieval time for a 0.75 Mgal tank to be 6 months and the total cost for eight tanks to be $15.7 million. Our estimated cost represents significant savings compared to recent government cost estimates for this project. In 1993 the General Accounting Office reported a cost estimate of $15 billion to retrieve waste from 177 tanks at the Hanford site, representing an average cost of $85 million per tank. MTEDT believes that cost-effectiveness and mechanical dependability are precisely the type of innovation the Tank Waste Remediation System program needs.

SECRT's two-step process remediates the pond sludge and water resulting in cleaned sediment, high quality effluent, concentrated solvents, and a minimal quantity of hazardous waste. Step One uses a multiple extraction process to remove contaminates from the sludge; the second step utilizes a forced-circulation evaporation system for volume reduction to concentrate the hazardous contaminates for disposal. Rather than destroy the solvents that are volatilized in the evaporator, SECRT's collector/separator recovers the marketable solvents for future sale. Additionally, SECRT condenses and collects the water vapor evolved from the evaporator for either reuse in the process or discharge as industrial quality water. These pollution prevention measures create beneficial products from an otherwise useless waste stream destine for disposal. The

total cost for the pond sludge and water remediation is $4.66 million, or $3.88/kg of waste. As a unique feature, SECRT is very transportable, and after treatment at the WERC site, may be dismantled and relocated to treat similarly contaminated sites. SECRT is highly adaptable to waste types and contaminant levels.

ABSTRACT

The University of Idaho Environmental Design Team (UIEDT) has completed a preliminary treatment design for Task II as described by WERC. This task involves 178,357 gallons (35 wt% solids) of contaminated sludge which has been removed from evaporation ponds and is temporarily being stored in 10,000 gallon tank. In compliance with the requests of WERC and the requirements of the USEPA, the treatment process remediates the sludge to a form which meets 30 year Land Disposal Restrictions (LDR) and Department of Transportation (DOT) shipping requirements. Also considered in the process design are the social and ethical responsibilities to the workers and community.

The remediation process designed by UIEDT focuses on the maximization of the permanent immobilization rather than stabilizing the contaminants in a support matrix. This not only ensures long-term safety, but also helps to minimize process costs by eliminating waste transported to a landfill. Each part of the treatment plan has been chosen and optimized to maximize process efficiency, minimize overall costs, and guarantee successful remediation. The proposed plan involves two primary phase treatments; the volatile organics with bioremediation and the heavy metals with immobilization.

The initial task in the process is to convert one of the existing storage tanks into a "treatment tank" where sludge from the remaining tanks will be pumped prior to treatment. Sludge in the treatment tank will be heated to volatilize off the organics, separating them from the high salt concentrations which are toxic to the microbial populations responsible for remediation. After being recondensed, the organics are sent through a two stage bioremediation process. The anaerobic reactor degrades the most complex organics into simpler forms over a nine day period. Effluent from the anaerobic stage is fed directly into the aerobic reactor where the remaining contaminants are degraded in a ten hour period. Streams exiting from the bioremediation phase are void of any restricting contaminant concentrations and can be released straight into the local sewer.

Simultaneously with the volatilization of the organics is the immobilization of the heavy metals. A reactive hydroxy apatite is fed into the treatment tank at 1% weight of the solids and mixed for a 24 hour period. The apatite provides nucleating sites for a reaction resulting in the precipitation of metal-substituted apatite minerals, which have leach resistance typically below EPA drinking water standards and almost permanent durability. The apatite has also proven to lower salt concentrations. After treatment, the soil and liquid phases of the sludge are separated by rotary vacuum drum filters. The resulting water stream has been approved for release into the local sewer and the solid phase can be returned to the land where it is useful not only as fill, but also as a continuing treatment process for any further leached contaminants from the site. The proposed treatment process can be completed in 100 days, with and operating schedules of eight hours per day, seven days per week during the summer months. Total remediation

costs for this site are approximately $166,000 or $0.93 per gallon of contaminated sludge, but would decrease significantly with and increase in the volume treated.

INTRODUCTION

WERC of New Mexico has requested a process design to stabilize/remediate 178,357 gallons of contaminated sludge which has been removed from shallow evaporation ponds and is currently being stored in a series of 10,000 gallon tanks. Prior evaluations of the site have eliminated grouting as a viable treatment and have also determined that the treated waste must meet 30 year stability criteria. In response, the University of Idaho Environmental Design Team (UIEDT) has developed a treatment process which will not only remediate the contaminated sludge at this site. but can also be transported and applied to contaminated slurries at other locations.

For the remediation, UIEDT's process involves bioremediation to treat the organic contaminants and a hydroxy apatite immobilization for the heavy metals and to reduce the salt concentrations. The following table includes the treatment standards that must be met:

Table I

The proposal discussed in this report focuses on the technical process description, including bench scale evaluations. However, the importance of a comprehensive treatment plan is recognized, and so the proposed design also includes an economic assessment, environmental requirements, health and safety evaluations, and consideration of a community relation plan.

SLUDGE TREATMENT

The UIEDT has developed a process to treat 178,000+ gallons of industrial waste sludge previously removed from evaporation ponds and currently being stored in a set of eighteen 10,000 gallon tanks. It has been a goal of the team to develop a treatment process, not only for this particular problem site, but one which can also be adapted and transported for use at other contaminated sludge sites.

Several aspects of handling a contaminated waste must be taken into account when determining viable treatment options. Listed or non-listed waste? In-situ or ex-situ treatment? Fixation or stabilization? On-site or off-site disposal? The treatment methods must be evaluated and the design concerns prioritized. When actually choosing a remediation design, UIEDT considered the following priority:

- reduce contaminant concentration to specified limits
- meet regulations for exiting streams (water. clean soil, etc.)
- minimize or eliminate waste to landfill
- maximize amount of clean soil returned to the land
- minimize costs
- maximize efficiency and up-time of process
- maintain safety as a top priority.

Process Design

Focusing primarily on the maximization of long-term (permanent) immobilization, UIEDT has chosen to actually remediate the sludge rather than stabilizing the contaminants in some form of matrix. Doing so not only ensures long-term safety, but also helps to minimize costs by eliminating waste transported to a landfill. The proposed process involves two primary phase treatments -- organics with bioremediation and heavy metals with immobilization. The 178,357 gallons of sludge is

treated in a series of 22 batches, each containing approximately 8,100 gallons of sludge.

The 10,000 gallon tank, which initially contains only 8,400 gallons of sludge, will be immediately adapted into a treatment tank where sludge from the remaining tanks will be pumped prior to treatment. Three hundred-sixty-five pounds (1% by wt.) of reactive phosphate hydroxy apatite will be added to the 8,100 gallon sludge batch being fed into the tank and mixed for 24 hours. Introduction of the apatite into the sludge, which contains mobile metals and other inorganic contaminants. provides nucleating sites for a reaction resulting in the precipitation of metal-substituted apatite minerals. Metals encompassed in apatite have almost permanent durability and leach resistance that significantly exceeds other stabilized waste forms because the apatite mineral structure is very stable over a wide range of environmental conditions and for geologically-long time periods. The leachability of metals sequestered in apatite are typically well below EPA drinking water standards, have proven insensitive to pH changes over the range of 2 to 12.5, and the bioavailability of ingested metals is minimal. Other advantages of using hydroxy apatite include small material requirements, rapid kinetics, and low cost. The apatite reaction requires less than 1%(wt) of reactant and under 24 hours for formation while the common grouting techniques tend to require as much as 30%-50%(wt) and up to 30 days for "set-up.'' (1) Since the phosphate mineral is naturally occurring in a number of forms ranging from ore to shark teeth and fish bones, it has the potential of being obtained for little more than transport costs from places such as fish canneries. (2)

During the same 24 hour period that the apatite reaction is being completed, a saturated steam coil will be used to evaporate off the organic compounds by raising the bulk sludge temperature from ambient (~27C) to the mixed boiling point of the organic compounds (~121C). During this time, it is also expected that approximately 5% of the water will evaporate off, helping to ensure the removal of the volatiles. UIEDT needs to separate the volatiles from the bulk sludge since the biological organisms used in the organic treatment are sensitive to the salt concentrations found in the sludge. For the organic compounds that might remain in the sludge and not evaporate, UIEDT will add 90 pounds (0.25%wt) of activated carbon to the treatment tank. Activated carbon is a common technique used to trap organic compounds because of the large number of reaction sites and the immediate reaction. However, using activated carbon as an actual treatment has the disadvantage that the used carbon itself must be treated, which can be more expensive than initially treating the volatiles. (3)

A simple, water-cooling condensing unit will trap the volatilized compounds and return them to a liquid phase prior to their being fed into a storage reservoir awaiting biological treatment. Biodegradation of the organics has been chosen because it is one of the few treatment options available that permanently removes the volatiles rather than trapping them or releasing them into the atmosphere in diluted concentrations. An anaerobic reactor is responsible for the degradation of tetrachloroethene (PCE), and will begin the degradation of methylene chloride, 2-butanone, and other volatile organic compounds (VOCs). The most difficult component to degrade is the PCE because it contains four chlorine groups surrounding a double bonded carbon. A reductive dechlorination process has been chosen since it optimizes PCE and VOC

degradation. The biodegradation pathway involves the use of an unidentified microbial population obtained from the anaerobic digester sludge of the primary digester at any local sewage treatment plant. (4) The anaerobic reactor is fed in batches of ~5,000 gallons of condensed organics every ten days, with nine days being required for the actual degradation and one day to transfer batches. Fresh nutrients should be fed at a volume of 0.2% (15 gal) every 24 hours with an equal amount being removed (and later recycled) so that the total concentration remains constant. The reactor is packed with one inch polypropylene mesh spheres for a growth support structure, operates at ambient temperature, and should maintain a pH in the range of 6.8 to 7.5.6

An aerobic reactor is then used to complete the degradation of the anaerobic bioreactor endproducts: trichloroethylene (TCE) and remaining VOCs. A process focusing on the degradation of TCE is used because it is the most difficult constituent left to treat due to the presence of three chlorine groups. Methanotrophs obtained from the upper three inches of a sedimentary pond are used as the microbial population and the methane monoxygenase enzyme responsible for the degradation is produced with the aid of a 5% methane and 3% propane mixture acting as an inducer.7

A continuous stirred tank reactor (CSTR), which is simple and easily available on an industrial scale, will be used as the aerobic reactor. The effluent stream from the anaerobic reactor is fed directly into the aerobic reactor where it is continuously mixed (200 rpm) and fed the inducer at a rate of 0.45 gpm for ten hours. Like the anaerobic reactor, the aerobic degradation is completed at ambient temperature and a pH of approximately 7.2. (5)

The effluent stream leaving the bioreactors primarily contains water, converted compounds, and biomass, and are void of any restricting contaminant concentrations. UIEDT can therefore release it straight into the local sewer for treatment at the waste-water treatment facility. (6)

The sludge remaining in the treatment tank has been sufficiently treated by the hydroxy apatite and activated carbon to immobilize the contaminants in both the water and soil phases. It is pumped directly from the tank into the feed reservoir for a series of two rotary vacuum drum filters (RVDF's). The RVDF's are efficient solid-liquid separators which work by drawing slurry from the feed tank onto a rotating drum, where a cake is formed on a filter cloth as a created vacuum pulls the filtrate through internal drainage channels. (7) Since it is not necessary for extremely high purity in the exit streams, which allows us to take advantage of lower capital, operating, and maintenance costs, RVDF's were chosen over other separation techniques such as sediment centrifugation or plate filtration.

Two streams emerge from the RVDF's: a slightly moist (<15%) soil cake and a water stream. (7) The soil can be moved with a small front end loader and returned to the original evaporation ponds as fill, with the additional benefit of being in a position to trap any further leached contaminants from the site with the hydroxy apatite reaction. (2) The water stream contains no detectable contaminants except for the salt concentrations which result in a moderately high TDS (total dissolved solids) level. Because waste-water facilities use biological systems for treatment, it could be expected that the salts would create a serious problem. However, since the total liquid stream containing the salts is only 138,000 gallons (released at less than 5.800 gallons/day), the high pH stream would be quickly neutralized by the much larger stream

contributions made by the rest of the community. Release of the water stream into the sewer has been approved by the waste-water treatment facility in Las Cruces. (8)
Fig. 1.
The treatment time for each of the 22 batches is 250 hours. based on the 24 hour requirement for the apatite reaction, 9 days for the anaerobic remediation, and 10 hours for the aerobic remediation. Since it can be done simultaneously with the biological treatment. the time necessary for the RVDF's and transporting the soil is encompassed within the 250 hours. The overall time. however, does not depend upon 250 hours for each batch since the bioreactors have been scaled up to accommodate approximately 3 batches at a time, allowing the "treatment tank" stage to run on a constant basis. But, it is necessary to account for the time needed to pump the sludge, volatiles, or water from one stage to the next. The total treatment time is approximately 100 days when also including set-up and training, down time, and take-down.
ECONOMIC ASSESSMENT
In order to determine the feasibility of a proposed project, it is necessary to complete an economic evaluation. The intent of this evaluation is to provide a cost estimate of the entire treatment process, based on three cost categories: capital. operating. and other associated costs. The cost estimate has been completed using both vendor quotes and a series of cost tables and charts found in Plant Design and Economics for Chemical Engineers by Peters and Timmerhaus. The assessment also assumes that detailed variations of the "six-tenths rule" applies to our equipment and that costs of similar processes are closely related to the costs involved in this process. An accuracy of approximately -30% to +30% has been reached with the resulting cost estimates.
The following economic assessment is based on the following:
Total Process Time -- 100 days
Set-up, training, inoculum, start-up ~ 2 weeks
Treatment ~ 72 days
Down time ~ 8-10%
Take down and clean-up ~ 1 week
Operating Schedule -- 7 days/week, 8 hours/day
Equipment Costs -- amortized by % depletion of total production capability over 15 yr. (10 yrs of actual operation)
Various operating and associated costs -- assuming a percentage of capital investment
Capital Costs
For this evaluation, capital costs include equipment and start-up costs, with items such as site preparation and R&D falling under associated costs. Expenses for installation and any necessary electrical or process control are included in the given equipment costs. The equipment costs are amortized on a percent depletion basis, assuming a total "life" of 7,000,000 gallons (180,000 gal/1 00 days for 15 years, with 10 years of actual operation time).
Table II
Table III
Operating Costs:
Labor

The proposed process will run eight hours per day, seven days per week. Since the process requires mostly supervision rather than a constant need for "hands-on" labor, there is not a need for very many employees. During the normal business week (Monday - Friday). the person hired as project engineer/manager will work a typical 40 hour week. A lead operator will also work a 40 hour week, but from Wednesday through Sunday to overlap with the engineer so that a supervisor will always be available. The operators will work approximately 40 hour weeks on rotating schedules. and will be on duty two at a time. UIEDT might need to adjust the 8 hour shifts and worker schedules periodically on those days between anaerobic bioreactor batches for transfer and cleaning. UIEDT will hire the operators locally, while the engineer will be brought in and given a living stipend of $125 per day.

Table IV

Utilities

The predominant utility cost is for electricity to run the pumps, agitators, and vacuum drums. Energy costs are assumed to be $0.08/kW-hr. Steam at 100 psig for the heating coil is priced at $3.50/1000# and the condenser cooling water is $0.10/1000 gallons. The sewer water costs are estimated at $2.20/1000 gallons.

Landfill

If land application is not approved at the site, UIEDT must take the treated sludge to a class C landfill. Landfill costs can be assumed to be $100 per cubic yard, and transport costs to the landfill is approximately 25% of the total landfill cost, which would result in a total disposal cost of almost $25,000.

Table V

Other Associated Costs

Not included in capital or operating costs are other necessary expenditures that can make up anywhere from 5-15% of the total process cost and vary significantly depending upon the actual process. Included in these are permit and regulation costs which are generally the obligation of the responsible party and vary from site to site (as a result, the value included here is only approximate permit fees for this site, and doesn't include legal costs).

Table VI

TOTAL PROCESS COST: $166,000

The total process cost of $166.000 is equivalent to $0.93 per gallon or $145 per ton of the contaminated sludge treated. Operating costs arc equal to 80% of the total cost, and labor itself is almost 70%. The bioremediation phase accounts for the majority of the treatment expenses, with the apatite treatment itself costing less than $40 per ton. Because of the nature of the design, the total cost per ton would decrease significantly with an increase in the volume treated.

REGULATORY AND LEGAL CONSIDERATIONS

Remediation and stabilization of the hazardous waste while preventing contamination of the surrounding land is the primary concern of the University of Idaho Environmental Design Team (UIEDT). In order to maintain credibility with the community and receive cooperation from governmental agencies WERC and UIEDT must comply with applicable environmental laws and regulations.

The legal and regulatory issues that are most important are those governing permitting, waste transport, generation and disposal of waste, and water and air quality. The primary regulatory instruments that are of

concern to UIEDT are the Resource Conservation and Recovery Act (RCRA-HSWA), Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), Hazardous Materials Transportation Act, (HMTA), Clean Air Act, Clean Water Act, OSHA, and finally state administered laws. (6,9) UIEDT will contract the services of a professional environmental consultant with extensive knowledge of federal and local regulations in addition to general permit requirements. Although professional assistance will be obtained, it is useful to discuss general regulatory requirements.

Permitting information is contained in 40CFR part 124. Permits are usually issued by the EPA, state of operation or both. Currently under the Hazardous and Solid Waste Amendments of 1984 (HSWA), until states receive specific HSWA authorization, all permits are handled as joint issuance, assuming the state has the authority to implement pre-HSWA provisions. Signatures by EPA and the state are necessary to provide the facility with authority to operate under RCRA. If the state has no authorization, EPA assumes authority to issue the permit. Specific requirements needed to receive the permit are not covered here, but can be found in EPA's Permit Applicant's Guidance Manual for Land Disposal,. Treatment, and Storage Facilities. (10)

The generation of wastes and the regulations covering those actions are the next concern of UIEDT. As mentioned earlier a myriad of regulatory activity surrounds the generation of disposal of wastes on all government levels. UIEDT will apply, to become a Corrective Action Management Unit (CAMU) through RCRA as regulated in 40CFR sections 260.264. 265,268.270. 271. These rules promulgate provisions under subpart S for CAMUs to be used for the purpose of facilitating remediation waste management activities at RCRA facilities. More specifically for a site remediation project under CAMU any waste managed within the CAMU s, which was generated as part of the corrective action at that facility (i.e., remediation waste) would not be subject to RCRA regulatory disposal requirements. Thus, waste generated from corrective action at the facility may be placed within the CAMU to the technology-based levels established under the RCRA land disposal restrictions (LDR) program. As a CAMU remediation project UIEDT would still be required to meet the remediation standards set by RCRA. (10)

The next concern of UIEDT is the transport of hazardous waste from the site. The transportation of hazardous wastes is regulated by both the Hazardous Materials Transportation Act (HMTA) and RCRA. (9,11) Section 3003 of RCRA required EPA to establish standards for transports and coordinate activities with the Department of Transportation (DOT). (10) WERC is also considered a TSD (Treatment, Storage and Disposal Facility) and is subject to 40CFR Sections 264, containing requirements applicable to new facilities or those possessing a permit. Treatment is any method, technique or process designed to change the physical, chemical, or biological character or composition of any hazardous waste so as to recover energy, or biological character or composition of any hazardous waste so as to recover energy or material resources from the waste, or to render such waste non hazardous or less hazardous: safer to transport, store, or dispose of; or reduce in volume [Section 260.10].

As a TSD, the WERC site should obtain an EPA identification number by submitting EPA form 8700-12 to the regional EPA office (Region VI, Dallas TX. 214-655-6700) or authorized state (New Mexico, 505-827-2924). Depending on the necessity of and business arrangement with the landfill,

WERC may be required to submit a detailed analysis of the transported waste as detailed in Sections 264/265.13.27

Location of UIEDT s operating waste remediation unit may also fall under jurisdiction of the EPA or state environmental authorities. Under Section 264.18. there are location restrictions which include:

Facility must be located 220 feet from an active Holocene fault.

Facilities are not allowed on a 100 year flood plain unless it meets the exemption conditions contained in [Section 264.18(b)]

Location subject to wetland restriction in accordance with Executive Order 11990(Protection of wetlands)

Further information on site-specific location standards can be found in EPA s Permit Writer's Guidance Manual for Hazardous Waste Land Storage and Disposal facilities. February, 1985 (OSWER Directive No. 9472-004).

Security measures are also the responsibility of WERC and are contained in Sections 264/265.14, requiring the prevention of unknowing or unauthorized entry of persons or livestock to the active portions of the facility. Security measures may include one or all of the following: 24 hour surveillance systems around the facility, signs, and barriers to prevent entry to the facility. Regulations governing these activities follow Sections 264/265.14(a)(b)(c).

Regulations regarding training of employees for the TSD facility is outlined in Sections 264/265.16. The training program must familiarize the employees with emergency procedures and emergency equipment shut-off controls. Regulations contained in Sections 264/265.32 require the facility to maintain an internal communications system, external communications system and adequate fire-fighting and response equipment. Communication with local authorities in the case of an emergency is required by sections 264/265.37(a).

WERC is also required to develop a contingency plan that describes the actions facility personnel must take in response to fires, explosions or releases [Sections 264/265.51 (a)]. A well developed contingency plan will follow the sample contained in OSWER Directive No. 9523.00 10.

UIEDT expects the site to close cleanly in accordance with Sections 264/265.11:264/265.112, and will not be subject to post-closure requirements [Section 264/265. 110]. Within 60 days of the closure, a certification must be prepared and submitted to the EPA [Sections 26z./265.225]. WERC may be subject to financial responsibility and liability requirements, Sections 204/265.14C(b) and 264/255.147, respectively. (10)

The Clean Air and Water Acts are of concern to UIEDT and WERC. UIEDT will make a significant effort to remove all contaminants from the water using bioremediation, and the use of phosphate ore. The processed water will be sent to a waste water treatment plant for final purification, after UIEDT has obtained a waste water discharge permit through the State of New Mexico Water Quality Control Commission. (12)

The only concern of UIEDT in the area of air quality is the volatilization of contaminants during remediation. Volatilization will be avoided by using a closed remediation system, thus the WERC remediation with respect to the Clean Air Act is free, for all intents and purposes, from regulatory requirements.

Overall, the areas of concern for UIEDT with respect to the proposed remediation are permitting, waste generation rules, transport, disposal requirements and finally, air and water quality. The regulations have

been presented primarily from a federal perspective, but it is equally important to recognize local and state authority, as mentioned earlier.

HEALTH AND SAFETY

The UIEDT regards the health and safety of the community and workers as top priority,therefore; UIEDT agrees to accept the responsibility of maintaining a safe working environment. The major objectives to uphold include: compliance with industrial safety standards (ACGIH. AIHA. and NIOSH), adherence to regulations (OSHA, EPA, State of New Mexico, City of Las Cruces), maintaining high worker morale, and achieving the most efficient level of clean-up. (13)

Before any work may begin, a Site Health and Safety Plan including medical surveillance of employees and documentation on site worker training is required by OSHA. Also encompassed in the General Health and Safety Plan are: the organizational structure, comprehensive work plan, training programs, standard operational procedures and informational programs. (13)

To meet these objectives in the clean-up process, UIEDT is primarily concerned with the maintenance of good ventilation, proper use of methane gas, worker protection/well trained workers, and a contingency plan in case of an accident. Maintaining good ventilation throughout the process is necessary to minimize the airborne contaminants. The bioreactors produce a substantial amount of CO and the mixing of the hydroxy-phosphate as well as the use of the drum filter could allow for aerosols. Consequently, a hood on-site would be beneficial for both the collection of endproducts as well as for proper air monitoring, which is a factor in the quality assurance program. A daily sample would be recorded in order to compare values and stay within regulations detailed in the FDR's. (10) In the event of a high reading, a warning signal would be activated which would be directly relayed to the project manager for response.

The use of methane gas in the aerobic chamber of the bioreactor demands special attention. The explosive nature of methane gas when it comes in contact with air is a problem that must be addressed. (14) First, all employees would be knowledgeable of the precautions necessary and what to do in the case of a gas leak. Next, specially designed pressure valves and reinforced sealed tanks will be purchased to insure the safe utilization of this gas. In addition, the above ground tanks will be stored in a more secluded area of the site approximately 300 yards away from the main location. Lastly, a methane and propane mixture was chosen because of the increased safety level as well as the enhanced biodegradation of the volatile organic compounds under these conditions. (5)

Protecting the employees is essential for a successful process. It is important that universal precautions are used in all situations, which involves the assumption that all materials in this process are a threat to the health of any exposed person. Following this assumption, protective clothing must be worn and safety regulations must be followed and strictly enforced at all times. This includes appropriate documentation of daily procedures in the event of having to backtrack the operation. In addition, all workers must have proper training about the contaminants on site and be familiar with the contingency plan. This type of instruction is fundamental to the proper execution of this process. To attain this knowledge, each employee will be required to take a 40 hour OSHA hazardous materials course which teaches precautions and appropriate preparation as contained in 29 CFR 1910.120 HAZWOPER TRAINER. (13)

Unfortunately the possibility of an accident will always be present, even if the requirements are met and the proper procedures are followed in this situation, a contingency plan would be necessary for the maintenance of UIEDT's high safety standards. The plan should include a flowchart which would clearly state the steps that must be taken to contain contamination and who to contact. The procedures outlined in the Material Safety Data Sheets (MSDS) for the chemicals involved in the process will guide emergency response and containment action. (15) Due to the precautions taken by the UIEDT, the worst case scenario is not likely, but the employees will be trained to be prepared for almost any situation.

COMMUNITY PLAN

The UIEDT recognizes the importance of developing a good relationship with the community regarding the removal and treatment of hazardous wastes. Cooperation will be essential for a successful process. To start the formation of a good community relationship, the following objectives regarding community relations should be instigated: encouraging public involvement, employment of effective communication, and the instigation of widespread education.

Encouraging public involvement in the remediation plan is a method for attaining cooperation from the community. The people in the surrounding areas have a right to be informed and a right to participate in any decisions that may affect their health or property. (18) It is imperative that WERC acknowledges these privileges and intends to involve the public from the beginning by allowing them to review any proposals before the important decisions are made. Any suggestions should be considered and a possible open forum setting could prove advantageous because this would provide an opportunity for individual expression. Additionally, articulation should be encouraged through a "suggestion box" in the city hall. A monthly committee composed of WERC employees and administrators could meet to answer these questions and distribute the answers in a newsletter format.

Effective communication is essential in any relationship, especially when one of the parties is less informed. Most importantly, WERC should develop honest open ties with the citizens. To attain this alliance, any concerns should be addressed immediately and questions should not be avoided but answered in an straightforward fashion. Furthermore. jargon and technical language should be kept to a minimum because they serve as barriers to effective communication. This includes limiting acronyms, abbreviations and raw data; instead expanding personal experiences and anecdotes. Ultimately, the interactions should be on a more personal level instead of on an abrupt detached level.

Finally, the instigation of widespread education would help to produce a more informed public. The significance of providing informative seminars where the general public can learn more about the processes involved in hazardous waste treatment is well documented. If the people can be taught the importance of treating the wastes and how it can benefit them in the future, they will most likely be more willing to cooperate. Another way to educate the public is to use the media in an effective manner. In today's society, many busy Americans depend on the media to provide information, so WERC should be open and accessible to reporters and members of the media.

In conclusion, when the people are kept involved and informed, they are often more interested, realistic, and cooperative. These factors can mean

the difference between a successful project and a project plagued with continuous problems.

FINAL CONCLUSIONS

UIEDT's proposed treatment design for the contaminated evaporation pond sludge fulfills the requests and meets the requirements presented by WERC. The treatment process chosen -- involving bioremediation, apatite immobilization. and a solid-liquid separation technique -- is designed and optimized to be a successful, efficient and cost effective alternative. With this process, the contaminated sludge is remediated to a form which allows the solid portion to be returned to the site for land application and the liquid portion to be fed directly into the local sewer. Literature and experimental results confirm that the contaminant concentrations are reduced to levels well below the requirements for 30 year LDRs (WERC rqmt.), DOT (WERC rqmt.), and also for UIEDT's intended application. Analysis and reviews also confirm the permanent stability of the process, resulting from the fact that the sludge is remediated rather than just stabilized.

This proposal includes a preliminary technical design for the described treatment site, and also addresses the economic, environmental, safety, and social considerations. Additional information concerning the site would be required for a more detailed process design, and further on-site tests should be performed to confirm the large scale applicability of the process.

Potsdam, NY 13699-5715

ABSTRACT

A solidification and stabilization (S/S) technique was developed for a chemically complex mixed waste sludge containing nitrate processing wastes, sewage sludge, and electroplating wastwaters. The sludge has high concentrations of nitrate salts; cadmium, chromium, and nickel concentrations of concern; and low levels of organic constituents and alpha and beta emitters. Because this waste is classified as both a listed hazardous waste and a low-level radioactive waste, land disposal

in a mixed waste landfill was identified as the only suitable method for the long term management of the sludge.

Preparation of the sludge was required to ensure compliance with all land disposal regulations. The S/S process identified and optimized for this sludge included sulfide reduction of nitrate and precipitation of metallic species, followed by evaporation to dryness and solidification of the dry sludge in recycled high density polyethylene with added lime. A modified Toxicity Characteristic Leaching Procedure was used to determine required treatment chemical dosages and treatment effectiveness. An economic assessment of the cost of this project showed over 50% of the total cost can be attributed to the transport and disposal of the solidified product in a mixed waste landfill.

The implementation of this process will involve compliance with several environmental and health and safety regulations. RCRA hazardous waste generator and NPDES permits are needed for this process. OSHA standards require adequate monitoring and protection of on site employees from exposure to radiation and chemical hazards.

INTRODUCTION

Solidification and stabilization (S/S) are established and widely used technologies for the preparation of hazardous wastes for land disposal. These techniques effectively reduce the mobility of hazardous constituents and provide a product with a suitable structural integrity for compliance with RCRA Land Disposal Restrictions (LDRs) (40 CFR 268). S/S has been incorporated into 28% of the CERCLA record of decisions written between 1982 and 1992, making it the single most widely used technology for hazardous waste sites (1).

Many S/S applications involve the use of cement, with or without a pozzolanic material, to bind the waste material into a solid monolithic form (2). These materials are most widely used because of their low cost and readily available processing equipment. The major limitation of cement-based S/S applications is the potential for incompatibilities between constituents in the waste and the cementation reactions. This is particularly true for wastes with a high ionic strength; many types of salts increase the setting times and decrease the durability of the cured concrete (3).

The research described here was conducted to find a suitable S/S process for a chemically complex mixed waste. The waste sludge has been dredged from solar evaporation ponds and is currently waiting for further processing before its ultimate disposal. The evaporation ponds had been used to reduce the volume of a wide variety of wastes including nitrate processing solutions, sewage sludge and electroplating wastewaters. The sludge is characterized by high concentrations of nitrates and heavy metals (Cd, Cr, Ni), low concentrations of several volatile and semi-volatile organic compounds, and low levels of alpha and beta radiation emitters. The precipitation of insoluble inorganic complexes and wind blown dust both contribute to the approximately 30% solids concentration in this sludge.

Regulations addressing two specific characteristics of this waste material effectively limit the ultimate fate of this waste to land disposal. First, the presence of alpha and beta radiation emitters classifies this waste as a low-level radioactive material. Storage in a regulated land disposal unit is the only option for the long-term management of these wastes. In addition, since the ponds were used for the treatment of electroplating wastewaters, the entire waste stream is

considered a listed waste (F006) and, thus, any byproducts derived from the treatment of this waste will also be considered a listed waste. The preparation of this waste for a mixed waste landfill by S/S was the only option suitable under current RCRA and NRC regulations.

The objective of this paper is to present the procedure and rationale used to develop an appropriate S/S process for this chemically complex waste sludge. Several factors were considered in this assessment; the most critical criteria included:

- immobilization of the heavy metals to comply with the Universal Treatment Standards (UTSs) defined under the LDRs of RCRA (40 CFR 268);
- reduction of the concentration of the highly reactive nitrates;
- production of a solid material with a structural integrity for compliance with RCRA and NRC regulations; and,
- minimization of the volume of waste requiring land disposal.

Considerations for the regulatory, economic, and health and safety issues that are impacted by this design are also discussed.

PROCESS IDENTIFICATION

Solidification Processes

The most important criterion for choosing a suitable binder to solidify the waste material is the compatibility between constituents in the waste and the characteristics of the solidification agent. Of the many constituents in this waste, those contributing to the high ionic strength were expected to cause the greatest incompatibilities with S/S techniques. Table I presents the approximate total concentration of primary ions in the sludge, illustrating the extremely high concentrations of sodium, potassium, and nitrate ions. Organic constituents were present at only low concentrations (10-100 ppb) and were not expected to cause any incompatibility problems. Literature sources describing the application of S/S processes to other complex waste streams were reviewed to identify an appropriate technique for this particular waste.

Table I

A significant amount of work has been completed showing the feasibility of encapsulating complex chemical wastes in polyethylene (4-5). In this process, dried waste is mixed with the polyethylene in a heated extruder. Microencapsulation of the waste in the plastic matrix effectively reduces the amount of leaching and greatly increases the structural durability of the waste material. The use of post-consumer polyethylene has the added benefit of using a waste product to treat a waste.

Polyethylene encapsulation has been used successfully for nitrate salt wastes with low levels of radioactivity (6-8). This technique has been shown to greatly reduce the leachability of salts; provide a solidified matrix that greatly exceeds durability standards set for both hazardous and nuclear wastes; and, be readily implemented at a full-scale operation (6,8). Previously published research on the polyethylene solidification of nitrate salts indicates, however, that the heavy metals may not be sufficiently immobilized by this process. For example, Kalb et al. (6) report a concentration of 3.6 mg/L chromium in the leachate generated from the toxic characteristic leaching procedure (TCLP). This concentration is sufficiently low to prevent the waste from being identified as hazardous based on its toxicity characteristic (40 CFR 261.24). However, for the land disposal of listed wastes, the TCLP leachate must have concentrations below the Universal Treatment

Standards. The UTS for chromium is 0.86 mg/L (40 CFR 268), well below the concentration achieved by Kalb et al. (6).

Based on the successful implementation of polyethylene encapsulation of nitrate salt wastes, it was decided to pursue this technique for the mixed waste considered in this research. The overall process for the solar pond sludge, however, requires additional processes: the waste must be dried prior to solidification in polyethylene; and, the heavy metals immobilized to meet the stringent UTSs for land disposal of a listed waste.

Chemical Stabilization Processes

Stabilization of metallic species is accomplished by conversion of the metal into an insoluble complex by way of chemical reaction. The insoluble solid form can then be separated from solution. Metals are often rendered insoluble by precipitation in a metal-sulfide, metal hydroxide, or metal carbonate form, or reduction to metallic form by reaction with a borohydride. For economic reasons sulfide and hydroxide precipitation are the more attractive options.

At the high pH conditions found in the waste, precipitation of metals as metal hydroxides would seem a reasonable approach. All three metals of concern (Cd, Cr, Ni) form fairly insoluble hydroxide complexes. Aqueous concentrations of less than 1.0 mg/L are theoretically achievable (9). Were it not for the amphoteric behavior of metal hydroxides, all of the metals would be stabilized by this method to a degree which could approximate the desired insolubility. However, the metal hydroxides are increasingly soluble at both low and high pH, and the pH of minimum solubility changes with metal and with solution characteristics. No optimum pH value exists at which all three of the metals of interest can be rendered insoluble to the desired degree.

Cadmium and nickel readily form metal sulfide species (CdS, NiS) which are also fairly insoluble. Nickel forms a sulfide complex of similar solubility as the nickel hydroxide complex, while binding cadmium as CdS reduces its aqueous solubility in dilute solution to approximately 10-7 mg/L at pH 11 (9). This greatly reduced cadmium solubility is desired in order to render the metal immobile and meet the UTS.

On addition of the sulfide based reducing agent to the waste, other oxidation/reduction reactions also take place. Nitrate salts in the mixture will be reduced to nitrite and the nitrite to more reduced nitrogen complexes. Reduction of nitrate salts to other nitrogen species is beneficial in that both nitrate and nitrite salts are strong oxidizers. In dried form, they can react violently with combustible materials, resulting in violent combustion or explosion (10).

Summary of Appropriate S/S Process

Based on a review of the chemical characteristics of the solar pond sludge and literature applications of S/S technologies, an overall strategy involving the stabilization of the waste through the addition of sodium sulfide and lime and solidification in polyethylene was identified as appropriate for this waste. The addition of sodium sulfide has the dual role of precipitating both nickel and cadmium as very insoluble complexes and reducing the nitrate to less reactive nitrogen species. The reduction of the nitrates has an added benefit of reducing problems associated with incompatibility. The addition of hydroxide as lime (CaO) ensures the maintenance of a high pH so that the precipitation of chromium in the hydroxide form is maximized.

One drawback to this process is the generation of a secondary by-product stream as water is separated from the waste material prior to encapsulation in polyethylene. Traditional separation processes for water and solid, such as filtration were rejected due to the very high dissolved solids concentration - including radionuclides - that would remain in the filtrate. Instead, evaporation of the water was identified as the best technique. Pilot-scale testing by Faucette et al. (8) identified that a horizontal thin film evaporator produced a dry salt from an aqueous nitrate salt waste with the most desirable physical characteristics for polyethylene solidification.

EXPERIMENTAL METHODS

Due to the very high ionic strength in the solar pond sludge, it is not feasible to predict the appropriate dosages of treatment chemicals based on chemical equilibrium calculations. Experimental testing was necessary to optimize the overall S/S process identified above.

A surrogate waste which approximated the ionic composition of the raw waste as indicated in Table I was prepared from reagent grade chemicals, water and kaolinite. Radioactive materials present in the solar pond sludge were omitted from the surrogate waste in order to avoid worker exposure to radioactivity. This mixture was allowed to react overnight before proceeding with treatment. Chemicals used to treat the surrogate waste mixture were sodium sulfide, lime, and polyethylene pellets.

Sodium sulfide was mixed with the surrogate waste mixture in separate batch experiments and allowed to react for 12 hours on a wrist action shaker before testing pH, nitrate and nitrite concentration in the mixture. In this manner the sodium sulfide dose required to fully reduce the nitrate and nitrite species was determined. Nitrate and nitrite concentrations were determined using commercially available colorimetric test strips (EM Quant, EM Science, Gibbstown, NJ).

Once the range of sodium sulfide dose required for reduction was determined, batch treatment of the waste was performed in a more limited range around this dose to determine the optimum dose for immobilization of the cadmium as CdS. Identification of the optimum dosage was determined based on the concentrations of metals in the TCLP extract from treated and solidified samples. Lime, if added for a particular test, was added to the dried waste mixture prior solidification. The drying and solidification steps mimic the procedure used to stabilize the waste in the full treatment process.

Drying was performed by heating the sulfide treated portion of the waste in a distillation apparatus until nearly dry. The waste mixture was removed from the distillation flask into a blender (Waring, Winsted, CT) for grinding to facilitate mixing with polyethylene.

A bench-scale mixing and extrusion apparatus was constructed to perform the mixing of treated, dried waste and polyethylene pellets. An aluminum tube with a 4.7 cm inner diameter and 17 cm in length was fitted with aluminum end caps. The tube was filled with a mixture of waste, lime and polyethylene pellets, placed on a laboratory hot plate and wrapped in heating tape along its entire length. The hot plate and heating tape were controlled by a rheostat in order to prevent excessive heating of the mixture. As the mixture melted in the tube, it was periodically mixed manually with a stir rod. Approximately one hour was required to fully melt and mix the components. The polyethylene and treated waste mixture was extruded from the tube by removing the end caps and pushing the mixture from the tube into a metal mold using a metal rod fitted to the

diameter of the tube. After cooling for ten minutes, the monolith was removed from the mold and used for further testing.

Leaching of the contaminants from the monolith was performed by a slight modification of the standard technique for TCLP. As metal species were the only components of interest, small polyethylene bottles (Nalgene) were substituted for the zero-headspace reactor. A bandsaw was used to cut the monolith into cubes not larger than 9.5 mm per side. Extraction fluid for an alkaline sample (TCLP Fluid #2, 40 CFR 261) was prepared and its pH tested to be 2.880.05. The final solution pH was verified and recorded. The extract was isolated from the waste cubes and diluted as necessary for analysis.

Metals analysis of the leachate was performed by graphite furnace AAS using a Perkin-Elmer Zeeman 5000 spectrophotometer. The method of standard additions (11) was utilized to minimize matrix interference effects.A Universal Testing Machine (Tinius Olsen) was used to perform the unconfined compressive strength test on the final monolith according to a standard testing protocol, ASTM D 2216-91. Freeze-thaw durability of the monolith over 12 cycles of freezing and thawing was determined by ASTM D 4842-90.

EXPERIMENTAL RESULTS

The initial batch tests were conducted to identify the sodium sulfide dosage required to reduce the nitrate species. Treatment with doses of sodium sulfide between 0 and 150 g/L were considered. The nitrate in solution was reduced to below detection following addition of approximately 85 g/L of sodium sulfide. Nitrite concentration was near the detection limit in the untreated waste and remained below the sensitivity of the test strips at all sodium sulfide dosages.

The dosage of sodium sulfide needed to stabilize the cadmium as CdS was then determined. Dosages ranging from 70 to 120 g Na_2S per liter of the surrogate waste were considered. The treated waste was then dried, mixed with polyethylene on a one-to-one basis by weight, extruded, cooled and subjected to the TCLP. The average cadmium concentration in the TCLP leachate as compared to Na_2S dose is given in Fig. 1. The UTS limit for cadmium of 0.19 mg/L is indicated by the horizontal line. Only one Na_2S dosage tested, 110 g/L, was able to meet the UTS requirement. Nine separate extractions were performed at this dosage to verify this result. Subsequent tests were performed using this treatment dosage.

A series of lime doses were added to the treated dried waste to ensure precipitation of the chromium in the mixture as $Cr(OH)_3$. Figure 2 displays the results of average chromium concentration in the TCLP extracts. These samples were prepared from 50% by mass polyethylene, the indicated percent by weight of lime and the balance dried waste. The horizontal line reflects the UST of 0.86 mg/L. Three individual tests at a 10% lime dose showed the UST could be achieved by this process. Nickel concentrations in the leachate from this product averaged 0.17 mg/L, well below the UTS of 5.0 mg/L.

Fig. 1 & 2

The polyethylene monoliths also met requirements for durability. The NRC requires a minimum unconfined compressive strength of 60 psi for generic waste forms containing low-levels of radioactivity (5). The waste material generated in this work had a measured compressive strength greater than 450 psi. This value was not affected by 12 cycles of freeze and thaw conditions. The freeze/thaw test also showed long-term

durability with insignificant mass loss (0.05%) over the period of this procedure.

Water evaporated during the drying of the waste was condensed and tested. There were no detectable concentrations of cadmium and chromium in the condensate, although a significant amount of hydrogen sulfide gas was emitted during the drying, which dissolved in the condensate. In the laboratory, hydrogen peroxide was used to promote the oxidation of the sulfide to sulfate ions. The treated condensate contained 54 mg SO4/L.

OTHER DESIGN CONSIDERATIONS

Regulatory Constraints

The Resource Conservation and Recovery Act (RCRA) and regulations under the Nuclear Regulatory Commission place severe limitations on the handling and final disposition of this waste material. The combined identification of this waste as a listed hazardous waste (F006) under RCRA, and a low-level radioactive waste effectively limits the ultimate management of this waste to landfilling in a mixed waste facility. Prior to landfilling, however, the waste must be processed to meet the constraints of the Land Disposal Restrictions defined under RCRA (40CFR 268). These restrictions require that there be no free water associated with the waste, that the leachate generated from the waste product by the TCLP have concentrations less than the Universal Treatment Standards, and that the waste have a suitable structural integrity. The testing summarized above indicates that treatment of the waste with sodium sulfide (110 g/L), evaporation of water, and mixing/extruding with lime (10%) and melted polyethylene (50%) produced a product meeting the requirements of the LDRs.

Although the on-site treatment of this waste will be conducted under a CERCLA record of decision, a RCRA permit will still be required to obtain status as a RCRA hazardous waste generator (40 CFR 262.12 and 262.20). This permit will provide the EPA identification number required for manifesting and transporting the solidified waste to an off-site disposal facility. The waste should be transported by a licensed hauler in trucks that are placarded according to 49 CFR 177.

Because this process generates a secondary waste stream, the evaporated water, additional regulations for this byproduct must also be considered. This stream is considered a listed waste since it is derived from the treatment of a listed waste. Analysis of the water evaporated and condensed during the drying operation showed that it contains no detectable levels of the heavy metals included in the F006 waste. Radionuclides in the original waste are present in ionic forms and will be concentrated with other salts as the water molecules are vaporized. Thus, it is recommended that an application for the delisting of this waste material be completed. This procedure is lengthy but will greatly reduce the volume of waste material that will require disposal in a landfill.

Assuming that the evaporated water is successfully delisted, additional regulations limiting discharges to the atmosphere (Clean Air Act) or a water body (Clean Water Act) will have to be considered. Significant concentrations of dissolved hydrogen sulfide gas were detected in the condensed water. While this gas will not render the water "hazardous, " it cannot be freely discharged to the environment. Laboratory treatment of the condensate showed that the sulfide ions can be successfully oxidized to sulfate ions. The concentration of sulfate ions (54 mg/L) in the condensate is very low relative to the proposed Safe Drinking Water

Act maximum contaminant level goal for this constituent of 500 mg/L. There should be no trouble obtaining a National Pollutant Discharge Elimination System (NPDES) permit for the discharge of the condensed water to a local surface water body.

Health and Safety

Additional regulations restricting the actions and exposure of employees to hazardous materials will also be applicable to this treatment process. These regulations include subparts of OSHA general industry standards (29 CFR 1910) and CERCLA (40 CFR 311)

The primary concern for the workers involved with the waste solidification process is the potential for exposure to alpha, beta, and X radiation. The X radiation is a byproduct of Bremmstrahlung reactions as beta particles are attenuated by shielding materials. With worst case assumptions, it was determined that all employees must maintain a distance of at least 1.5 m from all process equipment to ensure that radiation dosages are maintained below the allowable limits (29 CFR 1910.96). Film badges should be worn to monitor exposure levels and a lockout/tag out fence employed to maintain an adequate distance between employees and process equipment.

Monitoring and personal protective equipment should also be available for other potential hazards to employees. Grinding equipment for the treated dried waste should be enclosed and ventilated to minimize the inhalation of metal-laden dust. Other process equipment should be ventilated to ensure compliance with carbon monoxide and hydrogen sulfide air quality limits. Carbon monoxide can be produced during the polyethylene extrusion process while the hydrogen sulfide is a byproduct when sodium sulfide is added to an aqueous solution. The high pH of the waste will help to minimize the H_2S production.

Economic Considerations

The cost of processing 180,000 gallons of the solar pond sludge in a 6 month period was assessed. The cost of disposal of the solidified product in a mixed waste landfill was the most significant cost associated with this process. Rates for disposal vary between $360 and $1000 per cubic yard. Compared with equipment rental, utility and personnel expenditures, the disposal cost represents 50 to 75% of the total budget. Thus, any additional steps to minimize the volume of waste would lead to a reduced project cost.

Other researchers have used much lower polyethylene to waste ratios in their application of this technique for the solidification of waste materials. Monoliths with as little as 30% polyethylene have been successful for both incinerator ash (4) and nitrate salts (7). This variable was not considered in this research. With the small scale equipment used to conduct these experiments, it was difficult to achieve a homogeneous distribution of the waste product in the melted polyethylene. This became more problematic with a decreased fraction of polyethylene. The decreased polyethylene:waste ratio would substantially reduce the costs associated with the purchase of polyethylene and transport and disposal of the solidified product. With 30% polyethylene, however, it is expected that the concentrations of cadmium and chromium in the TCLP extract from these samples would increase. Kalb and Adams (7) found that with an decrease in the polyethylene fraction from 50% to 30% the cadmium concentrations increased by nearly five fold. Similar increases with the waste used in this work would restrict this solidified waste from land disposal. Further experimentation with full-scale

equipment would be required to adequately assess if higher waste loadings -- used to reduce the disposal costs -- can still met regulatory limits.

SUMMARY AND CONCLUSIONS

The solar pond sludge considered in this research was a complex mixture characterized by a very high ionic strength, elevated concentrations of heavy metals and low levels of radionuclides. Because of the presence of radionuclides and the classification of this sludge as a listed waste under RCRA, disposal in a mixed waste landfill was identified as the only appropriate management technique for this waste. With the complex chemistry of this waste, it was necessary to treat the sludge prior to solidification for land disposal. Two primary objectives were considered during the chemical stabilization of the waste: reduction of the reactive nitrate concentration and immobilization of heavy metals.

Experimental optimization was used to fully develop a S/S process for the solar pond sludge. The overall process includes the addition of sodium sulfide (110 g/L) to reduce nitrates and precipitate cadmium; evaporation of water; the addition of lime to precipitate chromium; and microencapsulation in a polyethylene monolith. The stabilized and solidified product met federal standards for durability and leachability making it acceptable for disposal in a mixed waste landfill.

An economic assessment of the cost of this project showed over 50% of the total cost can be attributed to the transport and disposal of the solidified product in a mixed waste landfill. Further work at a pilot-scale should be completed to assess the possibility of reducing the percentage of polyethylene in the final solidified product.

The implementation of this process will involve compliance with several environmental and health and safety regulations. RCRA hazardous waste generator and NPDES permits will need to be obtained. OSHA standards will require adequate monitoring and protection of on site employees from exposure to radiation and chemical hazards.

ACKNOWLEDGEMENTS

This research project was originally undertaken by a group of Clarkson University students participating in the 1995 Environmental Design Competition sponsored by the Waste-management Education and Research Consortium (WERC). This consortium is based in Las Cruces, NM and the competition directed by Dr. Abbas Ghassemi. The Clarkson students received the "Best Bench-Scale Demonstration" and "First Place" awards for their proposed solution to this problem.

Additional experiments were conducted by Michael Reardon and Matthew Abbato, Master of Engineering students, and AAS analysis completed by Ms. Eleanor Hopke, Laboratory Technician.

SPARTAN ENVIRONMENTAL TECHNOLOGIES PROPOSAL FOR REMEDIATION OF POND SLUDGE

Dianne K. Cole
Holly A. Herner
Edward R. Serzo
Michigan State University
Department of Civil and Environmental Engineering
East Lansing, MI

ABSTRACT

The Waste-Management and Research Consortium (WERC) requested a proposal to remediate and stabilize sludge, which was pumped from three solar evaporation ponds into 10,000 gallon tanks. The sludge was composed of a combination of sediments, water and dissolved and undissolved salts. The contaminants of concern in the sludge included heavy metals, low level radionuclides and organic chemicals (2). Because the sludge contained both hazardous compounds and radionuclides, it was required to be managed as a mixed waste regulated under the Resource Conservation and Recovery Act (RCRA) (1) and the Atomic Energy Act (AEA) (3).

The process proposed by Michigan State University ensured the sludge would be treated, stabilized, transported and disposed of in accordance with all applicable federal, state and local regulations. The design criteria that was used for this proposal is as follows:

- Minimization of the volume of mixed waste to reduce total remediation and disposal costs
- Maximization of the rate at which the sludge is processed
- Compliance with all federal, state and local regulations
- Development of positive community relations
- Minimization of negative health impacts by observing stringent safety considerations

At the time of the proposal the costs of disposing of a mixed waste was approximately 100 times greater per cubic foot than for disposing of a low level radioactive waste (4), thus the primary goal was to reduce the

volume of mixed waste in order to lower disposal costs. Volume reduction was achieved through a remediation process which removed the heavy metals and organic contaminants from the pond sludge. The proposed process was a two step acid extraction, in conjunction with cyanide oxidation followed by chromium reduction and metals precipitation. The treated sludge could then be disposed of as a low level radioactive waste outside the jurisdiction of RCRA.

INTRODUCTION

In 1995, the Waste-management and Research Consortium (WERC) requested a proposal to remediate and stabilize sludge from three solar evaporation ponds. Proposals were requested in an attempt to spark new ideas in the minds of students and to evaluate innovative technologies for the remediation of this site. Michigan State University formed a design team consisting of 22 students from four departments: civil, environmental and mechanical engineering and crop and soil science. These students formed a "company" called Spartan Environmental Technologies (SET) to investigate the problem and seek solutions which would be both physically and economically feasible. The following report details SET's research and the proposed process for remediation.

TECHNICAL ASSESSMENT

The sludge was composed of a combination of sediments, water and dissolved and undissolved salts. The contaminants of concern in the sludge included heavy metals, low level radionuclides and organic chemicals (2). Because the sludge contained both hazardous compounds and radionuclides, it was required to be managed as a mixed waste regulated under the Resource Conservation and Recovery Act (RCRA) (1) and the Atomic Energy Act (AEA) (3).

Several treatment and/or stabilization alternatives were investigated and evaluated based upon the following design criteria: time, economics, feasibility, efficiency, waste minimization, safety and community relations. Table I details the treatment alternatives that were investigated. At the time of this proposal, the options available for mixed waste disposal were extremely costly (4). Therefore, particular consideration was given to those processes demonstrating significant mixed waste volume reduction.

Table I

The proposed treatment process was a two step acid extraction, in conjunction with cyanide oxidation, chromium reduction with sodium sulfite followed by metals precipitation with sodium hydroxide and sodium sulfide (Fig. 1). Research done by SET showed that acid washing effectively removed the metals from the sludge. The proposed design would allow for more than 98% of the solid waste generated to be delisted, resulting in only 1,100 gallons of the solid material requiring disposal as mixed waste.

To prepare the mixed waste for transport and disposal, stabilization using polyethylene was chosen. Polyethylene greatly reduced the disposal volume over commonly used technologies. In addition, the stabilized waste passed compressive tests, toxicity characteristic leaching procedure (TCLP) tests and was shown to be stable in hostile environments (11).

Fig. 1

PROCESS DESIGN

The radioactive and non-radioactive metals were extracted from the sludge using sulfuric acid. The pond sediments contained an appreciable concentration of cyanide. To prevent the release of hydrogen cyanide

(HCN) during extraction, the sludge was first treated with sodium hypochlorite (NaOCl) to oxidize the cyanide (CN-) to carbon dioxide and nitrogen gas (N2). Ozone was studied as an oxidation alternative for sludges with high concentrations of phenol, pyrene or other organic chemicals. Recent work has shown the applicability of using ozone to oxidize these compounds in soils and sediments (7,13).

The complete removal of the radionuclides from the sediments was not feasible. Therefore, the treated sediments were neutralized with sodium hydroxide, dewatered using a plate filter press and could be disposed of as a LLW. Prior to disposal, it was recommended that a delisting petition be submitted.

Following acid extraction, the acid solution containing dissolved metals was treated with sodium sulfite. During cyanide oxidation, trivalent chromium was oxidized to hexavalent chromium. Sodium sulfite reduced the chromium back to its preferred trivalent state. Sodium hydroxide and sodium sulfide were added to precipitate the metals out of the acid solution as metal hydroxides and metal sulfides. Ferric chloride was added to aid in flocculation and settling of the metal precipitates. The metal precipitates were dewatered using a plate filter press. The extracted water from dewatering was returned to the inlet of the metals precipitation/ sedimentation tank to undergo a second acid extraction. The dewatered mixed waste was stabilized with polyethylene in a screw extruder and would ultimately be disposed of at a mixed waste facility. The effluent from the precipitation/ sedimentation tank was neutralized using sulfuric acid and discharged to a publicly owned treatment works (POTW). The treatment process is illustrated in Fig. 1. The equipment and chemicals for the proposed design are shown in Table II.

Table II

PROTOTYPE DESIGN

A prototype was designed to demonstrate the feasibility of the proposed treatment plan. The design was based on extensive laboratory analysis of the surrogate sediment. The surrogate sediment was prepared according to specifications provided by WERC (2,14). In accordance with the proposed full scale design, the metals were extracted from the surrogate sludge in a two stage process, first with 6 N sulfuric acid followed by 0.1 N sulfuric acid. The sulfuric acid solutions were added to the sludge in a 5 L basin equipped with a mixing shaft. Following extraction, the supernatant was siphoned into a second 5 L basin where 6 N sodium hydroxide, 25 mg/L sodium sulfide and 10 mg/L ferric chloride were added. The mixture was flocculated and allowed to settle. The extracted metals were first dewatered with vacuum filtration and then stabilized using polyethylene.

Due to the expense of a screw extruder, a steel mold was used to simulate the ability of polyethylene in retaining the waste during TCLP tests. The mold used for stabilization of the precipitated metals was a 5" x 4" x 4.5" block of steel that has a hollow interior measuring 4" x 3" x 3". The top of the mold was machined so one inch of steel would fit inside the mold to compact the mixture of polyethylene and waste metals. Eight vents were strategically placed to allow excess polyethylene to bleed from the mold. The bottom of the mold was attached using six countersunk machine screws, allowing for easy removal of the solidified block. The mold was placed in a compacting device consisting of two fixed steel plates. A 4 ton hydraulic jack was used to compact the mixture. A movable plate was then placed under the mold to maintain the pressure on the

mixing during melting. The hydraulic jack was then removed and the mold was placed in an oven for 16 hours at 180C. Following the 16 hour heating period and a cooling period, the sample was ready for disposal.

LABORATORY ANALYSIS AND RESULTS

Laboratory treatability studies were conducted using a surrogate sediment containing cadmium, chromium and nickel which are representative of the metals present in the actual pond sludge. Studies were conducted to determine the following:

- the efficiency of metal extraction from the sediment
- the removal of metals from the acid extract
- the ability to stabilize the material to meet RCRA standards

Preliminary studies were conducted to determine the efficacy of solvent extraction using di(2-ethyl-hexyl) phosphate (DEHPA) in hexane for the removal of the regulated metals from the sediments. The extraction coupled with acid washing produced favorable removal efficiencies. However, chromium could not be separated from the solvent phase. Without the ability to recycle the DEHPA, the cost increased significantly making the process economically unfavorable. In addition, the kaolin in the sediments could not be easily separated from the solvent phase. These problematic areas dictated the discontinuation of the solvent extraction studies.

Preliminary acid extraction studies were conducted using the original surrogate formulation provided by WERC (containing 1.7 wt % kaolin) (2). The results indicated that significant metals removal was achieved when the pH of the solution was less than 1. Subsequent studies were conducted using the revised formulation updated by WERC (containing 11 wt % kaolin) (14). To compensate for the possibility of lower metals removal due to a higher clay content, a more concentrated acid solution was used.

The efficiency of the acid extraction procedure was evaluated using a mixture containing approximately 410 mL of 6 N sulfuric acid and approximately 1,200 g of surrogate sediment. The acid and sediment were mixed for two hours followed by separation by filtration. The acid extraction process was repeated twice using 1,800 mL of 0.1 N sulfuric acid.

TCLP tests were conducted on the untreated sediment as well as the treated sediment after each extraction step. The results for these analyses are provided in Table III. TCLP and compressive testing of the stabilized metals sediment were also conducted and the results are shown in Table IV. These results indicate that sufficient metals removal from the sediments, to meet land disposal requirements, was achieved after two acid extractions. Results for the stabilized material shows that samples passed both compressive strength requirements and TCLP test requirements. After stabilization, the mixed waste met regulations for disposal at a suitable site.

Table III

Table IV

The metals present in the acid extract were precipitated out of solution by raising the pH of the extract using sodium hydroxide. As shown in Fig. 2, except in a narrow pH range (Cd, pH 9), the treated extract slightly exceeds the most stringent of standards for the discharge of a new source metal finisher to a POTW (40 CFR, Part 433). For this reason, combined metal hydroxide/ metal sulfide precipitation was used in the process in order to meet the standards.

Fig. 2

Polyethylene was chosen as the stabilization technique because of its ability to pass TCLP and compressive tests at high waste loading as indicated in Table IV. Advantages of polyethylene include: it's ability to withstand bacterial degradation, radiation effects, freeze/thaw conditions and biodegradation (10).

ECONOMIC ASSESSMENT

The proposed cost for the treatment and disposal of the pond sludge at the time of the contest was estimated at 5.8 million dollars or $1,840 per ton of sludge. The costs were determined after a thorough investigation of the capital, operating, material, transportation, labor and legal fees (see Table V).

Table V

The costs for the capital equipment were based upon the purchase of the equipment. These costs were amortized over 10 years at an interest rate of 9%. It was assumed that 1 year of equipment operation will be charged to this project to account for actual operating time, down-time for maintenance, or idle time. It was also assumed that the salvage value of the equipment at the end of 10 years will be $0.

BUSINESS PLAN

The proposed sludge remediation process would be completed in several stages over a period of 18 months. Figure 3 represents the proposed time schedule for the process.

Fig. 3

LEGAL AND REGULATORY CONSIDERATIONS

All proposed action for this remediation would be accomplished in compliance with all applicable federal, state and local regulations. The major statutes that would affect the remediation are as follows: AEA (3), RCRA (1), National Environmental Policy Act (NEPA) (46), Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) (47), Clean Water Act (CWA) (48), and the Occupational Safety and Health Act (OSHA) (49).

The pond sludge in the tanks contained several metals, organic chemicals and radioactive constituents (gross alpha and beta) that were present at levels that required it to be managed as a mixed waste. In accordance with EPA published guidance (50) waste containing low level radioactivity regulated under AEA and hazardous waste regulated under Subtitle C of RCRA are subject to both sets of statutory requirements (4). The strategy of the proposed process was to remove all hazardous constituents necessary to delist the waste and allow for disposal outside the jurisdiction of RCRA. Standards in 40 CFR 260.20 outline the procedures for delisting waste.

Transportation Considerations

Following the treatment of the pond sludge and the stabilization of the extracted radioactive metals, all the waste would be packaged and transported for disposal. All packaging, manifesting and transporting of the waste would be accomplished in accordance with the NRC requirements set forth in 10 CFR 71 and the Department of Transportation (DOT) requirements in 49 CFR 173. In order to determine the proper packaging requirements for radioactive material, the radionuclides in the material and the activity of the material would have to be identified.

Disposal Considerations

The waste streams created from the proposed process that would require disposal were the stabilized mixed waste, the treated pond sludge and the process wastewater. The stabilized mixed waste could potentially be

disposed of at Envirocare Inc. of Utah. The radionuclides and the listed waste code would have to be known prior to arranging for final disposal. The treated pond sludge would be considered a Class A LLW based on the information provided by WERC. The sludge could be disposed of at a licensed commercial LLW disposal site or at a DOE disposal facility. The wastewater resulting from dewatering during the treatment processes would be disposed of through a local POTW in accordance with the NPDES permit for the POTW and with the requirements set forth in 40 CFR 413 and 10 CFR 20. This wastewater would be appropriately analyzed for radioactive, hazardous and other characteristics to ensure this compliance.

HEALTH AND SAFETY CONSIDERATIONS

Several health and safety issues would have to be considered if the proposed process were implemented at the actual site. Safety training would be provided to all employees involved in remediation activities in the following areas: Right-To-Know Regulations (SARA, Title III), Radiation Safety, Emergency Response, Hazardous Waste Management (RCRA), and the use of Materials Safety Data Sheets (MSDS). OSHA and NRC regulations will be followed for all on-site operations.

Awareness seminars would be held to inform the community about the health and safety measures being utilized. An emergency evacuation plan would be in place for the site and its surrounding areas. Emergency response training would be made available not only to police, medical, and fire personnel, but also to community response teams so they may properly respond to hazardous waste and chemical emergencies. A qualified site safety officer would be available during remediation activities.

COMMUNITY RELATIONS PLAN

To establish a strong relationship with the community, a Community Relations Committee (CRC) would be formed, consisting of community leaders and representatives and environmental professionals. The primary role of the CRC would be to hear and evaluate public concerns relating to the remediation project. The following issues would be emphasized throughout the duration of the project:

Community participation is valued.

The proposed process significantly reduces taxpayer cost by minimizing the quantity of mixed hazardous waste that needs to be disposed of in a secured facility.

A toll free hotline would be provided to answer questions and concerns raised by the public. There would be separate toll-free numbers for Spanish speaking individuals and a TTY phone system for the deaf.

A well developed public relations plan would ease the worries of the community and make the project a welcome one.

CLEMSON UNIVERSITY'S VITRIFICATION RESEARCH LABORATORY: A DOE/INDUSTRIAL/UNIVERSITY JOINT EFFORT

Donald L. Erich
Thomas J. Overcamp
Clemson University

ABSTRACT

Clemson University's Vitrification Research Laboratory has been serving the needs of government, industry and education since its creation 3 years ago this spring by assisting in vitrification processing trials of surrogate DOE waste streams in commercial equipment. The use of surrogates allow runs to be conducted at very low cost compared to processing radioactive wastes, and permit trials that push processing and compositional limits. A waste composition that devitrifies into refractory rock at the bottom of the melter, or aggressively consumes the melter's refractory lining, is a relatively minor inconvenience in the Vitrification Lab. In a radioactive waste processing facility however, such occurrences would be very serious in terms of lost time, incurred expense and the creation of additional waste.

Waste treatment equipment suppliers can use our laboratory as a test bed for their equipment, thus gaining experience and knowledge regarding performance and improvement opportunities. Users of the technology, such as waste processors and those with waste streams, have the opportunity to tap an objective source of information obtained from Clemson University's past experience. Or, previously untested waste streams can be treated

using the Vitrification Lab's resources to evaluate the effectiveness of several treatment technologies.

Clemson University and its students benefit from the training and experience afforded by the studies conducted at the Vitrification Lab. Potential employers are identified for the students, the university derives support for research from the work conducted, and students, professors and the Vitrification Lab staff have the opportunity to publish the results of their work. Additionally, equipment manufacturers, waste processors and owners of waste streams that have a need for well educated engineers with practical experience on real-world equipment and processes will find the Vitrification Lab's undergraduate and graduate students well suited to their needs.

This presentation will describe the laboratory and its equipment, the surrogate waste streams tested, the results achieved and lessons learned. Work currently underway will be described, as will plans for future expansion and diversification.

INTRODUCTION

In 1992, Clemson University, DOE/Westinghouse Savannah River Company, Envitco, Inc. and Stir Melter, Inc. cooperated to form a vitrification research laboratory within the Department of Environmental Systems Engineering at Clemson University. Since then the lab has conducted a number a vitrification process development campaigns in support of DOE's mixed waste management programs. Studies are also conducted for the industrial partners to support their efforts.

The laboratory currently houses three melters, including a DC arc unit from Electro-Pyrolysis, Inc., and employs six full time and two part time staff. A number of graduate and undergraduate students are also involved in thesis projects or work/study programs.

CAPABILITIES

The current laboratory facility, shown in Fig. 1, was constructed in the winter of 1992-93 directly behind the L. E. Rich Environmental Research Laboratory at Clemson University. The vitrification laboratory building is a pre-engineered metal structure, 12.2m x 15.2m x 4.9m high at the eaves, insulated, heated and air conditioned. Three melters (1) are currently housed in the lab. Of these, the two joule-heated melters are owned by the Clemson Universities Research Foundation and the DC arc graphite electrode melter is owned by DOE/WSRC. The existing lab space is fully utilized by the three melter units and their auxiliary power, feed, offgas and data acquisition systems. In fact, with the addition of the DC arc melter in March 1995, warehouse space had to be leased for storage of materials and supplies previously housed in the lab. Clemson University plans to expand the Vitrification Lab in the spring of 1996, as discussed later in this paper.

Fig. 1

Processing

Envitco EV-16 Joule-Heated Melter - The melter was first operated in our laboratory in January, 1993 and has produced over 3175 kg of glass from surrogate wastes since then. A schematic is shown in Fig. 2.

Fig. 2

The Envitco melter has an 0.46m x 0.46m x 0.36m high (0.076m3) refractory lined melting chamber and is capable of continuously processing glass at rates exceeding one-half ton per day . Glass temperatures in excess of 1500C have been measured in the vessel, while the glass exiting the melter is typically in the range of 1300-1400C. This melter has a 100 kW

power supply and uses molybdenum electrodes. It is capable of cold top or hot top operation and has been operated with both dry or slurry feeds. In cold top operation with dry feed, the surface temperature of the feed layer is of the order of 200 C. This cooler zone of feed material decreases metal emissions by condensing and refluxing volatile metals into the melt.

Because of its high temperature capability, this melter allows a wide compositional range for a given waste material. The melter has achieved continuous melt rates of 30 kg/h on dry feed.

The Envitco melter is equipped with both dry and slurry type feeders. The dry feed system is equipped with a scale and feedback control circuit to ensure a constant feed rate. The slurry feed system utilizes a continuous loop to ensure that feed material is kept in suspension in the slurry. At the melter, a calibrated pump feeds the slurry into the melter.

WV-0.25 Stir-Melter - Clemson University's WV-0.25 Stir Melter is one of three stirred melters in operation. It has an Inconel 690 melt chamber with a 0.15m x 0.15m x 0.30m high working volume and an Inconel 690 stirring electrode. A schematic of the melter is shown in Fig. 3. Maximum processing temperature is limited to ~1070C because of the materials of construction. The melt chamber has an internal "tea pot" spout with an external drain tube, allowing for continuous operation. The melter has separate ports for dry feeding and slurry feeding of the batch and other additives. Ten kW of power is available for Joule heating through the stirrer/chamber circuit. In addition, there are external resistance heaters with a 7 kW power supply for startup and to maintain temperatures during tests.

Fig. 3

The stirrer is driven by a 325 W variable speed motor at speeds up to 1000 rpm. The impeller can be raised or lowered to optimize mixing and melting rates. There is a port for either a video camera or direct viewing. There is an additional port for the insertion of a thermocouple or other probe into the melt. The offgases flow into a sampling and treatment system; sampling is done downstream of the melter exit at the center of a 50.8 mm Schedule 40 pipe.

Offgas Treatment and Sampling - Each Joule-heated melter has its own offgas treatment system. For the Envitco melter, the offgas system consists of a quench chamber, steam atomizing scrubber, and packed tower for acid gas removal and neutralization. For the Stir-Melter, the offgas system is a spray quench/ejector venturi, jet sparging scrubber, and a counterflow packed tower for acid gas removal and neutralization. Each system has its own positive displacement blower.

The lab has complete sampling trains for the standard EPA Method 5 (particulate matter), Modified Method 5 (semivolatile organic compounds), Method 29 (multiple metals), and VOST (volatile organic compounds). In addition, size fractionated samples can be taken using a Pilat Mark 3 source test cascade impactor.

EPI DC Arc Melter - The EPI melter has a 0.33 m diameter x 0.53 m high (0.045 m3) graphite crucible contained inside a sealed, water-cooled, atmosphere-controlled vessel. A simplified schematic of the melter is shown in Fig. 4. The melter is capable of processing ~50 kg of material per charge and can be operated in either the cold- or hot-top mode. Power is supplied from a 100 kW DC supply through consumable graphite electrodes. The vessel cover contains three ports, located 120o apart, that can be used for addition of feed materials, thereby increasing the

melt capacity, or installation of a monitoring device such as a camera or pyrometer. While the current melter design allows only batch-type operation, it could be modified for continuous operation.

Fig. 4

Instrumentation - Through our research programs with WSRC, we have an automated data collection system for continuous sampling and recording major operating variables. For the Envitco melter, these include:

- electrode voltages and currents,
- melt chamber temperature,
- melter headspace (plenum) temperature,
- offgas flow rate and temperature,
- spray quench/ejector liquid flows and temperatures.

For the Stir Melter, these include:

- Joule and external heater voltages and currents,
- stirrer speed,
- stirrer motor current,
- melter chamber external temperature,
- drain tube temperature,
- melter headspace (plenum) temperature,
- offgas flow rate and temperature,
- spray quench/ejector venturi and packed column liquid flows and temperatures.

Deltech Melter - There is a separate laboratory in the L. G. Rich building for conducting crucible tests and glass analyses. This laboratory has a Deltech glass melting furnace model DT-31-12-RS. This is a bottom loading furnace with a temperature capability above 1700C, an optional stirring mechanism, and an element protection liner. In addition, there are a number of lower temperature furnaces for preheating, annealing, and devitrification studies.

Technical

In addition to the physical capabilities described above, the Vit Lab also has access to a number of skilled and experienced individuals. Thomas J. Overcamp, the principal investigator of the Vit Lab project, is a professor in the Environmental Systems Engineering department. Professor Overcamp's specialty in air pollution control has been very valuable to the vitrification project. The Environmental Systems Engineering department also has eight other faculty members involved in all aspects of environmental protection, remediation and compliance. The Vit Lab is staffed by seven full and part-time personnel. These include two experienced melter operators/technicians and two part-time administrative staff to handle and monitor purchasing, budgets, quality and other support issues. The remaining technical and management staff are responsible for designing, conducting and overseeing projects.

Education

The Vit Lab has played host to a number of graduate and undergraduate students, providing practical experience, research for graduate thesis topics, and financial support. Since beginning operation, thirteen Environmental Engineering graduate students and one Ceramics Engineering graduate student have been or are currently involved in vitrification-related projects. Nine of these students have left Clemson and two are now employed in the waste vitrification area.

EXPERIENCE

Compositional Studies

Durability studies of glass compositions that could be made from waste water treatment sludges located at Savannah River Site (SRS), Oak Ridge Reservation (ORR), Rocky Flats Plant (RFP), and Los Alamos National Laboratory (LANL) were conducted to determine whether they were candidates for vitrification. The range of the major oxide constituents estimated to be in the DOE site sludges are shown in Table I. By considering two levels of the major oxides, a space of 32 possible glass compositions was defined. To determine the ability of the glasses to effectively isolate hazardous metals, fixed-level oxide additions of 3 hazardous metals were made. Leaching studies found that at the higher ratio of glass formers (SiO_2, Al_2O_3 and B_2O_3) to glass modifiers (Na_2O, CaO, BaO, NiO, FeO and PbO), the most durable glasses were made, as measured by the sodium normalized release rate (NaNRR) and the 7-day Product Characteristic Test (PCT). It was also found in compositions with low former:modifier ratios that the relative quantities of soda and lime (two modifiers) affected the NaNRR. High Na_2O:CaO ratios further decreased the glass durability. At high former:modifier ratios the soda:lime ratio had very little effect. These studies provide a starting point in defining the additions that need to be made to various waste streams so that a durable glass will be formulated.

Table I

Surrogate Waste Processing Studies

Clemson University has conducted 18 major surrogate demonstration studies on vitrification of 1) five different wastewater treatment sludges from DOE facilities; 2) ion exchange resins in SRS simulated high-level waste slurry; and 3) high-sodium, low-level waste from Hanford Reservation. These tests have included production of sufficient glass to achieve steady-state operating conditions, durability testing of the waste glass, and measurement of the offgas emissions. A summary of these campaigns is given in Table II and discussed briefly below.

Table II

Results

Table III presents the compositions of the surrogate waste streams tested. The test results are summarized below.

Table III

M-Area - Borax, or sodiumboratedecahydrate, additions were made to provide borosilicate glass compositions with waste loadings of 70, 80, 90, and 95% for runs conducted in the Envitco melter, and 80 and 85% for runs in the Stir-Melter. These glasses processed well in both the Envitco and the Stir-Melter (2,3) and exceeded the requirements for TCLP and PCT. In general, it was found that the higher the waste loading, the more durable the glass.

WETF - A calcium aluminosilicate glass with 45% waste loading was made by adding perlite to the sludge surrogate for processing in the Envitco melter. Because of the Stir-Melter's limited temperature capability, two lower melting point glasses were selected for it. A borosilicate glass with 45% waste loading was prepared by adding 28% borax and 27% diatomaceous earth, and a soda-lime-silicate glass with ~35% waste loading was made by adding 42.3% precipitated silica, 13.0% lithium carbonate, and 9.4% sodium carbonate.

The glass compositions chosen for the Envitco melter were very difficult to process. Because of high viscosity and melting point, draining at the same rate as the melter was fed material was not possible due to glass build-up inside the drain tube. This composition was also found to

devitrify and form wollastonite (melting temperature >1800oC) during overnight and weekend hot holds. Despite these problems, nearly three melter volumes were made during the run.

The glasses chosen for the Stir-Melter were easier to process, exhibiting occasional blockages of the drain tube while producing over 5 melter volumes.

All the glasses made during this study exceeded the minimum values required for TCLP and PCT. In general however, the higher melting temperature calcium aluminosilicate glass was the most durable of the 3 compositions (2-4).

Rocky Flats Plant - A borosilicate glass with 50 % waste loading was made by adding 14 % Borax, 36 % Diatomaceous Earth, and 3 % aluminum oxide. The aluminum oxide was added to increase the viscosity of the glass to a level suitable for draining from the melter. In addition to the glass forming additives, activated carbon at 3 % was chosen as a feed additive to deter the formation of sulfate salts. The RFP sludge was fed to the melter as a slurry with 55 % solids content. This glass composition had a melting temperature of ~1150oC.

Processing of the RFP waste was very difficult. Offgasing and foaming, resulting from the high nitrate and high sulfate content of the waste, prevented continuous draining and feeding of the melter. Stable sulfate salts formed on the surface of the melt and hindered feed incorporation into the molten glass. The sulfate salts also caused blocking of the offgas treatment system, halting processing until the system could be cleared.

Despite devitrification tendencies due to high calcium content, the RFP waste glass passed TCLP and PCT requirements. Based on the Fe^{2+}/Fe^{3+} ratio, the waste glass produced was in a highly reduced state.

Volatilization of the plutonium surrogate and RCRA metals was low. Melter wear, especially for the electrodes, was high.

LANL Sludge - LANL TA-50 precipitate sludge contains precipitating agents and filter aids. A calcium aluminum silicate glass was made from this surrogate waste. Due to its high melting temperatures, there were some problems with devitrification in the melter. The product glass was very durable passing both the TCLP and PCT requirements.

High-Sodium Hanford - This is a high sodium, nitrate containing, low-level waste from the high-level waste vitrification process. A surrogate slurry was tested in the Envitco melter. The glass chosen was sodium aluminum-calcium silicate. Test using both slurry feed and dry feed after drying the sludge and glass forming materials was tested. The glasses produced were very durable and the offgas emissions of simulated radionuclides and heavy metals were very low.

Oak Ridge K-25 Plant B&C pond sludge - This waste is from a settling pond used for holding wastewater sludges from the K-25 plant. An alkali-lime-silicate glass with 50% waste loading was tested in the Envitco melter. Due to the low melting temperature, minimal processing problems were experienced with this waste. Even after extended hot hold periods in the melter, the glass did not devitrify. The durability tests have not been completed.

THE FUTURE

FY96 Planned Activities

Three major efforts in support of WSRC will be conducted at the Vitrification Laboratory during FY96. These are:

Support of the TVS - The TVS, or Transportable Vitrification System, is a 5 ton per day mixed waste vitrification facility built for DOE/WSRC by Envitco, Inc. The TVS was moved from Dreicor, Inc. in Irwin, TN on 15 flat bed trucks, was assembled and is temporarily sited on Clemson University property. The Vit Lab is supporting final modifications and shakedown surrogate runs of this facility by providing engineering and technical support, conducting surrogate trials in the EV-16 melter, and preparing the surrogate blends to allow processing 15 ton trial runs of glass through the TVS. A K-25, B and C pond sludge composition from Oak Ridge Reservation was successfully processed in the EV-16 melter during December of 1995, and CNF surrogate runs (in the EV-16 and in the TVS) are scheduled for early in 1996.

Landfill Stabilization - Processing trials studying the effects of various fluxing additions will be conducted in the DC arc graphite electrode melter.

Glove Box Offgas System - This project involves designing, building and testing a small off gas system intended to remove organics and Pu from mixed waste. The system will be installed on a small graphite electrode melter being build by the Idaho National Engineering Laboratory for WSRC. Clemson will test its offgas system design using the DC arc graphite electrode melter located in the Vit Lab.

Facility Expansion

A design, a construction financing plan and approvals to build have been obtained to expand the current vitrification laboratory by an additional 280 square meters. The enlarged laboratory will be enhanced with brick veneer, windows and landscaping and will accommodate new and larger melter systems or other waste processing equipment (6.1 m eave height). The expansion will also provide on-site storage space for materials and supplies, office space for the laboratory technicians and a designated feed preparation and mixing area.

Processing Diversification

The Vit Lab is currently negotiating with two equipment suppliers in response to their interest in establishing non-vitrification waste processing capability at Clemson University's Environmental Systems Engineering Department. The interest shown by these companies results from Clemson University's experience in waste processing, the existence of a dedicated pilot facility, and our ties with DOE through the Savannah River Site. Clemson University is interested in discussing working relationships with other equipment or systems manufacturers and waste treatment providers.

SUMMARY

Over the past 3 years, Clemson University's Vitrification Research Laboratory has been successful in 1) supporting DOE/WSRC in developing processing conditions for treatment of low-level mixed waste, 2) providing equipment manufacturers with the opportunity to better understand the capabilities and limitations of their equipment, and 3) providing educational and financial opportunities to students. As knowledge about the vitrification process is gained, attention turns to the treatment of actual wastes. either by DOE facilities like the TVS, or by commercial waste processors. Maturation and increased understanding of vitrification technology will deemphasize the need for the kind of work being done at the Vitrification Laboratory, requiring that the Vit Lab diversity and broaden its waste processing development activities. Discussions are now underway with several process developers, evaluators

and users to provide the desired broader base. If successful, this technologically broader laboratory will continue to provide valuable services to Government, Industry and Education.

ACKNOWLEDGEMENTS

The work discussed in this paper was conducted under contract No. DE-AC09-89SR18035 under the South Carolina Universities Research and Education Foundation Task Orders 95, 121 and 183 for the Department of Energy and the Westinghouse Savannah River Company's Savannah River Technical Center. The continued support and encouragement provided by WSRC is gratefully acknowledged.

COLLIMATED IN-SITU GAMMA SPECTROMETRY: A NEW METHOD FOR FAST CLEARANCE MEASUREMENTS OF LARGE AREAS OR BUILDING STRUCTURES OF NUCLEAR FACILITIES UNDER DECOMMISSIONING*

P. Guglhr
L. Hummel
Technical Inspectorate of Bavaria
Department Radiation Protection Munich, Germany

ABSTRACT

The requirements on a collimated in situ gamma spectrometer for the use in nuclear facilities under decommissioning is described. A prototype was developed and constructed. The equipment was used in seven facilities in Germany and France to check mass- or surface-specific activities on outdoor grounds and inside the buildings in restricted areas.
The results gained by in-situ gamma spectrometry are compared with "traditional" methods like sampling or measuring with contamination monitors. The advantages of this new technique are worked out. It could be shown that such a device is able to meet in the most cases the essential detection limits regarding national radiation protection ordinances or release criterias.

INTRODUCTION

The ideas in the late sixties which led to the use of bare spectrometric radiation detectors like NaI(Tl), Ge(Li) or nowadays high-purity germanium detectors (HPGe) in the field (in-situ gamma spectrometry) were to get easy and rapid information about the radiological state of outdoor grounds after nuclear weapon tests or to estimate dose rates created by natural radioactive nuclides in the soil.
In these cases, it was assumed, that there is no disturbance of the source-detector geometry for many hundred square meters around the detector. After the nuclear accident in Chernobyl in 1986 these

advantages focused strong scientific interest on the in-situ technique and in 1993 it was established in the German regulatory for emission surveillance after significant radioactive emissions (1).

MOTIVATION

In a late phase of the decommissioning of a nuclear power plant all components containing a significant inventory of radioactivity are removed, leaving large surfaces with often poorly known contamination levels. Especially for large areas e.g. outside the buildings "in situ gamma spectrometry may be the only method of achieving validation of the release criteria" (2). Taking in account only buildings of restricted areas in the next 50 years in Germany 7E3 Mg activated and 5E6 Mg contaminated concrete must be released from facilities under decommissioning.

Before the area inside the perimeter of the facility, including all concrete structures, can be treated as a building which can conventionally pulled down or used conventionally the remaining radioactivity must be determined in order to check the radiological relevance of the concerned part of the plant and to decide the possible path of material release. The basis of assessment maybe the so-called "10mSv-concept" (3).

COMPARISON WITH OTHER MEASUREMENT STRATEGIES

Today the mainly used strategies are analyzing samples, taken from the surface or measuring the surface activity via large proportional counters. In these cases we meet severe systematic problems:

How reliable are the results gained by taking samples and performing laboratory analysis (statistical significance of a number of samples)?

Drawing and analyzing samples leads for the single sample to more exact results than in-situ measurements do. The reasons are that in the latter case the source geometry is not known completely and the measuring times are normally much shorter because of the large number of measurements.

The main problem of the analysis of samples in the laboratory is the estimation of the representativity of a collection of samples. Comparing the results of in-situ measurements and laboratory analysis we noticed substantial differences which could be attributed to large inhomogeneities in the spatial distribution of activity. These were not resolved by sampling.

The importance of this problem can also be shown theoretically. In the publication of Ferguson (4) the number of samples are calculated to meet a defined statistical significance to find an existing contamination by sampling. As an example ~200 samples are necessary to find a circular contamination with a diameter of 35 cm on a relatively small area of 10 m2 with a safety of 95%.

Does a stable nuclide vector exist, in order to get reliable calibration factors between the count rate of a proportional counter and the surface activity? Are possible contaminations really surfacial or was e.g. a wall painted to fix old contaminations, so that quantitative values cannot be achieved by measuring the short ranged a- or b-particles?

A commercial contamination monitor meets a minimum detectable activity of 0,1 Bq/cm2 Co60 or Cs137 on a surface two- to ten-times faster than a collimated in-situ spectrometer. On the other hand shielding layers coming from decontamination coatings or migration of the radionuclides into the surface lead to relative small errors performing in-situ measurements whereas contamination monitors are not appropriate in the most cases to determine the remaining activity.

The actually discussed clearance levels for the unrestricted release of contaminated concrete or soils are so low, that even strong gamma emitters cannot be detected by measurements which are not nuclide specific.

Even a large surface contamination with 0,1 Bq/cm2 Co60 would create an additional dose rate smaller than 2 nGy/h. The detection of this contamination by measuring dose rates is impossible. In comparison an uncollimated in-situ measurement in a room will identify dose rates from not natural nuclides smaller than 0,06 nGy/h (!) in one hour measuring time.

The so-called "Freimeanlagen" used for clearance measurements of dismantled components or waste containing large plastic scintillation detectors in shielded boxes are normally not able to detect a few 10 Bq/kg of Co60 or Cs137 due to the variation of the natural background.

Errors arising from this sort of problems do not appear by measuring with a collimated high-purity germanium detector directly in the regions of interest ("in-situ"). There are only two problems left:

The vertical distribution of a contamination may be not known well enough.

This fact creates a uncertainty which can reach a factor of two. On the other hand this systematic error is solvable and furthermore small, compared to errors which can affect the quality of the results of traditional techniques.

A formal problem e.g. in the German radiation protection ordinance is, that the value of a surface contamination has to be achieved by a measurement averaging over 100 cm2.

It is obvious, that such an averaging area is not adequate for release measurements over thousands of square meters of probably contaminated walls, floors, roofs or soils. At the moment this subject is being discussed in Germany.

Apart from this the collimated in-situ gamma spectrometry allows to get very fast information about the radiological state of large areas and -if one takes in account the high quality of these information- for low costs.

DEVELOPMENT OF A COLLIMATED IN-SITU SPECTROMETER

It was obvious that using such a device for clearance measurements it had to be collimated to reduce the field of view. Reasons therefore are that

- possible contaminations must be locatable,
- there must be a well defined averaging area (e.g. some m), and
- contaminations outside the measured area must be effectively suppressed.

Selection of the Detector Type and Shape

The strong worsening effect to the minimal detection limits using a collimator required an efficient detector system. Because of the relative poor energy resolution of anorganic scintillation detectors they reach the same detection limit even for nuclides which dominate the spectrum in a measuring time about ten times higher than a germanium detector of "normal" size. Very small clearance levels or more difficult to measure nuclides in realistic nuclide vectors can only be detected with germanium detectors.

So we designed and constructed a prototype of a high-resolution in-situ spectrometer on the basis of 41%p-type HPGe-detector, surrounded with an optimized collimator made out of brass and a low natural activity lead-bismuth-tin-alloy.

The key aspect of the detector parameters is the detection efficiency, because it has a direct effect on the required measurement time and there is no provision for measurements in areas which exhibit a degree of contamination which would lead to dead-time problems (> 500 Bq/cm2). The use of a n-type detector would enable measurements of nuclides with low photon energies. As these detectors are more expensive and the measurement of low photon energies in old contaminations, and thus of the nuclides which have migrated into the matrix, is more difficult and leads to larger errors, we dispensed with this option and focused on achieving high detection efficiencies within a defined budget. An estimate of the measurement time and thus of personnel costs, on the one hand, and the higher acquisition costs for a more sensitive detector, on the other hand, shows that the use of a more sensitive detector is amortised after a measurement time of just a few weeks.

Fig. 1

The ideal form for the geometry of the detector crystal would be a relatively flat disc (L/D < 1, ratio of the length L and diameter D of the crystal), due to the fact that a preferential direction of sensitivity towards the front (or back) would thus be achieved in principle. However, extremely large disc shapes for use in detectors of the size described can only be obtained with difficulty because they would have to be manufactured from a very large germanium blank. For this reason, a virtually direction-independent detector (L/D 1) was acquired which also greatly simplifies the assessment of spectra recorded without collimation.

Detector System

In order to guarantee effective shielding against background radiation from the rear hemisphere, the detector end cap was set back 7 cm from the preamplifier housing in order to make room for a rear shield. With a capacity of 7.5 liters, the largest commercially available nitrogen tank for portable detectors was used. The holding time of the cooled system thus amounts to at least 4 days. The tank is designed for use in all spatial directions. The possible savings on weight via a smaller nitrogen tank are negligible in view of the collimator which weighs over 40 kg. The cable to the electronic measuring equipment was provided with a splash-proof Lemosa plug-and-socket connector.

Collimator

The materials used should have a sufficiently low natural radioactivity. The wall thicknesses must also guarantee sufficient lateral shielding even in the presence of high-energy radiation (e.g. Co60). This aspect is of particular importance, especially in the case of surface contaminations, due to the fact that contamination spread over a large area results in very large contributions from the large angles of incidence in relation to the surface normals. In this case, approx. 90% of the photons reach the collimator-detector system at an angle greater than 45. A minimum shield density of 50 to 60 g/cm2 for an angle of incidence parallel to the investigated surface can be seen as a compromise between portability and shielding effect.

The importance of material selection in the manufacture of the collimator is frequently overestimated. A collimator designed for Co 60 radiation could already be considered oversized for the radiation of the daughter of Cs 137 due to the energy-dependent attenuation. Thus, only high-energy radiation is of importance in further considerations. As a function of the wall thickness in g/cm, the attenuation is virtually independent of

the atomic number due to the fact that Compton scattering is nearly the only effect which occurs as interaction process at the relevant energies. Calculations show that the difference in the shielding effect between a steel and a tungsten collimator at the same mass per unit length amounts to only about 10%. However, this is compounded by additional effects stemming from the rotational symmetry of the problem; a linear increase in the density results in a more than indirectly proportional reduction in the collimator volume. This fact leads to a situation where our collimator has a maximum 15% poorer shielding-mass ratio than a collimator made of a tungsten alloy (e.g. Triamet). However, the costs of a tungsten collimator are several times higher than those of a "conventional" collimator.

An attenuation mass per area of ~53 g/cm2 was realized for radiation which reaches the collimator in an angle of incidence parallel to the investigated surface. Furthermore the detector is shielded for radiation from the rear hemisphere. Depending on the collimator used and the height of the detector above the surface our spectrometer averages over areas between 0.4 and more than 10 m2 in one measurement.Electronic equipment and Software

The electronic equipment consists of a battery-operated system with high voltage, the main amplifier and the ADC, and a Notebook for control and data storage. The electronic data are comparable with those of a laboratory measuring station. The electronic equipment weighs less than 6 kg and can be run in the battery mode for two to three hours. Any desired operating time is possible as an option with auxiliary batteries (2*12 V/16 Ah) or a mains supply (220 V).

Programs for automatic measuring sequences and for quality assurance are used (Genie PC / OS/2) in addition to conventional visualization and analysis software. The software is required for measurement cycles of up to 250 measurements per day. This means that the controlling of the spectrometer and the complex analysis algorithms run automatically in the background and the most important system parameters are simultaneously monitored during practical use. Standard graphics software (Stanford Graphics / Windows) is used for the visualization of the results of total-surface grid measurements in the form of a plot.

Measuring Apparatus

The measuring apparatus must be suitable for separately housing the relatively sensitive detector and the heavy collimator under exactly reproducible conditions. This also guarantees the maintenance of the calibration geometry during measurement. An apparatus for measuring vertical surfaces was developed for use inside buildings and as a transport device. A separate measuring setup was also to be developed for soils in relatively impassable outdoor areas. The two devices were designed in such a way that the same calibrations can be used.

The two devices can be set up and dismantled in a very short time using only a few tools. The set-up times, excluding the transport of the components to the measurement site, amount to roughly half an hour.

CALIBRATION

Collimated in-situ gamma spectrometry means measuring large volume sources of different chemical composition with any spatial distribution of the radionuclides. Experimental calibration proves to be difficult due to the fact that - understandably - calibration standards cannot be reproduced for all conceivable nuclide distributions which occur in in-situ gamma spectrometry. This situation is compounded by the fact that

these kinds of standards would also have to be very large and heavy. There are three possible solutions to this problem.

Experimental Calibration

Calibration curves can be calculated by recording a great number of individual spectra with point sources or small volume sources at different angles and depths and subsequently superimposing them as a function of the source geometry. This procedure can lead to errors, e.g. in the case of pure surface contaminations.

Numerical Method

It is also possible to use a purely numerical method for calibration by modelling the radiation source as well as the entire detector system in suitable program codes (e.g. Monte Carlo simulations). However, data obtained in this manner must be experimentally supported.

Standard Method

The calibration method suggested by Beck et al. 5 in 1972 is still the state-of-the-art today for the calibration of uncollimated systems. Given a correspondingly detailed analysis of the angular dependence term, this method can also be used to a limited degree for collimated systems. It combines experimental detector-specific data with numerical calculations. With the help of the so-called standard method and the corresponding published table values, an initial calibration can be determined relatively quickly and simply for uncollimated systems. However, the influence of the extreme angular dependence of a collimated spectrometer leads to extensive computational work for determining the calibration factors. The calibration factors used at this time are based on the standard method and were verified by purely experimental methods. By integrating the numerically determined calibration factors at a later date, a consistency test of the calibration can subsequently be conducted based on three completely independent methods. The following table summarizes several calibration factors for selected cases:

Table I

Several yield curves with calibration factors based on the standard method have already been verified experimentally. Further tests of the consistency of the various calibration methods are currently being conducted. According to our current experience, the two yield curves generally do not deviate from one another by more than 15%. Differences of more than 25% have not occurred up to this point. These tests make the individual calibrations very reliable, as the two methods are in no way related to one another and the occurrence of identical systematic errors is thus ruled out.

APPLICATION OF THE SPECTROMETER

Aside from the development of such a spectrometer we used our prototype inside the restricted area and outside the buildings of several nuclear power plants under decommissioning. Therefore we normally laid a grid of measuring points over the area, so that parts of the circular fields of view would overlap.

In the following nuclear facilities under decommissioning we used our spectrometer:

Outdoor grounds

(grassland and tracks): KKN (pressured tube reactor, D2O moderated CO2-cooled, decommissioned / Germany)

VAK (BWR / Germany)

NUKEM-A (fuel fabrication facility /

Germany)
WAK (fuel reprocessing plant / Germany)

Surfaces in restricted areas: KRB-A (BWR / Germany)
G3 (NUGG / France)
RAPSODIE (FBR / France)
WAK

Up to now with this campaigns new knowledge about the lateral distribution of contaminations, the variability of its composition or -by comparing with other measuring techniques- their systematic uncertainties could be quantified. We selected three examples:

Mapping of the short distance variability of the Chernobyl Cs137 fall-out by scanning 1500 m2 grassland completely with 3 m2 field of view in a single measurement

Fig. 2

With a personal expense of ~70 man-hours the above sketched area was measured completely. To take a stock of the radiological state of a large area in a such detailed matter can only be performed with this procedure. With the basis of such investigations specific rehabilitations can be made.

Investigation of the deviation in the measured surface activity via proportional counter and in-situ spectrometry for several surfaces with different histories and contamination scenarios.

At the moment four extensive floors were measured simultaneously with both methods. In all cases the in-situ spectrometry led to higher values because it "sees" also the deeper distributed activity. Depending on the history of the area the factor between the values can differ extremely between ~1,3 for airborne contamination on not decontaminated areas over factor 3-5 for decontaminated concrete surfaces to >30 for contaminations under coating (see below).

Investigation of a high contaminated, coated floor

Fig. 3

This example shows the advantage of in-situ measurements on three features:

1) The nuclide vector in this room is completely indefinite (logarithmic vertical scale !). Both the ratio and the extent of the contamination varies with orders of magnitudes. Taking samples makes no sense under this circumstances.

2) Due to the coating the measurements with contamination monitors lead to wrong information about localization and extent of contaminations.

3) Furthermore the variability of the nuclide vector makes a definition of calibration factors for contamination monitors impossible.

PERFORMANCE OF THE SPECTROMETER

The detection limit of a measuring device serves the assessment if this device is suitable for the required purpose. Here the values which can be reached depend strongly on the specific conditions (incl. the collimator used). The values in the table below were calculated from measurements in building free of contaminations and with a normal dose rate. The collimation was moderate, a measuring time of ten minutes and a horizontal homogeneous source distribution was assumed. An error probability of 10% was allowed. The basis of calculation is (6) and every value was calculated from more than three single measurements.

Table II

These values can rise on outdoor grounds and maximum collimation by a factor 3. But even then the actually discussed surface- and mass-specific clearance levels for the main nuclides Co60 and Cs137 can be achieved without problem.
Furthermore disturbing radiation from outside the interesting field of view is strongly suppressed. For low and medium energy gamma radiation (<700 keV) from nuclides distributed vertically and horizontally homogeneous in soil 90% of the total photon flux appear from an angle of 48 relative to the symmetric axis of the detector in the collimated case. Without a collimator this value would rise to 82, so it would be impossible to localize a source.
Fig. 4
Practical examples for minimal detectable activities are:
Under rigid conditions (maximum collimation, some migration of the nuclides in concrete) and normal dose rates due to natural nuclides detection limits of 800 Bq/m2 for Co60 and 1400 Bq/m2 for Cs137 in three minutes are reached.

A contamination with a nuclide vector containing only 20-30% of these nuclides can be detected according to the requirements of the German radiation protection ordinance.
For the relatively difficult to measure activity of U238 (via Pa234m) a detection limit of 150 Bq/kg is reached after 15 minutes.

Uranium can be measured on storage pits with any enrichment (f.e. (7)).

The observance of exemption values for deposition of waste contaminated with the more difficult to measure nuclides of the nuclear fuel cycle can be proved (f.e. (8)).
In the same time a surface contamination of 500 Bq/m2 U235 is detectable and can be discriminated from the natural Ra226 and U235 186 keV background in concrete containing 1 Bq/kg U235.

ABSTRACT

New gas-phase decontamination technology based on gaseous reactions utilizing volatile properties of carbonyl compounds of radioactive transition elements and fluoric compounds of actinides was developed. To determine the feasibility of this new technology, reacted under high CO pressure (50-200atm) with heating (about 350C), non-radioactive (cobalt, chromium, nickel, rhenium, molybdenum, manganese, ruthenium, zinc) and radioactive nuclides(cobalt-60, nickel-63, ruthenium-103) transition elements were removed as gaseous forms. Experiments with uranium using fluoric gases were also done. Forms of these volatile compounds were predicted to be carbonyl compounds and fluoric compounds. In the case of radioactive nuclides existed in the hard oxide layer of stainless steel, by utilizing pretreatment with supercritical CO2+I2+H2O, the hard oxide layer was removed completely and the gaseous reaction was promoted; cobalt-60 was mostly removed by 200atm CO gas, and cobalt-60, ruthenium-103 and uranium were removed 30-35%, 49-57% and 55-60% respectively by 200atm CO+COF2 gases. From these experimental results using non-radioactive and radioactive nuclides, the feasibility of this new idea was determined. This decontamination technology based on gaseous reactions has the ability and possibility to decrease drastically the large volumes of non-incinerable radioactive wastes, which include ash, many kinds of used-metals, and equipment.

INTRODUCTION

Decontamination and volume reduction of the radioactive wastes generated from atomic power plants, nuclear fuel reprocessing plants and nuclear institutes are very difficult. Gas-phase decontamination technology using fluoric gases(dioxygen-difluoride O2F2, chlorine-trifluoride ClF3, krypton-difluoride KrF2) to convert to fluoric compounds(hexafluoride forms) of actinides(uranium, plutonium) have been already proposed and developed (1-6). But, gas-phase decontamination technology of radioactive transition elements, or transition elements and actinides(simultaneous decontamination) haven't been studied and proposed. The purpose of this study is to investigate the feasibility of simultaneous decontamination using gaseous reactions. Many radioactive transition elements(e.g. cobalt-60, cobalt-58, nickel-63, manganese-54, chromium-51, etc) as well as other neutron irradiated products and fission products(e.g. molybdenum, technetium, ruthenium, actinides: uranium/ neptunium/ plutonium) are troublesome in most nuclear sites or wastes. In the cases of transition elements and actinides, their carbonyl and fluoric compounds are volatile. The objective of gas-phase decontamination is to use CO gas for carbonylation and fluoric gases for fluorination to convert many nonvolatile radioactive transition elements and actinides to volatile chemical species.

It is important to develop the decontamination technology using gaseous reaction, because gas-phase decontamination has many merits.

PRINCIPLE OF DECONTAMINATION TECHNOLOGY

Carbonyl compounds of normal transition elements have volatile properties. And, fluoric compounds of actinides also have volatile properties. Table I and Table II show the thermal properties of typical carbonyl compounds and fluoric compounds of transition elements and actinides. From these thermal properties; low melting point and/or low boiling point, many carbonyl and fluoric compounds are gaseous, volatile or sublimate at room temperature. New decontamination technology reported in this treatise is based on and utilized these volatile properties.

Table I

General properties of carbonyl compounds are;

1) Molecular structure and electron dispositions are similar to inert gas's.
2) Gaseous, volatile or sublimate(low melting point and/or low boiling point).
3) Insoluble in aqueous solutions(water, acid and alkali). Soluble in organic solvents(benzene, ether, alcohol, etc.).
4) Easily flammable in air.
5) Thermal decomposition at high temperature. After thermal decomposition, carbonyl compound is decomposed to raw metal and CO gas.
6) High toxicity.

Table II

General properties of fluoric actinide compounds and specific transition elements are;

1) Gaseous or volatile(low melting point and/or low boiling point).
2) Vigorous reactivity with water. After reaction with and decomposition by water, hydrogen fluoride is produced.
3) High toxicity.

By the reaction of CO gas with transition elements on a material's surface, carbonyl compounds are produced. If any radioactive transition elements(e.g. cobalt-60, cobalt-58, nickel-63, manganese-54, chromium-51, molybdenum-99, technetium-99, ruthenium-106, etc.) exist on a material's surface, these transition elements are evaporated as gaseous forms. In the case of actinides, volatile fluoric compounds are produced by the reaction with fluoric gases(e.g. F2,HF,O2F2,ClF3,BrF5, etc.). The principles of this decontamination technology are shown in Fig. 1 and Fig. 2. And, chemical reactions used are indicated in chemical Eqs. (1)-(3).

Fig. 1

Fig. 2

Chemical Reactions of Carbonylation:

Eq. 1

Eq. 2

Eq. 3

Use of this principle based on carbonyl and fluoric gaseous reactions is a new concept as a decontamination technology for nuclear wastes. If gas-phase decontamination technology can be developed, it will be very practical and economically advantageous, because it is now very difficult to decontamine and treat the large volume of nuclear wastes; especially non-incinerable radioactive wastes.

EXPERIMENTAL

The experimental apparatus is shown in Fig. 3. It consisted of gas supply high pressure syringe pump(max. 240atm; made by ISCO Co./type 500D), reactor(od. 0.5", length 5"; made of stainless steel: SUS316L) with valve

and high pressure gauge(max. 500atm; made by KEYENCE Co./type AP16), oxidation furnace with heated wire-shaped CuO(500-550C) column flowing air for the treatment of poisonous exhaust gas, and a gas trap with activated carbon for back-up at the last position.
Fig. 3
To evaluate the removal efficiency of various nuclides by gaseous reaction, an inductive coupled plasma analyzer and radiation detectors (for alpha-, beta- and gamma-rays) were used to measure the amount of decreased nuclides on the mounting material. Initially, test samples were made of glass (borosilicate: tube and plate) and stainless steel (SUS304: plate) for mounting radioactive nuclides to insert into the reactor to prevent the contamination of the reactor by mounting directly and the effects of oxide layer on the reactor's surface. Known amounts of radioactive nuclides, diluted by nitric acid solution (0.01-0.1mole/l), were taken and placed horizontally onto the samples; the nuclides were mounted inside tube sample and out-side plate sample. The test samples with nuclides were heated in an oven to about 110-120C to dry. In the case of stainless steel, test samples of stainless steel were heated for one hour at 500C in air in an electric furnace. By this pretreatment, a reddish golden oxide layer was grown on the surface of stainless steel, including the radioactive nuclides in the oxide layer. After inserting this pretreated sample into the reactor, remaining air in the reactor was purged completely by argon gas. Next, reaction gas was charged into the reactor, and was highly pressurized by the syringe pump. In the case of charging fluoric gas, another tank was used to charge the reactor, because the syringe pump was not resistant to halogen gas corrosion. After charging the reaction gases, the reactor was heated by an electric furnace. Tests were done varying the heating temperature, time, pressure, mounting sample's materials(glass, stainless steel) and nuclides. In addition, different trapping methods for volatile compounds by liquid or solid removers were examined.
Experimental conditions were set up as follows;
1) Reaction temperature :room temperature-500C
2) Treatment time:5-60min.
3) Pressure :1-200atm.
4) Gases :CO,COF2,F2,CO2,Ar
(high purity, packed in metal cylinder)
5) Mounting materials of nuclides
: glass[borosilicate] tube id. 8mmx50mm(l),plate 10mmx50mmx1.2mm(t)
: stainless steel[SUS304] plate 10mmx50mmx1.2mm(t)
6) Nuclides :Co-60, Ni-63, Ru-103,
Uranium(UO22+) as nitrate
RESULT and DISCUSSION
At first, to determine the feasibility of this principle as a gas-phase decontamination technology, cold tests using non-radioactive nuclides were done. Elements tested were cobalt, chromium, nickel, rhenium, molybdenum, manganese, ruthenium, zinc. The results of the cold tests are shown in Table III. From these results, all elements used were removed more or less by CO gas treatment. The removal efficiency of chromium, nickel, rhenium and zinc is sensitive to CO pressure. By the results shown in Table III, it was verified that carbonylation has feasibility as a new decontamination technology for radioactive transition elements.
Table III

Next, hot tests using radioactive nuclides were done. Figure 4 shows the radioactive cobalt(Co-60: 2700Bq) removal efficiency by carbonylation under conditions of CO 200atm, reaction for 30 minutes, and reaction temperature heated stepwise up from room temperature to 400C using the same sample contaminated with cobalt-60. After stepwise treatment, the overall removal efficiency of cobalt-60 was 88-93% . In Fig. 4, the line graph is the cumulative removal efficiency and the bar graph is the removal efficiency of each temperature step.

Fig. 4

The radioactive nickel(Nickel-63: 130Bq) removal efficiency by carbonylation is shown in Table IV. From the results of nickel-63, it was clear that the removal efficiency of nickel-63 is high at high temperature and pressure. Specifically, at the treated condition of 350C and 50 atms CO gas for 30 min., a removal efficiency of greater than 98% was obtained.

Table IV

The radioactive ruthenium(Ruthenium-103: 2700-3200Bq) removal efficiency by carbonylation is shown in Fig. 5. Compared with the results in Fig. 4, ruthenium-103 was removed under lower temperature than cobalt-60.

Fig. 5

Next, by simultaneous carbonylation and fluorination, the co-decontamination of cobalt-60, ruthenium-103 and uranium was tried. The glass plate contaminated with known amounts of cobalt-60(540-600Bq), ruthenium-103(2100-2800Bq) and uranium (101dpm) was treated repeatedly twice for 10 minutes at 250C, pressurized total 200atm of mixed CO+COF2 gases. Measuring the glass sample after this treatment, cobalt-60, ruthenium-103 and uranium were removed 37%, 81% and 66%, respectively. Cobalt-60 was removed as carbonyl compound, uranium was as fluoric compound, but it is assumed that ruthenium removed by both chemical forms as carbonyl and fluoride.

All tests mentioned above were done using a glass sample. Next, using a stainless steel sample, the gas-phase decontamination tests were done. Stainless steel samples were pretreated with cobalt-60 (700-740Bq), ruthenium-103 (2800-3100Bq) and uranium(101dpm). As be expected by the direct carbonylation using CO gas only, the removal efficiency of cobalt-60 and ruthenium-103 were small. To remove the surface oxide layer for promoting the gaseous carbonylation and fluorination, the pretreatment using supercritical CO2, halogen (I2) and adsorbed water for etching reagents was examined. The stainless steel pretreated sample was inserted into the reactor, next the sample surface was wetted with water vapor by introducing hot water vapor from outside, then iodine vapor also was introduced at about 0.4-0.7 mmol. After the set up, the reactor was heated at 110C, then CO2 was introduced at 150 atm. Under these conditions of pressure and temperature, CO2 is supercritical. The reaction time was 20 minutes. After this treatment by CO2+I2+H2O, two tests were done. In the first test, 1atm of F2 gas was introduced in the reactor heated to 300C for fluorination. By this treatment, Cobalt-60 was not simultaneously removed, but ruthenium-103 and uranium were removed at 14% and 19-20%, respectively. Next, in the second test, 200atm of CO gas or mixed CO+COF2 gases were introduced for reactions of carbonylation and fluorination. By utilizing pretreatment at supercritical conditions, 95-99% of cobalt-60 was removed. It is assumed that the small amounts of cobalt-60 that remained were diffused into the substrate of stainless steel during the 500C pretreatment. By utilizing supercritical

pretreatment of CO2+I2+H2O, the carbonylation temperature of cobalt was lowered clearly from 300-400C as shown in the results in Fig. 4 to about 100C. The reason for promoting carbonylation is assumed to be that Cobalt-60 reacted with iodine converted to iodide(CoI2), then the reactions of CoI2+CO+Fe(SUS)>Co2(CO)8+FeI2 progressed on the stainless steel sample. Next, by the direct treatment of mixed CO+COF2 gases after the supercritical treatment, the removal efficiencies of cobalt-60, ruthenium-103 and uranium were 30-35%, 49-57% and 55-60%, respectively. These removal efficiencies from oxidized stainless steel were similar to the tests on the glass sample. By utilizing supercritical pretreatment, the feasibility to remove radioactive nuclides from a metal surface with hard oxide layer was determined. The results mentioned above for co-decontamination(Cobalt-60, Ruthenium-103 and Uranium) using a glass sample, and the pretreatment effect of supercritical CO2 using a stainless steel sample are shown in Table V.

Table V

Because the treatment of supercritical CO2+Hologen(I2)+H2O has the ability to remove a hard oxide layer of stainless steel completely, it is expected that this treatment method will be useful in many other fields as a metal surface treatment or other applications.

CONCLUSION

The newly developed concept of gas-phase decontamination, which is an advanced waste management technology, was proposed. The results of the feasibility tests on this new technology, under high CO pressure(50-200atm) with heating(about 350C) using non-radioactive (cobalt, chromium, nickel, rhenium, molybdenum, manganese, ruthenium, zinc) and radioactive nuclides(cobalt-60, nickel-63, ruthenium-103) of transition elements, indicate that all these elements and nuclides were removed as gaseous forms. In the cases of cobalt-60 and nickel-63, they were removed to 88-93% and above 98% by treatment under CO 200atm, max.400C(30min.) and under CO 50 atm, 350C(30min.), respectively. In the case of stainless steel with a hard oxide layer, it was very difficult to remove the radioactive nuclides in the hard oxide layer by gaseous reaction. But removal of the oxide layer and carbonylation were promoted by utilizing the pretreatment of supercritical CO2+I2+H2O. Cobalt-60 in the hard oxide layer of stainless steel was mostly removed. From the co-decontamination experimental results using mixed CO+COF2 gases pretreated with supercritical CO2+I2+H2O, the removal efficiencies of cobalt-60, ruthenium-103 and uranium were 30-35%, 49-57% and 55-60%, respectively. By the experimental results indicated above using non-radioactive and radioactive nuclides, the feasibility of this new idea was determined. In the future, gas-phase decontamination will be a practical technology by determining the optimum treatment conditions. This proposed decontamination technology based on gaseous reaction has the ability and possibility to decrease drastically the large volumes of non-incinerable radioactive wastes, which include burned-ash, many kinds of used-metals, and equipment.

A NEW CUTTING AND PACKAGING TECHNOLOGY FOR LARGE ACTIVATED AND CONTAMINATED COMPONENTS FROM NUCLEAR POWER PLANTS

G. Gestermann
GNS
Gesellschaft fr Nuklear-Service mbH,
Hollestr. 7 A, 45127 Essen, Germany

ABSTRACT
In the past few years, large components from the primary cycle in a number of nuclear power plants have been exchanged.
These include steam dryers and steam separators with diameters and heights greater than 5 meters and with weights up to 50 tons. Since the construction of the components is in part very complex and they exhibit surface doses of several mSv, cutting with thermal equipment is very difficult and is associated with relatively high dose exposures for personnel. The complex design and the size of the parts make remote handling of the equipment practically impossible.
For these reasons, GNS had developed a concept in which the cutting is performed using a heavy-duty hydraulic scrap cutter, which is installed on an electrically driven caterpillar vehicle with an extending arm. Experiences with the cutting of similar, but unless complex components in a non-nuclear field of application are available and were taken into account in establishing the concept.
The cutting and packaging of a steam dryer and a steam separator are scheduled to take place in a German power plant; in the process the parts are to be packaged in final disposal containers and then brought to the final repository ERAM.
In the report, the concept for cutting and packaging shall be explained and the experience gained from the actual cutting in the nuclear power plant shall be discussed.

INTRODUCTION

In one German BWR-nuclear power plant, a steam dryer and a steam separator have been stored for about 20 years. These large components have not been cut up until now because, on the one hand, the dose rate at the components was too high, and on the other hand, a practical cutting technique was not available.
The present report begins with a description of the properties of the steam dryer and the steam separator as well as of the equipment planned to be used for cutting, and describes the sequence of cutting operations, the necessary auxiliary equipment and the estimated time required.
The cutting is planned to be done with a hydraulic scrap cutter, which is installed on an extending arm of an electrically-driven caterpillar. An essential requirement is the possibility of not having to perform the work by remote control.

Experience with the cutting of similar components, if not as complex, exists in the conventional field of application. Cutting trials as an approach of this cutting work have been performed.

DESCRIPTION OF THE COMPONENTS

Steam Dryer

The steam dryer has a diameter of approx. 5200 mm, an overall height of approx. 5500 mm and a overall weight of approx. 38 t. Its main components are pipes, water channels and conductive steel plates. The walls of the steel plates have a thickness of up to 10 mm.

The materials used are mainly high-alloyed steels with the designations 1.4550 and 1.4541.

More massive structures are contained in the supporting frame. It consists of a ring at the top (length of edge: 50 mm) and a ring at the bottom (length of edge: approx. 155 x 80 mm). In the vertical position, the bottom ring is at a height of approx. 1600 mm above the bottom, the top ring approx. 4200 mm. In the top ring, cross struts are still present (length of edge: 50 mm). The top and bottom rings are connected to each other by means of massive supports (length of edge: 50 mm).

The steam dryer rests on 4 legs, so that the lower pipe structures are not in contact with the floor.

Steam Separator

The steam separator has a diameter of approx. 5200 mm, an overall height of approx. 4400 mm and an overall mass of approx. 50 t. Its main components are the clamping ring, the bottom part and the separator part, that is to say the steel plates, the pipe-like structures and the channel profiles. The walls have a thickness of approx. 8-12 mm. More massive parts have also thicknesses up to approx. 60 mm. The materials used are X10 CrNiTi 189 and X10 CrNiNb 189.

The massive structures of the clamping ring are set on the floor. The rest of the steam separator with a maximum diameter of approx. 5200 mm rests thus on the clamping ring, whose diameter is approx. 4500 mm. The height of the clamping ring is approx. 450 mm. Cyclone structures are accommodated in the protruding segment. They are approx. 1500 mm high. Figure 1 shows the components to be cut.

Fig. 1

CONDITIONING CONCEPT

The conditioning of the components described in Section 2 is performed according to a principle which is successfully used by industrial facilities and installations for the conventional disposal as well as for the disposal of concrete structures.

For cutting, the equipment, which is described in detail in the following section, is installed on a manipulator vehicle. With the manipulator vehicle and the manipulator arms, the cutting equipment is positioned for cutting. For this purpose, it is planned to use two different types of cutter, which are dimensioned such that they can cut the metal structures. The cut-out parts can be picked up by the cutter and loaded into drums which have been prepared beforehand.

Cutting Equipment

As cutting equipment, a tank cutter well tried in the conventional industry and a scrap cutter are planned. The manufacturer's data about the dimensions and weights are summarized in Table I. Figure 2 shows the use of the cutter type UP 50 with scrap cutter mouth, and presents the difference between both cutter mouths which shall be used for the cutting of the components.

Fig. 2
Table I
Due to the difference of the structures (steel plates, massive bars) of the material to be cut in the components, the use of both cutter mouths presented is necessary (see Fig. 2). The change from the tank cutter mouth to the scrap cutter mouth takes approx. 1 hour according to the experiences gained in the conventional field. In order to switch the cutter mouths, the caterpillar sets the installed cutter mouth in a frame, the mouth is loosened and the extending arm of the caterpillar switches to the next cutter mouth. The new cutter mouth is installed according to the assembly instructions.

Manipulator

As the manipulator vehicle, a commercial crawler (caterpillar) is planned, on the arms of which the above cutting equipment is attached. With the crawler, the loading is evenly distributed on the ground. Since the vehicle, in the operation planned, can only be used in closed spaces, an electric motor is used instead of a combustion engine.

In order to ensure sufficient radiation protection for the handling personnel, a new handling cabin is installed.

The main dimensions and weights of the planned manipulator are presented in Table II.

Table II

The working range of the cutting equipment is presented in Fig. 3.

Fig. 3

The exact positioning of the cutting equipment is made possible by lifting and lowering the extending arms, with the possibility of turning the cutting equipment by 360 around the extending arm and with the right placement of the vehicle. When the scrap cutter mouth is used, the angle of the mouth during cutting is adjusted by the hydraulic cylinder so that the mouth side with the highest counterforce is stationary while the other mouth side closes the mouth opening, until the same work pressure is reached in both working cylinders.

Cutting and Packaging Concept

The cutting of large-volume components with the equipment planned here is state of the art in the non-nuclear field. The components planned now are different due to the high number of combinations of steel plates and massive supports and the geometric arrangement, which is often complicated. For this reason, a detailed cutting plan cannot be prepared at the moment. The execution of the cutting will more depend on the experience of the personnel on site and on the experiences successively gained.

The cutting is planned to be performed from the top downwards and from the outside towards the inside. All structures above the bottom support ring are cut. The only and necessary exceptions are the supporting bars between the bottom bearing ring and the yoke.

The replacement of the cutting equipment is done according to the cutting progress. For time reasons, as few replacements as possible shall be performed.

Placement of the Scrap into Drums

The parts cut out of the components with the tank cutting mouth have approximately the dimensions corresponding to the depth and width of the mouth. They are held in the mouth and are placed directly into a 200-l-drum ready for loading. Cut out sections which are longer can be pulled through the mouth without any external assistance and are slightly bent.

This "bent" strip can also be put in a prepared 200-l-drum using the tank-cutter.
During cutting with the scrap cutter mouth, only simple cuts can be made. This leads to the fact that some parts cut out remain on the components to be cut or fall onto the floor. The cuts are thus selected by the operator such that parts are produced which can be placed directly into a drum. These parts are picked up with the cutter and put into a ready drum. Larger parts are placed onto a specially prepared area and are further cut up.
Cut up scrap parts, which lie on the floor and can not be picked up by the cutter are pushed or pulled in to position from the edge of the steel plate with a manipulator or the cutter and from there picked up with a tool and placed into drums.
The mass of metal per 200 l-drum has been currently estimated to be approx. 50 - 200 kg, 100 kg on the average. For a total mass of the steam dryer of approx. 38 t, approx. 400 200-l-drums will be needed. Similar conditions apply for the steam separator.
Maintenance of the Equipment Used
The equipment planned has proven itself in conventional use. Maintenance and repair are only required after throughputs and lengths of time which are not expected for the present case.
The cutter with the differing mouths can be modified and maintained without any special expense or special equipment. Also, workers are trained for the project by the manufacturer/supplier in the scope of the preparatory functional testing.
The operating time of the moving mechanism for the further present cutting purpose is so small as compared with operating time in conventional areas, that extensive maintenance or repair work can be excluded. As a rule, all work can be performed by the power plant's own maintenance staff. The manufacturer or supplier is consulted if needed.
Radiation Protection
The radiation protection aspects of the conditioning campaign are as high a priority as the technical realization.
Through the use of heavy-duty equipment, for which no substantial repairs are expected, it is possible to cut and package the steel components rather quickly. Wherever possible in all working places, shielding is used, including in the shielded cabin which is installed on the manipulator vehicle. Conservative estimates of the individual and collective dose rate have been made and show that the work according to the concept described here is fully acceptable. The average individual dose for all persons involved with the cutting work is approx 3.6 mSv. The operators of the manipulator vehicle have the maximum individual dose of approx 9 mSv.
SUMMARY
The use of the cutting equipment presented in combination with the vehicle has been tried and tested for years and has proven itself in the conventional industry. This refers not only to the cutting concepts and the execution on site but also to all technical systems such as moving mechanisms, drive, hydraulic and electric supply.
Typical areas of use are the disassembly of chemical installations and refineries. Essential aspects are minimizing the aerosol load, avoiding risk of explosion, and the distinct acceleration of the cutting process compared to manual techniques such as flame-cutting.

Preliminary tests have been performed on various steel plates with a mobile tank cutter, which had been in service already for a long time. For this reason, there was too much leeway between the cutter and the holder (finger). Plates made of the material 1.4571 (with strength values similar to 1.4550) were used:
2 pcs. 4 x 500 x 500 mm
4 pcs. 10 x 500 x 500 mm
By combining various plates, material thicknesses of up to 30 mm were reached. Up to a thickness of 25 mm, all combinations were cut safely. When correctly adjusted, cutting of plates with 30 mm and more can be done satisfactorily.
In one further test with a UP 50 shears having a scrap cutter mouth, full-steel profiles with properties like 1.4550 were cut.
In order to demonstrate the cutability of the edge profiles on the steam dryer, cross-sections of 50 x 50 mm and 60 x 60 mm were used for the test. The profiles were able to be cut in a satisfactory manner.

A STUDY OF AIRBORNE RADIOACTIVITY GENERATED DURING THE PREPARATION OF CONCRETE WASTE FROM REACTORS UNDERGOING DECOMMISSIONING*
Nicolas K. Bates
Robert R. Landolt
Purdue University
School of Health Sciences
West Lafayette, IN 47907
ABSTRACT
The demolition of activated concrete waste from reactor biological shields undergoing decommissioning produces the potential for worker exposure to radioactive aerosols. The determination of appropriate derived air concentrations (DAC) for worker protection during routine and accidental situations depends on a knowledge of the particle size distribution of the aerosol. Measurements are described which were used to evaluate the mass median aerodynamic diameter (MMAD) and the activity median aerodynamic diameter (AMAD) for aerosols generated by cutting two types of activated reactor concrete under laboratory conditions using a sawing device and a coring tool. Samples were also taken during the actual demolition of the biological shield at the Experimental Boiling Water Reactor (EBWR). In the laboratory study, twelve sample collection experiments were performed as part of a 2x2 factorial statistically designed experiment with three replications. The results indicated that the type of cutting tool used significantly affected the MMAD and the AMAD with coring values being much larger than sawing values. The numerical value of the 60Co AMAD for sawing was found to be more than an order of magnitude greater than the ICRP recommended default AMAD of 1 mM. These results suggest that DAC values used at the worksite should be based on experimental data instead of regulatory assumptions, or that larger default values should be used in practice. The results also showed that particle size distribution was not significantly different for the two types of concrete studied. Also, the MMAD and the AMAD were found to be not statistically different for the various samples. In contrast to this, one of the field samples taken during the demolition of the concrete reactor shield by an air-hammer under wet conditions at the EBWR had an AMAD much smaller than the MMAD and also smaller than the 1 mM default value. One possible explanation is that 60Co is being leached

from the concrete dust by the water spray resulting in smaller aerosol droplets. Further research with other types of concrete and other cutting devices is needed, and the author is seeking such samples from other reactors being decommissioned.

INTRODUCTION

The demolition of reactors undergoing decommissioning usually involves the cutting of large pieces of activated concrete for shipment to waste disposal sites. Each of the cutting techniques produces a radioactive dust, and although efforts are made to mitigate the dust production, there still remains the possibility of inadvertent worker inhalation through accidents, respirator failure and enclosure failure. Very few studies have been performed to date on the specific radiological hazards of these airborne radioactive particulates. The purpose of this research was to characterize the particle size distribution of these concrete aerosols in order to provide data for the determination of appropriate derived air concentrations (DAC) for worker protection during routine and accidental situations. Specifically, determinations were made of mass median aerodynamic diameters (MMAD) and activity median aerodynamic diameters (AMAD) for aerosols generated from cutting activated reactor shielding concrete. In addition, factors which affect the parameters of the distributions were investigated. The factors included two types of concrete and two different cutting tools. Experimentally determined distribution parameters were compared to those assumed in regulations which limit the occupational exposure to radioactive aerosols. Mass distribution parameters were compared with their activity distribution counterparts. Qualitative comparisons were made between samples collected in the laboratory at Purdue and samples taken in the field at the Experimental Boiling Water Reactor (EBWR) at Argonne National Laboratory during actual reactor decommissioning procedures.

EXPERIMENTAL

For the laboratory study at Purdue, activated concrete blocks were obtained from the EBWR and the University of Washington Nuclear Reactor (UWNR). A diamond circular saw and a diamond coring tool were used to cut the activated concrete under dry conditions in a radiological glove box. An 8-stage cascade impactor was used to collect the aerosol samples. The air flow through the impactor was controlled by a critical orifice designed to maintain a 0.25 ft3 min-1 flow rate through the impactor. Masses collected on glass fiber substrates were measured with a microbalance, and 60Co activity was measured with a hyperpure germanium detector. Twelve sample collection experiments were performed as part of a 2x2 factorial statistically designed experiment with three replications. The cascade impactor was transported to the EBWR for use during the demolition of the biological shield with an air hammer. The air hammer moved in all directions, thereby dismantling the shield from the inside out. A water misting spray was used to reduce airborne aerosol concentrations. The cascade impactor was placed on a ledge of a penetration of the concrete shield approximately half-way up the shield and just inside a plastic curtain which had been erected to keep the dust out of the penetration.

RESULTS

The mass and activity data from each impactor stage used in the laboratory study were entered into a graphics software package which generated a log-probability plot along with a fitted least squares line. Figure 1 is a plot of the mass data from sample 11 as an example. The

equation of the line is given which yields an MMAD of 13.7 mM. Figure 2 is the activity plot of sample 11 which yielded an AMAD of 13.6 mM. Table I is a listing of the response variables for the 12 experiments. It can be seen that the 60Co AMAD values are more than an order of magnitude greater than the ICRP recommended default AMAD of 1 mM. Consequently, the usual practice of setting 60Co Annual Limit on Intake (ALI) and Derived Air Concentration (DAC) values based on an assumed AMAD of 1 mM would result in perhaps unnecessarily conservative regulations for dry cutting conditions. The results of an AMAD larger than the 1-m default value are consistent with observations presented in Dorrian and Bailey's recent review paper (1). The results also support the new recommendation of a 5-m default value given in ICRP Publication 66 (2).

Fig. 1

Fig. 2

Table I

The response variables are somewhat similar within each group of three replicates. This could be explained by the tight control on experimental techniques and methodologies used during the processing of a sample. It may also be attributed to the relative homogeneous nature of the concrete ingredients in those particular locations where cuts were made. The R2 values for all the samples are very close to unity. This indicates that the data follow a nearly perfect linear line. The aerosol distributions are, then, almost assuredly log normal in nature. This agrees with the ICRP functional form assumption of the aerosol distributions as used for setting ALI and DAC values.

The results of the statistical analysis on the two types of concrete and the two types of cutting tools are given in Table II. This portion of the statistical analysis shows that the aerosol particle size distributions are significantly different for the two types of cutting tool. Tests on every response variable showed this finding. It is important to note that the results of the statistical tests for MMAD and the mass fraction less than 10 mM agree with each other. The same is true for the agreement between AMAD and the activity fraction less than 10 mM. The reason for its importance is that the MMAD and the AMAD values for the coring samples were determined by extrapolating the log-probability plot fitted line. Whenever extrapolations of experimental data are performed the results become less credible. The mass and activity fractions less than 10 mM, however, were determined without extrapolation. The agreement of the statistical tests between these response variables indicates that extrapolation did not adversely affect the analysis.

Table II

The distributions were not significantly different for the two types of concrete. This finding is somewhat surprising given that the mixture components of the concrete are quite different. It indicates that cutting tool rather than type of concrete has a strong influence on the resultant aerosol distributions. Health physicists and program managers may wish to incorporate the range of particles produced by different cutting techniques in their decision making process for choosing particular techniques for demolition projects. An interaction between cutting tool and concrete type was found to be not significant for each response variable. Therefore, the effect of cutting tool on the resultant aerosol distributions was not influenced by the type of concrete being cut.

The second portion of the statistical analysis was to determine if the mass distribution response variables differed significantly from their

associated 60Co response variables. Table III lists the results of this test. The results of this analysis have shown that the mass response variables do not significantly differ from their 60Co activity response variable counterparts. This interesting finding may suggest that the particular levels where the cuts were made had uniform activation levels.

Table III

Table IV lists the response variables for two samples taken at the EBWR during actual demolition of the activated concrete bioshield wall. Comparisons with the laboratory study at Purdue are quite tentative because the samples were taken under quite different conditions. Nevertheless, a few observations can be made. Although the EBWR samples were taken under wet operating conditions, the MMAD were again much larger than 1 mM. The absolute MMAD values of the EBWR field study where demolition was done with a Brokk air hammer, were quite similar to the MMAD of particles produced by sawing in the laboratory study at Purdue.

Table IV

The 60Co activity measurements of the EBWR samples produced some unexpected results. While it was shown earlier that there was no statistical difference between the MMAD and AMAD of the Purdue samples cut under dry conditions, such is not the case for those collected at the EBWR. Sample 2 produced the most striking results in this respect. Although its MMAD value is much larger than 1 mM, its 60Co AMAD value is much smaller. This finding suggests that while the use of water does not have a great affect on the mass distribution of the particles produced by the cutting, it does change the radioactivity distribution to a large extent. A visual inspection of the after filter (AF) substrate revealed a conspicuous dark water stain. This substrate was measured as having over 60% of the total 60Co activity that was collected on all of the impactor stages. A possible explanation for the very small AMAD value could be that the 60Co was leached from the particles due to the use of the water misting spray. The 60Co may then have been attached to water droplets so small that they were not caught by the impactor stages until they reached the after filter. Under this operating condition, setting 60Co ALI and DAC values based on the ICRP recommended AMAD value of 1 mM may be too liberal.

The use of water during demolition operations is routine. Therefore, it appears incumbent upon health physicists to determine actual AMAD values during working conditions and calculate ALI and DAC values accordingly. This should be done instead of relying upon the ICRP recommended AMAD value of 1 mM. This applies for both dry and wet demolition conditions. The results of this research indicate that, under both dry and wet conditions, the usual assumption of a 1 mM AMAD would result in inaccurate worker internal dosimetry determinations. In addition, the water used in the misting spray or for cooling the cutting tools will be contaminated and should be collected and analyzed for radioactive concentrations. These results also indicate the importance of knowing the lung solubility classification and the leaching characteristics of radioactive concrete aerosol particles.

ABSTRACT

The current surface contamination limits used for release of facilities for unrestricted use are applied to decommissioning projects to verify that the levels of removable contamination or residual total (fixed and removable) contamination that could pose health risks to the general public are acceptably low. The acceptable amounts of residual radioactivity remaining should be taken in context of how the structure or surface is to be used in the future. Risks associated with various levels of residual surface contamination are correlated to accepted risk based standards. One of these risks is potential exposure to radioactive material in the industrial rubble resulting from structure or surface demolition and disposal. However, if the demolished material is used as dispersion media, this exposure risk is reduced and the projects costs are lowered by eliminating the need for costly surface decontamination. This paper will discuss the use of this methodology to release a structure.

DECISION PROCESS

The following is a list of items that must be considered in order to use surface contamination limits in building demolition.

1. Determine source term
Total radioactivity involved per radionuclide
Determine solubility class of radionuclides
2. Determine any hazardous waste concerns
RCRA or TSCA waste streams
3. Determine volume of rubble to be generated
4. Determine disposal options
Recycle
Road bed material
Erosion control
Construction fill
Ferrous metal recycling
Other metal recycling
Wood chips for fuel
Disposal
Industrial landfill
Sanitary landfill
5. Obtain regulatory approval

Perform pathway analysis and risk assessment
6. Perform soil sampling for release of structure footprint

DOSE CALCULATIONS

Internal exposure is the predominant exposure pathway during building demolition because surface contamination has a high potential for becoming airborne. Strict radiological controls are required at this phase to ensure the health and safety of the workers, the public, and the environment. Appropriate monitoring, including personnel air samples are required. At this point, occupational radiation exposure through the inhalation pathway is the primary area of concern.

After demolition, the primary exposure pathway is through external gamma irradiation from the deposition of the material. This exposure may come from submersion in a contaminated atmospheric cloud, immersion in contaminated water, or exposure to contamination on or in the ground. The Regulatory agencies may request a pathway analysis that determines the dose to members of the public from pathways of concern like food, fish, meat, water, and air. Dose can be determined by using the following equation:

Eq. 1

If the resultant public dose is less than 0.1 mSv/year (10 mrem/year) to any individual, the material may be disposed of in the manners proposed. The resultant public dose may be negotiable with the applicable regulatory body.

DISCUSSION

A determination should be made on the average contamination levels on or in the walls, floor, and ceiling. For simplicity, the building is assumed to be empty. Then, the density and thickness of the material is used to calculate the activity per gram. If, items like sheet rock and wood are crushed and mixed with the concrete and rubble during the demolition process the AVERAGE density may be used for the material where the contamination will be dispersed. This results in a surface activity level coefficient.

Eq. 2

Typical surface contamination limits are expressed in dpm/100 cm2, for example, 1000 dpm/100 cm2. If we divide this by 2.22 dpm/pCi we can obtain the pCi/100 cm2, for the above example we get 450 pCi/100 cm2. Taking the surface activity level coefficient and dividing it by the thickness of the material gives the activity per gram dispersed through the material as it is broken up during demolition.

Eq. 3

Estimations of additional material not accounted for in the contaminations is added to the activity concentration by dividing the estimated total activity by the sum of the total contaminated grams plus the total non-contaminated grams.

CONCLUSION

Eq. 4

By uniformly dispersing surface contamination during the building demolition process, the average activity per gram of the material will be well below any regulatory guideline. This process allows the material to be recycled for beneficial use without any harm to the health and safety of the workers, public, or the environment.

DECOMMISSIONING AND CLOSURE OF A MANUFACTURING PROCESS THAT GENERATED LOW LEVEL MIXED WASTES

David J. Wilson
Jeffrey E. Banikowski
O'Brien & Gere

ABSTRACT

This paper describes the strategy that was developed to perform facility decommissioning and license termination for a polymer manufacturing facility where uranyl acetylacetonate (UAA) and uranyl dinitrate were used as catalyst components for several blends of polymeric compounds. Elimination of this product line by the manufacturer resulted in the need to prepare a facility decommissioning and license termination plan acceptable to the New York State Department of Labor (NYSDOL) as the licensing agency, implementation of the plan consistent with New York State Department of Environmental Conservation (NYSDEC) regulations, and preparation of a facility closure and license termination report.

Upon elimination of the product line, excess UAA and UNH product intermediates and low level radioactive waste such as QA/QC samples required disposal as part of NYSDOL licensing requirements. Because the intermediates would be considered a low level radioactive waste, and the UNH possibly a mixed waste due to an oxidizing characteristic and, it was decided to reprocess the intermediates to a final product prior to disposal. The situation was further complicated by the fact that no disposal facility would readily accept the intermediates, the hazardous waste characteristics of the final product were unknown prior to reprocessing, regulatory approval by both the NYSDOL and NYSDEC to initiate reprocessing was required, and the Barnwell, SC disposal facility (the most likely receiving facility) was to close in the near future.

This paper describes the steps in developing the overall decommissioning strategy to successfully terminate the manufacturer's license. The most challenging aspect of the decommissioning procedure was to find and implement an acceptable regulatory strategy which would not require a Resource Conservation and Recovery Act (RCRA) treatment permit and still meet the time frame associated with closure of the Barnwell disposal facility that has since reopened.

INTRODUCTION

A manufacturing facility located in New York State utilized radioactive compounds as components for polymeric materials produced from 1987 to 1993 for use by the U.S. Department of Defense. A radioactive materials license was issued to the manufacturer to receive, possess, use, and transfer radioactive materials pursuant to the State of New York Industrial Code Rule 38, Ionizing Radiation Protection (12 NYCRR Part 38). Radioactive materials designated under the license were natural or depleted uranium compounds, uranyl acetylacetonate (UAA) and uranyl dinitrate hydrate (UNH), in a solid or liquid form in a quantity not to exceed 11 millicuries at any one time.

GENERAL PROCESS DESCRIPTION

UAA and UNH are low activity (46 microcuries per kilogram) materials. Formulation of polymer products required approximately 136 kilograms of UNH or UAA during a typical production year. During the manufacturing process, UAA and UNH were blended into an intermediate product from which a Part B product was made. A Part A product was also produced, but did not contain any radioactive materials. Parts A and B were mixed together

by the consumer to make a final product. It is important to note that the polymer product required UAA and UNH chemical properties and not their radioactive properties. Batch operations to produce UAA and UNH containing products required approximately two days of operation and were conducted approximately four times per year.

Boxed, one gallon metal cans of UAA and UNH were delivered to the facility's receiving dock, where the Radiation Safety Officer (RSO) documented shipment receipt, and personally transported the containers to the radioactive materials storage cabinet. Each one gallon can contained 3.63 kilograms of UAA or UNH in a plastic bag, within the can. The cans were not opened at any time during delivery to the storage cabinet.

When dispensed, one can of UAA or UNH was transported from the radioactive materials storage cabinet to a scale glove box, located in a mixing room. The can was placed in the glove box, the can and plastic liner were opened, and UAA or UNH powder was placed in a paper cup on the scale. When the desired weight of UAA or UNH powder was obtained, any remaining powder in the can was resealed in the plastic liner, the metal cover replaced, and the can returned to the radioactive materials storage cabinet. When empty, the can along with the plastic liner were placed in a 55 gallon drum for disposal. The scale glove box contained a local air exhaust duct to capture dust generated by the weighing operation.

The paper cup containing UAA or UNH was carried from the scale glove box to a mixing vessel, where the contents were poured into the vessel through an addition hatch. A local air exhaust duct was located at the addition hatch to capture fugitive dust. The mixing vessel contained organic solvents that dissolved the UAA or UNH. During mixing, a vacuum pump was used to degas this intermediate product.

When processing of the intermediate product in the mixing vessel was completed, it was drained from the bottom of the vessel and placed in another mixing vessel and blended with additional raw materials to make the Part B product. A vacuum pump was used to degas Part B during mixing. When mixing was completed, the Part B was dispensed from a bottom port of the mixing vessel and packaged into containers to be sent to the customer.

Samples of intermediate product and Part B were obtained from each batch produced for Quality Assurance/Quality Control (QA/QC) purposes. Samples of intermediate were filtered prior to dispensing to assure that no solids were present. QA/QC samples were transported to the QA/QC laboratory in covered containers. Filters and paper cups that contacted UAA or UNH containing material were placed in a 55-gallon drum for disposal. Gloves and paper coveralls worn by employees working with UAA or UNH were also placed in a 55-gallon drum.

Intermediate product and Part B samples were subject to different test procedures upon receipt by the QA/QC laboratory. Intermediate product samples were logged in and an aliquot was weighed on an analytical balance. Afterwards, it was dried and degassed in an oven, and volatilized in a furnace for residual analysis. Part B samples were logged in, and an aliquot reacted with Part A, cured in an oven, and the reacted product tested for physical parameters. Intermediate product and Part B samples not analyzed were stored in a holding area.

Unused intermediate product, Part B, and materials that came in contact with UAA or UNH were placed in a 55-gallon drum. The drum inventory at the conclusion of operations involving UAA and UNH consisted of twenty three 55-gallon drums. The drums were located in the shipping area and

consisted of 6 drums of dry solids, 6 drums of intermediate product, and 11 drums of Part B product. Product manufacturing components and laboratory apparatus associated with QA/QC continued to be used for non-radioactive product production. Figure 1 illustrates the handling steps associated with UAA and UNH in the manufacturing process.

Fig. 1

SITE RADIATION CONTROL

Existing procedures to control radioactive material contamination consisted of wipe sample counting and gamma readings following the use of UAA or UNH. If radioactive material was detected, the corresponding area was cleaned and resurveyed to assure the area was free of contamination. Wipe sample counting was conducted by facility personnel using a Ludlum Model 43-10 alpha sample counter attached to a Model 2000 scaler. Gamma measurements were collected with a Ludlum Model 3 survey meter.

Most surface contamination measured during surveys conducted by the manufacturer was less than 20 disintegrations per minute (dpm)/100 cm2 with the highest surface contamination at 1,000 dpm/100 cm2. Gamma levels detected were less than 0.5 milliroentqens (mR)/hr.

Based on existing records, survey information, and control procedures implemented during UAA and UNH use, wide-spread radiological surface contamination was not expected during decommissioning.

DECOMMISSIONING PLAN

Radiation survey methods submitted to NYSDOL and conducted at areas where loose UAA or UNH were handled or processed consisted of a real-time radiation survey with an alpha probe and collection and analysis of wipe samples for designated areas. Wipe samples were collected using paper backed smears by wiping a 100 cm2 surface area, and placing the sample in a coin envelope. Wipes were counted on site for alpha radiation with a Ludlum Model 43-10 alpha sample counter attached to a Model 2000 scaler to measure dpm/100 cm2.

Wipe samples were also collected where loose UAA or UNH were handled or processed. These areas consisted of the scale glove box, mixing vessel room floor, and associated mixers. In addition, the interior surface of the air exhaust system and the vacuum lines associated with mixing vessels were sampled. One wipe sample of 100 cm2 was collected per three square feet of surface area exposed to UAA or UNH dust. Floor areas were sampled at materials use locations. The air exhaust system was wipe sampled at the openings of the exhaust duct for the scale glove box. Wipe samples were collected at the exhaust clean-out door, blades of the exhaust fan, and the exhaust duct cap. Two wipe samples were collected from overhead rafters in the mixing room and two wipe samples were collected from the wall adjacent to the scale glove box.

An alpha and gamma survey was conducted in areas where UAA and UNH were used and also where wipe samples were not collected. Survey instrumentation consisted of an Eberline Model ASP-1 survey meter and to an HP-260 pancake probe.The area survey was conducted at the following locations:

- in and around the radioactive materials storage cabinet
- below the two mixing vessels
- the floor area next to the walls of the first floor mixing room
- the water drains in the first floor mixing room
- bench tops and hood interiors in the QA/QC laboratory
- interiors of the furnaces and ovens in the QA/QC laboratory
- shelves and floor area of the sample storage area

floor surface of the waste drum storage area.

A guideline to trigger additional wipe sample collection and measurement for alpha radiation activity was detection of gamma radiation in excess of 0.25 mR/hr at 1 centimeter from the surface.

The site decommissioning plan contained a decontamination plan that would be activated if surface wipe radiation contamination measurement exceeded 33 dpm/100 cm2. A clean surface was defined as a wipe sample measurement less than 33 dpm/100 cm2 and survey probe measurement less than 0.25 mR/hr at one centimeter from the surface. Also, five percent of surface wipes were to be quality assurance tested with a Canberra Model 2404 proportional counter to detect alpha particle radiation to a level less than 1 dpm.

Proposed personal protective equipment consisted of a dust mask (Moldex 3400 or equivalent), rubber gloves, and Tyvek coverall with shoe covering. Prior to leaving the decontamination area, workers were to be whole body surveyed with an alpha scintillation detector and/or beta-gamma detector. The worker whole body survey area was scheduled for a low radiation background area. Radiation contamination identified on workers was to be removed using soap and water located in the decontamination area.

When required, worker training was to be provided to workers conducting decontamination activities as specified in 12 NYCRR Part 38 and 29 CFR Part 1910.1200. Training included identification of the hazards associated with UAA and UNH and instruction in the use of personal protective equipment (PPE) required for these activities. Decontamination wipe methods and disposal of wipe cloths and PPE were to be discussed as well as personnel radiation monitoring and bioassay methods.

CONTAMINATED MATERIAL DISPOSAL

Termination of the NYSDOL radioactive material license required surface work areas to not exceed those levels identified in the decommissioning plan and the removal of all radioactive material associated with the license from the facility.

Containers located at the facility consisted of 6 drums of dry solids such as paper cups, Tyvec suits, and gloves; 6 drums of liquid intermediate product; and 11 drums of Part B product. The 6 drums of dry solids were characterized as a low level radioactive waste and did not exhibit a mixed waste characteristic.

However, based on material safety data sheet for UNH, the 6 drums of intermediate product and 11 drums of Part B product contained a quantity of UAA and UNH sufficient to classify them as a RCRA mixed waste if they were not reprocessed. The solution disposal of the 17 drums containing intermediate and Part B product was to remove the oxidizing characteristic from the material. Liquids required solidification to meet disposal requirements of the potential receiving facility, Barnwell, SC. Regulations and therefore a method to eliminate the oxidizer component and solidify the waste for disposal as a radioactive material were investigated.

Both the New York State Department of Environmental Conservation and NYSDOL were notified and concurred with the plan to solidify these liquid wastes for transportation to the Barnwell, SC disposal site.

The manufacturer indicated that the 11 drums of Part B product could be mixed with materials chemically similar to the Part A component originally required to be reacted with Part B to create the final polymer product. This process was anticipated to result in a hardened polymer

that would react the nitrate component of the UNH and therefore would remove the oxidizer characteristic of the waste. Stoichiometric addition of Part A component to the Part B waste was conducted by the manufacturer and allowed to cure in the waste drums.

The 6 drums of intermediate product required additional processing prior to reacting with a Part A component to eliminate the oxidizer characteristic. Records of waste drum contents were reviewed, addition materials were identified and stoichiometrically added to the intermediate product, resulting in polymerization that met solidification requirements. The additional polymerization material increased the total waste volume from 17 drums of liquid to 27 drums of solidified product. Samples of the solidified products were analyzed for radioactivity and RCRA hazardous waste characteristics. The solidified product did not exhibit a RCRA hazardous waste characteristic; therefore, the manufacturer was able to transport the solidified waste drums to Barnwell, SC for disposal as a low level radioactive waste.

CONCLUSION

Survey activities consisted of surface wipe samples and survey probe measurements at all locations associated with UAA and UNH material use. No areas were identified that exceeded the contamination criteria approved by NYSDOL in the decommissioning plan.

Removal of these radioactive drummed materials from the manufacturing site and the absence of surface contamination within the facility resulted in the NYSDOL granting decommissioning status to the facility and termination of the NYSDOL radioactive material license.

The successful conclusion of reducing mixed waste to a LLRW and thereby devising a disposal option was accomplished by advising the manufacturer to take the chemical process to completion and coordination with the involved regulatory agencies as well as the potential disposal facility throughout each step of strategy development and plan implementation.

ABSTRACT

In 1993, O'Brien & Gere Engineers, Inc. was selected under a Program Research and Development Announcement solicitation of the Morgantown Energy Technology Center of the U.S. Department of Energy (DOE) to develop soda blasting technology for removal of radioactive contamination

from surfaces. The project included demonstration of the technology in decontamination and decommissioning (D&D) operations at a nuclear facility. The contract award and management was through Lockheed Martin Energy Systems of Oak Ridge, Tennessee under the direction of DOS's Oak Ridge Operation Office (ORO). Work was performed at ORO's K-25 plant site and O'Brien & Gere Facilities in Oak Ridge.

O'Brien & Gere developed a scouring system that removes hazardous and fixed radioactive surface contamination and minimizes residual waste. It uses an abrasive sodium bicarbonate medium that is projected with great force at contaminated surfaces. It mechanically removes surface contamination while leaving the surface intact. Blasting residuals are treated using physical/chemical processes.

Bench- and pilot-scale testing of the soda-blasting system was conducted between December 1993 and September 1994 on surfaces contaminated with uranium, technetium, heavy metals, and PCBs. Areas of concrete and metal were blasted. Residuals were dissolved in tap water and treated for radioactive, hazardous, and organochlorine constituents. The treatment comprised pH adjustment, aeration, solids settling, filtration, carbon adsorption, and ion exchange. It produced treated water and residual solid waste.

These tests demonstrated that the system is capable of removing greater than 95% of radioactive and PCB surface contamination to below DOE's unrestricted use release limits. Aqueous radionuclides, heavy metals, and PCBs were below DOE and USEPA treatment objectives for residuals after treatment. Waste residuals volume was decreased by 70%.

Preliminary analysis suggests that this treatment system provides significant waste volume reduction and is more economical than available surface decontamination technologies. Full-scale system capital and operating costs are under development.

The DOE's emphasis in this demonstration procedure has been on comparing the economics and efficiency of the technique against other available and developing technologies.

INTRODUCTION

Increasing waste disposal costs and decreasing storage facility capacity are prompting the DOE and commercial utilities to explore new waste minimizing decommissioning and decontamination (D&D) techniques. Current D&D activities are generally labor intensive, use chemical reagents that are difficult to treat, and may expose workers to hazardous chemicals. Therefore, new technologies are desired that minimize waste, allow much of the decommissioned materials to be reused rather than disposed as waste, and produce wastes that will meet disposal criteria.

To support this D&D objective, the O'Brien & Gere Companies tested a decontamination system on concrete and steel surfaces contaminated with radioactive (238U and 99Tc) and hazardous (PCBs and lead) waste in Oak Ridge, TN. The principal objectives of this on-site soda blasting demonstration project were to evaluate the effectiveness of decontamination by blasting with sodium bicarbonate and to minimize waste volume by dissolving and treating blasting residuals through a wastewater treatment system.

BACKGROUND

Testing of a soda blasting system was conducted at DOE's K-25 former gaseous diffusion plant, Building K-29, in Oak Ridge, Tennessee between December 1993 and September 1994. This gaseous diffusion plant separated 235U from uranium ore for use in atomic weapons and commercial reactors.

The radioactive contamination on surfaces located in K-29 was considered fixed contamination, which is not easily removed by casual contact. Contaminants present on surfaces tested comprise 238U, 99Tc, lead, and PCBs. Uranium was present on concrete and metal surfaces from process operation and equipment releases during enrichment. 238U is an alpha-emitter with a half-life of 7.05 X 108 years. 99Tc is a byproduct of 235U fission in nuclear reactors. 99Tc entered the K-25 process as a volatile impurity in recycled uranium (1). 99Tc is a beta-emitter that has a half-life of 2.12 X 105 years. Lead was present in coatings found on the concrete and metal surfaces at K-29; and PCBs were the result of a heat transfer fluid conduit leak.

For this testing, the following cleanup objectives were established: the total beta/gamma activity and the total alpha activity of the material each were to be less than 5000 disintegrations per minute/100 cm2 (dpm). These criteria were obtained from DOE Order 5400.5 for unrestricted use. Waste volume reduction (soda blasting residuals treatment) objectives were developed as benchmarks to evaluate on-site testing results. These treatment objectives were developed based on DOE 5400.5 standards and federal limits under the requirement of the Safe Drinking Water Act (SDWA). Aqueous phase treatment objectives for total U, 99Tc, PCB, and lead were 12 mg/l, 100 pCi/L, 0.5 mg/l, and 15 mg/l, respectively.

SODA BLASTING METHODOLOGY

Soda blasting utilizes sodium bicarbonate media to physically remove contaminants from surfaces. Compressed air propels sodium bicarbonate at surfaces, which removes contaminants and surficial coatings. The physical and chemical characteristics (non-destructive, non-toxic, and water soluble) of sodium bicarbonate render it a desirable blasting media. The crystalline structure of sodium bicarbonate is aggressive enough to remove contaminants and coatings from metal and concrete surfaces while not degrading blasted surfaces. Sodium bicarbonate media will not introduce additional hazardous or toxic chemicals during operation. Waste volume may be minimized by sodium bicarbonate dissolution and contaminant removal.

Areas of concrete floors and columns and steel and aluminum surfaces were selected, based on radiological surveying and PCB wipe testing to evaluate the soda blasting process. Blasting tests were verified by post-blast analysis using direct reading instruments and smear and wipe samples.

On-site testing evaluated six operating variables: air pressure, water pressure, nozzle orifice diameter, nozzle orifice design, media type, and media flow rate. Ten 1-m2 concrete surface grids were used to evaluate these operating parameters. Blasting parameters were evaluated on concrete surfaces, because typically, if removal objectives are achieved on concrete, they will be equal or better on less porous surfaces such as metal. Once blasting parameters were determined, three concrete grids and several metal object surfaces were blasted to evaluate decontamination efficiency.

Subsequent to each blasting test, a tap water wash was utilized to remove blast residuals from the tested surfaces. Each test surface was triple rinsed using between 2 and 15 gal of water for each test grid. Between each rinse, blasting residuals slurry (water and spent sodium bicarbonate) was collected using a small wet/dry vacuum. The blasting residuals slurry was transferred to 55 gal drums in preparation for blasting residuals treatment.

WASTE VOLUME REDUCTION METHODOLOGY

The aqueous phase solubility of sodium bicarbonate provides a mechanism for separating blast media from contaminants following blasting. Sodium bicarbonate has a solubility of 96 g/l at 20oC (2). By mixing water with spent blasting media, sodium bicarbonate dissolves which physically separates contaminants from the blast media. This reduces waste volume. Soda blasting residuals solution contains elevated concentrations of dissolved sodium bicarbonate. Therefore carbonate complexes control the stability of uranium and other metals in solution. The dissolved solids also interfere with ion exchange processes. Treatment processes developed for this system were based on physical/chemical mechanisms controlling the fate of contaminants in the presence of a high ionic strength wastewater system. The treatment system comprised pH adjustment, chemical precipitation, solids removal, carbon adsorption, and ion exchange. Figure 1 presents a schematic of the blasting residuals waste volume reduction system. Based on bench and pilot-scale treatability testing, physical/chemical unit operations were selected. Treatment of each of the four contaminants was conducted as follows:

Fig. 1

Uranium, in an elevated carbonate system, will form carbonate complexes such as UO2(CO3)6-8 and UO2(CO3)3-4 (3). However, at low carbonate concentration and high pH, uranyl hydroxides (i.e., (UO2)3(OH)5+) form. The solubility of these hydroxide species varies with pH. At an optimum pH, the hydroxide formation is insoluble and can be chemically precipitated. Conversion of uranyl carbonate to uranium hydroxide is difficult in concentrated bicarbonate solutions.

To achieve effective uranium removal, carbonate was removed. Carbonate removal was accomplished in this study by depressing solution pH, to transform inorganic carbon as carbonate (CO32-) and bicarbonate (HCO3-), to carbonic acid (H2CO3). The reduction of solution pH converted inorganic carbon to dissolved carbon dioxide, which was lost to the atmosphere. This loss of inorganic carbon allowed the formation and subsequent precipitation of uranium hydroxide complexes at alkaline pH. To accomplish this conversion during on-site testing, approximately 30 gal of 70% nitric acid was added to acidify 450 gal of blasting residual from an initial pH value of 9.35 S.U. to a pH value below 5 S.U. Subsequent to acid addition, the blasting residual was aerated for two hours to remove aqueous phase carbon dioxide.

Similar to uranium, at elevated pH values lead forms insoluble metal hydroxide complexes. As with uranium, inorganic carbon removal enhances the conversion of soluble metal carbonate complexes to insoluble metal hydroxide complexes that facilitate lead removal by chemical precipitation. The solution pH was elevated to alkaline conditions (pH=11.5 to 12 S.U.) with sodium hydroxide to facilitate the formation of insoluble uranium and lead hydroxides. Blasting residual was flash mixed (10 minutes), flocculated (30 minutes), and then gravity settled. Subsequent to settling, clarified supernatant was gravity drained to the clarifier holding tank.

The clarified supernatant was pumped from the clarifier holding tank, at 3 to 5 gal/min, through two cartridge filters in series (10 mm and 5 mm pore size, respectively) to remove unsettled particulates, and a 15-gal granular activated carbon (GAC) upflow pressure vessel to remove dissolved PCBs. GAC has a high adsorption affinity for large, non-polar

molecules such as PCBs. Subsequent to U, lead, and PCB removal, the solution was pH adjusted from 11.5 to 6.3-6.8 S.U. using 70% nitric acid. 99Tc removal from neutralized (6.3 to 6.8 S.U.) water was accomplished using ion exchange. In waters in contact with the atmosphere, 99Tc is expected to exist in a +7 oxidation state as the highly soluble pertechnetate anion (TcO_4^-) (4,5). Ion exchange replaces the presaturant ion (typically OH^- or Cl^-) with TcO_4^- on the resin surface. Bostick and coworkers reported successful 99Tc removal using both strong base and cross-linked polyvinylpyridine (PVP) resins (5).

Two commercially available ion exchange resins (DOWEX 21KXLT and Reillex HP) were evaluated for 99Tc removal. A 2 in. diameter, 26 in. deep bed of each resin was utilized. During testing, 50 gal of pretreated blasting residual solution were processed through each column. Liquid residual flow rates were maintained at 1 L/min. Column effluents were sampled at 30-min intervals. Samples were analyzed for technetium and total dissolved solids.

TESTING RESULTS

Surface Decontamination

Table I presents pre- and post- blasting results for mean alpha and mean beta levels on concrete and metal surfaces. Initial contamination levels on the surfaces ranged from 5,000 to 75,000 dpm beta/gamma and 1 to 400 dpm alpha. Removal averaged between 95% and 100% beta/gamma and non-quantifiable to 100% alpha, for surfaces tested using selected blasting parameters. The non-quantifiable percent removals for alpha resulted from initial readings which approached background levels. In each test, the post blast alpha readings were below the release limit of 5000 dpm.

Waste Volume Reduction

The waste volume reduction system demonstrated effective removal of uranium, and heavy metals through chemical precipitation. Table I includes pre- and post- wastewater treatment analytical results of blasting residuals. The system effectively removed >97% of uranium and >99% of lead and PCBs. Ion exchange column testing results demonstrated technetium removal to below the 100 pCi/L treatment objective for both resins. The most effective resin ran for 160 minutes at a flow rate of 1 L/min before exhibiting effluent concentrations that exceeded the treatment objective of 100 pCi/L. Although this resin capacity for technetium removal in a high dissolved solids matrix may be less than its capacity in other less competitive applications, results indicate that it is technically feasible.

CONCLUSIONS

Soda blasting removes fixed radioactive and hazardous surface contamination, while leaving the surface intact. Blasting residuals are dissolved and effectively treated using physical/chemical processes. This system produced treated water meeting stringent water quality criteria and residual solid waste requiring off-site management.

Testing results demonstrated that this soda blasting/waste residuals treatment system provided a 70% reduction in waste volume as compared to blasting without treatment. The system is capable of removing greater than 95% of radioactive contamination, achieving DOE's unrestricted use release limits; U, 99Tc, lead, and PCBs were below DOE and USEPA treatment objectives after blasting residuals treatment. Testing results also suggest that this system is more economical than surface decontamination techniques that are commercially available. Estimated full-scale system capital and operating costs (including waste disposal)

are approximately $7.00 to $ 8.00/ft2 of surface area for 230,000 ft2 of concrete surface area (6). Unit costs may be less for metal surfaces due to lower solids generation rates.

ABSTRACT

The Los Alamos National Laboratory (LANL) Decommissioning Project has decontaminated, demolished, and decommissioned a process exhaust system, two filter plenum buildings, and a firescreen plenum structure at Technical Area 21 (TA-21). The project began in August 1995 and was completed in January 1996. These high-efficiency particulate air (HEPA) filter plenums and associated ventilation ductwork provided process exhaust to fume hoods and glove boxes in TA-21 Buildings 2 through 5 when these buildings were active plutonium and uranium processing and research facilities. This paper summarizes the history of TA-21 plutonium and uranium processing and research activities and provides a detailed discussion of integrated work process controls, characterize-as-you-go methodology, unique engineering controls, decontamination techniques, demolition methodology, waste minimization, and volume reduction. Also presented in detail are the challenges facing the LANL Decommissioning Project to safely and economically decontaminate and demolish surplus facilities and the unique solutions to tough problems. This paper also shows the effectiveness of the integrated work package concept to control work through all phases.

Keywords: plutonium, work package, health and safety, characterization, filter plenum, engineering controls, decontamination, demolition, transuranic waste, waste minimization, and volume reduction.

INTRODUCTION

Many of the challenges of the TA-21 Filter Building Decommissioning Project are not unique to LANL, and their solutions can be applied to other decommissioning projects and programs elsewhere. The TA-21 Filter Building Decommissioning Project presented safety, personnel exposure, and contamination control challenges that required extra care to ensure that rigorous radiation protection practices were followed by project personnel. The project goals were as follows: 1) the removal of as much plutonium holdup as possible through decontamination and component removal to downgrade from a Category 3 Nuclear Facility rating to a Radiological Facility rating; 2) the removal of all process exhaust systems including 1500 linear ft of ductwork, glove boxes, and hoods from Buildings 3 and 4 North to the firescreen; 3) the decontamination and demolition of the firescreen; 4) the decontamination and removal of the filter plenum and glove boxes from the Rotary Filter Plenum Building (Building 146); 5) the removal and disposal of the HEPA filter bank from the Main Filter House (Building 324); 6) the demolition of the stack; 7) the free release of all remaining building walls, ceilings, and cement slab foundations; and finally 8) classification of most of the radioactively contaminated demolition debris as low-level radioactive waste (LLRW) rather than transuranic waste through decontamination. Because of the existing 239Pu holdup (approximately 1 mCi/ft) the process exhaust system, which includes the firescreen and filter plenums, was regarded as a Category 3 Nuclear Facility. Paramount to the success of the project, the downgrading from the Category 3 Nuclear Facility rating to a Radiological Facility rating was needed at the beginning of the project. This downgrading was accomplished through the initial elimination of 75 to 80 percent of the plutonium holdup through decontamination and component removal (firescreens) from the Firescreen Building (Building 329) and the decontamination of the main filter plenum in Building 146. The decontamination objective was to reduce the plutonium source term below a certain level and not to free release the structures. The subsequent downgrading from a Category 3 Nuclear Facility to a Radiological Facility eliminated much of the initial engineering work (that is, Engineering Analysis, Title I and II Engineering Project Plans) required for a Category 3 Nuclear Facility.

Decontamination methodology is discussed in detail including decontamination equipment, decontamination techniques, decontamination effectiveness, solid and liquid radioactive waste generation, waste minimization techniques, and waste volume reduction.

History of TA-21

DP West began operations in September 1945. Its main purpose was to provide the capability to produce metal and alloys of plutonium from the nitrate solution feedstock provided by other production facilities. This process involved several acid dissolution and chemical precipitation steps to separate the plutonium and other valuable actinides from the feedstocks. A major research objective at DP West was the development of new purification techniques that would increase the efficiency of the separation processes. These separation techniques used a wide range of chemicals from the periodic table. In conjunction with improving purification techniques in the main process lines, research was conducted

into reprocessing the waste produced to further enhance recovery. In addition, other operations, such as nuclear fuel reprocessing, were performed occasionally at DP West. Activities unrelated to plutonium processing also occurred at DP West (Fig. 1).

Fig. 1

The main plutonium purification processes were contained in Buildings 2, 3, 4, and 5 and later in Building 150. Uranium and plutonium metal produced in these buildings was secured and stored in Building 21, the old vault. Research into methods of recovering additional plutonium from waste streams was conducted in Building 33. Additional research on the properties and uses of plutonium was conducted at Building 210, the plutonium research building.

In 1977 a transfer of work to the new plutonium facility at TA-55 began, and much of the DP West complex was vacated. At the time, cleanup of the old process lines was initiated. This cleanup included removing contaminated equipment and material from Buildings 2, 5, and 150 and from parts of Buildings 3 and 4. The buildings were then remodeled for use by other groups at LANL.

Filter Buildings

The filter buildings provided process exhaust to Buildings 2, 3, 4, 5, and 21 at TA-21. The process exhaust filter system consisted of the following: the Firescreen Building (Building 329); the Rotary Filter Plenum Building (Building 146); the Main Filter House (Building 324), and the Main Stack.

Ductwork exited Buildings 3 and 4 North and ran along elevated stanchions until it reached the firescreen. The exhaust stream entered this structure, which was an elevated, sheet metal enclosed building containing screen filters and washdown equipment. A transparent glass line exited the sheet metal enclosure and discharged into a liquid waste transfer line, which ran to the on-site liquid waste treatment plant. The exhaust then entered Building 146, a concrete block building that housed a large, circular HEPA filter array and a glove box assembly for changing out the filters (Fig. 2). The HEPA filter array consisted of an octagonal filter bank containing eight sets of three filters housed in a drum. The drum assembly rotated so that new filter faces could be presented to the airstream, thus reducing by a factor of eight the downtime needed for change out. The exhaust stream then entered Building 324, the filter house, which was added to the flow path in 1973. It contained 20 HEPA filters in parallel. Exhaust was then released through the stack at the north end of the building.

Fig. 2

Decommissioning of the filter buildings involved the removal of hoods, glove boxes, and interior process exhaust ductwork from Buildings 3 and 4 North; the elevated ductwork that ran into Building 146; the HEPA filters and glove box and drum assemblies in Building 146; the firescreen, all ductwork, and the stack in Building 146; the HEPA filters in Building 324; and all ductwork and the stack in Building 324. Both buildings were then demolished.

LANL was responsible for overall project management, health physics, environmental compliance, criticality engineering, and waste management. Subcontractor oversight in the areas of engineering and health and safety also were performed by LANL. Dismantlement and demolition activities were performed by the on-site maintenance subcontractor, Johnson Controls

World Services, Inc., who also provided industrial hygiene services and was instrumental in developing work packages.

INTEGRATED WORK PROCESS CONTROLS

A key element to the success of the project was the application of the integrated work process control called the work package. Work packages typically included a specific task work procedure, a Task Hazard Analysis (THA), a Radiological Work Permit (RWP), and an ALARA Job Review, if required.

A THA was developed for each specific task and was an assessment of all nonradiological workplace hazards. The THA along with the RWP was the basis for developing work procedures and documenting the need for special permits and controls. The THA was signed by each employee who worked on the task, including supervisory personnel, and generally included the following:

- general information including historical sampling data related to the task;
- task description including procedures required to minimize hazards;
- descriptions of specific hazards;
- hazard control measures including personal protective equipment (PPE), permits, and training;
- any special decontamination procedures not covered by the RWP (for example, chemical decontamination); and
- spill prevention, containment, and response and/or accident mitigation.

As part of the work package, all decommissioning work that had a potential for personnel internal or external radiation exposure and/or contamination spread required an RWP. The RWP placed controls on personnel entry into controlled and radiological areas. The RWP identified the specific work activity, evaluated potential radiological exposure conditions, and established appropriate levels of radiological control technician job coverage, monitoring instructions, action levels and hold points, PPE, radiological controls for demolition, and dosimetry assignment for entry.

Work packages were typically developed within days of the actual work by the site superintendent, construction supervisor, lead radiological control technician, and other key health and safety personnel. This process provided project personnel a usable work plan, which included a detailed task procedure, a work evolution hazard assessment, personnel protection based on the hazard assessment (confined space permits, burning/welding permits, engineering controls, respiratory protection, PPE, and dosimetry), and all contamination controls. One key benefit from this approach is that the work package was developed in real time. Therefore, recent and pertinent survey data, lessons learned, and personnel experience obtained from preceding job evolutions were continuously incorporated into new work packages.

CHARACTERIZE-AS-YOU-GO METHODOLOGY

Characterization of the entire facility was not conducted. Instead, LANL uses a characterize-as-you-go methodology for decommissioning projects. Rather than extensively characterizing the entire project, enough data are collected early in the project through surveys, historical documentation search, and interviews conducted with individuals who have historical knowledge of the site. Types of important information include the specific processes conducted at the site, chemicals and radionuclides used in the various processes, and locations of any spills and releases. Detailed work procedures are developed as the work progresses, and

additional information is collected as necessary. This process avoids efforts that can be rendered useless by newly discovered problems, but it requires flexibility in scheduling and completing activities. This section discusses the application of this approach to the filter buildings.

Important to the characterize-as-you-go methodology is the detailed project characterization directory developed and revised as the project progresses. The characterization directory is a living document that includes digital photographs of key areas, rooms and system components to be decontaminated and/or decommissioned, diagrams, any historical information on the key system or component, survey data points, and any other pertinent information. This directory is updated continuously as information is made available. Key uses of the directory are to write the work packages, conduct prejob briefings, and orient new project personnel.

Engineering data requirements consisted of utility and structural information. Specifically, the locations of all utilities and any necessary reroutes must be identified. Structurally, the characterization effort had to ascertain whether the Building 146 drum assembly would rotate. The drum had not been turned since the 1970s, and seal integrity and the opposite filter banks were items of concern. Existing drawings were collected for reference and were annotated to identify the as-left facility condition. Historical records were reviewed to identify any abandoned utilities and any facility modifications that could affect decommissioning.

Knowledge regarding types and quantities of contaminants is essential for decommissioning operations and waste handling. Radioactive waste may be either low-level or transuranic, whereas chemical contamination may result in hazardous or mixed waste. Potential contaminants were identified from the remedial action work plan, operating summaries, decommissioning summaries, and historical interviews. Radionuclides of concern were 235U, 238U, 238Pu, 239Pu, 99Tc, 241Am, 243Am, 237Np, 232Th, and 231Pa. Chemical concerns included asbestos (146 HEPA filters), metals (146 HEPA filters), polychlorinated biphenyls (PCBs) (lighting ballasts), perchlorates (ductwork, 146 filters), and picric acid.

Because the data address waste management and safety concerns, exact readings were not as important as bounding readings. The data should identify thresholds for waste categories or PPE requirements.

ENGINEERING CONTROLS

Unique engineering controls developed for the project were modifications to the process exhaust system and the compartmentalized support tent with its attached "body glove" glove bag. Other engineering controls used during the project included standard glove bags, HEPA filtration methodology (both portable HEPA filtration units and the reliance on the existing process exhaust system), and strippable coatings.

Before beginning any major decommissioning activities, modifications to the process exhaust were necessary primarily because of considerable system negative pressure. Before any modifications, the system negative pressure was approximately 3 in. of water, too much to allow its use during decommissioning. Dampening was possible by cutting a 36-in. hole in the process exhaust downstream from the two stages of system HEPA filters directly below where it entered the stack. A cylindrical 38-in. long by 36-in. diameter sheet metal piece was then welded to the hole with a circular plate attached to provide the dampening (Fig. 3). System

negative pressure was adjustable from 0.2 to 3 in. of water with this modification. The negative pressure was adjusted to suit the task being performed.

Fig. 3

Because of significant plutonium holdup in the entire process exhaust system, the reliance on engineering controls to reduce this hazard was a LANL Health Physics group requirement. Data made available during the initial characterization of the firescreen, verified through surveys and air sampling, indicated the average surface plutonium contamination at >4.0E+06 dpm/100 cm2 removable and airborne contamination levels up to 1500 derived air concentration (DAC) -hours. One significant engineering control developed specifically for the project and used with great success was the body glove. The body glove with its attached support tent (Fig. 4) provided maximum contamination control and worker protection. The support tent was compartmentalized for maximum contamination control in the event of a body glove failure. All negative ventilation was provided by the existing process exhaust with portable HEPA units attached to the support tent as backups. The body glove is essentially a glove bag that personnel enter to perform work; whereas, a normal glove bag surrounds a highly contaminated item within the bag, and personnel work from the outside. Before erecting the body glove, all necessary tools and equipment for a particular task were introduced into the firescreen. Then the body glove was inserted directly into the firescreen, unfolded, and supported by a rigid metal internal frame. Work was performed inside the bag using a series of gloves positioned on the sides and top of the body glove.

In highly contaminated areas, such as the firescreen and main filter plenum, the body glove isolated workers from both seriously high surface and airborne contamination (Fig. 4). Airborne contamination levels were reduced from the initial 1500 DAC-hours to <1 DAC-hour, which allowed most work to be performed using supplied-air respirators that were required in the event of a body glove failure.

Standard glove bags were used throughout the project. All demolition and size reduction of overhead process exhaust ductwork was done using glove bags, a skill developed during the demolition of Buildings 3 and 4 South. When the interior process exhaust system was removed, Buildings 3 and 4 North were active facilities, and extensive use of glove bags prevented release of radioactive contamination and avoided costly cleanup efforts.

Fig. 4

DECONTAMINATION AND DEMOLITION METHODOLOGY

The objective of the TA-21 Filter Building Decommissioning Project was to reduce the plutonium contamination on surfaces below transuranic levels. If possible, metal surfaces were to be decontaminated further to meet Science and Ecology Group (SEG) waste classification guidelines to enable the metal to be recycled at their facility in Oak Ridge, Tennessee. SEG is a large recycler for radioactive-contaminated metal that deals mainly with the commercial sector. It has been used by LANL for less than one year. It was possible to recycle all plenum walls and ceilings, but floor surfaces were sent to LANL's LLRW landfill at TA-54. Project surface contamination acceptance criteria for LLRW and transuranic waste and SEG waste acceptance criteria are found in Table I. Ninety percent of all radioactive waste for the project was characterized as LLRW. Twenty percent of this material was shipped to SEG. Equipment was either decontaminated in situ or brought to the project decontamination area, an

old hot cell in Building 4 North. Sheet plastic was fastened to the floor, walls, and ceiling with duct tape, and two 1800 cfm HEPA-filtered negative air units were added to mitigate large amounts of surface and airborne plutonium contamination. All decontamination and size reduction of material was performed in glove bags and under negative pressure. Airborne contamination levels reached approximately 2000 DAC-hours during a certain decontamination operation that resulted from a glove bag failure. Typical airborne radionuclide concentrations inside the hot cell ranged from 3 to 50 DAC-hrs. All work was performed in air purified respirators.

Table I

The project relied on the following five proven methods of decontamination: vacuuming, wiping, scrubbing, using strippable coatings, and shot blasting. Vacuuming, wiping, scrubbing, and strippable coatings were primarily used to decontaminate the firescreen plenum, the main filter plenum, glove boxes, and ductwork. Shot blasting was used to decontaminate concrete surfaces especially the concrete slab in Building 146. Vacuuming, wiping, and scrubbing were used to remove radioactive dust and particles from plenum surfaces. Vacuuming was performed using HEPA-filtered vacuum cleaners. Surfaces were then wiped/scrubbed with a damp rag and an industrial all-purpose cleaner. Rags were discarded as radioactive waste.

After surfaces were vacuumed and wiped down, strippable coatings were applied. Decontamination factors ranged from 10 to 100 depending on the presence of grease or oily residue on surfaces. The use of strippable coatings involves the application of a polymer mixture, either by a paint roller or airless sprayer, to a contaminated surface. Both application methods were used in this project. As the polymer hardens, the contaminants are entrained into the material. The coating is then pealed off, containerized, and disposed of. This technique is best suited for floors, walls, and ceilings because of their easy accessibility. Strippable coatings were also used with limited success on internal glove box and ductwork surfaces.

Shot blasting was used on the concrete slab on Buildings 146 and 324 after all equipment was removed from the buildings and the ceilings and walls were removed. Most of both building structures were free released and sent to a local sanitary landfill for disposal. Shot blasting is an airless method that strips, cleans, and etches the surface simultaneously. The technique is virtually dust free; therefore, shot blasting of the concrete slabs was conducted without using respirators. Portable shot blasting units move along the surface as the abrasive is fed into the center of a completely enclosed centrifugal blast wheel. As the wheel spins, the abrasives are hurled from the blades, blasting the surface. The abrasive and removed debris are bounced back to a separation system that recycles the abrasives and sends the contaminates to a dust collector.

Demolition methodologies followed current, accepted industry practices. The general decommissioning sequence consisted of 1) HEPA filter removal from the main rotary plenum and from Building 324, 2) main filter plenum removal from Building 146, 3) hood and glove box removal, 4) exhaust system removal, 5) utility piping removal, 6) final system disconnects (that is, electrical and fire protection), and 7) a final status survey of both buildings to determine their suitability for free release. After additional spot decontamination of masonry block wall surfaces, the

buildings were demolished using a trackhoe. Finally, both buildings'concrete slabs were decontaminated by shot blast, surveyed for free release, and then removed using a trackhoe.

WASTE MINIMIZATION AND VOLUME REDUCTION

LANL and Department of Energy policy precludes the free release of any material with detectable activity above background levels, even when the surface contamination is below release guidelines. Although some materials have been released to a municipal landfill following demonstration of no detectable activity, waste minimization activities primarily emphasize volume reduction through on-site waste compaction and recycling of contaminated scrap metal. Concrete was cleaned using a shot vacuum system, and the remaining slabs will be crushed and used as on-site fill. Through recycling, steel decontamination, and concrete crushing, LLRW from decommissioning was reduced compared with previous decommissioning projects.

Soil remediation was coordinated with LANL's remedial action project. Sampling and other activities also were coordinated to ensure data applicability and cost effectiveness.

A significant amount of data currently exist for this project.1 This information was obtained during a LANL-wide project to quantify special nuclear material holdup in ventilation systems. These data indicated that sizable portions of the process exhaust would be classified as transuranic waste. Ductwork was decontaminated during decommissioning to minimize the volume of transuranic waste. Accordingly, during decommissioning the removed ductwork and decontamination waste were characterized for waste disposal purposes. This approach also recognizes the difficulty and expense of sampling exhaust systems before removal. Likewise, HEPA filter sampling was best left until actual removal, at which time the filters were cored and samples were obtained more easily. Additional data were collected to measure radioactivity in systems not addressed during previous holdup measurement campaigns. Measurements were made using nondestructive assay methods with sodium iodide and germanium detectors. Items likely to be free of contamination were surveyed to verify that no unexpected radioactivity was present. Appropriate engineering controls were used during decommissioning to protect uncontaminated materials.

Except for one small spot of contamination on the floor of Building 146, no historical releases occurred within either Building 146 or 324. The walls and floors were surveyed before demolition and were decontaminated if contamination above detectable limits was indicated. The long-range alpha detector, an experimental system developed at LANL,2 and conventional gas-proportional instruments were used to systematically survey the structures to verify that the material was uncontaminated.

Facility processes did not involve hazardous wastes listed under RCRA. The RCRA facility investigation work plan identified metals as a potential contaminant of concern, so the Building 146 filters were sampled for metals. Sampling for metals, like the surveys for radioactive constituents mentioned above, were performed when the filter was removed. Building 146 was sampled for perchlorates. This sampling was repeated after the drum had been turned. Historical records suggested that picric acid was used for some experiments. Building 146 was tested for picric acid before and after turning the drum, and the result was negative. During disassembly, duct systems were routinely tested for perchlorates and were all found to be negative.

The HEPA filters contained asbestos, and the roofs of both buildings were thought to contain nonfriable asbestos-contaminated material. All roofing material was tested for asbestos. Lighting systems were inspected for PCBs during disassembly, and fluorescent bulbs were handled as hazardous waste.

LESSONS LEARNED

An important lesson learned is that the observational approach is very effective from both cost and schedule perspectives. By minimizing characterization activities, initial expenses and time to completion are reduced. Moreover, involving the people who will be doing the physical work during the planning stage simplifies the techniques used and guarantees the feasibility of the chosen techniques. Perchlorate and other unusual chemical contaminants (such as picrates) may be hazards in old chemical processing facilities and should be sampled for.

Finally, an extremely important lesson learned is that a small, autonomous project team, capable of internal decision-making, is essential for staying on track. The customer must be part of the team.

ACKNOWLEDGMENTS

This work is funded by the U.S. Department of Energy and is being carried out under the LANL Environmental Restoration Project.

DEVELOPMENT OF A MODEL DECOMMISSIONING/INTERIM MEASURES PLAN FOR AN INDUSTRIAL FACILITY: A CASE STUDY

Shannon Farrar Dechert
B. Marie Moore
Richard A. Moore

Erwin, Tennessee 37650

ABSTRACT

Many industrial facilities are faced with remediation of contaminated environmental media. For these facilities, workplans may be required by more than one regulatory agency prior to beginning clean-up activities. For sites regulated by multiple agencies, the development of multiple documents to satisfy all regulatory authorities may be a lengthy, expensive, and difficult process.

A nuclear materials fabrication facility located in East Tennessee is regulated by, among other agencies, the Environmental Protection Agency (EPA), the Nuclear Regulatory Commission (NRC), the State of Tennessee Division of Solid Waste Management (DSWM), and the State of Tennessee Division of Radiological Health (DRH). As presented in this case study, a single remediation plan was developed to satisfy the requirements of each regulatory agency. An overview of the development of the multi-purpose

remediation plan, a discussion of the benefits and limitations of the multi-purpose approach, and applicability of the multi-purpose approach to other industrial facilities is presented.

INTRODUCTION

As required by the Nuclear Regulatory Commission (NRC), Nuclear Fuel Services, Inc. (NFS), a nuclear materials fabrication facility located in East Tennessee, is currently conducting decommissioning activities. These activities are also regulated by the Environmental Protection Agency (EPA) and the State of Tennessee. Traditionally, prior to performing remediation activities, a facility would be challenged with the development of multiple remediation workplans to satisfy requirements of all respective regulatory authorities. This case-study describes an alternative approach in which NFS successfully developed a single, multi-purpose environmental remediation plan which encompassed the requirements of the EPA, the NRC, and the State of Tennessee.

Background

NFS, which began its Tennessee operations in 1957, processes radioactive materials under a License from the NRC. The company's first contracts were to manufacture a variety of nuclear materials including uranium and thorium metals and various compounds and alloys of these materials. Prior to 1966, land disposal of low-level radioactive and solid waste materials occurred in a section of the NFS property. Land disposal of these materials was an accepted disposal method at that time. The disposed material was ultimately covered, and the area became commonly referred to as "Pond 4." In 1990, Pond 4 was identified as a Solid Waste Management Unit (SWMU) by the EPA. Prior to NFS remediating Pond 4, EPA, NRC, and State of Tennessee regulatory authorities requested a remediation plan for the area. Regulatory review and approval of the Pond 4 remediation plan was requested by the agencies before NFS began remediation activities.

REMEDIATION PLAN DEVELOPMENT REQUIREMENTS

Facilities operating under State and EPA permits and State and/or NRC licenses may need the approval of each agency prior to remediating contamination attributable to solid and/or hazardous waste and radiological materials. Decommissioning for NRC regulated activities must be performed in accordance with an approved decommissioning plan. Similarly, environmental remediation activities that are (1) required by EPA due to the presence of contamination determined to be potentially dangerous to public health and/or the environment; or, (2) initiated by the permitted facility, may be performed in accordance with an approved interim measures plan.

NRC requirements for the development of decommissioning plans are included in Title 10 of the Code of Federal Regulations (CFR) and in an NRC draft regulatory guide. The CFR regulations applicable to NFS are located in Parts 30, 40 and 70. These parts are entitled "Rules of General Applicability to Domestic Licensing of Byproduct Material," "Domestic Licensing of Source Material," and "Domestic Licensing of Special Nuclear Material," respectively (1).

The applicable regulations contained in 10 CFR addressing facility decommissioning and the development of a decommissioning plan are summarized in a regulatory guide developed by the NRC entitled "Standard Format and Content of Decommissioning Plans for Licensees under 10 CFR Parts 30, 40, and 70" (2). This document provides a suggested format and describes the suggested content of a decommissioning plan. Specific

requirements for each section of a decommissioning plan are identified in the regulatory guide and are as follows: 1) general information; 2) description of decommissioning activities; 3) description of methods used for protection of occupational and public health and safety; 4) final radiation survey; 5) decommissioning funding; and, 6) facility and radioactive material security and safeguards.

EPA requirements for the development of an interim measures plan are contained in Title 40 of the CFR and in an EPA developed guidance document. The applicable CFR Regulations are located in Part 264, which is entitled "Standards for Owners and Operators of Hazardous Waste Treatment, Storage, and Disposal Facilities" (3). Subpart F of 40 CFR, Part 264, which is entitled "Releases from Solid Waste Management Units," contains information related to interim measures requirements.

The regulations contained in 40 CFR relative to facility interim measures and the development of an interim measures plan are included in an EPA guidance document entitled "RCRA Corrective Action Interim Measures Guidance" (4). A facilities' HSWA permit also contains requirements for development of the interim measures plan. Although the EPA guidance document (4) and the NFS HSWA permit include information relative to the required content of an interim measures plan, information relative to a suggested format is not provided.

A third EPA document, entitled "EPA Handbook: Stabilization Technologies for RCRA Corrective Actions," (5) was recommended by the EPA as a reference related to interim measures. This document does not contain requirements for the development of an interim measures plan. It does, however, contain information relative to interim measures technologies recognized by the agency.

REMEDIATION PLAN DEVELOPMENT STRATEGY

The NFS strategy for development of the remediation workplan for Pond 4 consisted of eight main steps as depicted in Fig. 1. These steps were 1) identification of regulatory requirements; 2) preliminary outline development; 3) presentation to regulatory officials; 4) outline revision; 5) assembly of multidisciplinary project team; 6) remediation plan development; 7) plan review/revision; and, 8) regulatory approval.

A primary objective of the NFS strategy was to optimize communication with regulatory officials both in the initial planning stages and throughout plan development. Regulatory contacts were initially briefed regarding the potential for the development of a single remediation workplan. At this point, the State officials indicated agreement with the NFS approach and advised following federal EPA/NRC remediation plan development requirements. EPA and NRC officials agreed with the preliminary approach presented by NFS.

Once development of the decommissioning/interim measures outline was completed by NFS, formal meetings were conducted individually with EPA and NRC contacts. The outline was approved by the NRC without revision and minor revision was requested by the EPA. The completed preliminary outline for the Pond 4 Decommissioning/Interim Measures Plan is presented as Fig. 2.

A secondary objective of the NFS strategy was to utilize a multidisciplinary project team approach. The multidisciplinary approach was selected by NFS management due to the technical nature of the subject material required for development of the Decommissioning/ Interim Measures Plan. The project team assembled by NFS consisted of a Hydrogeologist, a Health Physicist, a Waste Management Specialist, an

Engineer, and an Environmental Scientist. The Environmental Scientist was assigned responsibility for coordinating the team and development of the plan. A project schedule was developed, using Timeline project management software (Fig. 3), which allowed for 60 working days (i.e., approximately three months) to develop the Decommissioning/Interim Measures Plan for submittal to the EPA, the NRC, and the State of Tennessee.

Fig. 1

Fig. 2

Fig. 3

Once the initial draft of the document was completed, the review process began. The plan was scheduled to receive three "in-house" reviews by NFS: peer review, project management review, and senior management review and approval. These reviews were scheduled to ensure the document was complete, accurate, and of the quality suitable for submittal to the regulatory agencies for review and approval. Document revision was the responsibility of the Environmental Scientist; however, some revisions required the collaborative efforts of the project team. Resolution of some technical issues required meetings between the project team and management personnel. These meetings informed the managers of the technical issues and involved management in the resolutions. Once approved by the senior managers, the document was ready for submittal to regulatory agencies.

Regulatory submittal of the document by NFS was approximately three weeks behind the project schedule due to additional time required for in-house document revision. The document was approved by NFS senior management and was submitted to the NRC, the EPA, and the State of Tennessee for review and approval on December 7, 1993.

The NFS Pond 4 Decommissioning/Interim Measures Plan was jointly approved by the EPA and the State of Tennessee Office of Solid Waste Management on March 22, 1994. Minor comments to the plan were received from the NRC and the State of Tennessee Division of Radiological Health in early May, 1994. The NRC and State comments indicated the remediation strategy and approach proposed by NFS were acceptable; however, minor revision to the plan was required.

Prior to revising the plan, NFS verbally communicated the planned revisions to the NRC and to the State of Tennessee. The plan was subsequently revised by NFS and Revision 1 of the plan was submitted to the EPA, the NRC, and the State of Tennessee on June 16, 1994. The plan revisions primarily consisted of providing clarification of radiological health and safety issues. Approval of the plan by the NRC and the State was received on June 23, 1994.

DISCUSSION

The strategy implemented by NFS for the development of a single Decommissioning/ Interim Measures Plan for Pond 4 was successful as demonstrated by approval of the plan by all respective regulatory agencies, on schedule and within budget. The single document approach facilitated the regulatory review process, lessened the duplication of effort required in the development of two or more separate but similar plans, and was more time and cost efficient. Timely approval of the plan may not have been a reality had NFS not maintained open and frequent communication with the regulatory authorities and if the agencies had each been reviewing different plans.

Development of the plan addressed complex technical issues including engineering, health physics, hydrogeology, waste management, and

environmental science. Utilization of a multidisciplinary project team approach ensured the technical depth and accuracy of the document, thus providing the essential information for regulatory review and approval. Open communication was always maintained between NFS and the regulatory authorities. This communication began in the initial planning stages and continued throughout the completion of the plan. Involving the agencies in the initial planning stages helped to ensure that their approval would be received prior to expending the time and effort required to develop the comprehensive plan. Development of the single plan facilitated the open communication between NFS and the respective agencies as well as streamlined the regulatory review and approval process.

While the multi-purpose approach was successful for NFS, the potential for changes in various agency regulatory requirements during plan development are of concern due to the dynamic nature of the regulatory system. New regulations are constantly being proposed and promulgated by the EPA and the NRC. Changes in regulations within a particular agency, when encountered during the plan development or agency review and approval stages, may delay the approval of the plan, thereby delaying the start-up of remediation work. However, maintaining frequent and open communication with the regulatory authorities may enable the regulated party to be informed of potential changes in regulations before they occur.

Currently, approximately 250 industrial facilities exist, which like NFS, are regulated by the NRC, the EPA, and the State. As demonstrated in this case study, the "multi-purpose" approach utilized by NFS may also be an effective strategy for other facilities planning environmental remediation activities which require approval or concurrence by the EPA, the NRC, and the State. Similarly, it may also be prudent for facilities to apply the multi-purpose strategy to other overlapping EPA/NRC regulated activities; an example would be the development of a single workplan for an EPA RCRA Facility Investigation/NRC Site Characterization.

EQUIPMENT DECONTAMINATION THE BENEFITS OF REUSE AND AVOIDED DISPOSAL USING THE TECHXTRACT PROCESS

Michael W. Bonem
EET, Inc.

4710 Bellaire Boulevard, Suite 300
Bellaire, Texas 77401

ABSTRACT

The need for and benefits of effective and economical decontamination technologies for nuclear facility decommissioning are substantial and without question. Decontamination and decommissioning (D&D) programs in the U.S. Department of Energy (DOE), nuclear utility industry, and international markets are growing rapidly. With this growth, the acceptability and costs of traditional D&D approaches, which rely largely on demolition and disposal, are being increasingly called into question. Disposal in particular is a major complicating factor as disposal costs are rising, and the long-term availability/public acceptability of disposal capacity is a significant uncertainty for the industry.

Thus, the stage is set for innovative technologies which can decontaminate structures and equipment to below regulatory levels, thereby avoiding large-scale bulk disposal. Such technologies must be effective in the removal of a variety of contaminants from different types of materials and substrates. They must also offer total economics (considering process costs, disposal, reuse, future liabilities, and other factors) which are attractive versus demolition and disposal.

The TECHXTRACT process is a chemical technology for the extraction of radionuclides, heavy metals, PCBs, and hazardous organics from solid materials such as concrete and metal. Specifically designed chemical blends are used to penetrate below the surface and remove contaminants which have leached into the substrate. The technology has very high decontamination rates (e.g., 90-99% per cycle). In addition to decontamination performance, economic analysis indicates that TECHXTRACT can save 25-75% of total project cost versus traditional methods. It is a full-scale, commercialized technology which has been used in the DOE complex, electric utility, and private industry. This paper discusses the technology in more detail and offers a case history from a recent full scale decontamination project for a private industry manufacturer.

DESCRIPTION OF THE TECHXTRACT TECHNOLOGY

The TECHXTRACT technology is a patented, sequential chemical extraction process for the removal of radionuclides, PCBs, and other hazardous organic and inorganic substances from solid materials such as concrete, brick, steel, and exotic metals. The technology uses advanced chemical formulations and carefully engineered applications to achieve significant penetration and removal of these contaminants from below the surface of these materials.

The chemistry is based on several hypotheses relating to contaminant migration and removal. The first hypothesis is that contaminants migrate along the grain boundaries and into pores and microscopic voids (Kirkendall effect) of a material, even for seemingly non-porous media. Mobility of the contaminants, time, and secondary forces often drive these contaminants to deeper levels in the substrate. Furthermore, contaminants tend to become chemically or electrostatically bonded to the substrate. In many cases, the time between the contamination event and decontamination efforts will allow the contaminant migration pathways to become partially closed by organic and inorganic impurities.

All of these factors point to the need for a sophisticated chemical system which:

Reopens the pores and capillary pathways to the maximum possible extent (electrocapillary effect),

Penetrates into the pores as deeply as possible,

Breaks the electrostatic and chemical bonds which hold the contaminants in place,

Complexes or sequesters the contaminants to prevent recontamination,

Activates the capillary rise effect (Young and Laplace equation).

The TECHXTRACT chemical formulas are designed to address each of these complex needs, using over 25 components to incorporate dissolution, oxidation, reduction, hydrolysis, decomposition, wetting, complexation, microencapsulation, and flotation chemistry principles. The chemistry further compensates for situations in which the contamination is a mixture of pure elements, oxides, and related compounds with varying solubility indices. The spent chemical solutions, without contaminants, do not contain any TCLP constituents and have been disposed of by incineration, solidification (and land disposal), and discharge to liquid effluent treatment systems.

The technology incorporates a tailored process for applying and removing each of the chemicals in the right sequence and combinations to achieve optimal results. In most projects, three different chemical formulas are used. Chemicals are applied in low volumes, usually as a spray, to minimize consumption and secondary waste volume. After being applied, the chemicals are scrubbed into the contaminated surfaces, left to dwell for a defined time, and rinsed and removed. The application and removal of all three formulas constitutes one complete process cycle, and typically requires one day (24 hours). Sampling and/or surveys can be performed at the end of any cycle, and often shows reductions of 90% or more per cycle.

The TECHXTRACT process has been found to be most applicable in remediation or decontamination projects when one or more of the following conditions apply:

The acceptable level for any residual contaminant is very low (e.g., free release at 5,000 dpm/100 cm2 or lower),

Simple surface cleaning is ineffective,

Disposal is undesirable, either because the volume and resulting disposal and replacement costs are too high, or due to resource recycle or waste minimization objectives,

Significant safety concerns - such as flammability, corrosivity, creation of airborne contaminant particles, fugitive emissions or generation of toxic fumes and/or explosive gases - are raised,

Decontamination is to be performed on surfaces that are not flat and horizontal, such as equipment, walls, ceilings, structural beams, and internal piping,

For radioactively-contaminated metals, the technology is particularly applicable in situations involving equipment which is needed for ongoing operations or for return to a vendor, when there is a high salvage ("as is") value, when the scrap value is much higher if unrestricted release is achieved, or when other factors make metal melting (and restricted use) impracticable or unacceptable. For radioactively-contaminated concrete, it offers the potential to avoid the high costs associated with demolition, repair, replacement, and disposal of large waste volumes.

CASE HISTORY - EQUIPMENT DECONTAMINATION PROJECT

EET and SEG were recently contracted to perform a turnkey radiological decontamination project for a private industry manufacturer. The customer's plant produces filaments for light bulbs. In the past, the raw materials for their process had included small amounts of radioactive

thorium. Routine operations had resulted in widespread contamination, including the major manufacturing equipment, ancillary piping, and the floors and walls of the surrounding rooms.

Due to a change in operations, radioactive materials were no longer being handled at the facility. The facility's objective was to eliminate all radioactive contamination, with minimal impact to ongoing operations. The area of greatest concern were the large production machines which house the treating bottles and which are central to the manufacturing process. These machines had the highest levels of contamination, were critical to ongoing operations, and would be extremely expensive to replace and to dispose of as low level radioactive waste.

The major portion of the decontamination activities were scheduled to be performed during a two-week plant turnaround in the July, 1995. A successful demonstration of the TECHXTRACT technology was performed on-site by EET in May, 1995. This demonstration proved the effectiveness of the technology on typical machinery components. It allowed the plant to include full decontamination in its base line decontamination plans and to avoid ordering replacement equipment, much of which would have required long lead times and custom fabrication.

The production machines and treating bottle racks are complex pieces of equipment. Each treating bottle rack is approximately ten (10) feet long and fifteen (15) feet high and contains four (4) treating bottles. Each treating bottle is approximately eight (8) feet high, with an aluminum base and a double-walled copper bell that fits over the metal bars as they are being treated. This presented a number of difficult to access areas for decontamination.

Radiation levels on the equipment varied greatly. Initial levels as high as 200,000 dpm/100 cm2 (fixed alpha) were observed, with typical levels around 5,000 dpm/100 cm2 (fixed alpha). Elevated levels were also observed on the internal surfaces of the equipment and other components. The plant's decommissioning plan, which had been filed with and accepted by the state, called for radiation levels on equipment to be reduced to less than 500 dpm/100 cm2 of fixed alpha radiation.

During the project, EET personnel performed decontamination of the equipment using the TECHXTRACT process. SEG provided health physics support and project management. SEG also performed decontamination of other areas using traditional techniques. The machines were partially disassembled to allow access to all contaminated surfaces.

Several different decontamination approaches were used during the project. Small components were dipped and scrubbed in a series of TECHXTRACT chemical baths. Other disassembled items which were too large for the baths were cleaned by hand. In some cases, the radioactive matter was trapped in layers of water scale. This was dissolved using one of the chemical blends. The main machine structure was decontaminated in place, with the upper sections reached from scaffolding. Work was done in two, twelve-hour shifts to meet the plant's turnaround schedule.

EET and SEG encountered a number of unexpected conditions during the first few days of the project. Radiation levels were much higher and contamination was much more widespread than expected. There was also a significant amount of radioactive hold-up in the joints between components and other difficult to access areas. This resulted in more cleaning and more surface area for decontamination than expected. The hard water scale was another unique challenge of the project.

Despite these challenges, all of the equipment was decontaminated to the required levels for free release 500 dpm/100 cm2 (fixed alpha) under the plant's decommissioning plan. No components required disposal and replacement, and all of the precision machined parts remained within tolerance after chemical decontamination. The overall decontamination schedule was delayed, due to the circumstances described above, but this portion of the project was completed in approximately six weeks, and the first two machines were returned to the customer within their original time frame. As a result, the plant was able to resume production with minimal impact on its operations due the decontamination project.

CONCLUSION

The results from this project clearly show the ability of the TECHXTRACT technology to perform effective decontamination and extraction of radioactive contaminants. Other private industry and DOE projects have confirmed these capabilities for the decontamination of concrete, metal, equipment, and other items. The effectiveness of the technology lies in its ability to penetrate into the substrate so that contaminants such as radionuclides and PCBs can be solubilized and extracted. This technology offers significant benefits in the reuse of previously contaminated buildings and equipment, waste reduction, and avoided disposal cost. EET continues to perform research to improve the TECHXTRACT process and broaden its applications.

ABSTRACT

A series of site characterization measurements were performed in 1994 in preparation for the decontamination and decommissioning (D&D) of the Old Hydrofracture Facility (OHF) at Oak Ridge National Laboratory. The OHF was one of four sites in Melton Valley used in the development and full-scale application of the hydrofracture process, a unique disposal method that involved injecting radioactive liquid low-level waste mixed with grout and additives into a deep, low-permeability shale formation. The OHF facility did not appear to have been decontaminated before it was

abandoned; most of the equipment and piping used in the cells and control room are still present.

The objective of the site characterization was to determine the nature and extent of radioactive and hazardous materials and other industrial hazards in and around the structures. This information will be used in subsequent planning to develop a detailed approach for dismantling and disposing of the structures: 1) to evaluate and design the most cost-effective D&D approach; 2) to determine the level and type of protection necessary for D&D workers; and 3) to estimate the types and volumes of wastes generated during D&D activities and support decisions on waste disposal. The D&D characterization scope included the entire OHF structure, including the foundation and equipment or materials within the structure. To estimate potential worker exposure from the soil during D&D, the characterization scope also included the soils underneath and surrounding the building to a distance of 5 ft from the structure.

This paper will discuss measurement results, data analysis methods used to quantify various types of contaminants, and modeling used to estimate the relative isotopic distribution of the contaminants. Results from different types of measurements along with modeling results will be used to infer the spatial distribution and correlation of the contaminants and radiation fields they generate. The contribution of loose and fixed contaminants to the total general area radiation fields will also be estimated. The measurement methods included gross alpha, beta, and gamma surveys; directional gamma surveys; gamma spectroscopy; concrete coring; photography; and collection of soil and miscellaneous samples.

INTRODUCTION

Portions of the Old Hydrofracture Facility (OHF) at Oak Ridge National Laboratory (ORNL) were characterized in 1994. Characterization activities centered on various aboveground structures at OHF, equipment outside and inside those structures, and the soils immediately surrounding some of those structures.

The site characterization was performed under the ORNL Remedial Investigation/Feasibility Study (RI/FS) Project and made extensive use of the existing programmatic infrastructure. Permanent records of the investigation (including logbooks, photographs, laboratory analytical results, and engineering calculations) are maintained as RI/FS Project records.

Site characterization activities followed the Site Characterization Plan for the Old Hydrofracture Facility at Oak Ridge National Laboratory, Oak Ridge, Tennessee (1).

LOCATION

OHF, also known as HF-3, is approximately 1 mile southwest of the main ORNL complex in Melton Valley, near the intersection of OHF/WAG 5 Road and Intermediate Pond Access (Fig. 1). OHF was one of four sites in Melton Valley used in the development and full-scale application of hydrofracture operations. OHF covers approximately an acre; its boundaries coincide approximately with ORNL grid coordinates N17100, E28500 and N17300, E28700.

Fig. 1

HISTORICAL MISSION

OHF was constructed in 1963 to allow experimentation and operations with an integrated solids storage, handling, mixing, and grout injection facility. The facility was shut down in 1980 and transferred to ORNL's Surveillance and Maintenance Program.

The hydrofracture process was a unique disposal method that involved injecting waste materials mixed with grout and additives under pumping pressures of 2000 psi or greater into a deep, low-permeability shale formation (Fig. 2). The injected slurry spread along fractures and bedding planes for hundreds of feet from the injection points, forming thin grout sheets (often less than 1/8 in. thick). The grout ostensibly solidified and immobilized the liquid wastes.

Fig. 2

The facility was used for 7 experimental injection campaigns in 1964 and 1965 and 18 operational campaigns from 1966 to 1979. The experimental campaigns injected grout plus radioactive tracers; the operational campaigns injected group plus approximately 969,000 gal of liquid low-level waste (LLLW). The experimental injections were at an average depth of 945 ft; operational injections were at an average depth of 792 ft (2).

OBJECTIVES AND SCOPE

The objective of the field investigation was to provide information necessary for

- engineering evaluation and planning of decontamination and decommissioning (D&D) approaches,
- planning for protection of D&D workers, and
- estimating waste volumes from D&D activities.

The site characterization focused principally on OHF components for which the ORNL D&D Program is responsible: Building 7852, the four bulk solids bins, water tank T-5, pump P-3, and the pump house (excluding the valve pit, which is under the control of ORNL Waste Operations) (Fig. 3). For the purpose of characterization only, this report also addresses two items assigned to the ORNL Remedial Action Program:

- the injection wellhead in Building 7852, and
- the soil underneath and surrounding the D&D structures (e.g., Building 7852 and the pump house) within 5 ft.

Fig. 3

Characterization consisted primarily of inspections, radiological measurements, and radiological and chemical sampling and analysis. Inspections determine general facility conditions, as-built information, and specialized information (such as structural evaluations). Radiological sampling and measurements define the quantity and distribution of radioactive contaminants; this information is used to calibrate a dose model of the facility and estimate the total activity, in curies, of each major radioactive isotope. The radiological information from sample analyses is used to refine the radiological model of the facility, and the radionuclide and hazardous chemical analyses are used for waste management planning. This paper presents data from the field investigation and laboratory analyses in the form of summary tables of radiological and chemical contaminant concentrations, and a waste volume estimate.

Field investigations of ancillary aboveground external piping with 5 ft of the D&D structures was limited to visual identification and cross-referencing to existing drawings; no excavation was performed to locate or characterize underground piping or drains or investigate underground tanks and piping.

POTENTIAL CONTAMINANTS IN INJECTED WASTE

Huang et al. (3) estimated that the average concentration of radionuclides in the grout mixture prior to injection was approximately

0.26 mCi/mL or less for beta/gamma emitting radionuclides and 10 nCi/g or less for transuranic (TRU) alpha emitting radionuclides.

The radioactive tracers injected with the grout during the experimental campaigns was gold-198 (30 Ci), cerium-144 (4100 Ci), cesium-137 (5200 Ci), ruthenium-106 (40 Ci), strontium-90 (1400 Ci), and cobalt-60 (20 Ci) (4). The LLLW injected during the operational period contained approximately 604,000 Ci of cesium-137, 38,600 Ci of strontium-90, 233 Ci of Curium-244, and 5.8 Ci of TRU other than curium (5). Thus, the two principal contaminants of concern are cesium-137 and strontium-90.

Additional information on potential contaminants can be obtained by referring to analytical results of the contents of waste tanks T-1, T-2, T-3, T-4, and T-9, which were sampled during 1988 (6,7). The tanks were used to store LLLW until it was ready to be blended with grout, and they still contain significant quantities of liquid and sludge waste. In addition to cesium-137 and strontium-90, other beta/gamma emitters found in the tank contents were cobalt-60, europium-152/154/155, carbon-14, and tritium. Alpha emitters included uranium-233, plutonium-238/239, curium-244, americium-241, thorium-232/238, and californium-252.

Based on analysis of the water and sediment in the OHF impoundment and waste pit T-4 as reported by Huang et al. (3), beta/gamma emitters included cesium-137, strontium-90, cobalt-60, europium-154, and cesium-134; alpha emitters included curium-244, plutonium-238/239, americium-241, and uranium-235/238.

An overview of the potential Resource Conservation and Recovery Act (RCRA) status of the OHF tank contents is provided by Autrey et al. (6). None of the waste tanks contained a RCRA ignitable waste or were classified as RCRA corrosive. The pH of the tank liquids was basic (pH of 8.8 and higher). Toxicity characteristic leaching procedure (TCLP) tests were not performed, but Autrey et al. indicate that potential inorganics of concern include chromium, lead, and mercury based on elevated total concentrations, particularly in the sludges. In general, the tank contents contained little organic matter. However, volatile organic compounds of concern (TCLP constituents detected in tank samples) consisted primarily of solvents; RCRA-listed semivolatile organic constituents consisted primarily of various phthalates and ploynuclear aromatic hydrocarbons.

De Laguna et al. (8) indicate that the approximate chemical content of the waste solution (prior to mixing with solids) included NaOH [0.05 molar solution (M)], NaNO3(0.8M), NH4)2SO4(0.15 M), Al2(SO4)3(0.05 M), NaCl(0.05 M) and NaCO3(0.05 M).

CHARACTERIZATION APPROACH

Inspections

Activities included photography, measurement of as-built dimensions, inspection by a structural engineer, and inspection by an industrial hygiene specialist for lead paint and asbestos. Extensive photography was performed to document the current condition of the facilities and to help plan D&D activities. The photographs will be particularly valuable because different contractors will do different phases of the work, and new D&D participants will be able to quickly familiarize themselves with the buildings with minimal personnel radiation exposures. Measurements of as-built dimensions was necessary in this case because no as-built drawings were available and modifications had been made to the structures during their operating lives; such measurements might not have been necessary in a well-documented facility. Inspections by specialists such

as a structural engineer and an industrial hygienist add insight to the conditions and hazards that may be present and help to plan for these conditions.

Radiological Measurements

Field measurements of the radiological conditions in these D&D buildings are of primary importance; measurements can be conveniently divided into "general area" and "location-specific." General area measurements included exposure rate surveys, directional gamma measurements, and gamma spectroscopy. The exposure rate surveys provide the general area exposure rates needed for ALARA planning and D&D task sequencing. Directional gamma measurements provide radiation profiles for modeling radiological sources within the buildings. Gamma spectroscopy provides isotopic information for radiological modeling and waste management planning. All of these general area measurements are amenable to both direct surveys and remote measurements where human access is impractical or not ALARA.

Location-specific measurements (field counts and smears to quantify loose contamination) were done on potentially contaminated structural surfaces within the buildings. A protocol was developed to help ensure quantitative results under field conditions. First, calibrated field instruments were source- and background-checked before each day's use. Second, at each selected location the measurements were as follows:

Using a 10 cm x 10 cm square template, the location was outlined and numbered.

Using a 0.68-cm standoff spacer, an alpha measurement consisting of three integrated counts was conducted.

Using a 10-cm standoff spacer, a beta/gamma (open window) measurement consisting of three integrated counts was conducted.

Using a 10-cm standoff spacer, a gamma (closed window) measurement consisting of three integrated counts was conducted.

A smear sample was collected inside the 10 cm x 10 cm outline.

The location was photographed.

Third, the field instruments were source- and background-checked at the end of each day's use. Primary instruments for these measurements were the Eberline HP-270 beta/gamma detector and the Eberline AC-3 alpha detector, both with the Eberline EPS-2 counter. The smear samples collected were to be analyzed for gross beta/gamma, gross alpha, and gamma isotopes (spectroscopy); strontium-90 analysis was to be conducted if gross beta levels were high and could not be accounted for by gamma spectroscopy results.

Sampling

The objectives of sampling were to 1) identify radioisotopes present, including certain TRU isotopes; 2) determine depth of penetration of radionuclides into concrete surfaces; and 3) screen for the presence of hazardous chemicals. Samples would consist primary of concrete cores and subfoundation soil samples, but provisions were also made for collection of miscellaneous "opportunity samples" that might be identified in the field. Because of the small size of these facilities and the high cost of laboratory analyses, sampling activities were limited to just a few in each room or cell. Laboratory analyses would include a full suite of radionuclides and hazardous chemicals. Analysis of radionuclide penetration into concrete surfaces was done by taking core samples of the concrete; these core samples were analyzed by slit-scanning with a high-purity germanium gamma spectroscopy system. Slit-scanning involves shielding the detector so that only a 1/8-in. or 1/4-in. slice of core is

measured. Each 1/8- or 1/4-in. increment is measured down the length of the core to develop a contamination profile.

Summary of Approach

A site characterization approach should be based on the data needed to plan and execute D&D of the facility. Table I summarizes the data needs, uses, and collection methods for characterization of OHF.

Table I

SUMMARY OF FINDINGS

The facility did not appear to have been decontaminated before it was abandoned; most of the equipment and piping used in the cells and control room are still present. Exceptions are the high-pressure pump and diesel engine used for grout injection, which have been removed from the pump cell and engine pad, respectively. The cells contain other items such as ladders, drums, cleaning equipment, ropes and cable, pins and bolts. The integrity of the OHF structures is adequate (i.e., the structures will remain structurally intact) for safe decontamination or demolition. All rooms and cells are contaminated with hotspots. The pumphouse, control room, and cell areas are all contaminated, with most of the contamination fixed to the surface of the room/cell walls and floors. Exceptions are the loose grout on the floor of the mixing cell and grout in piping. The exteriors of water tank T-5, pump P-3, and the four bulk storage bins were surveyed and found to be free of loose surface (smearable) contamination.

The concrete foundation slab of the room/cells ranges from 4 to 9 in. thick. The floor slabs in the mixing and pump cells consist of two distinct layers: a top layer (approximately 3 in. and 1 in. thick, respectively) and a bottom layer (approximately 6 and 7 in. thick, respectively). Slit scanning of the concrete cores indicates that most of the measured gamma activity is within the first few inches of the surface. The activity along the length of the core is nonuniform; the activity is generally high at surfaces, decreases to near background level, and increases slightly again near the bottom where the core contacts underlying soil. The two-piece core from the mixing cell behaves differently than the others; the top portion has high activity at the surface, decreases to near background level, and increases at the interface by a factor of 20. The bottom section behaves the same as the other cores.

General area measurements and concrete and soil sample gamma spectroscopy results indicate that the primary gamma emitting isotope present is cesium-137/barium-137m. Other radiological contaminants include strontium-90/yttrium-90, cobalt-60, uranium, thorium, and plutonium, although in very small amounts. Comparison of direct measurement and smear results indicates that most of the contamination is fixed on surfaces.

The general area average exposure rates (closed window) in these areas range from 3 to 60 mR/h. Alpha activity is generally higher in the cells than in the control room, engine pad, and pump house. The average alpha activity ranges from approximately 59 to 4500 dpm/100 cm2; smear results range from approximately 1 to 800 dpm/100 cm2. In addition, there are several hotspots in the mixing and pump cells and the pump house. The elevated exposure rates in the mixing cell are on the bottom of the mixing tank and the suction lines used for transporting group to the pump cell (120-160 mR/h and 270-400 mrad/h) and in the floor drain (300 mrad/h and 150 mR/h). The elevated contact exposure rates were on the two grout

suction lines from the mixing cell (800 mrad/h and 120 mR/h and 3000 mrad/h and 300 mR/h) and the pipe suspended (hanging vertically) from the ceiling (1000 mrad/h and 800 mR/h; these exposure rates were measured before the pipe was shielded with lead blanket and lead sheet). A few areas on the pump house concrete pad under the lead shielding exhibit high exposure rates (maximum 2500 mrad/h and 1000 mR/h) approximately 6 in. from the floor.

Location-specific direct beta/gamma average readings about 10 cm from the surface ranged from approximately 5 to 200 mR/h (closed window) and 6 to 300 mrad/h (open window). The open window measurements were approximately 10 to 30% higher than the closed window measurements because of the beta field.

The total activity (i.e., curie content) of the radionuclides in the structural concrete and group deposits was calculated using the concrete and grout volume estimates, the location-specific measurements readings, and the radionuclide concentrations reported by the analytical laboratory for the concrete cores and grout samples. The calculations assumed a density of approximately 2.35 g/cm3 for both the concrete and grout. Concentrations of radionuclides in the floor slabs and grout deposits were assumed to be equal to the concentrations discovered in the concrete floor core and the grout samples, respectively. No samples were taken from the concrete block walls, and the radionuclide concentrations in the walls were inferred from results of location-specific radiological surveys rather than direct laboratory analysis. To be specific, the radionuclide concentrations in the walls were assumed to be represented by the floor core concentrations multiplied by the ratio of the average of the location-specific radiological survey readings on the walls to the average readings on the floor. The alpha survey results were used to obtain the wall-to-floor ratio for the alpha emitters, and the beta/gamma surveys (closed window) were used to obtain the ratio of the beta/gamma emitters.

As shown in Table II, the total activity for various radionuclides was calculated separately for the floors, walls, and grout deposits, and then summed to obtain a total curie estimate. For most of the radionuclides, the total activity in the grout deposits is significantly greater than that in the floors or walls.

Table II

The waste disposal volume estimates include Building 7852, the pump house, the bulk storage bins and associated equipment, tank T-5, and pump P-3, plus the foundations of those structures and the equipment or materials within Building 7852 and the pump house. They do not include the soils underneath and surrounding the structures or the ancillary external piping or drains leading to or from the structures. Remediation of the valve pit, the injection wellhead, the soils, and ancillary external piping is not currently considered a part of D&D implementation. Miscellaneous items such as furniture, tools, spare parts, electrical conduit, minor piping, unattached piping, trash, and investigation-derived waste (e.g., protective clothing and equipment used during D&D implementation) are not included in the volume estimate. The disposal volume was estimated on the basis of as-built conditions determined through field investigation and Energy Systems design drawings.

Volume estimates were performed for concrete, steel, and lead materials. The concrete volume estimates for the structures include the walls, floor slabs, and foundations/footings. The steel volume estimates include the

building roofs, the bulk storage bins and associated equipment, pumps, vessels/tanks, platforms and supports, ducting, and major piping inside the structures. The lead volume estimate includes lead shielding in the pump house, lead plates on the mixing cell roof, and (assumed) lead bricks in a 55-gal drum in the control room. The building material volumes were multiplied by the following swell factors to establish a disposal volume: concrete 1.25, steel 1.35, and lead 1.35.

One set of waste volume estimates was prepared assuming complete dismantlement of the D&D structures and demolition and removal of all the above- and below-ground materials. No partial dismantlement options were considered. Table III shows disposal volume estimates as a function of waste category, D&D structure, and construction material. A significant fraction of the disposal volume is due to the four bins and tank T-5; the table uses the bin and tank volumes prior to their being sectioned or cut up.

Table III

Concrete rubble is estimated to contribute approximately 1/4 of the volume of waste generated during OHF D&D. The bulk storage bins, tank T-5, and other scrap metal contribute most of the remaining fraction of disposal volume; however, the metal contribution is based on the assumption that the bins and tank are unsectioned or uncut. The waste volume from tank T-5 and the bins can be reduced by orders of magnitude if cut into smaller pieces.

None of the concrete cores or soil samples contain base/neutral/acid-extractables, pesticides, or inorganics that exceed the RCRA toxicity characteristic equivalent limits for solids, nor do any contain polychlorinated biphenyls that exceed the limit imposed by the Toxic Substances Control Act. Two potential RCRA constituent metals (chromium and lead) were identified in the paint chip samples. A TCLP test should be performed on the rubblized waste before disposal to determine whether the chromium and lead are RCRA constitutes; however, the paint is not expected to fail the TCLP test because of its relatively low leachability. Two samples were collected from the bins for asbestos analysis; test results were negative. The lead (shielding) plates in the room/cells are considered low-level radioactive mixed waste.

ABSTRACT
JAERI has been developing the remote controlled plant data acquisition system as a part of the technology improvement program for decommissioning of nuclear facilities under a contract with the Science and Technology Agency of Japan. The outline of the system development and some results is described in poster session.
Decommissioning procedure planning of nuclear facilities has to be based on the latest and exact plant data. But sometimes the latest data could not be constructed from the design drawings if long years had been passed after the construction and some modifications had been done after the start of operation. So the data acquisition works of the location and the dimension of the facilities are indispensable for the decommissioning. Also the development of remote controlled plant data acquisition system is necessary for the decommissioning procedure planning of the high radiation area because of the difficulty of the accessibility to the area.
JAERI has developed the remote controlled plant data acquisition system which use the small mobile robot equipped with ITV and laser pointer from 1992. This system is planned to apply to the decommissioning engineering of the JAERI's reprocessing test facility (JRTF).
Remote plant data acquisition system consists of three sections, mobile section, vision section and control section. Mobile section has two main drive wheels at the center of the body, two pairs of legs with 2 joints and 1 assist wheel at the front side and the rear side. By the movements of these parts, the robot is able to traverse the flat face and slope, and to cross the piping. Vision section is composed of the TV camera for normal view, the TV camera for close-up view, the laser pointer and the light, and be able to collect the pictures of the object and the data of its location and distance. Control section is composed of the TV monitor, the computer (EWS) for the control of mobile section and the computer for

data processing. The function of the control section is the operation of the mobile section and vision section, control of the movements and inspection.
JAERI has already made the system and performed the mobile function tests and the data acquisition function test. In the tests, JAERI have collected the fundamental data of the system.
JAERI will perform the measuring function test using the mockup model of the actual plant facilities. The data update function by comparison of the actual plant view from the ITV camera and the 3-dimensional CAD view based on the old design drawings will be added to the system. Also, the improvement of the 3D-CAD and evaluation the performance, the efficiency and the restriction of system will be done and the system will be developed to apply the actual decommissioning design works of the JRTF.

INTRODUCTION

Decommissioning procedure planning based on the latest plant data of the decommissioning objects is necessary on the decommissioning of nuclear facilities. But sometimes the latest data could not be constructed from the design drawings if long years had been passed after the construction and some modifications had been done after the start of operation. So the data acquisition works of the location and the dimension of the facilities are inevitable for the decommissioning. Also the development of remote controlled plant data acquisition system is necessary for the decommissioning procedure planning of the high radiation area because of the difficulty of the accessibility to the area.
JAERI has been developing the remote controlled plant data acquisition system (RDAS) to collect the layout information and dimensions of decommissioning objects under contract of the Science and Technology Agency. The production of the system has been finished and the function test has been performed. Outline of the design consideration and performance of the system are introduced. And the test plan for 3-dimensional measurement of the mock-up model are described here.

DEVELOPMENT OF RDAS IN JRTF

In the JAERI's reprocessing test facility (JRTF), the latest data has to be updated for the decommission engineering because of the several modifications after the construction. So the development of remote controlled plant data acquisition system is necessary for the decommissioning procedure planning.
JAERI has developed the remote controlled plant data acquisition method by which use the RDAS system small mobile robot equipped with ITV and laser pointer. The plant data will be updated by the comparisons between RDAS actual plant data and the 3D-CAD data of the old drawings and the decommission engineering will be performed by these updated data. The flow of the system is shown in Fig. 1.
RDAS system has been made in 1992 and 1993. The mobile function tests and the data acquisition function test has been performed in 1994.
Fig. 1

DESIGN CONSIDERATION OF RDAS

These conditions have been considered on the design of the RDAS system from the environmental conditions of JRTF.
1) Considering reduction of weight and simplification of the device from the viewpoint of mobility and transportation, these items are adopted in the system design.
- use of aluminum alloy in main structures
- external power supply with remote cable

- use of optical-fiber cable for the signal cable
- reduction of the transmission device by built-in driving motor in each wheel and joint

2) Driving mechanism consists of 4 legs and 2 driving wheels to realize the following driving capability:

- climbing step and slope
- crossing over the trench and piping
- driving and rotation in flat face

Design condition of the RDAS has been shown in Table I.

Table I

CONSTITUTION OF RDAS

RDAS consists of mobile section (see Fig. 2) and control section. Mobile section consists of driving mechanism and visual attachments. Driving mechanism has the two pair of legs with assist wheel in front side and rear side. Each leg has 2 joints (knee & hip). 2 driving wheels are equipped at the center of the body of driving mechanism. Visual attachments for plant data acquisition consist of ITV cameras for normal view and for close-up view, laser pointer and light. Vision attachments are able to rotate to any direction by the pan and tilt mechanism.

Fig. 2

Control section (see Fig. 3) consists of control panel, computer and monitor. This section is used for the control of mobile section, operation of the driving mechanism and the visual attachments, setting of the mobile condition, surveillance and measuring of distance and self position.

Fig. 3

In the control section, the measurement of the relative distance function and the measurement of the self-position function has been equipped. The absolute coordinate value of self-position of RDAS has been calculated from the relative distance between the self position and base points (more than 3 points) whose absolute coordinate values was precisely known. Flow of the measurement of the position is shown in Fig. 4.

Fig. 4

FUNCTION TEST OF RDAS

After the end of the assembling of RDAS, the following items have been performed as a function test of RDAS in 1994.

1) Driving forward, driving backward and change of the direction on flat face
2) Climbing the slope and step
3) Crossing over the trench and piping
4) Driving forward, driving backward and change of the direction on the girder
5) Measurement of the distance between the object and RDAS
6) Measurement of the absolute coordinate value of the object and RDAS

Design conditions has been confirmed by the test results.

FUTURE WORKS

The Combination test with 3D-CAD system will be performed in 1995. The main item of the combination test is as follows:

1) Comparison test of ITV view and 3D-CAD view
2) CAD data modification test by the result of RDAS measurement.

After these function tests, JAERI will evaluate the performance, the efficiency and the restriction of system and This system will be developed to apply the actual decommissioning works of the JRTF.

THE APPLICATION OF RECUPERATIVE FLAMELESS THERMAL OXIDATION IN THE TREATMENT OF VOLATILE ORGANIC COMPOUND VAPORS AND THE REMOVAL OF ASSOCIATED HYDROGEN CHLORIDE SCRUBBER SYSTEMS THROUGH RISK ASSESSMENT ANALYSIS

Eric C. Miller
Lockheed Idaho Technologies Company

Lynn M. Higgins
Parsons Engineering Science, Inc.

Craig L. Reese
Parsons Engineering Science, Inc.

ABSTRACT

From 1966 to 1970, approximately 88,400 gallons of organic waste from the Rocky Flats Plant were disposed in the Subsurface Disposal Area of the Idaho National Engineering Laboratory's Radioactive Waste Management Complex. As a result of the subsequent breach of this containerized waste, volatile organic compound vapors have migrated to the vadose zone in and around the Radioactive Waste Management Complex. A Record of Decision was signed on December 2, 1994, which specified vapor vacuum extraction with treatment as the selected remediation technology. The technology selected to treat the extracted volatile organic compound vapors was Recuperative Flameless Thermal Oxidation. This technology uses an inert ceramic matrix which acts as both a sink and a source for heat energy to bring the extracted volatile organic compounds to their oxidation temperature, thereby achieving a destruction efficiency of approximately 99.99%. This technology has numerous advantages, including a vapor destruction process which requires no regeneration or disposal of the matrix material and minimal by-product production. Typical volatile organic compound extraction treatment systems use hydrogen chloride gas scrubbers to lower hydrogen chloride emissions to acceptable levels. Risk assessment methods were used to show that risks from inhalation of untreated hydrogen chloride gas to workers and the public were within acceptable limits. This analysis facilitated negotiations with government regulators to eliminate hydrogen chloride scrubber systems, saving money and considerably simplifying treatment operations.

INEL BACKGROUND

The Idaho National Engineering Laboratory (INEL), formerly the National Reactor Testing Station (NRTS), encompasses 890 square miles and is located in southeast Idaho (Fig. 1). In 1949, the United states Atomic Energy Commission, now the Department of Energy (DOE), established the NRTS as a site for building and testing nuclear facilities. Waste generated during these activities was disposed within the boundaries of the site.

At present, the INEL supports many engineering and operations efforts of DOE and other Federal agencies, including nuclear safety, research, reactor development, reactor operations and training and waste management technology development. The DOE Idaho Field Office (DOE-ID), which is responsible for the INEL, designates authority to operate the INEL to contractors. The primary contractor for the DOE-ID at the INEL is Lockheed Idaho Technologies Company (LITCO), which provides management and operation services to the majority of INEL facilities. The remedial

design/remedial action contractor for LITCO at the INEL is Parsons Engineering Science, Inc.

OBJECTIVE

The objective of this paper is to explain the use of Recuperative Flameless Thermal Oxidation (RFTO) in the treatment of organic vapors and to discuss the advantages and disadvantages of RFTO with respect to more traditional vapor treatment technologies for remediation of Operable Unit (OU) 7-08 at the INEL. In addition, the non-traditional application of risk assessment methods used to negotiate the elimination of hydrogen chloride (HCl) gas scrubbers normally used with the RFTO system will be discussed.

Fig. 1

PROJECT BACKGROUND

The Radioactive Waste Management Complex (RWMC), located in the southwest corner of the INEL (Fig. 1), was established in the early 1950s as a disposal site for solid, low-level waste generated by INEL operations. Within the RWMC is the Subsurface Disposal Area (SDA), where radioactive and organic waste is managed via interim storage operations, waste certification, technology development and preparation of the waste for future shipment to the Waste Isolation Pilot Plant in New Mexico.

From 1966 to 1970, approximately 88,400 gallons of organic waste from the Rocky Flats Plant were disposed of in the SDA. The organic waste included 24,000 gallons of carbon tetrachloride, 25,000 gallons of other volatile chlorinated hydrocarbons, machine oil and calcium silicate absorbent, used to reduce free liquids prior to shipping the waste to the INEL. The containers of volatile organic compounds (VOC) were typically dropped or dumped from the sides of pits and trenches in the SDA and covered with soil to varying depths.

As a result of the burial and subsequent breach of these containerized organic wastes, VOCs have migrated to the vadose zone beneath and within the immediate vicinity of the SDA in the RWMC. The vadose zone is the area between the ground surface and the Snake River Plain Aquifer. The organic contamination in the vadose zone (OCVZ) at the RWMC has been designated as OU 7-08. The remediation of OU 7-08, as part of the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) process, does not include the waste buried in the pits and trenches in the SDA. Remediation of these wastes will be considered under a separate action.

The OU 7-08 remedial action has been implemented in accordance with the signed Record of Decision (ROD) (1) for OCVZ dated December 2, 1994. The selected remediation technology identified in the ROD is vapor vacuum extraction with treatment (VVET), which involves the extraction of the most significant concentrations of VOCs from the vadose zone beneath and within the vicinity of the SDA, and VOC destruction through treatment at the surface.

Extraction and destruction of the VOCs will reduce risks to human health and the environment associated with the organic contaminants present in the vadose zone and ensure that contaminant concentrations that may migrate from the vadose zone to the Snake River Plain Aquifer do not exceed state and Federal maximum contaminant levels.

During development of the ROD, a treatability study (2) was conducted to determine the feasibility of VVET in remediating OU 7-08. For this study, carbon adsorption was the selected treatment technology. The results of

the treatability study indicated that the geology of the subsurface beneath the SDA is conducive to vapor vacuum extraction.

However, while carbon adsorption effectively contained the extracted VOCs, its regeneration and off site disposal posed significant logistic and regulatory problems. Therefore, catalytic oxidation, or an equally-effective VOC destruction technology, was specified in the ROD and incorporated into the Request for Proposal for OU 7-08. The treatment technology proposed by the successful bidder, RFTO (3), is discussed below.

RECUPERATIVE FLAMELESS THERMAL OXIDATION TECHNOLOGY

The RFTO units (Fig. 2) are designed to extract and thermally destroy VOC-laden vapor from the vadose zone. The extraction and treatment process consists of several sub-systems.

The overall process is divided into three basic operations: pretreatment, thermal oxidation, and post-treatment of the oxidizer exhaust gas. A discussion of the general specifications and performance of major process equipment follows.

Pretreatment

The function of the pretreatment equipment is to collect the fume into a header using a vacuum blower, inject air and/or supplemental fuel, and thoroughly mix the fume/air/fuel mixture.

Fume is withdrawn from the well head under vacuum and conducted through heat traced and insulated piping to the header on the process skid.

In the main header, supplemental air is introduced into the line by vacuum. The fume then enters a vacuum blower capable of producing the vacuum required at the well head and the pressure required to push the fume through the process system. Supplemental fuel is injected through a sparger in the line (as needed) to maintain the oxidation temperature set point.

The fume stream and fuel are then mixed in a static in-line mixer which ensures the air and fume are adequately mixed before entering the oxidizer. Once air and/or fuel has been mixed with fume, the combined stream enters the thermal oxidizer. Temperature, pressure and flow are monitored and controlled in the main fume header.

Fig. 2

Thermal Oxidation

The thermal oxidizer consists of four major components: 1) a preheater used to bring the oxidizer to operating temperature, 2) a metal shell or containment vessel, 3) the refractory lining, and 4) the "matrix." The function of the matrix is to contain and control the oxidation reaction. Basic control is achieved by balancing the mass velocity in an upward direction with reaction velocity in a downward direction to maintain the reaction zone within a fixed location in the reactor. Since total flow to the reactor is controlled, the only variable is reaction velocity, which is a function of temperature. If the fume is lean, supplemental fuel is added to the fume through the sparger; if the fume is rich, the temperature indicating controller (TIC) will reduce or eliminate fuel addition.

During startup, the main fume line is isolated from the thermal oxidizer. Combustion air and fuel gas are admitted to the oxidizer preheater pilot using a burner management system. The upper section of the oxidizer is then heated to establish an appropriate temperature profile.

The metal shell of the oxidizer provides containment of the process gases. The refractory lining acts as an insulating medium to minimize

heat loss and to prevent the metal shell from reaching the high oxidation temperatures found in the matrix.

The matrix consists of an inert material selected for its thermal and flow distribution properties. The matrix is divided into two zones, the mixing zone and the oxidation or reaction zone. Ceramic balls and saddles of various sizes are selected to provide good mixing and distribution of the fume in the mixing zone and to provide both a sink and a source for heat energy in the reaction zone. During normal operation, fume, supplemental fuel and/or air are thoroughly mixed as they flow through the mixing zone. As the combined stream flows towards the reaction zone, it absorbs heat from the matrix. When the stream reaches the oxidation temperature, organic compounds oxidize to form carbon dioxide, HCl, unoxidized VOCs and water vapor, releasing heat that is reabsorbed by the matrix. Temperatures, pressures and flows are monitored and controlled in the thermal oxidizer.

Post-Treatment: Non-Traditional Use of Risk Assessment Methods

Typically, risk assessment activities under CERCLA are conducted to adequately and accurately characterize the potential risk from a given site (i.e. Baseline Risk Assessment). In addition, risk assessment methods are often utilized to evaluate the effectiveness and efficiency of one or more potential remediation options as part of the remedy selection process. In most cases, the application of further risk assessment methods following the remedy selection is minimal. However, the application of these methods to refine the selected remedy for OU 7-08, while non-traditional, has resulted in considerable savings in time and money while ensuring adequate protection of human health and the environment.

It became increasingly apparent through the planning and design of the selected remedy that HCl gas scrubber systems would be both financially and, more importantly, logistically burdensome. The realities of maintaining stocks of potentially dangerous chemicals, the logistics of frequent water supply deliveries, the regulatory and logistical issues associated with spent scrubber solution, etc., combined to make the prospect of scrubber system elimination attractive.

However, in order to facilitate the elimination of HCl scrubber systems, assurance was needed that treatment unit workers, co-located RWMC workers, and members of the public would not be exposed to unacceptable risks from the inhalation of HCl gas from OCVZ treatment unit exhaust. Calculations were performed to estimate HCl effluent concentrations based on anticipated VOC inlet concentrations and destruction removal efficiencies. These concentrations were then used as input parameters to an EPA-approved air quality model to evaluate annual average or chronic long-term breathing air concentration of HCl gas. Concentrations at both the maximally exposed worker and public receptor locations (Fig. 3) were used to calculate hazard quotients for receptors at the locations. In each case, the hazard quotient for the maximally exposed receptor was less than 1.

Based on these calculations, it was determined that the risks to the maximally exposed worker and public receptor were acceptable. Agreement was subsequently reached with governmental regulatory agencies to allow the elimination of HCl scrubber systems from OCVZ treatment units.

SUMMARY

The VVET system has been operating since January 11, 1996. The RFTO treatment units are performing as expected with few complications.

Preliminary off-gas monitoring results indicate that the assumptions made and calculations performed to support the deletion of the HCl scrubbers are valid. Off-gas monitoring will continue throughout the operation phase of the remedial action.

Parsons Engineering Science, Inc.
ABSTRACT
The Idaho National Engineering Laboratory (INEL), formerly the National Reactor Testing Station (NRTS), encompasses 890 square miles and is located in southeast Idaho. In 1949, the United States Atomic Energy Commission, now the Department of Energy (DOE), established the NRTS as a site for the building and testing of nuclear facilities. Wastes generated during the building and testing of these nuclear facilities were disposed within the boundaries of the site. These mixed wastes, containing radionuclides and hazardous materials, were often stored in underground tanks for future disposal.
The INEL has 11 buried mixed waste storage tanks regulated under the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) ranging in size from 400 to 50,000 gallons. These tanks are constructed of either stainless or carbon steel and are located at 3 distinct geographic locations across the INEL. These tanks have been grouped based on their similarities in an effort to save money and decrease the time required to complete the necessary remediation. Environmental Restoration and Technology Development personnel are teaming in an effort to address the remediation problem systematically.
INEL BACKGROUND
The Idaho National Engineering Laboratory (INEL), formerly the National Reactor Testing Station (NRTS), encompasses 890 square miles and is located in southeast Idaho (Fig.1). In 1949, the United States Atomic Energy Commission, now the department of Energy (DOE), established the NRTS as a site for the building and testing nuclear facilities. Wastes generated during the building and testing of these nuclear facilities were disposed within the boundaries of the site. These mixed wastes, containing radionuclides and hazardous materials, were often stored in underground storage tanks for future disposal. At present, the INEL supports engineering and operations efforts for the DOE and other Federal

agencies in areas of nuclear safety, research, reactor development, reactor operations and training and waste management technology development to name a few. The DOE Idaho Field Office (DOE-ID), having responsibility for the INEL, designates authority to operate the INEL to contractors. The primary contractor for the DOE-ID at the INEL is Lockheed Idaho Technologies Company (LITCO), which provides managing and operating services to the majority of INEL facilities. The remedial design/remedial action contractor for LITCO at the INEL is Parsons Engineering Science, Inc..

BURIED MIXED WASTE TANKS

The INEL has 11 buried mixed waste storage tanks regulated under the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) ranging in size from 400 to 50,000 gallons. These tanks are constructed of either stainless or carbon steel and are located at 3 distinct geographic locations across the INEL. These tanks have been grouped based on their similarities in an effort to save money and decrease the time required to complete the necessary remediation. Environmental Restoration and Technology Development personnel are teaming in an effort to address the remediation problem systematically. The radionuclide contamination associated with the majority of the tanks is present at levels which will require remote handling techniques. In addition, the contents in at least one of the tanks meets the definition of transuranic waste (i.e. greater than 100 nanocuries/gram). Other contaminants of concern include volatile organics, heavy metals, and poly-chlorinated biphenyls.

The physical form of the waste contained in the tanks is a mixture of solid, sludge, miscellaneous debris and liquid. Studies were recently conducted to determine the approximate waste volume and radiological reading in each tank. Visual inspection was also performed using remote control techniques to determine relative tank integrity and impediments to tank pumping or mixing.

Work on the tank project is being performed in accordance with CERCLA. As such, project personnel must abide by regulations such as the CERCLA, Resource Conservation and Recovery Act, Toxic Substances Control Act, Clean Water Act, Clean Air Act, etc. In addition the tanks are a part of the INEL's Federal Facility Agreement and Consent Order where the DOE, Environmental Protection Agency and state of Idaho jointly work to solve remediation problems at the INEL. These three parties are kept apprised of the status of activities concerning the tank project and they will concur with any actions taken to remediate them.

The successful remediation of the INEL tanks will have benefits nationwide (and possibly worldwide) since many other areas with similar problems have not yet begun dealing with this challenge. The general strategy being applied to the tank project is to investigate the tanks in stages where each stage is completed at a specific decision point. The goal is to take advantage of the decision points to defensibly select a solution for each tank and implement that solution. A systems engineering approach is being used to reach a decision for each tank.

Fig. 1

Figure 2 depicts the decision process flow diagram.

This combination of contaminants, regulatory environment, physical location, and tank construction poses an interesting problem for the remediation engineer.

The remainder of this paper focusses on the remediation of one specific tank (referred to as "V-9"), the schedule, and finally conclusions reached to date.

The capacity of V-9, a sand filter tank, is 400 gallons; it is constructed of stainless steel and it has never been sampled. Based on historical records this tank was used for one day 40 years ago and then usage was discontinued because the sand filter clogged. Consequently project personnel are unaware of the level of contamination associated with the tank.

Tank V-9 is to be remediated through a cooperative arrangement between the DOE's Environmental Restoration (ER) Program and the Office of Technology Development (TD) with a carefully integrated scope, schedule and budget. ER and TD personnel have recognized the opportunity presented by the technical challenges of remediating mixed waste tanks and are using the expertise of each group to produce a technical and cost effective solution for Tank V-9. ER is contributing their expertise in preparing health and safety, CERCLA, and regulatory documentation and in coordinating and managing complex field operations and full scale systems. TD is contributing its expertise in field scale demonstrations of innovative techniques and in the application of commercial technology to new areas. This team approach provides the optimal solutions for the tank project and it will facilitate the transfer of the selected technologies to other sites.

Fig. 2

THE PROBLEM

The goal of the INEL buried mixed waste tank project is to answer the following questions and implement the results for each tank or set of tanks while keeping in mind all regulatory, technical, and management factors. Answering these questions provides the criteria which serve as the foundation upon which work is being conducted to remediate tank V-9 this year:

What is the preferred alternative for the tank using the CERCLA evaluation criteria?

Will the contents of the tank be removed?

If the contents are not removed, what are the requirements for monitoring and/or stabilization and how will they be implemented?

After removal, where and how will the contents of the tanks be treated and stored or disposed?

What requirements must be met for the contents to be stored or disposed?

What requirements must be met for the contents to be treated?

How can ER and TD team to solve the problem?

What technologies are available to minimize personnel exposure for all activities ranging from sampling to grouting to removal and disposal?

The INEL has begun the implementation phase of the tank project in order to answer these questions through the remediation of tank V-9.

THE PLAN

As previously stated this particular type of work has not yet been performed within the DOE system. Significant interest exists within the DOE as well as in the private sector to see how this project progresses. The tank project at the INEL will provide useful baseline information for mixed waste tank remediation world-wide. Key aspects and the associated schedule of the remediation plan for V-9 include:

Compilation of all existing data - complete

Characterization of tank contents to gather data to support risk assessments and treatability studies - summer, 1996

Grouting of the tank - summer, 1996

Monitoring of the grouted tank - summer, 1996 to spring, 1997

Preparation of documentation (sampling plan, health and safety plan, safety analysis documentation, environmental documentation, etc.) - spring, 1996 through spring, 1997

Removal, evaluation, and disposal of the tank and its contents (summer 1997)

In the case of V-9 the INEL buried mixed waste tank project is moving ahead with a treatment demonstration to grout the contents in a manner such that they can be easily retrieved, analyzed and retreated if necessary. The plan includes the sampling and grouting of the tank contents followed by monitoring using tracer tests for six (6) months. Removal of the tank and its contents is scheduled for the summer of 1997. During this removal, the grouted material will be sampled and analyzed to determine the success of the grouting demonstration. Final disposal of the waste form will also take place in 1997.

CONCLUSIONS

This paper discusses the work completed to date as well as future efforts (sampling, grouting, monitoring, removal, and disposal) for tank V-9. The results from this important activity will directly impact future decisions regarding grouting work at the INEL and elsewhere. Consequently, lessons learned from this project will be applicable to other government agencies as well as the private sector in remediating mixed waste tanks. Periodic status reports regarding the progress of this project are available from the authors. The results of this work will also be discussed in future publications.

SUCCESSFUL RETRIEVAL OF RADIOACTIVE WASTE BY BNFL AT SELLAFIELD IN THE UK

E. J. Williamson
P.A. Bigg
BNFL UK Group

S. A. Sharpe
BNFL Inc

ABSTRACT

British Nuclear Fuels Plc (BNFL) owns and operates both the UK's nuclear reprocessing facility at Sellafield in West Cumbria and the UK's principal low level waste (LLW) disposal site at Drigg, situated some 6km to the south east of Sellafield. Over a period of years routine nuclear reprocessing activities have given rise to both liquid and solid wastes of various types which must be retrieved in a controlled manner prior to their long term storage and disposal. As a result BNFL have an ongoing program for developing and implementing techniques for retrieving different waste types. This paper describes the successful implementation of three of the many retrieval projects currently being carried out by BNFL:

Fuel pool sludge retrieval

Fuel cladding swarf retrieval

The retrieval of dry solid transuranic contaminated waste

Although these activities relate to quite different applications they are all subject to common management controls which are aimed at achieving

cost effective solutions with high levels of safety to both personnel and the environment.

FUEL POOL SLUDGE RETRIEVAL

Background

The reprocessing operations carried out at BNFL's Sellafield plant involve extended immersion of spent nuclear fuel in water filled pools which are continuously purged with fresh water. This water passes through concrete settling tanks to remove traces of sludge and corrosion products. In the case of pool water from the Magnox (magnesium alloy full cladding) program a series of open settling tanks were used between 1960 and 1986, during which time approximately 170m3 of sludge accumulated. As part of the long term strategy for retrieval and storage of nuclear waste BNFL decided to retrieve this sludge for two main reasons. Firstly, the sludge itself gave rise to significant radiation levels around the tanks which severely limited working times in the area because of the problems of high dose uptake. Secondly, the tanks which were of an early single containment design were showing signs of ageing and it was decided to transfer the sludge to storage facilities built to current containment standards, pending its subsequent treatment then encapsulation in a concrete grout.

The Solution

After extensive design studies aimed at achieving the technical objectives whilst maintaining dose rates as low as reasonably practicable (ALARP) the concept of a remotely operated travelling unit was devised. Initially, a series of inactive commissioning trials were conducted on a mock up of the tanks. This step brought significant advantages to the project:

It permitted the optimization of operating and maintenance procedures before any exposure to the radiation environment.

Operating and maintenance personnel could be trained in the inactive environment. In this connection extensive photographic and video records were made for future reference.

Safety issues could be documented and the proposed procedures fully explained and justified to the regulatory bodies.

The actual machine installation is shown in Fig. 1.

Fig. 1

The retrieval machine comprised two desludging heads - a large one for the settling tanks and a smaller one for the inlet and suction chambers. These heads are suspended from a travelling bridge and crab unit which allows access to the full area of the tanks. This arrangement minimized lifts over the structure and reduced loading on the tanks. The machine was remotely operated from a control room, utilizing closed circuit television cameras. The sludge discharge and dilution water feed was achieved using double containment flexible connections to the pipebridge. The equipment resuspends the sludge using water jets in a controlled manner converting it to a slurry whilst minimizing disturbance at the tank surface and preventing spread of airborne contamination. The slurry is pumped via a pipebridge to intermediate settling tanks before transfer to the Site Ion Exchange Plant (SIXEP) and ultimately encapsulation in the Waste Encapsulation Plant (WEP).

Achievements to Date

Installation of the machine began in April 1992 and was completed by mid August 1992. Over the next two years desludging progressed at a rate better than the initial target figures as shown in Fig. 2, until minimal

residual sludge remains. Development and design work is now in hand to remove residual sludges and debris and to plan full decommissioning of the facility.

The success of the project was due mainly to teamwork and the use of a systems engineering approach. The video and photographic records were used to brief and train the workforce prior to undertaking critical tasks. The machine was installed with considerably reduced radiation exposure when compared with original predictions.

Fig. 2

FUEL CLADDING SWARF RETRIEVAL

Background

The decanning of spent Magnox fuel elements gives rise to intermediate level waste (ILW) in the form of irradiated magnesium alloy swarf. Over a period of years the swarf has been stored in a series of 22 water filled concrete silos or compartments at Sellafield as shown in Fig. 3.

There was a phased commissioning program in which the first six silos were commissioned in 1964 with the final silo brought into operation in 1983. The early silos contain a mixture of Magnox swarf, sludge and beta gamma waste. The contents of the last four silos are mainly Magnox swarf, with very little sludge.

Fig. 3

It is BNFL's intention to transfer all Magnox swarf to the Magnox Encapsulation Plant (MEP) which commenced operations in 1990. This plant encapsulates Magnox swarf in concrete grout in 500 liter stainless steel drums which are then transferred to a purpose built store prior to long term disposal.

The strategy for retrieval concentrated development effort on the equipment and operational requirements for retrieval of the swarf in compartments 19-22 which is suitable for direct encapsulation in MEP. The experience gained in this phase will then provide a valuable input to the design of the more complex equipment required for the mixed waste in the earlier compartments.

The Solution

The Swarf Retrieval Facility (SRF) designed for compartments 19-22 is shown in Fig. 4.

The machine is designed to interface with the standard silo opening and includes an hydraulically operated petal grab which is lowered via a hoist into the water covered swarf. When the full grab is raised a swarf bin is traversed to a position underneath it and the grab is opened to release the swarf into the bin. When the swarf bin is charged to a sufficient level the contents are monitored and raised via a gamma gate to a swarf bin transit flask which is used to transport the charge to the MEP facility.

Fig. 4

In developing this concept design and operational personnel worked as an integrated project team to ensure that safety and radiation issues adhered to the ALARP principle (As Low As Reasonably Practicable). This resulted in a number of notable features.

Because of the high levels of radiation and contamination the machine was designed to be as maintenance free as possible. It was constructed in modular form so that failed equipment could be easily removed and replaced.

A weight optimization study was carried out to minimize silo roof loadings whilst still maintaining a sufficient level of shielding to conform to modern plant standards.

A unique lifting beam was designed to achieve the required clearance when lifting transport flasks onto and off the machine.

The machine was designed so that equipment which protruded below its lower shielding could be retracted when the machine was moved. This had a twofold benefit of minimizing dose uptake and reducing the risk of collision and dropped objects.

Two independent seals provided an interface with the silo ventilation system. The integrity of the ventilation system was thus maintained by fulfilling the two main design criteria. The air gap between the water level and the silo roof was kept slightly less than atmospheric pressure to avoid spread of contamination to the operating environment and there was no undue build up of hydrogen.

Inactive testing was carried out off site at contractors works, saving radiation dose and providing invaluable training.

Achievements to Date

Because the machine had to be installed on an existing active plant much emphasis was placed on the need to achieve a "Right First Time" result by applying the principles of Total Quality Management (TQM) and teamwork. With this in mind a chargehole mock-up was built at the manufacturers. This allowed time to be spent proving the installation procedure, testing the machines durability and allowing modification while still in a clean environment. Procedures were developed and operations and maintenance personnel were trained in their use while the machine was still in an inactive situation. The benefits of this approach are demonstrated by the fact that actual dose uptakes during operation are significantly less than were originally predicted.

Due to these project management initiatives the SRF was delivered, installed and commissioned ahead of schedule and is currently exceeding its yearly productivity targets as shown in Fig. 5 overleaf. Original expectations were that it would empty a compartment in approximately 18 months. In practice it has already emptied one in a 14 month period which included an initial commissioning phase of one month and a one month division wide shutdown.

Fig. 5

As operations progress the project team is continuing to introduce improvements to allow for variations in the swarf quality. This experience is being fully documented and will be of benefit to other projects, particularly when the team faces the challenge imposed by the mixed wastes in the earlier compartments. This challenge includes construction of three larger, more complex Silo Emptying Plants (SEP I, SEP II and SEP III). Designs are well advanced and these machines will be manufactured and installed by 2001. A major downstream facility, Sellafield Drypac Plant, is being constructed on the same timescale to receive, treat and compact the waste prior to encapsulation.

DRY SOLID TRANSURANIC CONTAMINATED WASTE RETRIEVAL

Background

Transuranic (TRU) waste originating from the early UK defence program was placed for interim storage in existing structures, know as magazines at Drigg. A typical magazine is shown in Fig. 6. The waste was contained within steel drums of up to 205 liter capacity or in larger timber and plastic cuboid containers known as "crates".

Fig. 6

Design Philosophy

The general philosophy has been to provide semi-permanent structures (Magazine Modules) for the controlled removal of TRU Waste. These are modular mild steel fabrications bolted together with watertight sealed joints which are designed to interface with the entrance to each magazine in turn. The design has been executed on the basis that in-magazine retrieval operations will be carried out in protective clothing (supplied air suits) with provision incorporated to achieve high integrity containment at points of export from the magazine, such that all subsequent operations will not require extensive use of protective clothing.

Drum Retrieval

For the drums a procedure was developed to admit operators to each magazine in turn, maintaining magazine containment, so that each drum could then be checked, have containment improved by bagging or over-drumming as necessary, be checked free from contamination, have surface dose rate recorded and be assayed for fissile material content. In recognition that all of the drums would eventually require transport from the site they were all provided with additional containment, although inspection revealed that this was only an absolute requirement for less than 1% of the drums. Forced filtered extract from the magazine was provided inducing an air flow across the changeroom barrier in accordance with usual practice. Although there was a provision for operators to enter the magazines in pressurized suits supplied with air lines this facility was only used on an as required basis. Even in some cases where it was used it was only a precautionary measure because portable equipment used to measure alpha in air could not always discriminate adequately between plutonium and high levels of radon/thoron.

Fissile material assay was accomplished using a combination of direct weighing (from which density of the waste matrix was derived), low resolution gamma spectrometry (gives plutonium content result independent of burnup in reactor or age since separation, when energy band is carefully chosen from the measurement, and with an absorption correction based on matrix destiny) and passive neutron counting (for high density waste matrix). No reliance was placed on their earlier records or labels.

Retrieval facilities were moved from one magazine to another by contractors, each move taking less than a week to prepare hardstanding. Over the period 1976 to 1986 some 10,500 drums were retrieved from the magazines and those magazines that were then empty were decontaminated as necessary and returned to unrestricted use. Although the team of operators was not employed full time on this task direct labor and supervisory input to the project averaged three man years per year with additional maintenance, management and health physics input as required. For these personnel the group average radiation dose uptake did not exceed 2 mSV per annum during the drum retrieval project. The capital cost of the equipment employed was of the order US $200,000 (mid '70's money values), excluding the cost of an interim store which was constructed on the site as a buffer between the retrieval operation and subsequent off-site transport.

Crate Retrieval

Five of the ten magazine stores on the Drigg Site contain some 160 non-drummed packages still to be removed, and 120 drums which are presently inaccessible or too heavy for removal by manual means.

The items are to be retrieved, overcrated or re-drummed, monitored and transported (within appropriate containment) by rail and road links to Sellafield for subsequent storage and processing for disposal.
A new specially designed module is ready for use and regulatory permission is awaited to start operations, see Fig. 7. The crates will be retrieved, overcrated, monitored (to determine fissile material content and to demonstrate acceptable levels of radiation or external contamination) and transported to Sellafield for storage awaiting treatment.
Fig. 7
The facility will be relocated at intervals of approximately one year in order to carry out operations at the five magazines still containing TRU waste. The modules are steel fabrications bolted together, incorporating weathertight sealed joints capable of multiple dismantling and re-erection over a five-year period without loss of alignment. Each module is thermally insulated with floors suitably reinforced to sustain a ten tonne floor loading. The modules when assembled, provide for access of personnel in protective clothing and systems for the loading, assay and handling retrieved wastes. From knowledge of the relatively low prevailing dose rates within the magazines and that wastes being retrieved are TRU, the principal radiological hazard is considered to be the spread of contamination and release of airborne activity. A dedicated ventilation extract system is provided to draw clean air through the modules (low contamination) to areas of higher contamination.
Considerable attention has been paid to appropriate fissile content assay systems. Initial monitoring takes place immediately out of the magazine environment in the magazine extension. Crates and drums will subsequently be moved to a Central Monitoring Facility.
The central monitoring building, Fig. 7, contains the following items:

A crate monitor of sufficient size to enclose the largest overcrated TRU waste package and monitor each crate for up to 48 hours to obtain an accurate fissile material content.

A drum monitor capable of accepting up to 500 liter drums which uses total and coincidence neutron counting and gamma spectrometer techniques to determine the fissile content of all drummed waste.

An area of the monitoring building is partitioned so as to form the monitoring control room.

Adjacent to the central monitoring building is a storage compound for monitored, unmonitored and unused overcrates and drums. Within this area the monitored overcrates and drums will be loaded and secured inside ISO freight containers for transportation to Sellafield Site. Unloaded ISO freight containers are to be returned to Drigg for re-use.

Safety

It will be appreciated from the foregoing description that the retrieval facilities have taken account of the following key safety aspects:

Criticality: measurement of the contents of crates/drums as close to the point and time of retrieval as possible, following a careful initial move.

Plutonium ingestion: containment of magazines, contaminated areas and of the waste itself using physical barriers, air flows, developed transport containers, and suitable protective clothing for operators.

Fire: minimization of combustible material loading, including over-containment, with fire-detection and alarm systems.

External radiation: monitoring of items, use of suitable handling equipment with area gamma radiation measurements and alarm systems.

Industrial safety: suitable equipment provided for in-magazine and subsequent handling of heavy items.

CONCLUSIONS

The three projects outlined in this paper illustrate BNFL's structured approach to the retrieval of nuclear waste prior to long term storage and disposal. In all cases, the key to a successful conclusion was the development of a team philosophy with designers, operators and maintainers combining their expertise throughout project life. The use of initial commissioning trials on inactive mock-ups proved to be a very effective method of ensuring that key operational and safety targets were achieved.

The major success factors included:

Safe operation of the integrated Sellafield site including storage, reprocessing, retrieval and waste treatment facilities.

Concentration on strategy, waste categorization and front end design at the early stages of the projects.

Use of TQM and a team building approach to problem solving.

Investment in development and off site inactive commissioning facilities.

The experience gained so far has demonstrated that BNFL has the ability to undertake difficult and complex waste retrieval and management projects in the UK and elsewhere in the world.

DETECTION OF ALPHA CONTAMINATION INSIDE PIPES

ABSTRACT

Traditional alpha monitors sense the presence of alpha-emitting contaminants by directly detecting the alpha particles. Thus the sensitivity of these monitors is limited by the short range of alpha particles in air (typically less than 10 cm). Contamination inside pipes is a particular problem; if the pipe is too small to permit insertion of a monitor, there is no way to detect internal alpha emission with a traditional monitor. In contrast, monitors using the long-range alpha detection (LRAD) technique detect the ionized molecules produced by interactions of the alpha particles with ambient air. Such monitors are limited by the lifetime of the ions (the observed several-second lifetime allows transport of the ions over many meters or tens of meters) rather than the range of the alpha particle. The characteristics of LRAD monitoring are ideally suited to measurements inside pipes. All of the ions created by all of the contamination inside a pipe can be measured in a single detector located outside the pipe. Because air is the "probe", convoluted or twisted sections of pipe can be monitored almost as easily as straight sections. A collaborative exercise between LANL and BNFL Instruments Ltd has resulted in both laboratory field testing of an LRAD-based pipe monitoring system at LANL and BNFL's Sellafield reprocessing

facility in the UK. In this paper, we will report the first results of these tests.

INTRODUCTION

The decontamination and decommissioning (D&D) programs within the US DOE and BNFL have identified a continuing and significant need for development of appropriate measurement technologies for use on residual activity in process vessels, pipework, and structural material. BNFL Instruments Ltd, a wholly owned subsidiary of BNFL, has shown that it would be beneficial to measure alpha contamination within interconnecting pipework both before and after removal of contaminated material from the plant. Both planning and execution of decommissioning and subsequent waste disposal would be facilitated by this knowledge.

Traditional methods of monitoring the interior of pipework, especially for alpha-emitting contaminants, are difficult at best and impossible at worst. Many of the characteristics of the long-range alpha detection (LRAD) technique are ideally suited to measuring contamination inside enclosed volumes such as pipework. A collaborative exercise between LANL and BNFL Instruments Ltd has resulted in both laboratory and field testing of an LRAD-based pipe monitoring system at LANL and BNFL's Sellafield reprocessing facility in the UK.

TRADITIONAL PIPE MONITORS

Locating small quantities of alpha-emitting contaminants such as plutonium and americium inside small pipes is often complicated by the poor penetrating ability of the alpha particle. Probes based on a, b, g, and neutron detection have been employed with varying degrees of success. The alpha particles commonly generated by these contaminants cannot penetrate the walls of even a very-thin-walled pipe and, in fact, cannot penetrate more than a few centimeters of air. Thus direct alpha probes cannot be used outside a pipe and must be close to the contamination when deployed inside a pipe. A small traditional alpha detector can be inserted into a pipe to search for contamination. This technique works well with simple systems of large diameter pipes but becomes rapidly more difficult as the complexity of the pipework increases.

Beta particles are not produced by many of these contaminants and have poor penetrating ability as well (although not as poor as the alpha particle). Thus, except in special cases, beta particles are not useful probes for alpha-contaminated pipes.

Many (but not all) alpha-emitting contaminants also emit low-energy gammarays or X-rays or both as they decay. These gamma and X-rays can be difficult to detect outside the pipe when large sources are present and extremely difficult or impossible on small sources.

Finally, passive and active neutron measurements are very useful for determining the location of large amounts of contaminant within an accessible pipework system before operational materials are cleaned out of the system. These techniques have only limited usefulness in the low-level contamination and buried pipework scenarios common in facility D&D.

Thus, traditional measuring technologies can provide useful information on large amounts of alpha-emitting contaminants and contaminants located in simple or exposed pipe systems. However, many contaminated pipes do not fall into one of these categories. There are often a number of less-than-satisfactory alternatives including partial monitoring (of exposed surfaces), physical destruction of the pipe, complex internal monitoring systems, and handling and disposal of the pipe as contaminated waste, whether or not it is truly contaminated.

LRAD TECHNOLOGY

In contrast to traditional particle detectors, LRAD-based monitors detect the ionized air molecules generated by an alpha particle interacting with ambient air. A typical 5-MeV alpha particle will produce about 150,000 electron-ion pairs throughout its several-centimeter range in air. The electrons attach relatively quickly to neutral air molecules, producing heavy negative ions in equal numbers to the originally produced positive ions (1). The ions are transported to an electrically conductive detection grid, where the current produced by the ions can be measured with an electrometer or similar instrument. The observed current is proportional to the number of ions, which is in turn proportional to the amount of alpha contamination in the system. Although the principles of the LRAD technique have been discussed in detail elsewhere (2-4), we will discuss the basic principles, especially as related to pipe monitoring systems, in this paper.

The air ions can be transported to the detection grid by an electric field (electrostatic LRAD) or an air current (airflow LRAD). An electrostatic LRAD-based system utilizes a weak electric field (there is no gas gain in standard LRAD systems) to transport ions from a relatively flat surface to an ion collector plate. Airflow LRAD monitors (such as the pipe monitors discussed here) rely on a moving air current to transport the ions to a collector grid. An example of a generic airflow detector system is shown in Fig. 1.

Fig. 1

Monitoring systems based on the LRAD principle have several inherent advantages over other types of detector. These can be broken into three categories: 1) operational advantages, 2) engineering advantages, and 3) physics advantages.

Operational Advantages

Monitors based on LRAD technology operate in real time. The monitoring results are available to the workers in the field who can use it to decide about the safety of particular operation.

In Situ monitoring has been defined many ways. One useful definition is that the contaminated area is undisturbed and that no secondary waste is generated. Well-designed LRAD-based monitors satisfy these criteria and provide a combination of sensitivity and portability that is not available from other types of monitors.

All of the ions from a widely distributed area of contamination can be collected onto a single measurement grid. This gives the LRAD monitors the ability to monitor extended sources in a single measurement rather than requiring the summation of many smaller measurements.

Using ambient air as a detection and transport gas has additional advantages beyond those of a windowless detector. It is very easy for air to flow through a complex pipe network without getting caught on turns or constrictions. Thus, the air can penetrate complex pipe networks (except for blind limbs) more easily than traditional detectors.

Engineering Advantages

The LRAD detector system is very simple. There are no moving parts, no high-voltage power supplies or pulse electronics, and no special detector gases. As shown in Fig. 1, the only critical parts are the ion collector plate (or grid) and the dc electrometer required to measure the ion current.

This simple design implies the required field reliability. There are no fine wires, thin windows, gas handling systems, optical connections, or

complex electronics. This small number of parts leads to a long life expectancy, but, more importantly, LRAD-based detectors are rugged enough to stand up to repeated use in field conditions. The "sensitive" element in an LRAD-based detector is typically a thick piece of metal (generally aluminum or copper); temperature changes, scratches, or even deformation do not affect its detection ability.

Physics Advantages

As detailed in Ref. 2, LRAD detector systems are capable of measuring contamination levels of less than 100 disintegrations per minute (dpm) or less than 10 dpm/100 cm2. The length of time required to make these measurements is often limited by the counting statistics of the alpha particles rather than by the detector itself.

LRAD PIPE MONITORS

Both applications of LRAD-based monitors to D&D projects in general (5,6) and prototype pipe monitoring systems (7,8) based on the LRAD technique have been described in some detail previously. The data presented here were taken with the 10-cm-diameter pipe monitor described in Ref. 8 and with the more rugged and adaptable monitor illustrated in Fig. 2 and described below.

Fig. 2

The adaptable pipe monitor consists of two modules that can be attached to random sizes of pipe. Each of the modules has a 15-cm iris valve for connection to pipes between 1 and 12 cm in diameter. The other significant part of the input module is a 15-cm-diameter air filter for removing particulates from the ambient air. The mixing volume allows air to be drawn through the entire filter rather than just a smaller area at the center.

The second, or output, module again has an iris valve for connection to the pipe. An ion collection grid (similar to that shown in Fig. 1) is mounted inside the second mixing volume. The final component is a small fan oriented to draw air through the monitor. This system is identical in principle to the monitor described in Ref. 8 but is better suited to use with a variety of pipe diameters and wall thicknesses.

LABORATORY TESTS

Two important parameters that were not fully addressed in the work presented in Refs. 7 and 8 are the effects of air velocity and pipe diameter. Figure 3 illustrates the results obtained when the detector was connected to a 600-cm length of 10-cm-diameter pipe; the two curves represent the response to an alpha source which was placed either 60 or 540 cm away from the collection grid. The intrinsic sensitivity of an LRAD sensor is expressed as detected electrons per radioactive decay. Converting this sensitivity into measured quantities [the output of the LRAD is measured in femtoAmperes (fA) or picoAmperes (pA) and source strength is measured in dpm] reveals that a physical measure of the sensitivity of the detector to radiation is fA (or pA) per dpm.

Fig. 3

Both response curves exhibit a pronounced peak at about 100 cm/sec. The maximum sensitivity of this detector grid at 60 cm is about 0.11 fA/dpm and at 540 cm it is about 0.051 fA/dpm. The 540-cm curve is lower because some of the ions produced at 540 cm recombine before detection. We interpret the loss of efficiency at low velocity as loss of efficiency in transporting ions from the source to the detector. The loss at high velocity is probably due to "punch through," a phenomenon where some of the quickly moving ions pass through the holes in the detector without

being attracted to the grid. The grid is held at several hundred volts (see Fig. 1), which is insufficient to collect all fast-moving ions.

To examine the details of LRAD detector response at lower airflows, we made a series of measurements in the system illustrated in Fig. 2. A 15-cm LRAD grid was attached to a section of 5-cm-diameter pipe that was either 1.22 m (data shown in Fig. 4a) or 6.10 m (data shown in Fig. 4b) long. The air speed through the pipe was varied by adjusting the voltage applied to a variable speed fan.

Fig. 4

The response in a 1.22-m pipe has a broad plateau extending from about 70 cm/sec to above the measurement limit of 120 cm/sec. The plateau with a longer (6.10 m) pipe starts at a much higher airspeed (about 100 cm/sec).

FIELD TESTS

We have identified a number of field tests that will further validate both the concept and practical design of the LRAD-based adaptive pipe monitor. These can be broadly divided into three areas: sensitivity, geometry, and other effects.

Sensitivity

To assess the sensitivity and limit of detection of the LRAD monitoring system, it will be used to measure small alpha sources placed within sections of stainless steel pipe with dimensions typical of those commonly found in operating and decommissioned facilities on the Sellafield site.

Geometry

The sensitivity tests will be repeated using pipes of varying length, diameter and curvature and varying the airflow through the pipe. In addition, the alpha sources will be placed at a number of positions within the pipes.

Other Effects

The effects of environmental changes will be evaluated by repeating the sensitivity tests throughout an 8-hour period and logging the temperature and humidity during the same period. Additional measurements using external (to the pipe) gamma-emitting sources (typically 370 kBq) will determine the sensitivity of the LRAD monitor to background radiation interference.

CONCLUSIONS

We have reached a number of tentative conclusions from the laboratory tests. Many of these will be investigated further during the field testing phase.

Perforated plate detectors of the same diameter as the pipe, such as that illustrated in Fig. 1, have a relatively sharp efficiency peak as a function of airspeed. In a 10-cm diameter pipe, this peak is at about 100 cm/sec.

Increasing the diameter of the detection grid relative to the diameter of the pipe (as shown in Fig. 2) can widen this sensitivity peak.

Increasing the air flow through a pipe can partially compensate for increased distance to the contamination. In particular, the optimum airspeed for a short pipe is not necessarily optimum for longer pipes.

The results obtained in short sections of clean 5-cm and 10-cm pipe are significantly different; larger changes in the pipe will probably result in larger changes in optimum detector design.

Golder Associates (UK) Ltd
Nottingham, England

ABSTRACT
This paper describes a concept of a specialized decommissioning tool designed to operate underwater and to reduce the volume of radioactive components by shearing and compacting.
The shear compactor was originally conceived to manage the size reduction of a variety of decommissioned stainless steel tubes stored within a reactor fuel cooling pond and which were consuming a substantial area of the pond. The main objective of this tool was to cut the long tubes into shorter lengths and to compact them into a flat rectangular form which could be stacked on the pond floor, thus saving valuable space.
The development program undertaken on this project investigated a wide range of factors which could contribute to an extended cutting blade performance, i.e.: materials of construction, cutting blade shape and cutting loads required, shock effects, etc. The second phase of this project was to review other aspects of the design, such as radiological protection, cutting blade replacement, general maintenance, pond installation and resultant wall loads, water hydraulics, collection of products of shearing/compacting operation, corrosion of the equipment,

control system, operational safety and the ability of the equipment to operate in dry environment.

The results of the development and study phase provided the confidence to justify proceeding to a fully detailed design, supported by all the necessary calculations. The paper summarizes the extended work program involved with this shear compactor tool.

TECHNICAL REQUIREMENTS

Although the volume reduction system was required to be designed to handle steel tubes, the equipment had to be sufficiently flexible in concept to be capable of treating other decommissioned materials.

The prime aim of the chosen equipment was to treat stainless steel tube, of two sizes, both of 48 mm external diameter with a wall thickness of either 3 mm or 4.5 mm. Any system developed was to be able to operate in a reactor fuel cooling/storage pond, filled with demineralized water. The depth of the operation was to be such that the pond water would provide the radiological protection for the workers located on the pond surround. The chosen system could, if required, utilize the pond manipulator for manoeuvering long tubes and the resultant compacted products under water. As the pond in which the equipment was to be operated could, at any time, be connected by a sluice door arrangement, to another pond housing a small research reactor, the chosen system was to be designed to avoid inducing any underwater shock to the reactor or the pond structure. Because the space allocated to the volume reduction system was restricted, the equipment had to be easily removed and parked when not in use. Excellent visibility in the pond had to be maintained at all times and as a result, any hydraulic systems employed had to be water powered. There were, therefore, a number of important reasons why the equipment and any support structure used were to be of light construction, they being: to reduce the reaction loads in the pond walls to an absolute minimum and to prevent overloading of the pond crane when removing any equipment from the pond.

CHOOSING THE SYSTEM

A wide variety of volume reduction processes were considered for this application including sawing, slitting, grinding, shearing, etc. but because it was the system which produced no, or minimal secondary waste products like swarf or chippings, the shearing process was selected. The shearing action did, however, need qualifying. The shearing blade shape would need careful design to avoid any jamming of one blade against another and to produce a significant volume reduction, the shear action would need to be allied with a compaction system to flatten the tubes between each cut.

As a result of all considerations the combined shear/compactor was chosen as the most likely candidate system for this application. At this point in the investigations, it was decided to attempt to combine the shearing with the compaction operation, all in one machine, if possible. Before proceeding with the detail design, however, it was necessary to undertake some development work.

RESEARCH AND DEVELOPMENT

Compaction Tests

The first objective was to determine what loads were required for compacting the 4.5 mm thick tube, the worst case to be considered. A small rig was designed and built, generally as shown in Fig. 1. The test rig consisted of a base carrying two vertical pillars, these pillars guiding a moveable top plate. Both base and top plate were arranged to

carry the various shear blades to be tested at a later date, but for the compacting tests the shear blade slots were blanked off.

Fig. 1

By positioning this rig on the bedplate of a 1000kN Amsler tensile test machine and using the machine in it's compressive condition, the top anvil of the Amsler could be brought to bear on the top plate of the test rig, the applied load being accurately recorded on the tensile test machine's control system. During these tests, the degree of compact was recorded for a given load and tube thickness, by measuring the distance between the base and top plate of the rig. It is interesting to note that even though the tubes were compacted to a theoretical dimension of 2 x thickness, the actual dimension after relaxation of the compaction load was always slightly more, the recovery being due to the natural hysterisis of the stainless steel material. A variety of different lengths of tube were compacted, the tests showing that a length of 200 mm would be the optimum for underwater handling by the pond manipulator.

A summary of the results of the tests to compact a 48 mm diameter x 4.5 mm wall stainless steel tube of 200 mm length are shown in Table I.

Table I

Shearing Tests

The most common form of shear blade is shown in Fig. 2a. The problem associated with this particular form is that of the offset load, tending to force the blades apart. If the blades are not sufficiently stiff, the condition shown in Fig. 2b. arises, resulting in either a broken blade or the tube becoming jammed between the blades. The last condition would be particularly disastrous on a remotely operated machine in radioactive conditions. If the blades were made stiff enough to prevent these conditions occurring, the resultant weight would be such that they would prove very difficult to manoeuvre with remote tools. The risk of one blade galling or self welding to its partner could also not be overlooked, especially in an unlubricated system which relies on two heavily loaded faces moving past each other with very little clearance. It was, therefore, decided that the most promising form of shear blade to test was that shown in Fig. 2c. It was hoped to design the blades to provide sufficient load to reach the maximum tensile stress of the tube material before the cutting edges touched each other. If this could be achieved in the tests, it would mean that a definite stop could be installed on the final design of the machine to prevent the edges contacting and thus give a longer cutting edge life and minimize the need to change them. This type of blade would also prove very difficult to jam. The resultants of the cutting load would be equal and opposite to each other, imparting no side loads on the machine, providing the blades are correctly aligned. It was decided to test a variety of blade materials, hardness required, included angles, degree of pre-compaction, etc.

A derivative of the double blade is shown in Fig 2d. This type of cutter utilizes one of the previously discussed pairs in conjunction with a flat plate and was considered to be of interest because it obviates the need for the accurate alignment of the double blade arrangement. This variation was tested to compare the cutting loads required of the two systems.

Fig. 2

In reviewing the results of all the shearing tests, it was decided to opt for the double blade system, with an included angle of 750, because of

low load requirements, tool life and general durability. The tests had also revealed that the high stress/ no blade contact theory was valid and identified the gap that was required between the blades to achieve the desired tensile stress. The principle of compacting, while shearing took place, ensured that the sample was not ejected when the stress produced the break in the material. For the same reason, no shock was evident, a distinct requirement of the pond location. A summary of the results of shearing are shown in Table II.

Table II

To summarize, a combined shearing / compaction operation on a 48 mm diameter tube with a wall thickness of 4.5 mm and a length of 200 mm, employing a double shear blade with an included angle of 750, required a load of 970 kN. This force resulted in a product measuring 200 mm long x 13 mm thick. The combined shearing/compacting results are shown in Table III.

Table III

THE SHEAR / COMPACTOR MACHINE

To ensure that no shearing / compacting loads were transferred into the pond wall structure, the machine was designed as a self consuming load system. However, before commencing the design work, a number of important decisions were made, particularly in the light of the development test program results. These were:

as a water hydraulic cylinder capable of an output force of 1000kN was commercially available and any larger unit would have to be specially constructed, it was decided to use that equipment. It was constructed in the correct grade of stainless steel and had a proven performance when operating on a demineralized water fluid.

as a force of only 1000kN was available, with little in reserve over the required 970kN developed during the test program, it was agreed to limit the degree of compaction to provide a finished thickness of approximately 17 mm against the proposed 13 mm, demanding a reduced compaction load of 680kN. This important decision meant that the designers had some 30% spare capacity in the available hydraulic cylinder with a corresponding penalty in the finished thickness of the compact. It was considered acceptable to pay this loss of reduction for the cost advantage gained from using proven, available equipment.

The initial design layouts indicated that the overall size of the machine would be determined by two basic factors :

the maximum movement required between the two cutting blades and

the diameter of the power unit used to produce the force of 1000 kN

The size of the hydraulic cylinder mounting flange determined the dimensions of the cylinder mounting block. See arrangement of machine in Fig. 3. Parallel to the cylinder block and joined to it by four large tie bars, is the reaction block. Sliding along the four tie bars and moved by the hydraulic cylinder piston rod, is the moving block. Positioned on both reaction and moving blocks are the cutting blade location fittings, designed to permit the changing of the cutting blades without having to remove the machine from the water. These location fittings are so designed that they ensure correct alignment of the cutting blades and the tube being treated, an important requirement revealed by the test program.

Fig. 3

To ensure that the cutting edges do not come into contact with each other, four reaction blocks are fitted to the corners of the blades. The

shape of the blade and the reaction blocks control both the cutting and degree of compaction obtained. Two cutting edges are fitted to each blade, the top horizontal set for cutting vertical tubes and the vertical set for the horizontal tube arrangement. Both sets of blade location fittings have been designed to bolt to the flat surfaces of the moving and fixed reaction blocks. Thus, with the 250 mm stroke available from the hydraulic cylinder and a change of location fitting and cutting blade, tubes up to 190 mm diameter can be dealt with if required.
Bridging the bottom two tie bars and positioned below the blade location fittings, is a fixed stop plate which is 200 mm from the horizontal cutting edges. To one side of this fixed stop plate are two location pins which locate the adjustable and removable horizontal stop. This stop can be adjusted to any distance up to 910 mm from the vertical cutting edges.
On the top surface of the reaction block is a single lifting lug for removing the machine from the support structure. Fitted either side of the cylinder block are the machine support plates, joined at the top by a cylindrical bar.
All materials specified for the machine is generally stainless steel. Where friction of moving couples was involved, the stainless steel for construction was changed to a type with a high molybdenum content, thus minimizing the risk of galling or self welding. As weight was a dominant factor, particularly as the capacity of the pond crane was limited, and the reactions in the pond structure should be as low as possible, considerable thought was given to providing a light but structurally stiff assembly.
The estimated weight of the machine, in air, is 2,040 kg.
SUPPORT STRUCTURE
The support structure for the machine is constructed of three basic components:
  the top section which straddles the pond surround and clamps to it. To prevent overloading the wall with this manually operated clamp, a collar is placed between the handwheel and the clamp shaft support
  built into the top section is an operator's platform, complete with guard rails, giving an uninterrupted view of the machine some 3 m below the water level. All materials used in the construction of the top section are of normal carbon steel suitably protected against corrosion by plastic coating.
  The lower machine support section is suspended from the platform assembly by a stainless steel, 3 tube configuration. The three tubes are cross braced at regular intervals by fabricated diaphragms, to reduce the strut length of the rear tubes which are subject to a compressive load. Each of these tubes was left open at each end to permit the entry of water, thus maintaining adequate shielding for the operating personnel.
The fabricated lower machine structure is also fabricated from stainless steel, suitably stiffened with welded ribs. To reduce the weight of the machine support, each of the heavy side plates are, in fact, formed from two light plates some 25 mm apart, joined on all edges by a bridging closure plate. To provide an amount of positive buoyancy and reduce the wall reactions, no water is allowed to enter the enclosed hollow side plates.
The shear / compactor machine locates in the tapered vertical slots and the overhung machine weight is reacted through the adjustable stops provided on the inside of the side plates. Attached to the lower support structure is a perforated aluminum alloy tray fitted with a collector box

for the compacted tubes. The collector box can be removed when full and the tray can be hinged downwards when the space is required in the pond. The estimated weight of the support structure, in air, is 910 kg. The arrangement of machine, support structure and pond wall reactions are shown in Fig. 4. The wall reactions were all calculated for the 'in air' condition. The true reactions when the equipment is suspended in water will be reduced due to a degree of buoyancy inherent in the system.

Fig. 4

HYDRAULIC SYSTEM

To keep the size of the shear / compactor to an absolute minimum, a pressure of 210 kg.cm-2 is used to obtain an output from the hydraulic cylinder in excess of 1000 kN. The return stroke of the cylinder delivers in excess of 690 kN.

A normal oil pump is used to pressurize an actuating cylinder which is mechanically linked to a smaller diameter injection cylinder. The injection cylinder is filled on its suction stroke with demineralized water. On the injection cylinders pressure stroke, the shear / compactor machine cylinder is pressurized and moved a small distance. By continuing to inject demineralized water into the machine cylinder, the complete stroke is obtained by means of a series of small stepped movements.

By using this form of circuit, only the injection cylinder, machine cylinder, non return valves and vent valves are filled with demineralized water, thus reducing the stainless steel hydraulic equipment to a minimum.

OPERATING PROCEDURE

With the support structure clamped to the pond wall, the shear / compactor machine can be lowered into the water, with hydraulic system pipes connected, until the machine's horizontal bar locates into the tapered slots in the support structure. By continuing to lower the machine it will rotate about the bar until the machine is horizontal and supported in a cantilevered attitude. The crane hook should then be disengaged from the machine lug. Removing the machine from the pond is the reverse of the above procedure.

The recommended procedure for operating the machine is to undertake the horizontal cutting of the long tubes using the guide to produce lengths of around 900 mm, the resultant pieces being handled with the in-pond manipulator. It is accepted that a length of some 200 mm adjacent to the cut will be compacted but this will not affect the later operations.

With the bottom stop adjusted the 900 mm lengths are handled vertically into the machine until the tube rests on the stop. Operation of the hydraulic cylinder will result in a 200 mm compacted length falling from the cutting blade area, on to the inclined tray and then into the collector box fitted to the tray. This procedure to continue until the box is sufficiently loaded with compacted samples, when the crane hook can be used to remove and park the filled box elsewhere in the pond. A replacement box can be fitted and the operations continued.

MAINTENANCE

The only regular maintenance envisaged for the machine is the inspection and, if necessary, the changing of such items as the hydraulic seals, sliding bearings and the shear blades. Obviously, the life of these items will depend on usage and the period between changes will have to be determined by operational experience.

The equipment most frequently changed, however, will be the shear blades, although the development program indicated that something in excess of

200 cuts should be achieved before their efficiency is impaired. It was for that reason that the shear blade assemblies were made removable.

CONCLUSIONS

The main conclusion reached at the termination of this design/feasibility study was that a machine with a capability to produce 1000 kN of force, would produce a compacted product measuring 69 mm x 17 mm x 200 mm, with the machine suspended in water from a pond wall, with all operations able to be achieved remotely.

Although this shear / compactor machine was designed to handle tubes of 48 mm diameter, the stroke of the main cylinder and the distance between the tie bars is such that larger diameter tubes could be treated, if required. To undertake the larger tubes, however, it would have to be accepted that the wall thickness would need to be less. For example, it has been calculated that a tube of 190 mm diameter could be treated in the machine, providing the wall thickness did not exceed 1.8 mm. Different shear blades would be required for such an operation.

Other candidate materials which could be considered for treatment would be fuel assembly structures and tie bars, etc.

The machine was designed primarily for underwater operation, but as it could be demounted from it's support structure, it could be transferred to a 'hot cell' if necessary. It could, in that case, still employ the demineralized water hydraulics but would need a bench stand to position the machine at a height suitable for viewing through a cell window.

All of the very detailed development work, design and calculations produced for this exercise provided the authors with the confidence that the equipment should be built to become an essential tool for any cooling pond decommissioning project. Being a light structure throughout, the results of decommissioning this tool at the end of it's life would not add significantly to the overall cost of any dismantling program.

ACKNOWLEDGMENT

The authors would like to express their gratitude to Gradel S.A. of Luxembourg and Golder Associates (UK) Ltd, for their support and assistance in the preparation of this paper.

ABSTRACT

This paper presents a method for the rapid characterization of gamma-ray-emitting radioisotopes in large samples of earth-like materials: concrete shielding blocks in this case. Active regions are identified with a sensitive radiation-survey instrument and then examined in detail with a high-efficiency lead-shielded Ge spectrometer. Naturally-occurring gamma-ray emissions from the decays of uranium, thorium, and potassium are used to calibrate the spectrometer. A simple relationship exists between the observed counting rate in a characteristic gamma ray and the activity in the block. This method, taking only tens of minutes per sample at the

nano-Curie/gram sensitivity level, replaces much of the expensive coring and laboratory analysis methods needed otherwise.

INTRODUCTION

Following many years of productive work, the SuperHILAC and Bevalac accelerators at Lawrence Berkeley National Laboratory were closed, leaving thousands of concrete shielding blocks available for reuse or disposal. The process history of these blocks as shielding precludes free release pending radiological characterization.

For the first half of its nearly 40 year lifespan, the Bevalac accelerator ran beams of protons at energies as high at 6.2 GeV. (Subsequent heavy-ion beams contributed small amounts of additional activation.) Interactions of these primary-beam protons on targets and machine components generated secondary particles, predominantly neutrons with long mean-free-paths, that activated parts of the shielding. As detailed in Refs. 1 and 2, the dominant process by which accelerator shielding blocks are activated involves capture by thermal neutrons. The isotopes 46Sc, 59Fe, 60Co, 65Zn, 134Cs, 152Eu and 154Eu are produced this way. To a lesser extent, fast neutron activation accounts for the production of 22Na and 54Mn. As discussed in References 1 and 2, thermal-neutron activation may increase slightly with depth, reaching a maximum several cm into the concrete. Fast neutron-activation, on the other hand, is at a maximum at the surface. Activities fall off approximately exponentially after the maximum with a half-thickness on the order of 10 cm. The very few blocks at 0 to GeV beams could have very different distributions. Since most of the high-intensity light-ion runs at the Bevalac occurred prior to 1971, only the longest lived products remain, namely 60Co and 152Eu.

A large number of Bevalac shielding blocks have been examined with a 2.54 cm diameter x 2.54 cm thick NaI survey instrument and found to exhibit surface activities over a range from several mR/hr above background to over 1000 mR/hr above background. Subsequent to this survey, several examples of blocks were examined with a high-efficiency lead-shielded Ge spectrometer to identify and quantify the activity. This spectrometer can easily distinguish natural activity (U, Th, and 40K) from added activity (mainly 22Na, 60Co, and 152Eu). The natural activity may be used to calibrate the detector for the quantification of added activities. Following calibration, this technique makes most coring and laboratory analysis unnecessary.

THEORY

As shown in Fig. 1, the detector views a volume of the sample defined by the solid angle of the lead collimator and a depth determined by the gamma-ray attenuation in the sample. Each unit volume contributes gamma rays that may be detected in a lead-shielded detector located next to the slab. For an activity of Av Disintegrations/minute/unit volume, and a fraction (BR) of disintegrations that produce a particular characteristic gamma ray, Av x BR gamma rays at the energy E of the characteristic gamma ray are emitted per unit volume. The observed count rate in the detector in counts/minute (CPM) is:

Fig. 1

Eq. 1

where m(Z,E,r,ri) is the gamma-ray absorption in a thickness ri, (Z is the effective atomic number, E is the gamma-ray energy, and r is the density.) e(E,W) is the detector efficiency. (Dependent on gamma-ray energy E and detector solid angle W, and the sum extends over all

elements DVi. Note that e(E,W) depends on W, and not on the distance between the sample and the detector face.
Converting to disintegrations/gram: A r = Av
Eq. 2
where e is, essentially, the absorption- and efficiency-weighted mass of the sample examined and is determined by comparing the CPM observed with the activity determined by measuring the activity of a core sample in the laboratory.
The activity A is determined by:
Eq. 3
PROCEDURES
Part I: Determination of Intrinsic Activity by Laboratory Analysis
The intrinsic activity of the bulk concrete is determined by gamma-ray analysis of kg-sized samples obtained by drilling 2.5 cm diameter holes into the concrete. Typically 6 holes 15 cm deep were used to obtain enough material. The hammer-drill used pulverized the material into a fine powder which was collected in a plastic bag. The contents were transferred to a Marinelli beaker and counted for 1 day on a calibrated 30% p-type germanium spectrometer at the LBNL Low Background Facility. Concentrations of uranium, thorium, and potassium were determined for various samples of normal- and high-density concrete.
Part II: Detector Calibration
Prior to drilling, a lead-shielded 80% Ge spectrometer was used to measure activity in-situ at the same sites as the core samples were taken. (This procedure, shown in Fig. 2, will be described more fully in the next section.) The detector response e is determined by comparing the observed count-rate (CPM) from characteristic gamma-rays from U, Th, and K observed in-situ with the U, Th, and K activities (A) determined via laboratory analysis as described above.
Fig. 2
Eq. 4
Bevalac shielding blocks are made of two different kinds of concrete having different physical and radiological properties. Normal-density concrete, specific gravity 2.4, and high-density concrete, typically containing iron-ore aggregates of specific gravity 3.5 were used in different parts of the shielding. Normal-density concrete contains the natural decay products from U, Th, and 40K at levels 10 times higher than high-density concrete.
Part III: In-situ Measurements
The spectrometer used consisted of an ORTEC 80% p-type germanium detector mounted in a low-background cryostat and powered by an ORTEC Nomad system. The 8192 channel analog-to-digital converter and internal memory accumulated and stored data for read-out via an attached lap-top PC. Resolution was 1.9 keV @ 1333 keV. The spectrometer shielded with 5-10 cm of lead (5 cm in the early measurements and 10 cm in later measurements) and mounted on a cart as shown in Fig. 2. The cart is positioned next to the block for measurements. Note that the distance between the spectrometer and the block is not critical as long as the field of view from the detector sees only the sample.
Characteristic gamma rays from naturally-occurring radionuclides over the energy interval 238-2614 keV were used to generate detector response curves as shown in Fig. 3. The response to characteristic gamma-rays from added activities were determined by interpolation. The curve from Fig. 3 was used to generate a table relating the observed CPM in a

characteristic line to activity. This table was used to determine added activities.
Fig. 3
Most of our observations involved counting times on the order of 1 day, with the exception of background counts (with an additional 5-10 cm lead shielding over the front face of the detector) which lasted several days. With these counting times, we were able to measure activities <0.01 pCi/g for 60Co, <0.1 pCi/g 152Eu, and <0.2 pCi/g 22Na. For activities in the nCi/g range, counting times of only a few minutes are required. Figure 4 shows a spectrum from a sample containing 10 pCi/g of 60Co, adjusted to represent a 5 minute counting time.
Fig. 4
Part IV: Comparison with a Survey Meter
The naturally-occurring radioactivity in concrete can easily provide surface dose rates of several micro-R/hr above background, rates at which a survey meter with a 2.54 cm diameter x 2.54 cm thick NaI crystal can easily measure. Such a meter can be used to survey large areas in short times. For 60Co in high-density concrete, an empirical relationship between dose measured with the survey meter and activity was determined:
Dose rate (mR/hr) = 1.7 * Activity (pCi/g)
For example, 10 pCi/g of 60Co provides approximately 17 mR/hr reading on the survey instrument, an amount easily detectable above the several mR/hr background in the region where we did our measurements. Thus, release criteria of 10 pCi/g for 60Co, for example, can be determined reasonably well with a survey meter. Readings <10 mR/hr, uniform over the surfaces, are probably from naturally-occurring radionuclides alone. Readings above 20 mR/hr, particularly if they are not uniform over the surfaces, almost certainly indicate manmade isotopes. Criteria such as these, combined with judicious application of the detailed characterization described in Part III, can provide inexpensive and sufficient characterization of large samples, such as concrete blocks, for disposition.
CONCLUSIONS
The combination of survey-meter readings and the detailed characterization techniques described above, provide inexpensive and thorough characterization of concrete blocks for reuse or disposal. Following detector calibration, The characterization technique is simple enough that a technician can be trained to perform in-situ measurements in tens of minutes per sample, including analysis. On-the-spot decisions regarding the suitability of a sample for transportation or disposal can then be made. Spectra are retained as permanent records of the radioisotopes in the block.

ABSTRACT

A solvent extraction bench-scale treatability study was performed for the U.S. Department of Energy (DOE) Rocky Flats Environmental Technology Site (RFETS) in Golden, Colorado by Resources Conservation Company (IONICS RCC) and Harding Lawson Associates (HLA) using IONIC RCC's patented Basic Extraction Solvent Technology (B.E.S.T.) and additional process technologies for which patents are pending. The bench-scale treatability study was performed in two phases. Each phase was designed to address feasibility study data needs regarding the effectiveness of solvent extraction to remove radionuclides from RFETS soil and vegetation.

Two surficial soil samples and one vegetation sample were collected from three separate areas downgradient of the 903 pad in Operable Unit Number 2 (OU 2). Before treatment, soil sample #1, soil sample #2, and the vegetation sample contained the following plutonium concentrations: 740 picocuries per gram (pCi/g), 1200 pCi/g, and 640 pCi/g, respectively. During the time this treatability study was performed, cleanup levels were not yet established. Therefore, the effectiveness of this technology was primarily evaluated on the basis of the percent of total plutonium-239 and plutonium-240 removed from each soil and vegetation sample following treatment.

The most favorable results of the bench-scale study showed plutonium concentrations in soil sample#1, soil sample #2, and the vegetation sample were reduced to 83 pCi/g (89 percent removed), 102 pCi/g (92 percent removed), and 23 pCi/g (97 percent removed), respectively. The plutonium was concentrated in a residual solvent sidestream that was estimated to be a small fraction of the original contaminated soil and vegetation sample weight. The success of the bench-scale treatability study indicates that plutonium can be removed from RFETS soil and vegetation effectively. After cleanup goals for the radionuclides have been established, a pilot-scale study should be performed to refine the process parameters and costs for full-scale application.

INTRODUCTION

Facilities at Rocky Flats Environmental Technology Site (RFETS) had two main historical missions during the period of operations from 1952 until 1990: producing triggers for nuclear weapons and processing retired weapons for plutonium recovery. The past manufacturing activities have resulted in the contamination of soil and vegetation with radionuclides (i.e., plutonium and uranium), organic compounds, and metals. The samples collected for this specific treatability study were contaminated primarily with uranium and plutonium, and included two soil samples and one vegetation sample from three separate locations downgradient of the 903 pad area.

The 903 pad is located on the south eastern side. This pad was established in 1958 to store plutonium-contaminated oil and uranium-contaminated oil drums outside. The pad covers an area of 113 meters by 120 meters. Deterioration of drums and contamination of soil in the 903

pad area was reported in 1964. From 1967 to 1968 the drums stored at the 903 pad were transported to a building (Building 774) onsite for processing. However, during the years of 1967 through 1968, high winds and heavy rainfall spread contamination to surrounding areas including a ditch near the 903 pad. From 1968 through 1969 installation of a concrete pad to cover the contaminated soil on the 903 pad was started and completed.

Under the Federal Facilities Agreement (1991) for the Rocky Flats Plant DOE has agreed to investigate and remediate contaminated soil at RFETS. Since 1991, an ongoing remedial investigation/feasibility study (RI/FS) has been conducted for the RFETS in an attempt to assess the nature and extent of contamination of all media. As part of the ongoing feasibility studies (FS) for remediation of soil and vegetation at the RFETS, solvent extraction was selected as a potential technology for further evaluation in the FS process. Harding Lawson Associates (HLA) and Resources Conservation Company (IONICS RCC) assisted the Department of Energy (DOE) in evaluating the feasibility of solvent extraction to remove radionuclides from RFETS soil and vegetation samples by performing a bench-scale treatability study. To fulfill the purpose of this treatability study, the following overall program objectives were established: 1) evaluate the effectiveness of solvent extraction on the basis of the percent of total plutonium 239 and plutonium 240 removed from each sample; 2) assess whether the technology could reduce uranium and plutonium concentrations to levels within the treatability study benchmarks (TSBs) range; and 3) identify the near optimum operating parameters including the number of extraction stages required to meet the TSB range. The target radionuclides identified for solvent extraction treatment for this study are presented in Table I with their associated TSBs based on residential hypothetical cancer risk.

Table I

OVERVIEW OF THE SOLVENT EXTRACTION PROCESSES

The specific solvent extraction processes selected for the RFETS bench-scale treatability study were the B.E.S.T. process developed and patented by IONICS RCC and a enhanced solvent extraction process for which patents are pending. The B.E.S.T. process can be used to extract organic contaminants from mixed wastes. The radionuclides can then be extracted using the enhanced solvent extraction process. Both of these solvent extraction processes are described separately in the following paragraphs.

The B.E.S.T. process exploits the unique solvent properties of triethylamine to remove water from soil or sludges and contaminants from both soil and water. In the B.E.S.T. process, triethylamine works to remediate soil or sludges in two basic steps. First, the triethylamine, through its inverse miscibility property (discussed below), effectively removes water from the soil or sludge. Secondly, after soil and sludge moisture is removed, the triethylamine can directly extract organic contaminants from soil particles.

Triethylamine exhibits an inverse miscibility property by being completely miscible with water at or below 60 degrees Fahrenheit (F); however, when heated above 60F, triethylamine and water are only partially miscible. The inverse miscibility property is used to remove water bound to contaminated soil particles by initially extracting contaminated soil with chilled (below 60F) triethylamine to form a homogeneous, single mixture of triethylamine/water/contaminant (primarily

organics). After soil moisture is removed, the efficiency of subsequent extractions, performed at warmer temperatures, is enhanced because the triethylamine is able to achieve complete contact with each component of the contaminated soil.

Before the extraction process is begun, feed material is screened to remove oversize material (i.e.,greater than 1/4-inch diameter at bench scale; greater than 2-inch diameter at full scale) and the pH adjusted to an alkaline condition (pH > 10.5). The feed is then mixed with triethylamine in an extraction vessel until equilibrium is reached, and the solids are removed from the solution phase by settling or, if necessary, by centrifugation. Multiple extraction stages may be required to achieve contaminant removal target levels.

The liquid fraction, a single-phase triethylamine/water/contaminant mixture, is heated to a temperature greater than 60F and two distinct phases from a heavier aqueous phase, and a lighter organic phase made up primarily of organic material and triethylamine. The phases are separated by decantation. The organic contaminant mixture/triethylamine phase contains contaminants initially present in the soil. The triethylamine is recovered from the organic contaminant mixture/triethylamine phase by evaporation, leaving a concentrated organic contaminant fraction. Recovered triethylamine is chilled and recycled for use in subsequent extractions.

The B.E.S.T. process produces water, a concentrated organic contaminant fraction, and treated solids. Ideally, the product water can be conveyed to a water treatment facility where it may require minimal treatment before discharge to the environment. The concentrated organic contaminant fraction, which contains contaminants originally in the influent soil, amounts to a very small fraction (i.e.,0.1 percent) of the influent contaminated soil weight. This fraction may require further treatment (i.e., incineration) if the contaminant levels in the feed soil are high. The treated solids fraction may be returned to the site and possibly revegetated or sent to a disposal facility.The enhanced solvent extraction process combines the pretreatment of contaminated soils or sludges with oxidizing and complexing agents,to remove contaminants (i.e.,metals and radionuclides) from the solid waste materials into the water phase. The contaminants can then be removed from the water phase by using the B.E.S.T. solvent extraction process to preferentially dehydrate the weak aqueous solution to concentrate and capture the contaminants by leaving the contaminants in a dense brine phase.

This paper presents the bench-scale solvent extraction program test design and the results of the bench-scale solvent extraction program performed for RFETS. The bench-scale solvent extraction program included three components: sample preparation, Phase I bench-scale tests, and Phase II bench-scale tests. Each of these components is discussed below.

BENCH-SCALE PROGRAM DESIGN

Sample Preparation

The two soil samples were prepared by screening, blending, and dividing each sample into separate test and analytical samples. The screening process involved using a standard Tyler sieve to remove material greater than 1/4 inch in diameter. The blending process involved splitting the screened sample into two portions, recombining the split sample, and mixing the recombined soil thoroughly. The blending process was performed a minimum of eight times. Following the blending, each separate soil sample was split into analytical and bench-scale test samples. Chemical

analyses of the analytical samples provided baseline chemical characterization data to evaluate the effectiveness of the blending process and plutonium removal efficiencies during bench-scale testing.
The "as received" vegetation sample consisted of two root balls and their accompanying stems and leaves. The stems and leaves were clipped with scissors and set aside. The root balls were rinsed with water to remove most of the soil adhering to the surface of the vegetation. Any floating material was skimmed off the water surface and set aside.
The remaining root balls, stems, leaves, and skimmed material were combined and then ground in a meat grinder. The resulting ground vegetation mixture was blended by hand using the split and recombine technique described above for the two soil samples. Following the blending step, analytical and bench-scale test samples were split. Chemical analysis of these vegetation analytical samples provided baseline chemical characterization data to evaluate the effectiveness of the blending process and to evaluate plutonium-239,240 removal efficiencies during bench-scale testing.

BENCH-SCALE TEST DESIGN

Bench-scale testing was performed in two phases. Each phase was designed to address feasibility study data needs regarding the effectiveness of solvent extraction to remove radionuclides from RFETS soil and vegetation. The bench-scale tests for Phase I consisted of screening tests and solvent extraction tests. The results of the screening tests were used to direct the approach in the Phase I solvent extraction tests. Phase II consisted of solvent extraction tests using the most effective combination of operating parameters identified during the Phase I solvent extraction testing.

Phase I Screening Test Design

Screening tests were performed to evaluate plutonium removal efficiency using several combinations of oxidizing, reducing, and complexing reagents as well as other potential solubilizing agents. Each screening test consisted of adding one or more reagents and conducting one extraction stage. Generally, an extraction stage consisted of adding reagent, mixing the sample with the reagent solution, separating liquids from solids (centrifugation), and recycling solids to the extraction vessel. Gross alpha screening was performed on the extract solution after each reagent addition to evaluate plutonium removal for each reagent or combination of reagents tested. Screening tests showing greater than approximately 20 percent plutonium removal were tested further using a maximum of six extraction stages. These subsequent extraction stages are referred to as solvent extraction tests. The specific technical approach used during the screening tests for soil sample#1 and soil sample#2, and the vegetation sample are described in the following paragraphs.
Fifteen screening tests were performed on soil sample#1 and eleven screening tests were performed on soil sample#2 during Phase I testing. A summary of the test parameters used in the soil sample#1 and soil sample#2 screening tests is provided in Table II. Generally, 100 grams of soil were used for each test. The reagents added to the soil for each test are presented in Table II. The addition of reagent resulted in a liquid-to-solid ratio ranging from 1:1 to 100:1 by weight. The liquid and soil mixture was then agitated for 30 to 60 minutes at temperatures ranging from 34 degrees Fahrenheit (F) to 190F. A small aliquot of extract solution was removed after each reagent addition for gross alpha screening. Screening tests showing greater than 20 percent gross alpha

removal were subject to additional extraction stages, up to a maximum of six extraction stages, with modifications to the screening test parameters. However, with the exception of soil sample#1, Test 1 was a control test and used five extraction stages.

Eight screening tests were performed on the vegetation sample during Phase I testing. A summary of the test parameters used in the screening tests is provided in Table II. Generally, the test parameters were similar to those described for soil samples #1 and 2. For example, 50 grams of vegetation were used per test, reagents listed in Table II were added to the vegetation resulting in a liquid-to-solid ratio of 8:1, the liquid and vegetation mixture was agitated for 30 to 90 minutes at temperatures ranging from 34F to 190F, and a small aliquot of extract solution was removed after each reagent addition for gross alpha screening. Screening tests showing greater than 20 percent gross alpha removal were subject to additional extraction stages with modifications to the screening test parameters.

Table II

Phase I Solvent Extraction Tests

Solvent extraction tests were performed following each soil and vegetation screening test showing greater than 20 percent gross alpha removal. Each solvent extraction test consisted of subsequent extraction stages following the screening test (the screening test being the first extraction stage of the solvent extraction test). Generally, each extraction stage consisted of adding reagent, mixing the sample with the reagent solution, separating liquids from solids (centrifugation), and recycling solids to the extraction vessel. After completion of all extraction stages, triethylamine was added to the separated reagent solution, contaminants were concentrated, and water and triethylamine were recycled. (Triethylamine was used to remove the water from the contaminant solution, allowing the water to be recycled without evaporation or other separation techniques.) A block diagram of the bench-scale test process is presented in Fig. 1.

Fig. 1

Four screening tests for soil sample#1 (Tests 1, 4, 10, and 15) and soil sample#2 (Tests A, B, C, D) were subject to subsequent extraction stages, with modifications to the screening test parameters, as shown in Table III. These subsequent extraction stages are referred to as solvent extraction tests. A step-by-step description of soil sample#1, Test 15 is given below to further clarify the extraction sequence used during Phase I sample testing.

Table III

A 100-gram portion of soil sample #1 was placed in a 1-liter extraction vessel. A solution of hydrogen peroxide, used as an oxidizing agent, was added to the extraction vessel to achieve a liquid-to-solids ratio of 8 to 1 by weight. The solution was agitated for 60 minutes at 150F. After stopping the agitation, the settling characteristics of solids were observed and it was concluded that centrifugation would be required. The solids were then separated from the extract by centrifugation. The extract solution was sampled and analyzed using a gross alpha screening technique to obtain an estimate of the extraction efficiency of the peroxide solution.

Citric acid, used as a complexing agent, was then added to the extraction vessel. The mixture was again agitated for 60 minutes at 160F. The solids were separated from the extract by centrifugation. The extract solution,

referred to as interstage extract solution, was analyzed using a gross alpha screening technique to obtain an estimate of the extraction efficiency of the peroxide/citric acid solution. This extract solution, free of suspended solids, was sampled and later analyzed for isotopic plutonium. The extracted solids, referred to as interstage solids, were sampled and later analyzed for isotopic plutonium.

The above extraction procedure was repeated three more times for Test 15, starting with the addition of hydrogen peroxide to the solids and liquid remaining in the extraction vessel, for a total of four extraction stages. The final treated solids and final extract solution were later analyzed for total uranium and isotopic plutonium. After the final extraction stage, a composite extract solution was formed by combining the extract solution from each extraction stage. Triethylamine was then added to the composite extract solution to concentrate the contaminants to a minimal volume. (Addition of triethylamine forms a two-phase system; a light phase containing triethylamine and water, and a heavy phase containing the contaminants and a small amount of water.) The heavy phase was then analyzed for isotopic plutonium.

Four solvent extraction tests (Screening Tests V-1, V-2, V-3, and V-7) were performed with modifications to the screening test parameters, as shown in Table III. The step-by-step procedure used for the vegetation sample was similar to that discussed for soil sample #1.

Phase II Solvent Extraction Tests

Phase II solvent extraction tests were performed using the most effective combination of oxidizing/reducing agents, complexing agents, triethylamine, extraction time, and extraction temperature identified during Phase I solvent extraction testing. The process operating parameters used in Phase II testing are presented in Table IV for soil sample #1, soil sample #2, and for the vegetation sample. The sample size and number of extraction stages were increased during Phase II testing as compared to Phase I testing (sample sizes were doubled during Phase II testing and 12 extraction stages were conducted during Phase II instead of the 3 or 4 stages used during Phase I testing). Generally, each extraction stage consisted of adding a reagent, mixing the sample with the reagent solution, separating liquids from solids (centrifugation), and recycling solids to the extraction vessel. After completion of all the extraction stages, triethylamine was added to the separated reagent solution, contaminants were concentrated, and water and triethylamine were recovered. (Triethylamine was used to remove the water from the contaminant solution, allowing the water to be recycled without evaporation or other separation techniques.) A block diagram of the solvent extraction bench-scale test process is presented in Fig. 1. Solvent extraction testing procedures used during Phase II for soil sample #1, soil sample #2, and the vegetation sample are described in further detail in the following paragraphs.

Table IV

Two solvent extraction tests were conducted during Phase II testing on soil sample #1 and soil sample#2. The test parameters used for each test are presented Table IV. A step-by-step description of one of the two tests for soil sample#1 is given below to further clarify the extraction sequence used during Phase II sample testing.

A 200-gram portion of soil sample #1 was placed in a 1-liter extraction vessel. A solution of hydrogen peroxide, used as an oxidizing agent, was added to the extraction vessel to achieve a liquid-to-solids ratio of 8

to 1 by weight. The solution was agitated and heated to 190F. Citric acid, used as a complexing agent, was then added to the extraction vessel. The mixture was agitated for 60 minutes at 190F. After stopping the agitation, solids settling characteristics were observed and it was concluded that centrifugation would be required. The solids were then separated from the extract solution by centrifugation. This extract solution, free of suspended solids, was analyzed for isotopic plutonium and total uranium.

The above extraction procedure was repeated 11 more times, starting with the addition of hydrogen peroxide to the solids and liquid remaining in the extraction vessel, for a total of 12 extraction stages. The final treated solids were analyzed for total uranium and isotopic plutonium. After the final extraction stage, two composite extract solutions were formed by combining the extract solutions from extraction stages 1 through 6 and the extract solutions from extraction stages 7 through 12. An aliquot of each of these two composite samples was analyzed for isotopic plutonium and total uranium. These two composite extracts were then combined to form a single extract solution composite. Triethylamine was then added to the extract solution composite to concentrate the contaminants to a minimal volume. (Addition of triethylamine forms a light phase containing triethylamine and water, and a heavy phase containing the contaminants and a small amount of water.) The heavy phase, produced by adding triethylamine to the composite extract solution, was then analyzed for isotopic plutonium and total uranium. The water recovered from the extract solution was sampled and later analyzed for isotopic plutonium and total uranium.

One solvent extraction test was performed on the vegetation sample using the test parameters shown in Table IV. The step-by-step procedure used for the vegetation sample was similar to that for soil sample #1.

RESULTS AND DISCUSSION OF THE BENCH-SCALE SOLVENT EXTRACTION PROGRAM

The Phase I and Phase II bench-scale tests produced both process and analytical results. Process test results for each soil and vegetation sample included approximate values for extraction temperature, extraction time, solids settling and centrifugation characteristics, oxidation/reduction agent addition, complexing agent addition, feed to reagent (i.e., oxidation/reduction and complexing agent) ratios, and solvent to reagent ratios. Phase I screening test showing greater than 20 percent plutonium removed were tested further using a maximum of six extraction stages and some modification to process parameters. The additional testing performed on these screening test samples were called the Phase I solvent extraction tests. These analytical and process parameter results from the Phase I bench-scale solvent extraction testing were then used to identify the process parameters to be used during Phase II testing. In addition, the analytical results provided data for mass balance calculations. Results from the three components of the bench-scale testing (sample preparation, screening tests, and solvent extraction tests) are summarized in the following paragraphs for soil sample#1, soil sample#2, and the vegetation sample.

Sample Preparation Results

Following the sample screening, blending, and splitting, the chemical characterization analytical samples were submitted to the laboratory for chemical analysis to provide data to evaluate the effectiveness of the blending process. The results of the plutonium characterization analyses for each sample are presented in Table V, which presents the analytical

results for both the Phase I and Phase II feed samples. The variations in the vegetation and soil feed concentrations may be attributed to analytical variance and the inherent heterogeneity of the sample matrix. A statistical evaluation of the chemical characterization analytical results was performed and the results are presented in Table V.

Table V

Phase I Solvent Extraction Tests

The process data collected during Phase I bench-scale testing of soil sample #1 are summarized as follows:

The extraction temperatures varied from 34F to 190F.

The extraction times varied from 30 minutes to approximately 14 hours.

Solids settling times of up to 30 minutes were tested and centrifugation was required.

The oxidation/reduction and complexing agents tested are presented in Table VI.

The ratio of feed to reagent (i.e., oxidation/reduction and complexing agents), expressed on a weight-to-weight basis, varied from 1:1 to 1:100.

The ratio of solvent to reagent, expressed on a weight-to-weight basis, varied from pure solvent to a ratio 19:1.

Table VI

Table VII

The results of plutonium 239,240 and total uranium analyses conducted on soil sample#1 and soil sample#2 feed, interstage (i.e.,first extraction, second extraction, etc.), and final treated solids from Phase I solvent extraction tests are presented in Table II. The analytical results show that in Tests 10 and 15, plutonium-239,240 was reduced from a mean feed concentration of 740 picocuries per gram (pCi/g) to 86 pCi/g and 95 pCi/g, respectively, in the final treated solids. The analytical results for soil sample #2 indicate that in Tests A and C, plutonium-239,240 was reduced from a mean feed concentration of 1200 pCi/g to 170 pCi/g and 180 pCi/g, respectively, in the final treated solids.

The process data collected during Phase I bench-scale testing of the RFETS vegetation sample are summarized as follows:

The extraction temperatures varied from 34F to 190F.

The extraction times varied from 30 to 90 minutes.

Solids settling times of up to 30 minutes were tested and centrifugation was required.

The oxidation/reduction and complexing agents tested are presented in Table VI.

The ratio of feed to reagent (i.e., oxidation/reduction and complexing agents), expressed on a weight-to-weight basis, was 1:8.

The ratio of solvent to reagent, expressed on a weight-to-weight basis, was 5:1.

The results of plutonium-239,240 and total uranium analyses conducted on feed, interstage (i.e.,first extraction, second extraction, etc.), and final treated solids from Phase I solvent extraction vegetation testing are presented in Table II. The analytical results show that in Test V-2, plutonium-239,240 was reduced from a mean feed concentration of 640 pCi/g to 87 pCi/g in the final treated solids. Because the vegetation samples could not be ground to a small uniform particle size, the observed variability in the interstage solid results may reflect heterogeneities between the small sample aliquots used.

SUMMARY OF RESULTS AND CONCLUSIONS

Results of the solvent extraction treatability study using the enhanced solvent extraction process indicate that significant removal of plutonium-239,240 from RFETS soil and vegetation samples was achieved. The most favorable Phase II test results indicate plutonium concentrations in soil sample#1, soil sample#2, and the vegetation sample were reduced to 83 pCi/g (89 percent removed), 102 pCi/g (92 percent removed), and 23 pCi/g (97 percent removed), respectively. Additionally, Phase II test results indicate plutonium was concentrated in a residual solvent sidestream that was estimated to be a small fraction of the original contaminated soil and vegetation sample weight. After cleanup goals for the radionuclides have been established, a pilot-scale study is recommended to refine the process parameters and costs for full-scale application.

EVALUATING A REAL-TIME BERYLLIUM MONITOR AND THE IMPLICATIONS FOR ITS USE

K. L. Creek

M. A. Vigil
Los Alamos National Laboratory
Los Alamos, NM 87544

ABSTRACT

This study shows that a laser-induced breakdown spectroscopy (LIBS) monitor is effective at identifying peak times of worker exposure to beryllium and enables the industrial hygienist to better evaluate peak exposure levels of airborne beryllium.

Los Alamos National Laboratory (LANL, Laboratory), a US Department of Energy laboratory managed under contract to the University of California, has developed an instantaneous read-out instrument, which is based on laser-induced breakdown spectroscopy (LIBS) and indicates the airborne concentration of beryllium. The principal investigators (PIs, investigators) tested the instrument during operations at LANL's Beryllium Operation Facility. To evaluate the real-time instrument, we compared and contrasted data from current industrial hygiene monitoring methods to the instantaneous data from LIBS.

The investigators took short duration side-by-side personal samples by attaching the LIBS monitor onto one lapel of a worker's personal protective clothing and a standard personal industrial hygiene sampling train onto the other. Each sample collected by the LIBS monitor covered a 30-second interval. The computer then summed all intervals and also stored the data electronically for further study. The sum of all the 30-second intervals indicates the steps of the beryllium operation that are associated with peak personal exposures, providing an "exposure profile." Using the relative peaks and lows of real-time data, the investigators correlated work practices and control measures. In addition, we used the LIBS device to identify "hot spots" or potential areas of increased exposure. Our assessment of procedures at the Beryllium Operation Facility verified that instantaneous read-out equipment facilitates exposure assessments and control. n sulfide, carbon monoxide, cyanide, mercury vapor, and a few other substances. Their use is generally limited to intermittent evaluations to determine if respiratory protection should be used and when to initiate personal monitoring. Colorimetric tubes are also used for screening, but not generally used to determine an exposure profile, because it is difficult to take sufficient samples and the time lag in between samples ranges from one minute to 20 minutes.

This study shows that a laser-induced breakdown spectroscopy (LIBS) monitor is effective at identifying peak times of worker exposure to beryllium and enables the industrial hygienist to better evaluate peak exposure levels of airborne beryllium.

Beryllium is a highly toxic chemical with an occupational exposure limit (OEL) of 2g/m3 during an eight-hour workday (1,2). OELs also exist for the 30-minute ceiling of 5g/m3 and the instantaneous peak limit of 25g/m3. The proposed pathogenesis of chronic beryllium disease (CBD) is that certain individuals can develop a cell-mediated immune response to beryllium that has been associated with the development of a pulmonary granulomatous reaction. One CBD case revealed that a facility relied unduly on averaged beryllium concentrations and disregarded the significance of peak exposures that were hidden in the mean exposure figures. Excessive exposures that last hours, days, or weeks may cause CBD; peak exposures must be taken into account (3).

Established industrial hygiene sampling technology cannot measure instantaneous peak or ceiling OELS for many air contaminants, such as metals. If real-time instrumentation is unavailable, costly generation of a large number of samples is necessary to determine peak exposure times. Beryllium sample analyses range from $25 to $100 per sample. Large numbers of samples limit an in-house laboratory's availability to provide

analytical support for industrial hygiene evaluation of other processes. Even if a large number of standard industrial hygiene samples were taken, it remains difficult to determine what part of a facility's operation is creating the different exposure levels. The standard sampling method only provides average concentrations over the sampling period; therefore, one can make only an estimate of the actual time of highest exposure.

BACKGROUND

LANL scientists developed the LIBs monitor (see Fig. 1) in the early 80s (4). LIBS can rapidly detect airborne or surface particles. In the LIBS method, powerful laser pulses are focused to generate microplasma. Material in the plasma is vaporized and reduced to its elemental constituents, which are electronically excited. The LIBS monitor can identify the unique spectral signatures of atoms by spectrally resolving and recording the energy radiated as the excited atoms drop to lower or ground-state energy levels.

Fig. 1

METHOD

Investigators used a portable LIBS monitor equipped with a focused high-powered Q-switched neodymium:yttrium-aluminum garnet (Nd:YAG) laser. The laser beam induces a dielectric breakdown of air in the sample stream and forms a plasma spark. Beryllium particles in the region of the spark are vaporized and the beryllium is excited. A fiber-optic cable focused on the sample port collects the light emitted with excitation decay. The light is directed to the entrance slit of a small spectrograph tuned to the most intense beryllium (II) line of 313.1nm. In this study, a photomultiplier tube detected the beryllium emission and an analog-to-digital processor located inside a computer integrated the signal and digitized the resulting voltage. The resulting signals were stored in the computer's memory. The laser has a repetition rate of 10 hertz with a sample interval of 30 seconds.5 The laser spark volume was 0.03 cm3 and the output energy was 100mJ/pulse. The computer controlled all instrument operations.

A plastic shipping container completely contained the instrument to reduce potential contamination. Figure 2 shows a photograph of the LIBS monitor and the spray chamber. The computer was kept in an area of low contamination and attached to the monitor with a 30-foot cable. A 0.95-cm-diameter hose approximately 10-feet long, which had a flow rate of 10.7 Lpm, was attached to the LIBS monitor. The computer displayed two real-time histograms: a "shot" histogram for the 30-second intervals and an "average" histogram of the accumulated sums of the 30-second interval intensities. All histograms are stored electronically for future study.

Fig. 2

PIs studied the beryllium powder-spray operation by conducting seven sampling events. We collected side-by-side samples using both the LIBS monitor and standard industrial hygiene technique. For most of the sampling events, the LIBS monitor was inside the beryllium-limited access area, with the computer located outside in the air-lock room. Work inside this area requires full personal protective equipment that includes respiratory protection.

We conducted separate sampling events that took place during various operations: cleaning the spray chamber, spraying parts, and conducting equipment repair and troubleshooting. In Fig. 2, one can see the spray chamber (behind the LIBS monitor), a vessel approximately four-feet in depth by three-feet in diameter. The chamber is closed during spray

operations and filled with an inert gas. The chamber must be opened for workers to retrieve the sprayed part, clean the inside, or repair the equipment.

The investigators collected industrial hygiene samples using pre- and post-calibrated pumps operating at approximately 3.5 Lpm. We analyzed samples using inductively coupled plasma according to the National Institute for Occupational Safety and Health 7300 method (6). From the seven sampling events, the PIs could use eight air sample results to correlate with the LIBS monitor's response.

RESULTS

Of the seven sampling events, only four generated standard industrial hygiene samples. During two runs, the LIBS instrument had unreliable responses that were possibly due to either overheating from the laser enclosure or radio frequency interference from the plasma spray operation. Results from another run, submitted to an analytical laboratory accredited by the American Industrial Hygiene Association, did not provide valid results as evidence of a blind quality control sample.

For the first sampling event, the principal investigators (PIs, investigators) attempted to correlate area industrial hygiene samples with the LIBS monitor response. The sample location we selected held the highest potential for airborne beryllium. However, the LIBS monitor was not responding at the location of the area sampled; therefore, we conducted personal samples.

We obtained exposure profiles for sample operations using the "average" histogram and field notes. Two types of data are available for an exposure profile. The instrument logs the sum of intensities and the sum of the number of "shots" with response-above-background for the 30-second intervals. The latter is used for most figures in this paper to display the exposure profile data. Figure 3 shows a sampling event conducted when a worker was cleaning the inside of the spray chamber. The investigators did not collect all of the personal exposure because the LIBS monitor was sampling areas for the initial part of the sampling event. From this data, we found clear evidence that the spraying of vacuumed parts with a cleaning agent and wiping them creates airborne beryllium. We concluded this cleaning method should be avoided and replaced by either spraying a towel with the cleaning agent or using a wet sponge.

Fig. 3

Figure 4 shows a sampling event that occurred when workers were troubleshooting and repairing equipment. From the exposure profile, one may easily learn what parts of the operation create the highest airborne concentrations: airborne beryllium levels were relatively high for opening the chamber, working deep inside the chamber, removing the plasma spray torch, and wiping the surface of parts. Airborne beryllium levels were relatively low for repairing the equipment, vacuuming inside the chamber, and installing parts inside the chamber. The data show clearly that engineering controls do not capture all particles when workers initially open the chamber, parts must be vacuumed prior to their manipulation, and a vacuum attachment should be used to reduce the amount of time or eliminate working inside the chamber.

Fig. 4

Another sampling event showed that the workers themselves were generating airborne beryllium when they moved about in beryllium-contaminated clothing. Consequently, this study resulted in a changed work practice; workers now change their visibly contaminated clothing.

Airborne beryllium concentrations and sample times for the industrial hygiene samples range from 5.7 g/m3 to 105 g/m3 and 11 minutes to 62 minutes respectively. Figure 5 shows one sampling run in which standard industrial hygiene sample results were imposed on exposure profiles from the LIBS monitor. From this study, we observe correlation of LIBS response and standard industrial hygiene sampling does not result in a straight-line. Many factors could have contributed to the differences: concentration variability from one lapel to another; overheating of equipment; particle size effects; and the 2g upper particle size limit for total vaporization of the sample (7).

Fig. 5

CONCLUSION

The value of this study is that it proves the LIBS instrument detects airborne beryllium in the workplace. The instrument identifies operations of higher exposure potential associated with higher concentration levels. Use of the LIBS monitor demonstrates that some established, accepted work practices produce unexpected exposure situations. Conventional industrial hygiene sampling methods would not have shown the level of detail necessary to determine when exposures occur. Because of the data collected by this real-time instrument, the investigators identified work practices producing emissions which were than easily modified, therefore reducing potential worker exposure to a highly toxic chemical.

Regardless of the contaminant, most exposures in a non-manufacturing production line setting occur during short intervals. Personal experience shows that while screening tests may show higher airborne concentrations, a full-shift sample generally does not approach the OEL. Therefore, one could deduce that most of the exposure comes from higher short-term, intermittent levels that are not adequately evaluated by an eight-hour sample.

In general, there has been limited use of real-time monitors to create exposure profiles of work operations. Limited use could be due to the lack of available contaminant-specific equipment, difficulty in storing or logging results, time commitments, or undue reliance on averaged standard industrial hygiene sampling methods. However, this study makes it clear that even though an instrument may not be fully quantitative, real-time monitors can still be a very valuable tool. The industrial hygiene community should increase its use of real-time monitors in conjunction with personal sampling to obtain better evaluations of peak levels.

THE CHEMICAL EXPOSURE ASSESSMENT PROGRAM AT LOS ALAMOS NATIONAL LABORATORY: A RISK BASED APPROACH

Dale J. Stephenson
Los Alamos National Laboratory
ESH-5, MS K494
Los Alamos, NM 87545
(505)665-4784
dalej@lanl.gov

ABSTRACT

The University of California Contract and DOE Order 5480.10 require that Los Alamos National Laboratory (LANL) perform health hazard assessments/inventories of all employee workplaces. In response, LANL has developed the Chemical Exposure Assessment Program. This program provides a systematic risk-based approach to anticipation, recognition, evaluation and control of chemical workplace exposures. Program implementation focuses resources on employee exposures with the highest risks for causing adverse health effects. Implementation guidance includes procedures for basic characterization, qualitative risk assessment, quantitative validation, and recommendations and reevaluations. Each component of the program is described. It is shown how a systematic method of assessment improves documentation, retrieval, and use of generated exposure information.

INTRODUCTION

The Los Alamos National Laboratory (LANL) Chemical Exposure Assessment (CEA) Program provides a systematic, risk-based approach to the anticipation, recognition, evaluation, and control of chemical workplace exposures. The program's purpose is to ensure that employees are not adversely affected from exposure to chemical stressors in the workplace. Primary functions of the program are the qualitative assignment of risk and the quantitative validation of potential chemical workplace exposures. Because workplace exposures cannot be totally eliminated, this program strives to control hazards to an acceptable level and be an effective primary prevention tool against occupational injuries and illnesses.

DEFINITIONS

Exposure Group (EG) A group consisting of an employee(s), job assignment(s)/task(s), and chemical stressor(s), such that exposure monitoring of one individual within the group is representative for all individuals within the same group.

Exposure Rating (ER) A numerical value between 0 and 4 that represents the qualitative employee exposure risk to a chemical stressor. The exposure rating is based on the level of hazard control, the frequency and duration chemical use, and the ability of a chemical to become airborne.

Health Effects Rating(HR) A numerical value between 0 and 4 that represents the severity of a chemical's health effect and/or its toxicity.

TWA Time-Weighted Average: The time-weighted average exposure concentration for a normal 8-hour workday and a 40-hour workweek, to which nearly all workers may be repeatedly exposed, day after day without adverse health effects.

STEL Short-Term Exposure Limit: A 15-minute TWA exposure which should not be exceeded at any time during a workday.

Ceiling Value An exposure concentration which should not be exceeded during any part of the working exposure.

PROGRAM IMPLEMENTATION

The components of the LANL CEA Program (described in the ensuing subsections) follow the AIHA strategy for occupational exposure assessment (1). Figure I graphically illustrates the relationship of each component.

Fig. 1

Basic Characterization

The first component in the LANL CEA process is basic characterization of the workplace, work force, and occupational chemical stressors. Workplace characterization highlights operations, activities, and areas with potential chemical exposure pathways. It provides information on process flow and process chemistry. Information is gathered on routine operating conditions (e.g., temperature, pressure, concentration), types of process equipment, types of process controls, and potential exposure considerations. Work force characterization involves gathering employee demographic information for an understanding of how employees interact with operations, processes, or tasks. Chemical stressors are characterized so that the industrial hygienist has sufficient information on frequency, duration, personal protective equipment, and controls to make informed qualitative decisions on exposure risk.

The outcome of Basic Characterization is a complete demographic inventory of employees, their job assignments/tasks, the chemical stressors that they are exposed to, and a description of the processes that they perform. Exposure Groups (EGs) are formed using the information gathered during basic characterization.

Qualitative Risk Assessment (QRA)

QRA is performed on each chemical stressor. The purpose of QRA is to identify the degree of exposure risk posed by each chemical within an EG. The element of the QRA process are the Health Effects Rating, Frequency of Use Rating, Level of Control Rating, Dispersion Rating, and Exposure Rating (2). It is important to note that decisions regarding the degree of exposure risk and its application to the CEA Program are often subjective and professional judgement by competent industrial hygienists is mandatory.

Health Effects Rating

All chemicals are given a Health Effects Rating (HR). The HR is a numerical value ranging from zero (low) to four (very high). The HR is used to define the toxicity or potency of target organ response to

hazardous material exposure, using criteria developed at LANL (3). The HR provides a first cut evaluation of the degree of risk for an adverse health effect upon exposure to a chemical stressor. The objective is that if a chemical has a low risk of conveying an adverse health effect then less scrutiny is placed on it. Thus, chemicals carrying an HR of 0 (zero) or 1 are documented and automatically assigned an Exposure Rating of 0 (zero). An exception to this occurs when professional judgement dictates that factors not adequately reflected in the HR (e.g. dose, oxygen deficiency, flammability, reproductive or mutagenic properties) produce an adverse exposure scenario. In this instance, chemical stressors remain in the QRA process for further exposure risk evaluation. Chemical stressors carrying an HR of 2, 3, or 4 automatically continue in the QRA process.

Frequency of Use Rating

The Frequency of Use Rating reflects the degree of workplace chemical use. Duration and other chemical use factors are taken into account and used with professional judgement to assign the appropriate Frequency of Use Rating. Table I is used to assign Frequency of Use Ratings. Chemical stressors assigned a Frequency of Use Rating of 2 or less are assumed to carry a reduced risk for an adverse exposure. This qualitative assignment is documented and the chemical stressor is given an Exposure Rating of zero. Again, professional judgement must be used to determine whether an adverse exposure could occur, even at low Frequency of Use Ratings. If so, the chemical remains in the QRA process for additional exposure evaluation. All chemical stressors carrying a Frequency of Use Rating greater than 2 continue in the QRA process.

Table I

Level of Control Rating

The extent an exposure is prevented or reduced through the use of engineering controls, work practices, or personal protective equipment is evaluated with the Level of Control Rating. As shown in Table II administrative controls and personal protective equipment are not assumed to be adequate substitutes for engineering controls. Even so, professional judgement is used to adjust the Level of Control Rating when administrative and/or personal protective equipment is effectively used in association with engineering controls. All chemicals carrying a Level of Control Rating equal to 1 are documented and are given an Exposure Rating of zero. Those chemicals having a Level of Control Rating greater than 1 continue in the QRA process.

Table II

Dispersion Rating

The Dispersion Rating reflects the ability of a chemical to become airborne and available to the inhalation pathway in the work environment. Table III defines the criteria used to assign the Dispersion Rating for each chemical. All chemical stressors making it to this step in the QRA process are assigned a Dispersion Rating and are applied to the ER Matrix discussed below.

Table III

Exposure Rating (ER)

An ER is a numerical representation of the degree of exposure risk to a chemical stressor. An ER of 1 through 4 is assigned to those chemical stressors that have been applied to each step in the QRA process. The ER is determined by use of Eq. (1) and its application with the ER matrix shown in Table IV.

Eq. 1
Where:
F = Frequency of Use Rating
L = Level of Control Rating
D = Dispersion Rating
Table IV
VALIDATION
A required follow up to QRA is quantitative validation of assigned ERs. Elements of the validation process are described below.
Sampling
A sampling strategy is developed based on a chemical stressor's ER. Table V shows how the ER dictates the number of annual samples required for quantitative validation. Exposure scenarios in LANL's research and development environment do not always allow for classical sampling strategies. Thus, professional judgement must be used to determine a practical approach.
Table V
Monitoring
All monitoring is conducted in accordance with LANL policy and with NIOSH or OSHA sampling and analytical methods. When a NIOSH or OSHA sampling and analytical method is not available for a chemical stressor, a chemist in the analytical laboratory is consulted for an alternative collection strategy.
Interpretation and Decision Making (2)
This element of the validation process provides statistical insight into the significance of exposure measurements collected. For the purposes of this paper all exposure distributions are assumed to be lognormal.
Centering Value
A Centering value is used to measure the center of an exposure distribution. For lognormal exposure distributions the centering value used is the geometric mean.
Tolerance Level Value
The Tolerance Level Value is calculated to measure the variability in the exposure distribution. This statistical tool reflects the percent of the expected exposure values that are below a set level. For example, the 90% Tolerance Level Value is the exposure value at which 90% of the exposure opportunities are below. Thus, the calculated geometric 90% Tolerance Level Value is that exposure level at which 90% (i.e., 900 out of 1,000) exposure values are likely to be at or below.
Eq. 2
Where:
Tol90 = 90% Tolerance Level
GM = Geometric mean
GSD = Geometric standard deviation
1.28 = Number of standard deviation units corresponding with the 90th percentile of the distribution
Confidence Level
The Confidence Level is a measure of the distribution of exposure values around the Centering Value. A 95% two-tailed Confidence Level is determined using the calculated standard errors of the exposure distribution.
Eq. 3
Where:
GSD = Geometric standard deviation of the distribution of exposure

values;
n = Number of samples in the data set.
A 95% two-tailed Confidence Level is now calculated:
Eq. 4
Eq. 5
Using the statistical tools above, this discussion now answers the following question:
Q: What is the exposure level of an employee in an exposure group?
A: The Centering value provides an estimate of the most likely exposure level. The Tolerance Level Value and Confidence Level provide an estimate of how extreme the exposures can be.
Validation of ERs
Qualitative ERs can now be validated by application of the 90% tolerance limits to the appropriate exposure rating matrix shown in Tables VII & VIII. If an exposure rating is not validated then errors in the QRA process are investigated.
Table VI
Table VII
RECOMMENDATIONS AND REEVALUATION
Recommendations
LANL CEA Program recommendations are based on validation of a chemical's ER. An exception exists when an imminent hazard is identified during basic characterization. In this case, a recommendation for increased control measures is made immediately, prior to assignment and validation of an ER. In general, typical program recommendations identify the need to alter existing control methods and the level of effort required for chemical sampling and monitoring. In a broader usage of LANL CEA Program information, recommendations are made to aid in the performance of reproductive health hazard assessments, carcinogen use hazard assessments, personal protective equipment hazard assessments, and determinations for the need of employee medical surveillance.
Reevaluation
It is the intent of the LANL CEA Program to reevaluate Exposure Groups (EG) annually. This periodicity may be insufficient for some EGs and too frequent for others. Thus, there are three guidelines which are followed to determine the necessity of a reevaluation:

Awareness by a field industrial hygienist of a new EG or change in status or scope of an existing one.

The presence of a highly dynamic EG. The more dynamic the EG the greater the periodicity of an exposure assessment.

Three years have past without the performance of an exposure assessment.

LIMITATIONS
The LANL CEA Program is limited to evaluation of normal operating conditions. Off normal occurrences are more complex and beyond the scope of this paper. This program utilizes a single stressor model for exposure assessment. This means that an overall ER does is not calculated for simultaneous exposure to multiple chemicals. In the case of exposure to a mixture of chemicals having additive (similar toxicological effects) or independent effects the exposure is documented and a professional industrial hygienist determines an appropriate characterization strategy. Also, ERs applied to sensitized individuals may not adequately reflect their risk for an adverse response to a chemical exposure. During Basic Characterization, if a sensitizer is detected then the information is

documented and a professional industrial hygienist determines the appropriate action to take to minimize the exposure to an acceptable level.

CONCLUSION

The LANL CEA program shows that chemical exposure assessment can be performed in a systematic fashion. Using a risk based approach aids in prioritizing time and resources to areas where they are needed most. The validation component of the LANL CEA Program gives the industrial hygienist a template for determining the type and degree of exposure sampling required for a given EG. Through the use of computer automation CEA information can be rapidly shared among the many program stakeholders. Occupational medicine can use employee exposure information as a tool for primary prevention of injury and illnesses. Exposure Ratings can be used to justify the need for increased control measures to operational and line management. Regulators can be shown the risks of chemical exposure, where they are occurring, and what employees are receiving them.

It is this author's opinion that exposure assessment is not a new concept, but simply a systematic way to apply the fundamental principles of industrial hygiene. Too often, industrial hygiene programs are forced to operate in a reactive mode to satisfy the multitudinous needs of their customers. This hinders program consistency and makes retrieval and historical use of exposure assessment information elusive and difficult to decipher. A standardized approach, like the LANL CEA Program, addresses these problems and helps an industrial hygiene program proactively manage exposure assessment information.

ABSTRACT

Characterization is a critical step in the remediation of contaminated materials and facilities. Severe physical- and radiological-access restrictions made the task of characterizing the World War II-era underground radioactive storage tanks at the Oak Ridge National Laboratory (ORNL) particularly challenging. The innovative and inexpensive tank characterization system (TCS) developed to meet this

challenge at ORNL is worthy of consideration for use in similar remediation projects.

The TCS is a floating system that uses the existing water in the tank as a platform that supports instruments and samplers mounted on a floating boom. TCS operators feed the unit into an existing port of the tank to be characterized. Once inserted, the system's position is controlled by rotation and by insertion and withdrawal of the boom. The major components of the TCS system include the following:

- boom support system that consists of a boom support structure and a floating boom,
- video camera and lights,
- sludge grab sampler,
- wall chip sampler, and
- sonar depth finder.

This simple design allows access to all parts of a tank. Moreover, the use of off-the-shelf components keeps the system inexpensive and minimizes maintenance costs.

The TCS proved invaluable in negotiating the hazards of ORNL's Gunite and Associated Tanks, which typically contain a layer of radioactive sludge, have only one to three access ports that are usually only 12- or 24-in. in diameter, and range from 12 to 50 ft in diameter. This paper reviews both the successes and the difficulties encountered in using the TCS for treatability studies at ORNL and discusses the prospects for its wider application in remediation activities.

INTRODUCTION

As the contractor for the Oak Ridge National Laboratory's (ORNL's) Remedial Investigation/Feasibility Study (RI/FS), Bechtel is responsible for developing plans and procedures, conducting field investigations, and reporting characterization results. The 8,800 acres of the ORNL reservation have been divided into 20 Waste Area Groupings (WAGs) with approximately 250 known Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA)-contaminated sites and RCRA solid waste management units. In one of these WAGs, Bechtel developed and deployed a new robotic system to characterize underground radioactive waste storage tanks. These underground storage tanks were built in the 1940s of Gunite, a sprayed-on concrete frequently used for in-ground swimming pools. Detailed characterization of these tanks was required to provide information to an ongoing Treatability Study.

The tanks contain sludges and liquids. They have been used to collect, neutralize, store, and transfer radioactive and/or hazardous chemical wastes since the beginning of ORNL operations in 1943. A significant portion of the sludge in this tank farm was recovered during a sludge mobilization campaign in 1983. That sludge removal project was stopped before the tanks were completely cleaned; the present work is to characterize the remaining contents. These tanks are either 25 or 50 feet in diameter and have dome-shaped roofs up to 18 feet high. They are buried under approximately 6 feet of soil. There are between one and three available entry risers for each tank, with internal diameters of either 12 or 24 inches.

The needs of the ongoing Treatability Study program were as follows:

1. selectively retrieve samples of sludge and objects (from areas throughout the tanks) to determine waste properties for remediation system designs;

2. measure the depth of the sludge to refine volume estimates for waste management planning; and
3. videotape the inside of the tanks for waste management and remediation engineering planning.

To perform these studies, we designed and fabricated a number of unique tools and a deployment system to pass through 24-inch, and in some cases 12-inch, manholes and enter the tank. Seven Gunite tanks were characterized using the newly developed ORNL Tank Characterization System (TCS). The ORNL TCS uses simple principles and off-the-shelf technology to solve difficult problems. It includes four major subsystems: the floating boom and support system, the video camera and lights, samplers including a grab sampler and a concrete chip sampler, and a sonar depth finder. These systems aided in determining the locations, quantities, and compositions of materials in the tanks as the basis for remediation planning. With the TCS, we were able to inspect the tank above and below the water, map the sediments in the bottom of the tanks, take samples of the sediments or debris, and take small samples of the Gunite walls of the tanks. The TCS tools reach up to 50 feet horizontally away from the manhole.

FLOATING BOOM AND SUPPORT SYSTEM

This is the structural portion of the TCS and consists of a flexible floating boom and boom support (Fig. 1). It is used to transport tools and characterization instruments to any lateral location in the tank. The boom support is fabricated from aluminum and consists of a base, a "lazy Susan," and support channels that extend down into the tank through the riser. The boom support can be installed by two men in less than 30 minutes at the manhole. In our application, the base was simply clamped to the riser flange at the tank manway. The support channels can be lowered at least 25 feet into the manhole, and the "lazy Susan" can be rotated 360 degrees.

The floating boom is constructed from commercially available plastic chain. The chain is rigid laterally and is built to roll in only one direction. Foam is added for flotation, and the boom is deployed by sliding the chain down the support
channels to the water surface. By rotating and inserting or withdrawing the plastic boom, any part of the tank can be reached. By measuring the length of boom inserted and the angle of deployment, the operator can pinpoint the location of the tool at the end of the floating boom.

Fig. 1

VIDEO CAMERA SYSTEM

The TCS includes a custom-mounted video camera that can inspect either above or below the waterline. All camera system functions are controlled from a control box outside of the immediate work area. The camera system consists of the following sub-systems: camera with built-in pan-and-tilt, waterproof housing, and lights (Fig. 2).

The video camera is a standard resolution color camera with 8 times zoom, manual focus, 1 lux light rating, and auto iris. The pan-and-tilt unit is an integral part of the camera with 180 degrees pan and 180 degrees tilt envelope. This is an inexpensive off-the shelf unit that was modified for remote operation and placed in a specially fabricated waterproof housing. The waterproof housing was fabricated from PVC. It is designed to be rugged, lightweight, and able to float without the use of any additional flotation material. It houses the camera, pan and tilt unit, and an electrical connector for the camera control cable. The face of the

housing is a clear plastic dome that allows the camera to operate through its full pan-and-tilt range. The camera system can be removed for maintenance or adjustments by sliding the top cover out of the housing, The housing system also includes a pneumatic actuator that tilts the whole housing up to 90 degrees so that the camera's 180 degree tilt can cover floor-to-ceiling or front-to-back underwater.

The basic lighting system consists of a 50 watt quartz halogen light lamp. The bulb was placed inside the metal housing, which serves as a heat dispenser and allows it to operate both in and out of water. The unit is then placed in a waterproof PVC housing. The light is also designed to be self-floating. An electronic transformer in the control box is used to supply 12 volt AC to a dimmer that controls the brightness. Additional lights can be mounted on the floating boom or camera housing, and drop lights suspended from the boom to just a few inches above the sediments were also successfully tested.

Fig. 2

REMOTELY ACTIVATED SAMPLERS

The ORNL TCS includes two remotely activated samplers, a clamshell grappler for taking samples of bottom sediments and debris, and a concrete wall chip sampler. The clamshell grappler system is designed to retrieve sludge and debris samples and small objects from tanks with limited access. The grappler system consists of two sub-systems: grappler and winch.

The grappler is a double-jaw sampler operated pneumatically from a remote location (control box). It can be open or closed as often as required without the need for manual reset. Force at the jaws can be adjusted anywhere from 0-60 pounds on the current design, and more with minor modifications (Fig. 3). All parts are waterproof and fully submergible. The body is fabricated from PVC, which was selected for its light weight, low cost, and ease of cutting and machining.

The winch system is an electric driven winch floating on the water directly above the grappler. It will lower and raise the grappler to and from the bottom of the tank remotely. Deployment depth is determined by monitoring lowering and raising times, by an electronic pulse read at the control box, and/or by direct observation with a video camera. A worm drive gear reducer can stop and hold the grappler at any depth and at any distance from the winch system to facilitate the entry and exit from the tank manhole.

Fig. 3

The concrete wall chip sampler consists of a small pneumatic die grinder that is mounted on a float at the end of the floating boom. The grinder is maneuvered to the desired sample location and the bit is placed in contact with the wall. A small venturi is used to create suction and collect the grindings in a sample bottle. By grinding the wall, small samples of concrete are collected for radiological analysis. These data will be used to model dose rates and residual contamination levels.

SONAR SLUDGE MAPPER

An off-the-shelf sonar depth finder was mounted on the TCS floating boom to map the depth of sludge in the tanks. By varying the sensitivity of the sonar, the operator can distinguish the sludge surface (high sensitivity) and the concrete floor of the tank (low sensitivity). This technique allowed us to refine sludge volume estimates in any tank with at least 2 feet of water. Figure 4 shows examples of the sludge maps generated from TCS data.

Fig. 4

CONCLUSION

The ORNL TCS demonstrates that innovative use of off-the-shelf technology, combined with remote operations know-how, can solve difficult problems at low cost. This system was used to characterize seven highly radioactive underground storage tanks at ORNL. Data collected included sonar depth information, sediment samples, debris samples, concrete samples, and video observations. The TCS concept can be easily modified to accept a variety of samplers and sensors. For example, addition of radiation detectors would be a simple matter as would collection of liquid samples, if these data were required by a project. Data from the characterization campaign in now being used in planning and executing the treatability study that will lead to final remediation of these tanks. The floating boom concept is ideal for characterization of large underground tanks, aboveground tanks, waste basins, and ponds.

MEETING THE REGULATORY CHALLENGE WITH COST-EFFICIENT TRAINING

G. Lasswell
J.S. Thompson
Benchmark Environmental Corporation
Albuquerque, New Mexico 87110

ABSTRACT

Navigating the regulatory maze to identify and interpret mandatory training requirements is often a perplexing, frustrating experience. By necessity, training regulations indicate only general categories of information that should be covered in a training program, not how the information relates to a particular site or how it should be presented to employees. Training regulations are, by definition, performance-oriented because they are designed as guidelines for meeting specific safety, health, and environmental management needs. The regulations leave it to employers to figure out how to implement a program that will ensure that workers can perform their jobs in a manner that meets the statutory requirements.

Cost-efficient training is not simply training that is cheap to design and deliver. Cheap training that is ineffective will be costly over the long term. Cost-efficient training is a function of effective, valid training outcomes. Because the training regulations are performance-oriented, the training program must be performance-based to ensure that critical job-related knowledge and skills are acquired by the trainee. The key to the challenge of creating cost-efficient training that meets regulatory requirements is to wisely invest time at the front end of the process, i.e., thoroughly analyze job functions and assess the tasks that are performed. When trainers clearly understand the individual components of a job, they can more effectively design training to address critical job-related knowledge and skills and integrate meaningful information that meets regulatory mandates. Cost-efficient training accurately targets the employee population requiring each specific training course thereby optimizing training resources and minimizing employee down time. This paper focuses on the job analysis process that must take place before designing a training program. Job analysis is a crucial, and often underutilized, step in a systematic approach to training. Three methods for acquiring job analysis data are presented, and the advantages and disadvantages of each method are discussed. This paper also describes the

process for assessing the analytical data and emphasizes the importance of using automated data processing tools to optimize the analysis process by increasing data management efficiency.

PROBLEM

A number of unsatisfactory outcomes, ranging from mildly irritating to potentially disastrous, may result from training programs that are designed without the benefit of a thorough job analysis. Some of the most common outcomes resulting from inadequate or absent job analysis information include the following:

Training content does not reflect relevant job-related knowledge and skills; therefore, it is of limited effectiveness.

Trainee time is wasted or is minimally productive.

Training is not useful because it deals with knowledge or skills that the trainee does not need or has already acquired.

Training does not ensure competent job performance.

Inadequate training programs compromise worker health and safety or may result in adverse environmental impacts. Training staff and managers may be held liable for these consequences.

A training program that is designed without the benefit of a thorough job analysis is like a sailboat without a rudder. The rudderless boat may look majestic and proud when its sails are unfurled, but it will have no directional control. It may by sheer chance reach its intended destination, but the route is likely to be costly in terms of time and energy. More likely, it will simply drift and flounder at the whim of the winds and currents, never quite reaching its goal. Data from job analyses give a training program directional control and clarify the destination. After that, it is up to the training design and implementation to provide the most direct route to the destination, but when the way is in sight, the probability of success greatly increases.

SOLUTION

Using a systematic approach to training, managers can create a sound, defensible training program by documenting the links between job functions, training requirements, and available training. The process will also identify gaps in the training program and serve as a navigational aid to future program development.

Job analysis forms the foundation on which the remainder of the training program is built. Assessing the job analysis data establishes the boundaries for the design and development steps that follow, ensuring that training resources are targeted appropriately. Job analysis data helps managers prioritize their training decisions based on sound rationale and a hierarchy of needs, especially important when training resources are limited.

Fortunately, job analysts have a choice of strategies available to derive the necessary data. The method that is ultimately chosen is based on several considerations as described in the examples that follow.

Method 1Observation/Interview

This job analysis strategy, which is the most comprehensive of the three methods described in this paper, involves observations of workers performing assigned job duties and in-depth interviews with key personnel. This method is applicable when work processes, procedures, and workers' job functions are not adequately documented and validated.

Under ideal circumstances, the job analyst observes workers perform the full suite of functions within a given duty area. A duty area is a set of similar job functions. For example, a worker who has a duty area

assignment of "waste handling" may perform several related waste-handling functions, such as waste acceptance, transport, storage, treatment, and disposal. A set of discrete "tasks" describes subactivities within a given function. For example, the waste storage function may include tasks involving overpacking, bar coding, palletizing, and stacking drums.
Typically, a given duty area comprises job functions that are performed at variable intervals, i.e., some are performed frequently (on a daily basis), while others may be performed only as a result of an unusual and infrequent occurrence (e.g., a spill or other emergency). For this reason, it is not always feasible or practical for a job analyst to be able to observe the performance of every job function. In such instances, interviews with one or more persons knowledgeable about the task is necessary.
Whether the information is derived from personal observation or interview, the job analyst must be an astute observer, a probing questioner, attentive to detail, and a meticulous note taker. Video cameras and audio tape recorders are useful tools for documenting observations and interviews. Videotape of the function can be used later when developing training or writing procedures. Video can be especially useful in this era of computer-based, multimedia training delivery.
The job analyst uses the observation and interview material to draft detailed job function descriptions. The draft descriptions are reviewed for accuracy and completeness by the workers who were observed and other subject matter experts (SMEs). Final descriptions provide the basis for identifying task-specific individual qualification requirements and training plans.
Method 2Table Top Job Analysis
An innovative method called Table Top Job Analysis (TTJA) optimizes the use of SMEs to develop comprehensive task lists through a consensus decision process. In contrast to the method described above, which can take weeks to complete, a TTJA can elicit detailed job information in a matter of two to three days, even for complex jobs.
TTJA can be used in place of the observation/interview method. It is especially useful when a new or significantly modified operation is being initiated and when work processes are not adequately described in written procedures. The TTJA process pools the collective knowledge of several qualified SMEs. (Three to five SMEs is ideal; less than three reduces the synergy effect and more than five becomes unwieldy. An odd number is best to avoid tie votes.) A skilled facilitator is an essential ingredient in the success of the TTJA method.
In the TTJA method, a facilitator first guides the SMEs through a brainstorming session that results in identifying major functions that comprise a given duty area. The facilitator must be skilled at keeping the discussions focused at the appropriate level during this stage and at establishing positive group dynamics for the difficult decisions to come later. When the group agrees that all major duty areas and functions have been identified, the discussions shift to identifying and sequencing all tasks associated with performing each function. Depending on the complexity of the job, this can be an interesting process, as the SMEs must reach consensus on each item.
An assistant helps the facilitator document the decisions as they are made by entering the functions and task statements into a database. The lists can become the basis for writing procedures and developing training for each job function.

Method 3Documentation Review

This final job analysis method is the simplest and fastest of the three methods; however, it is only applicable when job descriptions, procedures, and work processes are adequately documented. Taking advantage of a variety of written documents, such as standard operating procedures, detailed operating procedures, special work permits, management plans, emergency plans, health and safety plans, and job descriptions, the job analyst examines the documentation, identifies the major job functions, and extracts task statements that represent each function. Data gathering can be enhanced through personal interviews and/or the use of questionnaires. The task statements are validated by job incumbents, supervisors, and other SMEs and become the basis for training decisions.

PROS AND CONS

There is no one perfect job analysis method. Given careful consideration of each situation, the job analyst can optimize the advantages by using the most appropriate method. Disadvantages can be minimized by acknowledging the limitations imposed by the method. It is important to use a sound, systematic approach, and each of the methods described yields information that meets this requirement. A table comparing the advantages and disadvantages of each method is displayed in Table I.

Table I

TASK RATING CRITERIA

As previously mentioned, effective job analysis uses a systematic approach. As we have seen, the first step in the process is to identify duty areas, functions, and related tasks for each function using one or more of the methods described above. The next step involves assessing each task against task criteria to answer the following questions:

- How difficult is the task?
- How important is the task?
- How frequently is the task performed?

Applying an objective approach to answer these questions results in train, no train, or overtrain decisions.

To optimize the rating process, each task must be described in the form of a simple task statement, e.g.,inspect waste drums, use forklift to move drums to staging area, overpack damaged drums, contain spills, record data on inspection checklist, etc. SMEs rate each task against specified task rating criteria. Figure 1 provides an example of typical rating criteria. It is necessary to ensure that each rater assesses each task against clearly identified criteria. When the rating process is completed, the analyst compiles the numerical averages of the responses and uses a decision matrix to make initial determinations of tasks selected for training. Figure 2 is an example of a decision matrix that is useful to aid in the rating process. Decision matrices are available in job analysis textbooks or other publications, or they can be customized to fit the specific facility and operations environment. The matrix depicted in Fig. 2 was adapted from the DOE Training Accreditation Program Performance-Based Training Manual (1). The task rating process results in recommendations to train, not to train, or overtrain as follows:

- TRAINProvide initial training (either classroom, self-paced, on-the-job, drills, simulations, job performance aids, or a combination).
- NO TRAINNo formal training is necessary; the task can be learned on the job or through required reading.

OVERTRAINProvide a combination of formal training plus periodic retraining at specified intervals.The initial training decisions are not unyielding. They are intended to be guides to making reasonable training decisions using an objective approach. Training decisions can, and should, be modified using the analyst's knowledge of the task or by applying regulatory requirements as intended and neededselectively, as appropriate for the facility and job functionusing a graded approach. Modifications to initial training decisions should be based on sound, logical rationale and the reasons should be documented and consistently applied to other similar situations.

Fig. 1

Fig. 2

DATA MANAGEMENT

Because the job analysis process typically generates a significant volume of information, it is advantageous to use automated data processing software to manage the data. Benchmark developed a customized relational database for this purpose. The Total Training Tool (T3) can be used to record duty area and task statements. T3 simplifies the task rating process by automating the calculations and the decision process. Training specialists identify mandated training requirements, assess existing training, and create the linkage to functions and tasks. Using T3, individual training plans and other customized reports can be quickly generated for facility managers, line supervisors, auditors, and inspectors. T3 is useful for generating reports sorted in a variety of ways, e.g., by worker, regulatory requirement, job function, task, or training course.

CONCLUSION

Training should not be conducted simply as a knee-jerk reaction of blind adherence to a regulatory requirement. Training requirements do not exist solely for the purpose of being complied with. Compliance should serve a purpose, i.e., it should address behaviors and attitudes and provide workers with the necessary skills and knowledge to perform their jobs safely, effectively, and in a manner complying with applicable regulations. Training should support this purpose by being appropriate for the workers, applicable to the operations, and instrumental in fostering improvements in the workplace.

Facilities that use the "blanket" approach to training may have a compliant program, i.e., everyone is covered, thereby ensuring compliance, but the program is unlikely to be cost-efficient. Cost-efficient training goes beyond compliance by integrating mandatory training requirements with performance-based job-related knowledge and skills and selective application of training to the appropriate audience. The key to successful, cost-efficient training is understanding the finer points of the work processes and worker behaviors. Gaining this understanding requires putting in the effort at the beginning to save time and energy along the way. Job analysis information provides the navigational map and clarifies the goal. Using an appropriate job analysis method, assessing the job analysis data, and following through with an approach that reduces the subjectivity in the training decision-making process will result in a defensible training program that will withstand the regulatory challenge and meet the needs of workers.

UNIVERSITY FACULTY AS A RESOURCE FOR STATE LEGISLATURES CONSIDERING NUCLEAR WASTE ISSUES

A.W. Fentiman
B.K. Hajek
K.M. Mancl
J.E. Heimlich
R.N. Christensen
The Ohio State University

ABSTRACT

In 1995 the Ohio General Assembly considered legislation that would enable Ohio to begin work on the siting, licensing, construction, and operation of a low-level radioactive waste disposal facility for the Midwest Compact. The legislation was signed into law on June 9. Prior to their vote on the enabling legislation, members of the General Assembly and their aides gathered information related to low-level waste. They frequently turned to a team at The Ohio State University that had produced educational materials designed to provide the citizens of Ohio and their elected officials with accurate, research-based, unbiased information on radiation and low-level waste. This paper outlines the types of educational materials developed and ways in which a State University was able to serve as a resource to the State Legislature as it prepared to deal with a technical, and somewhat unfamiliar, subject.

BACKGROUND

When Michigan's membership in the Midwest Interstate Low-Level Radioactive Waste Compact was revoked in the summer of 1991, and Ohio became the Compact's first host state, a team of faculty members at The Ohio State University (OSU) recognized that Ohio's citizens and their elected officials would eventually be discussing low-level radioactive waste. The team from the OSU Nuclear Engineering Program and OSU Extensiona anticipated the need for accurate, research-based, easy-to-understand materials on low-level waste. A proposal to prepare such materials was written, and funding was sought. In the spring of 1992, the Midwest Compact Commission agreed to fund the educational program.

MATERIALS DEVELOPMENT

A great deal of information on low-level radioactive waste has been prepared. Some of it has been written by groups with a specific point of view to express. Some is in technical sources such as textbooks, formal reports, and research journals. Materials written in an effort to persuade the reader to support a particular point of view can be inaccurate or incomplete. On the other hand, many of the technical books and journals, while accurate, are written for a small, technically-trained audience and are not widely distributed. These materials often fail to provide the information people want.

When citizens and their elected officials are discussing and making decisions on technical issues, they would like to have accurate, unbiased information that is easy to understand. A university is a logical source of such information. Faculty have access to the latest texts and research journals and the expertise to interpret them. In addition, faculty working in technical fields can team with professors having expertise in development of educational materials for the general public to produce easy-to-understand documents on highly technical topics.

Educational materials developed for the public on a technical topic should be made available in several formats. Each individual has a preferred method for receiving information. For example, some like to watch a video, while others prefer to listen to a presentation and ask questions, and still others want something they can read and study at their leisure. If the technical information is to be truly accessible to the non-technical audience, it must be presented in multiple formats that meet the audience's needs.

Under the Statewide Low-Level Radioactive Waste Education Program at Ohio State, materials development began with the writing of 27 fact sheets. Each fact sheet was only one or two pages long and addressed a single issue. The fact sheets fell into four general categories: 1) radiation science, 2) characteristics of low-level waste, 3) technology related to low-level waste, and 4) historical and legal topics. Information in these fact sheets was to become the basis for the development of educational materials in several other formats.

First, however, to ensure that each fact sheet was accurate, unbiased, as complete as possible, and easy to understand, an extensive review was conducted. A fact sheet written by a team of nuclear engineers and faculty with expertise in presenting technical information to the public was first reviewed by other people with technical expertise on the topic being addressed. After revisions were made based on comments by the technical experts, the fact sheet was sent to a 5-person review panel. This volunteer panel consisted of a physician working in nuclear medicine, a nuclear engineer with expertise in nuclear safety, an expert in science education, a representative of a national environmental group who specialized in nuclear energy, and a retired judge. The panel reviewed all fact sheets in an effort to ensure that they were technically accurate, easy to understand, and unbiased. Finally each fact sheet was sent to all "interested parties" for their comments. The "interested parties" included environmental groups in Ohio, generators of low-level waste, some legislators, journalists, educators, and anyone else who indicated that he or she would like to review the fact sheets.

After the fact sheets were completed, information in them was used to prepare several other types of educational materials. A set of four table-top exhibits was built for use in places such as mall shows, county fairs, and meetings of civic groups. Overhead transparencies were produced to be used at live presentations by team members, and a slide-tape program and a video were made using some of the same visual images. In addition, a large exhibit was built for use at the Ohio State Fair.

The educational materials were distributed both by the project team in Columbus and through the OSU Extension network which has an office in each county. Sets of fact sheets were delivered to County Commissioners, local health departments, hospitals, newspapers, libraries, high school teachers, college faculty members, civic organizations, and interested citizens. Approximately 13,500 sets of fact sheets were distributed. Exhibits were displayed at many meetings and community events. Dozens of presentations were made to local officials and interested groups. In addition, time was spent serving as a resource for the State Legislature. The remainder of this paper focuses on those activities.

RESOURCES FOR THE STATE LEGISLATURE

When the fact sheets were completed, about a year and a half before enabling legislation related to low-level waste was considered in the Ohio General Assembly, the Low-Level Radioactive Waste Education Project

Leader briefed members of the Ohio House and Senate and their aides on the fact sheets. A set of fact sheets was delivered to each legislator's office. They were intended not only for use by the legislators and their aides but also as reference material that legislators might copy and send to their constituents who were interested in the topic. Following elections, sets of fact sheets were sent to new legislators. Project Team members answered questions from legislators or their aides related to the fact sheets and provided additional sets to constituents when asked.

Approximately four months before the enabling legislation was introduced, the Project Leader presented a half-day seminar on fundamental concepts related to low-level waste to state agency personnel. A group of state agencies, including the Environmental Protection Agency, Department of Health, and Department of Natural Resources, asked that the seminar be held for people in their agencies who might be asked to field questions on low-level waste from state legislators. The seminar included information on radiation science, characteristics of low-level waste, technologies related to low-level waste (such as treatment, minimization, transportation, and disposal), and the history of low-level waste management in the United States. This seminar was designed to give agency personnel background information that could help them provide accurate and timely information to legislators.

Shortly after enabling legislation was introduced into the Ohio Senate, the Education Project Leader was asked to give a seminar for aides to the State Senators. The goal of the seminar was to provide the aides with basic information on radiation and low-level waste. The presentation focused on fundamental scientific concepts, sources, volumes, and characteristics of low-level waste, alternative technologies available for managing low-level waste, and additional sources of information that the aides might consult. The four table-top exhibits were set up at the seminar.

The Project Leader was also asked to testify at hearings on the low-level radioactive waste legislation held by the Senate Energy, Natural Resources and Environment Committee. Testimony at these hearings focused on the goals and organization of the Education Project. It seemed necessary to establish that a major effort had been made to have the educational materials reviewed by people with a wide range of views on low-level waste and to produce accurate, unbiased documents.

When the enabling legislation moved to the Ohio House, the Chairman of the House Committee on Energy and the Environment invited the Project Leader to be the first witness at the hearings on the bill. The Chairman specifically asked that the Project Leader not bring and read the usual written testimony but rather that she bring overhead transparencies and present a seminar. The goal of the presentation was to provide Committee members with an understanding of some of the basic concepts in radiation science, the nature and sources of low-level waste, and the technologies used to treat and dispose of that waste. Committee members were encouraged to ask questions, and several did. Copies of the overhead transparencies were provided to the Committee.

Two months later, the House Committee Chairman asked the Project Leader to return for another "seminar". Committee members had heard a great deal of testimony, some of which had prompted more questions about radiation science. In addition, Committee members had questions about how radioactive material moves through the environment and what factors should be considered when determining how hazardous a particular

radioactive isotope might be. The first part of testimony in the "seminar" format was a review of the material presented earlier. The second half focused on how radioactive material might escape from a disposal facility and how factors such as particle size, chemical form, solubility in water, and affinity for soil might affect how the material, once released, moves through the environment. Some Committee members also wanted clarification of the definitions of low-level and high-level radioactive waste.

As a vote on the enabling legislation neared, one Ohio Representative asked the Education Project Leader to present some fundamental concepts related to low-level waste at a town meeting in his district. Both proponents and opponents of the legislation spoke at the town meeting. The Education Project Leader's role was to speak first, providing background information and defining some of the terms that would be used in the ensuing discussion. She did not take part in the discussion other than to clarify definitions or to provide technical descriptions.

DISCUSSION AND CONCLUSIONS

From its inception, Ohio State University's Low-Level Waste Education Project was designed to provide accurate, research-based, unbiased information. It established that position with a project team made up of faculty with diverse backgrounds and by having all of its materials reviewed by dozens of people with widely varying views on low-level waste. The Project took no position on the low-level waste legislation. The Project Leader was, therefore, able to serve as a credible witness, one to whom legislators could turn for sound, fundamental technical information they required to make a decision.

States throughout the nation are struggling with the problems related to storage and disposal of radioactive waste, decontamination and decommissioning of nuclear facilities, and cleanup of contaminated sites. Legislators will have to make decisions on some of these matters, but nuclear science is not a topic familiar to most legislators. By anticipating the information needs of the legislators, preparing accurate, unbiased, easy-to-understand educational materials on those topics, and making themselves available to talk with legislators, their staffs, and their constituents, university faculty members with nuclear expertise can provide a valuable service to their states.

23-36

USING THE WORLD WIDE WEB TO IMPROVE K-12 SCIENCE TEACHING

Michael Robinson
Mark Rodrigues
University of Nevada
Department of Curriculum and Instruction
Reno, Nevada

ABSTRACT

The use of the World Wide Web (WWW) to improve science teaching and to provide more equitable access to science resources, including those that apply to nuclear energy and radioactive waste management, are addressed in this paper. For the past five years, the Yucca Mountain Office of the DOE has been supporting science education in Nevada through greater use of educational technology, most recently by supporting rural school connectivity to the WWW. This paper gives the details of how six rural Nevada schools are being connected to the Web. It further addresses how

they will take part in an international effort of the International Alliance in Education for Radioactive Waste Management to a) promote nuclear literacy and b) educate the public to be more receptive to the need for safe repositories to store radioactive nuclear waste.

INTRODUCTION

The improvement of science, mathematics and technology instruction in pre university level education continues to be an educational priority of government and business in the United States and other industrial countries in the world (1). In the belief that science and math education are tied to our economic well being and standard of living, the U. S. federal government has made it an educational priority and set goals for improving it. One educational goal of the Bush administration was to establish a coordinated government effort to improve science and mathematics education (2). The new national standards in mathematics and science and the proposed standards in technology are all aimed at improving education in what the federal government considers to be the essential areas needed to protect our technological advantage in the world economy (3).

Federal money continues to support two key areas in education. First, pre-service and in-service training for teachers of science and mathematics. Second, the development of better curriculum and instruction in science and mathematics. To support this second key area, the federal government has made networking and infrastructure development, particularly support of the Information Superhighway (the Internet) a priority. In 1991, the federal report America 2000, directed the secretary of education, in consultation with the president's science advisor and the Director of the National Science Foundation (NSF), to determine how electronic networks might provide American schools with ready access to the best information, research, instructional material and educational expertise (4).

By the spring of 1995 35% of American schools had access to the Internet but only three percent of instructional rooms (classrooms, labs, and media centers) were connected to the Internet (5). No data is currently available on what per cent of schools using the Internet have a graphical user interface (GUI) such as Mosaic or Netscape to give graphical retrieval ability from the World Wide Web (WWW). But, according to information compiled by mkgray@netgen.comnet.Genesis Corp. of Cambridge, Massachusetts, there are nearly 16,000 Web hosts in the world ranging from Armenia to Venezuela. [The World Wide Web is a special segment of the Internet that supports the transfer of documents containing text, graphics, sound and full motion video (6). The Web is further defined as a graphical representation of Internet resources based on the "hypertext" concept. In hypertext, the reader is not constrained to follow text in a linear fashion, but, can view randomly through resources on the WWW that include graphics, sound and video.]

This paper will address how the U. S. Department of Energy (DOE) is supporting the improvement of science instruction, through the use of educational technology. Specifically, it will discuss how WWW access is being developed in rural Nevada schools, and the potential that access to Web sites offers for improving science education in all schools.

RATIONALE

In line with two of the national goals of science educationa, the DOE, through the Yucca Mountain Project Office, already has a history of supporting the use of educational technology to improve science education

in Nevada, particularly in rural schools. Previous DOE help has included the donation of many personal computers, the purchase of modems, support for dedicated phone lines, and underwriting the training for teachers on how to use the Internet. One major justification of the DOE for this support has come from the need to try to equalize educational opportunities throughout the state. Research indicates that rural areas do not have the learning opportunities both in and outside the schools that are present in the large urban areas, e.g. Las Vegas and the smaller urban area of Reno (7). For many years, Canada and the U. S. have had telecommunications that carry educational programming to rural schools and other sites (8). The equipment required is generally quite expensive, especially when two way video is used at each site. The authors of this paper have suggested that the WWW might be a much less expensive way to provide instruction as well as make educational opportunities in science more equitable in rural schools.

From a science pedagogy point of view, further justification for the WWW is the support it offers to the Science Technology Society (STS) teaching method and the Constructivist Learning Model (CLM). The STS teaching method and the CLM are being promoted to improve science teaching in both Benchmarks of AAAS and the National Science Education Standards of the National Research Council. Currently the STS science teaching method and the CLM are thought to be the best ways of promoting science literacy in all students. Furthermore they can make science more relevant and interesting by helping students see the connections between science concepts and technology applications in society. In this paper, the STS teaching method is defined as the science teaching method and philosophy that believes science should be taught in the context of human experience and that science is a necessary part of the education of every citizen (9). From the perspective of the CLM, knowledge is a mental representation of the natural world and learning is a social process during which students use what is already known to make sense of new experiences (10).

Studies have shown that student performance in science and mathematics is enhanced by access to and experience with computers and various science equipment (11). The WWW offers the prospect for helping students experience a connection between their lives and the science that occurs outside the classroom. As science teachers try to make students see the connections of science to other disciplines, e. g., social studies, mathematics and foreign languages, the WWW can provide the information source. With the WWW, students have the possibility of interacting with a variety of resources inside and outside the U.S. that would not usually be available inside their classrooms. Moreover, the real life experience of collecting and sharing a variety of information on the WWW supports the STS teaching method and the CLM. Many science teachers and students already use networks such as Newton (where questions can be posed to working scientists in the DOE), NASA, the Weather Underground, Ask Eric (an education resource for teachers) and some of the environmental science networks, e. g. EcoNet, that address a number of common problems such as global warming and air pollution.

Unfortunately, only a small number of rural schools have the capability of accessing and downloading the color graphics found on the WWW. The possibilities for improving science instruction with the WWW are truly exciting. As a small example, think of a class studying and comparing various energy sources such as solar, nuclear, wind power and fossil

fuels. If that class had access to the WWW it could in fact access a computer in Sweden (http://www.ida.liu.se/~her/) and view a diagram of the Chernobyl, Soviet designed nuclear reactor. Think what an exciting learning experience this could be for a classroom in anisolated rural school and how much more relevant and interactive science would be to that class.

A MODEL FOR ESTABLISHING RURAL SCHOOL WWW ACCESS

Background

As mentioned earlier in the paper, the DOE has been active in helping Nevada schools gain more educational technology. DOE help for Nevada schools started four years ago with the donation of surplus computers and support for teacher training on how to use the Internet. The support for teacher training on the Internet has continued for the past four years. More recently funds were provided, in collaboration with the University of Nevada at Reno, for the purchase of a file server for the Nevada Schools Network (NSN), an Internet server which is now used by over 2,000 students and teachers throughout the state.

In the current project, the DOE Yucca Mountain Office has provided the money for some equipment, software and training to establish WWW capability in six rural Nevada schools. The number of sites is limited because of funds, hardware and connectivity pre requisites. Some requirements for rural school access to the Web include a computer with preferably at least eight megs of RAM, a Macintosh or a computer with Windows, a high speed modem and a local Internet access provider which in this case is the Great Basin Internet Service.

The establishment of WWW capability is part of a larger DOE grant that supports the International Alliance in Education in Radioactive Waste Management (IAERWM). The International Alliance has representatives from 12 of the OECD/NEA countries. All of these 12 OECD/NEAb countries have the need for an organization with links to public education and dedicated to: a) Finding ways of raising the level of nuclear literacy in the general public; and b) Educating the public to be more receptive to the need to site and build safe repositories to store radioactive waste. Acknowledgement that common educational strategies to address a) and b) above was first agreed upon in an educational workshop on radioactive waste management (RWM) held in Switzerland (12) and attended by educators from 12 of the OECD/NEA countries in 1991. The International Alliance of the 12 countries was formalized in the fall of 1991.

Since that time Alliance Conferences have been hosted by the UK, The Netherlands and Canada. Educational materials on RWM from participating countries were shared at each of the three conferences. One goal of the 1993 meeting in The Netherlands was to explore the use of the Internet for disseminating educational information on RWM. No Alliance meeting was held in 1994 but the 1995 meeting in Canada continued to explore the use of the Internet as a way of disseminating RWM information to schools. A four hour workshop dealt with the possibility of using the Internet and some of it's tools, e. g. gopher and the WWW, to establish nuclear education links between the Alliance countries. All participants of the conference agreed that having Web sites in their information agencies would be an ideal way to provide access to educational materials on nuclear energy and radioactive waste management. To carry this out it was suggested that each Alliance country; a) Establish a homepage and support access to it by students and teachers from a few schools; and b) List on

their homepage their educational resources on nuclear energy and RWM for teacher and student access and retrieval.

Nevada Web Sites

During the Fall of 1995 and continuing into the Spring of 1996 at least six sites with WWW graphical access will be established in rural Nevada with the monetary support of the DOE and technical support from the College of Education, University of Nevada in Reno.

The development of the school sites with web capability will be a cooperative effort which will involve each school's science teacher in an effort to establish specific education in science including nuclear energy and RWM. Additional curriculum materials will be available on the DOE Yucca Mountain Office web site (http://www.ymp.gov/). One author of this paper is responsible for part of the technical support, including teacher training and any help needed to establish a good platform for accessing the Web.

The Web development at the initial six rural school sites involved the consideration of several components; including specialized telecommunications lines, computer hardware, special 28.8 modems, and HTML editing software. The first phase of the development also involved discussion with the local telephone company for determining the best telecommunication line setup so that schools will not be hindered when graphically accessing the WWW. Initially the five of the six schools will have a regular dial-up remote connection at the 28.8 baud rate which is provided with a charge by Great Basin Internet Service. The goal is to move up to the faster speeds that are provided by ISDN lines. At this point only one of the six schools is scheduled for an ISDN line.

The second phase of the development is focusing on science education content and the process of developing the content into home pages. This phase will also include teacher training at each site so that each school can develop its unique educational interest in science education for the WWW. This second phase will also directly involve development of nuclear energy educational curricula by DOE at Yucca Mountain. At the end of the second phase, each school should have graphical access to the WWW with the knowledge of how to setup and manage a homepage. The six rural Nevada schools (Virginia City, Lovelock, Hawthorne, Battle Mountain, Silver Springs and McDermit) will also be helped to establish school partners in other OECD/NEA countries initially through AECL (http://www.aecl.ca) in Pinawa, Canada and OECD (http://www.nea.fr/) in Paris, France. Another site recently opened through British Nuclear Fuel in the UK and certainly other sites will continue to be developed.

As other nuclear information office homepages come on line with additional nuclear energy curriculum materials, Nevada students will make use of the information. At this point, the web server homepage (http:://nspweb.ed.unr.edu:443/) for the six schools is on line and located in the Department of Curriculum and Instruction of the University of Nevada, Reno. Many science links are already available on the homepage and more information is being added each week. Three rural schools are now using the WWW and the other three will soon be connected. Soon, training will be provided at each site to show the teachers how to use the Web for direct instruction and how to set up their own web page.

Evaluation

An attitude scale (see appendix) was designed to be taken by students prior to the establishment of WWW capability in their schools. So far, only three six in the three on-line schools have taken it. The other

three schools will take it as soon as they are connected. The attitude scale will not be repeated until after the Waste Management Symposium and that data will not be available until at least Spring after the students have had at least two months to use the Web. Control group classrooms, not on the Web, are also being used for comparison to classrooms with web capability.

The 15 item attitude scale is designed to measure the attitudes of the students toward science in general with a few specific questions on nuclear energy. It is broken into three, five question parts; feelings toward science, knowledge of science, and science behaviors. The independent variable is the new instructional strategy, use of the WWW. It is hypothesized that when students use the Web to access, retrieve and share information on science topics, e. g. nuclear energy, student attitudes toward the study of science in general and nuclear energy topics in particular will improve. The learning process provided by the Web as well as the additional science information available to students are both expected to be a positive influence on attitudes toward science learning, including nuclear energy. This information is important in Nevada, a state where there is a lot of negative feeling toward the possibility of Yucca Mountain becoming the U. S. nuclear waste repository.

CONCLUSION

Complete conclusions regarding the survey and any anecdotal information from teachers, students and principals can not be made until all six schools are on-line and have had a few months to use their WWW capability.

Some comments are offered concerning what changes in attitudes are expected as a result of the WWW use by students and teachers in the identified rural schools. It is generally expected that student attitudes toward science, including nuclear energy, will improve for several reasons; some of which are based on variables that cannot be realistically controlled in this kind of research. First, the teachers and schools were selected based on past interaction with them that indicated a greater probability for setting up successful WWW capability. The identified teachers already use computers and other contemporary technology in science instruction and they wanted to take part in a project that would give them WWW capability. They are teachers that have been identified as science teachers who are known to have characteristics that are attributed to exemplary science teachers (13). Such characteristics include making science interesting, using lots of materials and resources, showing a high interest in science, asking lots of questions, and letting students pursue ideas in which they have an interest. Furthermore, the principals of the schools generally have a record of supporting technology and helping their teachers gain access to better instructional tools.

It is hoped that the data from the six sites will help a) further the research on the use of educational technology to improve science teaching, b) improve student attitudes toward science and c) improve the knowledge base of students in nuclear energy and RWM. Unquestionably, the possibility for helping equalize education opportunities in rural schools by providing WWW capability is a worthwhile educational goal in its own right and should be pursued.

APPENDIX

Survey of attitudes toward science

More and more information is in the daily news to explain the importance of studying science in school. It is said that students need a better understanding of science in modern society because science impacts on so many everyday life issues that good citizens in a democratic society are expected to have a understanding of even if they are not scientists or engineers. It is also said that students who have taken more science courses are easier to train for jobs that require some understanding in science. For whatever the reason, science is becoming a basic requirement in the education of American students as well as students in other industrialized societies such as Germany and Japan.

In the following 15 questions, please circle your response using the scale of 1-5. The key for the numbers is a follows:

1. Strongly Agree
2. Agree
3. No Opinion
4. Disagree
5. Strongly Disagree

1. I like science because it is more interesting than other subjects.

1 2 3 4 5

2. I like science because it is useful in my everyday life.
1 2 3 4 5

3. I like science because it affects me personally.
1 2 3 4 5

4. I like science because I know it is important for my future.
1 2 3 4 5

5. I like science because it makes me curious about the things around me.
1 2 3 4 5

6. I like science because it helps me analyze whether people know what they are talking about when they state an opinion.
1 2 3 4 5

7. I like science because it helps explain things in life that I have questions about, e. g., photosynthesis, spontaneous combustion and radioactivity.
1 2 3 4 5

8. I like science because it helps me solve problems outside of school, e. g. how to predict changes in the weather.
1 2 3 4 5

9. I like science because it helps me identify and try to solve problems that affect the community; e. g.; water resources, air pollution or hazardous waste disposal.
1 2 3 4 5

10. I like science because it gives me the knowledge to make decisions about important science based issues, e. g. the nuclear waste repository in Nevada.
1 2 3 4 5

11. I like science because it teaches me how to design an experiment to test a hypothesis, e. g. to test my ideas.
1 2 3 4 5

12. I like science because it teaches me how to use the right resource to find information when I need it.
1 2 3 4 5

13. I like science classes because I don't just study ideas but I get to do things with interesting materials and resources.
1 2 3 4 5

14. I like science because I get to discuss and compare my ideas with other students.
1 2 3 4 5

15. I like science because I get to identify problems and try to solve them.
1 2 3 4 5

TURNING INSPECTION REGULATIONS INTO TRAINING TOOLS

Dixie Finley
Dean Wheatcraft
Lawrence Livermore National Laboratory*

ABSTRACT

In response to suggestions from internal and State of California auditors, the Hazardous Waste Management Division (HWM) at Lawrence Livermore National Laboratory prepared an Inspection Schedule and

Guidance Document that summarizes the Laboratory's inspection schedule and procedures for waste treatment, storage, and disposal facilities (TSDFs). Because it explains and comments in detail on the inspection schedule, forms, and procedures, this document is a centralized reference for HWM managers and personnel performing TSDF inspections at the Laboratory. It is also a training tool for experienced and new inspectors, standardizing the inspections of personnel with experience and explaining to novices what to look for and why. This poster presentation traces the team effort that created this document and provides specific examples of how the document was developed and how it is used.

THE REGULATORY FRAMEWORK

The environmental regulations governing the hazardous waste treatment, storage, and disposal facilities (TSDF) at Lawrence Livermore National Laboratory (LLNL) are basically the same as those governing any TSDF anywhere in the United States. Although our regulator and permitter is the California Department of Toxic Substances Control (DTSC), the regulations we must abide by are those of the U.S. Environmental Protection Agency (EPA) and the Resource Conservation and Recovery Act (RCRA). The EPA has given CDTSC authority over waste management operations at LLNL and throughout California because CDTSCs regulations are as stringent as or more stringent than EPA's and RCRA's.

So, what is true of waste management operations as a whole is therefore true of the inspections of the TSDFs at the Laboratory that keep them safe. At LLNL, waste management operations are the responsibility of the Hazardous Waste Management Division (HWM), a part of the Laboratory's Environmental Protection Department (EPD).

Both federal (40CFT264.15 - General Inspection Requirements) and State of California (22CCR666264.15 - General inspection Requirements) regulations require that an owner or operator of a hazardous waste management facility must inspect the facility for malfunctions and deterioration, operator errors, and discharges that may be causing or may lead to 1) release of hazardous waste constituents to the environment or 2) a threat to human health.

These regulations provide a general framework for inspections but rely on the owner or operator to provide the specifics in terms of what units are inspected and the format of that inspection. However, the regulator has approval and audit authority over all of the above, and ultimately, the inspection schedule and its particulars are subject to regulatory approval.

The owner or operator must develop and follow a written schedule for the inspection (i.e., an inspection log or checklist) of monitoring equipment, safety and emergency equipment, security devices, and operating and structural equipment (such as dikes and sump pumps) that are important to preventing, detecting, or responding to environmental or human health hazards. The inspection schedule must be kept at the facility and the schedule must identify the types of problems that are to be looked for during the inspection.

Specifically, the regulations require that aboveground portions of all tank systems be inspected once each operating day to detect corrosion or release of waste. Regulations covering tanks also include a schedule and procedure for inspecting overall controls. Data gathered from monitoring and leak detection equipment must be inspected to ensure that the tank system is being operated according to its design. The construction

materials and the area immediately surrounding the externally accessible portion of the tank system, including the secondary containment system, must be inspected daily to detect erosion or sign of releases of hazardous waste. The owner/operator must document all of these items on a daily basis.

Once each week (every 7 days), all container storage units must be inspected. During these inspections, the emphasis is on a wider range of issues (e.g., safety equipment, labeling, compatibility, etc.) as well as on leaks and spills.

Finally, other areas subject to spills but not always in continuous use must be inspected daily when-in-use. Examples are loading and unloading areas, container storage areas not in constant use, treatment and filtration units used intermittently, and staging areas used for temporary placement of waste during facility moves or prior to shipment.

IMPLEMENTATION OF THE REGULATIONS AT LLNL

The Hazardous Waste Management Division at LLNL has had an inspection program in compliance with federal and state regulations in place for many years. Over the years, the forms for the daily, weekly, and daily when-in-use inspections have evolved to cover the Laboratory's expanding and increasingly complex waste management and treatment needs, and the inspection process includes fairly complex corrective action and close-out procedures to make sure that health and safety issues revealed by the inspections are resolved.

Several years ago after an audit of the Laboratory's inspection schedule and process, State of California auditors requested that HWM prepare a guidance document that would summarize the Laboratory's TSDF inspection schedule and procedures and explain and comment on them as a centralized reference source for the HWM managers and personnel performing these inspections. In addition, our in-house quality assurance personnel came to a similar conclusion following an internal audit of the adequacy of HWM's inspections and the effectiveness of state/federal inspection program implementation. HWM therefore agreed to prepare and update annually an inspection schedule and guidance document. This document is not a procedure as defined at LLNL, but it has been formalized by the "controlled document" process and is readily available to all supervisors and inspection personnel. The inspection logs upon which this guidance document is based are included with the Laboratory's Part B Permit Application and its revisions and updates.

Document Development Team and Resources

The task of preparing and updating this Inspection Schedule and Guidance Document fell to HWM environmental scientists. The environmental scientist assigned the task formed a team that included an editor/writer and managers and supervisors of HWM storage yards and treatment facilities.

The environmental scientist and the editor/writer reviewed all of the existing inspection forms with the members of the team to determine the scope of each kind of inspectiondaily, weekly, and daily "when-in-use"and its general compliance with RCRA regulations. They also reviewed each individual inspection form with their contacts from HWM operations to learn the particulars of each feature of each storage area or treatment facility inspected. They accompanied inspectors on numerous daily and weekly inspections of all storage areas and treatment facilities to become knowledgeable first hand of what specifically was being inspected, how, and why. The goals of this long and sometimes arduous process were

first to learn the inspection forms and processes up close and then to reconcile, insofar as possible, differences in inspection forms and practices from one part of HWM's facilities to another as well as to standardize the forms accordingly based on the input and consent of those responsible for the inspections.

Then the environmental scientist and editor/writer set about making minor revisions in the forms and drafting the Inspection Schedule and Guidance Document. They chose an "Information Mapping"a format for the document because of its reader friendliness and organized the document around the basic types of inspectionsdaily, weekly, and daily "when-in-use," adding appendices for each type of form where samples of all the forms are collected as well as an appendix for the National Fire Protection Association (NFPA) 704 System signs and one explaining the various classes and types of fire extinguishers.

After an initial draft of the document was completed, it went through an extensive review process that included HWM management and supervisory personnel, a seasoned representative from the EPD's Operations and Regulatory Compliance Division (ORAD), and experienced HWM inspection personnel. The guidance provided by the document was revised repeatedly and extensively based on the input of these various reviewers before its ultimate review and approval by top HWM managers, publication, and distribution.

The Document Development Process

To provide a sense of how we developed the guidance provided by the Inspection Schedule and Guidance Document, we will focus on one part of one inspection form and the development of the guidance provided there. We have chosen the General Facility section of the Weekly Inspection Log for Area 514 Facility Storage Units. Figure 1 shows the entire Weekly Inspection Log for the Area 514 Facility Storage Units; Fig. 2 shows the General Facility Section of that log. We will concentrate on the part of the General Facility section dealing with emergency equipment, Question 10, and discuss how our research, team interaction, interviews, tours, and staff reviews led us to the guidance provided by the document.

Fig. 1

Fig. 2

Question 10 of the General Facility section of all weekly logs for all facility storage units is the same and asks for evaluation of the functionality and accessibility of fire extinguishers, showers, eyewashes, and telephones/paging system. According to our investigation of the inspection process, this part of the weekly inspection logs did not need to be revised, but it did need extensive clarification and explanation.

Fire Extinguishers. Through discussions with facility supervisors, HWM inspection personnel, and our ORAD contact, we discovered that all fire extinguishers in HWM's facilitiesand, indeed, at the entire Laboratoryare examined at least every 12 months by the Laboratory's Fire Department to ensure that they are charged and in proper, safe working order. This inspection is documented on an inspection tag attached to the extinguishers. Thus, one of the first jobs of an HWM facility inspector is to examine the inspection tag to see that the extinguisher has been inspected within the last 12 months. They then look at many of the same features of the extinguishers that are examined by Fire Department inspectors. For example, they must inspect the no-tamper seal attached to the pin that must be pulled to activate the extinguisher to see if the

seal is present and remains unbroken. They look at the pressure gauge to see that it is in the operating range. They also examine other salient features of the extinguisher, such as the hose and nozzle, for defects and wear. And they affirm that the extinguisher is unobstructed and visible, that the operating instructions on the nameplate are legible and facing outward, and that the unit is properly mounted off the ground or floor. Finally, the HWM inspector dates and initials the inspection tag. If, however, all is not well with a given extinguisher or extinguishers, the inspector notes this fact on the inspection form and follows the guidance in Section IV. Corrective Action and Close-Out to correct the problem(s).

As a supplement to the section on fire extinguishers, we included an appendix on the types of fire extinguishers available. We used the National Fire Code and a booklet entitled "Fire extinguishers: Your small fire NFPA Defense" to develop the appendix. The information is intended to serve as a quick reference for the technicians who attend specific training on this subject. We included the symbols for the classes of fires and types of extinguishers and other symbols that might be found on the extinguisher. These symbols include pictographs indicating what type of material the extinguisher is used for, e.g., trash, wood, liquids, grease, electrical equipment. Appendix E also explains the relative rating on Class A and Class B extinguishers. It also has an important reminder to the HWM inspector. In the event of a fire in the treatment and storage facilities, employees should call 911 immediately to report the fire. They should use a fire extinguisher to fight a fire ONLY if they are trained to do so and know, based on the training, that the extinguisher is appropriate to the kind of fire present.

Showers. All emergency showers and eye washes in HWM facilities are physically collocated, but because they have different purposes and function somewhat differently, they are covered separately in the guidance document so that the inspector will look at each piece of equipment in its own right. Both, however, must be accessible if they are to be used in an emergency. Therefore, one of the inspector's primary jobs is to make sure that the "Keep Clear" caution at the unit is being observed and that the unit is unobstructed and can be accessed quickly in an emergency.

From the experience of HWM personnel and that of our advisors in ORAD, we learned that other basic concerns with the showers are that the water 1) must be easily and quickly turned on, 2) must stay on by itself, and 3) should flow at a constant rate and sufficient pressure to do its cleansing work. We have provided guidance accordingly. In addition, we caution inspectors to capture the water generated by their tests in a large bucket stored near the shower so that the bermed area around the shower stays dry and the inspection tests do not, therefore, create a cleanup problem. Satisfied that the shower is working properly, the inspector initials and dates the tag attached to the shower. Again, if there are problems with a shower, the inspector notes the deficiencies on the inspection form and follows the guidance in Section IV of the guidance document to correct the problem.

Eye Wash(es). Basically, the inspection guidance concerns for the eye washes are the same as those for the showersflow initiation, rate, pressure. However, because the water from the eye washes is used to cleanse the eyes, it is important that the inspector also checks to see that it is free of rust by checking water clarity and color. Also, the

eyewashes have two nozzles, both of which should be operating at equal pressure and flow rate, and these nozzles are protected when the eye wash is not being used by caps. The water pressure should be sufficient to pop these caps off when flow is initiated; the caps need to be replaced after inspection and testing.

Telephone(s)/Paging System. Phones are found throughout our waste management facility. However, some of the phones are rarely used, so it is important to test them on a weekly basis to assure that they are working. The inspector tests the phone by calling the HWM operator. HWM's paging system is connected in the two largest of our facilities, the Facility 612 Area and the Facility 514 Area. To test them, the inspector calls the appropriate number listed in the guidance document. Again, the inspector reports his finding in the prescribed way on the inspection form and schedules remedial action if a deficiency is found as described in Section IV of the guidance document.

To illustrate the document development process and how it influenced the guidance provided, we have intentionally chosen a simple example with obvious health and safety implications. We should note, however, that the Hazardous Waste Management storage and treatment facilities inspected at Lawrence Livermore are numerous and include complex, sophisticated waste treatment equipment and storage areas containing many kinds of both hazardous and low-level radioactive waste. Yet the process used to develop guidance for this equipment and these storage areas was essentially the same as that used for the less complex emergency equipment discussed above. Through a variety of meansaccompanying inspectors on their rounds, discussions with facility personnel and managers, reviews by in-house experts, research of the regulationswe sought to get to the heart of the area or piece of equipment being inspected, to see what made for its safe operation within regulatory guidelines. Our goal was to provide the inspector with a clear sense of what to look for and why in order to assure a thorough and complete inspection. Such inspections are an important way of promoting the safe operation of equipment and storage of waste as well as the health and safety of those who use that equipment and maintain those storage facilities.

RESULTS

The Inspection Schedule and Guidance Document puts the inspection process in Lawrence Livermore's waste treatment and storage facilities into a comprehensive plan. Rather than a set of individual forms and a loose set of procedures for regulatory-driven inspections, we now have an organized approach to the complete inspection process that can serve as a refresher for experienced inspectors and a training tool for novices.

In one place, HWM inspectors and their managers can find:

The inspection logs.

A discussion of the rational behind and the regulatory basis for inspections.

A schedule of inspections.

A compendium of what facilities get inspected how frequently.

Procedures for documenting inspection findings, initiating repairs, and following up to ensure that a deficiency has been corrected.

And perhaps most important of all, what to look for in particular when doing an inspection of a specific area or piece of equipment.

The Information Mapping format of the document makes it easy to follow and use. And an annual update of the inspection Schedule and Guidance

Document ensures that the information about the inspection logs, the inspection process, and the equipment and facilities being inspected is kept current.

ABSTRACT

The U.S. Department of Energy (DOE) Uranium Mill Tailings Remedial Action (UMTRA) Project has, over the last three years, developed an Environmental, Safety, and Health (ESH) audit process that is continuing to demonstrate positive results. The audit process is a cooperative effort between DOE and DOE contractors, the Remedial Action Contractor (RAC), and the Technical Assistance Contractor (TAC).

The UMTRA audit process stresses site compliance with numerous code enforcement authorities using best management practices to design site safety and health procedures and site operating procedures that can be applied to all sites.

The audit process demonstrates proactive ESH programs that are reducing incident rates on the DOE UMTRA Project. The UMTRA ESH Audit Process paper discusses the cooperative audit process.

UMTRA ESH AUDIT PROCESS

The U.S. Department of Energy's (DOE) Uranium Mill Tailings Remedial Action (UMTRA) Project is an environmental restoration and protection program. The UMTRA Project's congressional mandated mission is to clean up and control residual radioactive materials from designated DOE-owned inactive uranium processing sites. Also, the UMTRA Project is required to eliminate present and future environmental health hazards that may result from those sites.

The DOE goal is to achieve its mission in a manner that protects the public and the environment; ensure safety and health of workers; meets or exceeds requirements of applicable federal, state, tribal, and local laws, regulations, permits; and uses "best management" practices.

The DOE policy is to conduct operations in compliance with both the letter and the spirit of applicable environment, safety, and health

statutes, regulations, and standards. The DOE strives for continuous improvement and excellence rather than just meeting minimum compliance requirements. Thus, the UMTRA Project is firmly committed to implementing the most technologically advanced environmental protection practices, while following proactive safety and health management policies and goals.

The UMTRA Project is committed to sound environmental management and worker safety practices; minimizing risks to the environment, the public, and workers; while anticipating and addressing potential problems before they pose a threat to workers, the environment, or the public.

The UMTRA Project is committed to employing "best management" practices to minimize generation of contaminants, wastes, and other residual materials requiring disposal or release to the environment through source reduction, recycling, treatment, and other pollution-prevention methods.

Protection of the environment, workers, and the public is of paramount importance to the UMTRA Project. Project administration has always recognized this, and as a result, the Project experiences a level of public trust not evident in many environmental restoration endeavors.

DOE's policy is that all contractors must incorporate this commitment to worker safety and environmental protection in all of their activities. The DOE requires its contractors to conduct their operations in an environmentally sound and safe manner that reduces risks to the environment, workers, and the public to as low as reasonably achievable (ALARA). The UMTRA Project actively oversees its contractors' activities to ensure compliance with this policy.

The DOE developed the UMTRA Project using a Remedial Action Contractor (RAC) to perform field restorations at 24 former uranium mill sites located mainly in the western United States. To assist DOE UMTRA Project management in administering environmental, safety and health (ESH)policies on the RAC-controlled sites, a Technical Assistance Contractor (TAC) was retained. The TAC provides technical expertise to DOE UMTRA Project management.

The UMTRA Project, RAC, and TAC management have developed an audit process to ensure ESH procedures implemented at UMTRA sites are adequate for worker, public, and environmental protection and comply with all applicable regulations.

Audits are scheduled to correspond with site construction schedules to place UMTRA, TAC, and RAC auditors at UMTRA sites during times of critical operations. Auditors provide additional assistance and resources to site ESH personnel. Programmatic and records review audits are conducted throughout the operating seasons. Audits are conducted a minimum of three times per construction season at each UMTRA site. Audits are conducted more frequently at sites experiencing elevated ESH incidents. Unannounced audits are conducted throughout the construction season at all sites.

Audit reports are DOE documents, prepared for the UMTRA ESH manager by the TAC audit group. Reports focus on key ESH aspects of the fundamental implementation of an adequate ESH program at the UMTRA sites. ESH procedures, training, implementation, operations or practices that are less than minimum code requirements are reported as Findings. Comments that will improve ESH programs are expressed as Observations and Recommendations. Findings must be acted upon immediately by site personnel while Observations and Recommendations may or may not be acted

upon by RAC ESH personnel. UMTRA ESH management may require the site to respond to Observations and Recommendations with an action plan.
RAC ESH groups that have developed innovative ESH procedures or operating procedures, called Noteworthy Practices, are recognized by comments in the audit report. The comments describe the practice and are sent to all sites for possible application.
The audit process begins when the UMTRA ESH manager hosts a monthly scheduling meeting with UMTRA, RAC, and TAC ESH personnel. A tentative schedule is developed for each UMTRA site for the anticipated construction season. Audit schedules are flexible so audits can be conducted at the most opportune time to cover as many construction aspects as possible. Also, audit schedules must remain flexible so circumstances of personnel, equipment, weather, and site operations can be considered. Cooperation between all participants makes the audits a very valuable tool in providing effective health and safety programs on the UMTRA Project.
The UMTRA ESH manager is responsible to notify the RAC ESH manager in writing of the actual date the announced audit will be conducted. Notification is required ten (10) working days prior to the site audit starting date.
Upon arrival at the site by all personnel necessary, the DOE UMTRA Project ESH Quality Assurance Implementation Plan is followed. The opening meeting is held, all necessary site orientation and training of auditors are completed, and then the audit is conducted.
DOE UMTRA PROJECT ESH QUALITY ASSURANCE IMPLEMENTATION PLAN
INTRODUCTION
Provide guidance for use during DOE auditing activities at the UMTRA site.
POLICY
Statement requires DOE and contractors to take all reasonable precautions in the performance of UMTRA Project work to protect the health and safety of workers, the public, and the environment.

Daily Close-out Meeting

Discussion of daily objective evidence
Site Close-out Meeting
Discussion of all objective evidence
Provide copy of all objective evidence
POST AUDIT ACTIVITIES
Initial Draft to DOE ESH manager 10 Days from site close-out meeting
Meet with DOE, RAC, and TAC to discuss Initial Draft Final Draft to DOE ESH manager 10 Days following draft discussion
RAC Corrective Actions Response to DOE ESH manager 10 days from receipt
DOE Review and Request Additional Responses or Close Audit
Post Final Audit Report at Contractor Site
AUDIT RESULTS REPORTING
Additional Site Conditions, Deficiencies, or Noteworthy Practices
AUDIT RECORDS
Complete Audit Files To Document Control
The UMTRA, RAC, and TAC auditors are escorted by the RAC site ESH management personnel and sub-tier contractor ESH representatives. All personnel travel together at the site(s) to observe the physical plant, operations, and personnel safety performance.
Whenever a question concerning health and safety of personnel, public, or property is raised, the site RAC ESH manager is made aware of the situation, and the information is recorded as "objective evidence." Objective evidence collected during the day is discussed with the UMTRA, RAC, RAC sub-tier contractors, and TAC representatives each day during the daily close-out meeting. Audit ESH checklists are used throughout the audit process.
Audit checklists have been developed from 29 CFR 1910 and 29 CFR 1926 for general health and safety codes, construction and demolition codes, and industrial hygiene issues. The use of checklists is for review by the auditors and are not specifically checked at each audited site.
Auditor on-site participation is completed upon conclusion of the final audit close-out meeting where all objective evidence is discussed with UMTRA, RAC, and TAC representatives. Objective evidence is compared to codes, regulations, and best management practices. Results obtained by reviewing the objective evidence is placed in the final audit report.
The UMTRA, RAC, and TAC auditors recognize that site work will be on-going during the audit, and attempts to minimize disruptions to site work are made. Site operational/ESH responsibilities come first and RAC and subcontractor site ESH personnel are to leave the auditors and manage their responsibilities to keep work activities safe.
The UMTRA, RAC, and TAC auditors follow the DOE UMTRA Project Audit Quality Assurance Implementation Plan and develop the site Health and Safety Audit Report.
HEALTH AND SAFETY AUDIT REPORT
INTRODUCTION
UMTRA site contractors, personnel, and personnel responsibilities.
BASIS FOR AUDIT
DOE, state, tribal, and local codes that influence operations at the site.
SITE OPERATIONS AND CONDITIONS
Current operations and conditions at the site.
DEFINITIONS
Objective Evidence
Findings

Observations
Recommendations
Noteworthy Practices
AUDIT SUMMARY
Audit team summary of audit, including specific objective evidence to support summary.
AUDIT RESULTS
Objective Evidence is discussed to demonstrate influence on operations and health and safety of workers, the public, and the environment. Findings are condition(s) as found, that violate specific codes. Observations and Recommendations are based upon auditor experience to improve operations. RAC response is not required unless UMTRA ESH manager requests.
LIST OF CONTRIBUTORS
All personnel conducting the audit, review, and technical investigations.
The ESH audit report format has been standardized for this project and is used for all sites.
The TAC auditors complete the final audit report and submit it to the UMTRA ESH manager for transmittal to the RAC. The TAC maintains records of all audits and subsequent correspondence for audit closure. This record provides valuable tracking of audit documents and is used to audit internal performance.
DOE UMTRA SITE AUDIT RECORD
  Site
  Date -- Doe Notification Letter To RAC
  Date -- Actual Audit Dates
  Date -- Draft Mailed to RAC for Review
  Date -- Draft Returned From RAC Review Date -- Final Draft Mailed to RAC
  Date -- RAC Response
  Date -- DOE Acceptance or Rejection of RAC Response
  Date -- DOE Audit Closure.
The audit process and documents currently developed for UMTRA audits have been in use for three audit seasons. The process is flexible in application but remains independent of biased influence and accurately reflects current ESH conditions at each site. The UMTRA, RAC, and TAC auditors must be flexible in approach to achieve the best possible ESH program for the UMTRA Project. Also, auditors must focus independently on the ESH issues and be determined to achieve quality ESH programs. Audits from each UMTRA site are shared with management at all other UMTRA sites. The audit process followed on UMTRA sites has produced positive results in program development, training, implementation, accountability, and has reduced the number of incidents and losses at UMTRA sites. RAC and TAC contractor records indicate incident rate at approximately 10-15% of the rate other contractors experience in similar industry categories.

DEVELOPMENT AND IMPLEMENTATION OF WASTE MINIMIZATION TRAINING AND AWARENESS MARKETING PROGRAMS AT DEPARTMENT OF ENERGY FIELD OFFICES
Terry A. Kuykendall
Parsons Engineering Science, Inc.
ABSTRACT
Waste Minimization and Pollution Prevention (WM/PP) programs are integral elements of waste management operations at Department of Energy (DOE)

field offices. One of the major challenges for these field offices is effective accomplishment of the activities required to develop, implement, and oversee training and awareness programs in support of a comprehensive WM/PP program.

WM/PP Training Programs involve the development of a Waste Minimization Program Training System and related courses for personnel involved in waste minimization programs, as well as for general site employees. The WM Program Training System will provide input for the updating of site-level general training courses to the latest WM/PP program requirements. The programs may consist of the following elements.

1) Development of a core Waste Minimization Training Program;
2) Updating the Waste Minimization Sections of site training courses such as Comprehensive Annual Training, General Employee Training, and Radiation Worker Training;
3) Evaluating and updating WM training modules for technical personnel such as design and operations engineers; and
4) Evaluating and updating training requirements and related training modules for Pollution Prevention Opportunity Assessments.

A properly implemented WM/PP Awareness and Marketing Program will support the development and implementation of efforts targeted to the DOE site office as well as for DOE prime contractors and subcontractors. This program may consist of the following elements:

1) Program planning -- This effort addresses development of a Pollution Prevention Awareness and Marketing Program Plan for implementation of a comprehensive pollution prevention education campaign.
2) Documentation of Accomplishments -- This involves documentation of WM-PP accomplishments and developing highlights in terms of reduced cost, site savings, and disposal avoidance.
3) Implementation of a "Green Building" Program -- This includes development and maintenance of a program to promote building-specific opportunities for WM/PP.

The proposed approach to WM/PP programs, development of modules for WM/PP training, and the targeting of these modules for specific audiences presents a specialized approach that may be of benefit to any personnel involved in WM/PP programs. An effective WM/PP training and awareness program may be implemented by targeted training and promotion of WM/PP concepts through an awareness campaign.

BACKGROUND AND OVERVIEW

WM/PP programs are becoming increasingly important elements of integrated environmental operations for industrial and federal facilities, and in particular at DOE field offices. At many sites, WM/PP operations have been instigated by organizations responsible for large-scale oversight programs such as waste management (WM), environmental restoration (ER), and decontamination and decommissioning (D&D). For these programs, WM/PP goals are accomplished by:

Administrative planning and controls to limit the generation of primary and secondary wastes, and to avoid creating uncontrolled releases;

Engineering considerations for systems, equipment, processes, and technologies to minimize the generation of wastes and to manage pollution and waste streams; and

Incorporation of operational concepts such as reuse, recycling, and free release to minimize the volumes of wastes and pollutants generated during site projects.

Due to the limited capacities of on-site waste treatment and pollution control facilities at many sites, the concepts of waste minimization and pollution prevention have become critical elements of continued operations and of cleanup efforts. The limited availability of adequate off-site waste treatment and disposal capacity and the protracted delays in permitting of planned disposal sites for wastes have contributed to the elevated emphasis on WM/PP programs.

Parsons Engineering Science (Parsons) has been active in providing support for the analysis of WM/PP opportunities and in the development and implementation of WM/PP programs. WM/PP programs have been designed to support the planned and future ER, WM, D&D efforts which are considered to be a major portion of the activities to be conducted at aging industrial and federal facilities. Since these programs and process have the potential to generate considerable amounts of radioactive, hazardous, and mixed waste products, the application of the concepts of WM/PP are paramount to effective and efficient environmental compliance and protection program management.

WM/PP PROGRAM OBJECTIVES

Most WM/PP programs have common bases, or objectives that necessitate the development and implementation of such programs. These bases must be integrated into the development of training and awareness programs. In most cases, WM/PP programs are designed to:

Foster a philosophy to conserve resources and create a minimum of waste and pollution in achieving environmental management objectives.

Promote the use of nonhazardous materials in ER, WM, D&D operations to the extent practicable in order to minimize the potential risks to human health and the environment;

Enhance employee awareness of pollution prevention goals, objectives, and methods;

Enhance communications of waste minimization objectives, goals, and ideas laterally and vertically among site/facility organizations;

Promote integration and coordination of waste generators and waste managers on waste minimization matters;

Create incentives for pollution prevention; and

Collect and exchange waste minimization information through technology transfer, outreach, and educational networks.

All of these elements must be included in comprehensive site-wide WM/PP programs, and emphasized as functional bases for training and awareness programs development.

Implementation of WM/PP policies and procedures is a function typically assigned to a specific site organization associated with waste management programs. This organization will oversee the publication of site-wide procedures that evolve from policy/program implementation. New procedures must be written, or existing procedures revised, to ensure that WM/PP goals and ideas are put into practice. Other means of communication such as presentations and articles in employee newsletters should be utilized to the extent practicable. Employees should be encouraged to attend seminars and to communicate with other sites on WM/PP practices.

REGULATORY BASIS FOR WM/PP PROGRAMS

Other than the advantages of voluntary establishment of WM/PP programs, there are regulatory 'drivers' and incentives that give emphasis to WM/PP program implementation. At the federal level, direction may be derived from specific sections of:

The Resource Conservation and Recovery Act (RCRA);

The Comprehensive Environmental Response. Compensation and Liability Act (CERLCA);

The Superfund Amendments and Reauthorization Act (SARA, of CERCLA), Title III, which includes the Emergency Planning and Community Right-To-Know Act, Sec. 313;

Executive Order 12856, Federal Compliance with Right-To-Know Laws and Pollution Prevention Requirements; and

The Pollution Prevention Act (PPA).

These laws are augmented by other EPA guidance that has been released in published format, such as "Waste Minimization Certification" (09/85), "Waste Minimization" (10/85), "Waste Minimization Requirements" (06/87), and "EPA Waste Minimization Program Activities." (06/87).

In typical applications, these rules and guidance are supplemented by program- or site-specific guidance. For example, the U.S. Department of Energy (DOE) derives guidance for WM/PP programs at DOE nuclear weapons production sites under several directives:

DOE Order 5400.1, General Environmental Protection Program

DOE Order 5400.3, Hazardous and Radioactive Mixed Waste Program

DOE Order 5820.2A, Radioactive Waste Management

DOE/S-0108, DOE Strategic Plan

In order to define, establish, and implement an effective WM/PP program, it is important to understand the directives under which this program must perform. When incorporated into the training and awareness program, these regulatory and statutory bases provide credence to WM/PP implementation.

TYPES OF WM/PP PROGRAMS

In most instances, an integrated program of WM/PP involves activities that take advantage of every opportunity for effectiveness. The types of WM/PP programs that may be developed, implemented, maintained and that must be addressed training include:

Source Reduction, which is the major priority in WM/PP programs; eliminates problems associated with waste handling; and includes concepts such as materials substitution, process optimization or modification, technology changes, and administrative changes (including inventory control and housekeeping practices such as waste segregation).

Recycle, Reuse, Reclamation, which is used for wastes that cannot be eliminated or minimized; allows potential waste materials or materials destined for disposal to be put to beneficial use; and includes resource recovery (use, reuse, reclamation).

Treatment of Wastes, which includes techniques to reduce the volume, toxicity, and/or mobility of waste streams and waste forms.

ELEMENTS OF WM/PP TRAINING

WM/PP training typically is performed by presentation of audio/visual material. The course presentation may be classroom, computer based, video, or self-study as deemed appropriate by the responsible organization. The course materials should be approved and entered into the site training database in order to ensure that the site program receives credit for accomplishments. Specific task elements required to establish a WM/PP training program may include:

Conduct of Job/Task Analysis;

Description of Course Terminal and Enabling Objectives;

Development of Lesson Plans;

Development of Study Guides;

Preparation of Training Support Material, including graphics, visual aids, computer-based training, case studies, and/or printed material for handouts, as appropriate;
Development of Test Plans;
Conduct of Examinations;
Issuance of Course Evaluation Forms; and
Documentation of Results.

Training activities for WM/PP are most effective when combined with other [existing] site-wide training programs. The goal is to make each employee and contractor aware of waste generation, its impact on the site and the environment, and means by which waste can be reduced and pollution prevented. The training program should include waste minimization concepts that can be incorporated into every job aspect, thereby ensuring that these concepts will be integrated into each phase of an operating procedure or design consideration.

PROGRAM PLANNING FOR WM/PP

WM/PP program planning involves the development of a Pollution Prevention Awareness and Marketing Program Plan for implementation of a comprehensive pollution prevention education campaign directed at both internal and external audiences. Key elements for an effective internal communications program will include developing information products that are customized for use within each DOE site employee communication framework, and providing liaison with the site organizations responsible for disseminating the information.

Key elements of the external communications program will include developing information products appropriate for external audiences, including other DOE sites, commercial industries and the general public, and coordinating with the site public affairs department in implementing offsite release of information.

Key elements of the external communications program will include developing information products appropriate for external audiences, including other DOE sites, commercial industries and the general public; providing liaison with offsite photographers/videographers or other documentary services during production of program elements; and coordinating with the appropriate DOE site public affairs department in implementing offsite release information.

DOCUMENTATION OF WM/PP ACCOMPLISHMENTS

In order to foster the culture of an effective, implemented WM/PP program, the awareness and training organization should document accomplishments and display this documentation in a manner that provides convenient employee access. The elements of this process may include: development and updating of a book (a living document with scheduled updates) to document WM/PP active programs and related accomplishments; gathering information on pollution prevention accomplishments by fiscal year; and developing text highlighting accomplishments in terms of reduced cost, site savings, and disposal avoidance.

IMPLEMENTATION OF A "GREEN BUILDING" PROGRAM

The "Green Building" concept has been popularized throughout the federal government, and has a high notoriety for involvement of personnel at the various levels of an organization. The idea is that a "Green Building" is a more environmentally friendly facility, providing some impetus for productive competition among corresponding units. This concept involves: initiating and promoting a "Green Building" waste minimization program that highlight building-specific opportunities for WM/PP; maintaining

open lines of communication with custodians of site buildings that have committed to the program of WM/PP; pursuing the "Green Building" program in non-participating buildings by developing education materials on recycling, eliminating waste streams, and the benefits of each; and encouraging site management support of the "Green Building" program by developing presentations with programmatic recommendations.

EMPLOYEE AWARENESS PROGRAMS

The WM/PP training program has a very important function: increasing the awareness of employees and contractors on topics of WM/PP. Awareness programs may include display of WM/PP progress and success stories by use of pictorial essays, graphs and charts that track specific elements, site bulletin boards, and communications utilizing site media (e.g., newsletters, electronic mail, routine staff meetings, etc.).

Slogan contests have been conducted routinely as awareness program activities. By involving the site personnel in these contests, the awareness of WM/PP issues is heightened.

Incentives such as awards, plaques, and other forms of recognition may be utilized to provide motivation, and to boost employee cooperation and participation. Meeting WM/PP goals provides a measure for evaluating the job performance of managers and employees through the performance management system and applicable performance objectives.

Suggestion boxes provide a vehicle to elicit participation from employees. Awards may be given to employees whose suggestions result in gains in WM/PP objectives such as volume or cost reduction.

PPOA TRAINING

A specialized and very important area of WM/PP training is Pollution Prevention Opportunity Assessment (PPOA) training. A performance-based WM/PP training course focusing on the PPOA program should be designed to examine methods for developing, conducting and using waste minimization audits to determine PPOA's. This type of course should highlight key elements and protocols for effective audits. The course is to be entered into the site training computer database. D&F will provide support in the form of instruction of the pilot presentation of the course to a selected audience in order to receive comments and incorporate changes prior to turnover.

BENEFITS OF WM/PP TRAINING AND AWARENESS PROGRAMS

A well designed and implemented WM/PP training and awareness program will yield the following benefits:

Reduction or elimination of liabilities associated with the generation of project wastes;

Compliance with applicable regulations;

Reduction of waste management and compliance costs;

Reduction of resource usage;

Reduction or elimination of reportable inventories and releases of hazardous chemicals; and

Improvement of public perceptions and concerns.

In order to achieve these benefits, the effective implementation of a WM/PP training and awareness program must include certain iterative and cyclic elements that ensure that appropriate measures are conducted.

INDEPENDENT MONITORING OF SOLID LOW LEVEL RADIOACTIVE WASTE DISPOSALS IN THE UK

S. Newstead
P. Schwemlein
Her Majesty's Inspectorate of Pollution
UK

S. Daish
Taylor Woodrow Environmental Consultancy
UK

ABSTRACT

Her Majesty's Inspectorate of Pollution (HMIP) has responsibility for authorizing and regulating releases of radioactive waste to the environment in England and Wales under the Radioactive Substances Act 1993. To ensure that solid low level radioactive waste (LLW) disposals are within authorized limits, waste consignments are seized before disposal and their contents assessed. This paper outlines the regulatory framework for control of LLW disposal in the UK, describes the methods used for independent assessment and indicates the findings obtained.

INTRODUCTION

UK Legislation

The disposal of radioactive waste to the environment is subject to the provisions of the Radioactive Substances Act 1993 (RSA'93) (1). Although a recent Act its purpose was to consolidate an earlier one, the Radioactive Substances Act 1960 (RSA'60) (2) with amendments introduced by subsequent legislation including Part V of the Environmental Protection Act 1990 (3). RSA'60 also replaced earlier legislation; the Radioactive Substances Act 1948. There is therefore a long-established legal framework in the United Kingdom for exercising regulatory control over radioactive wastes.

Authorization

Limits and conditions on the disposal of radioactive wastes are detailed in site specific Authorization Certificates. Over 1100 sites in England and Wales are authorized. The majority of these consist of hospitals, universities and industrial research or manufacturing centers. The more significant radioactive discharges however are from a relatively small number of sites licensed under the Nuclear Installations Act 1965 (4). These are generally referred to as "nuclear sites" and are also authorized under RSA'93 to discharge radioactive wastes. These nuclear sites include nuclear fuel fabrication and reprocessing plants, nuclear

power plants, atomic research establishments and isotope production centers.

Regulatory Authorities

Her Majesty's Inspectorate of Pollution (HMIP) is responsible for administration and enforcement of RSA'93 in England and Wales. In the case of nuclear sites in England, Authorizations for disposal of radioactive waste are issued jointly by HMIP and the Ministry of Agriculture, Fisheries and Food (MAFF). In Wales these functions are undertaken by HMIP and the Welsh Office with the support of MAFF. Separate but similar arrangements exist in Scotland and Northern Ireland where Her Majesty's Industrial Pollution Inspectorate and the Alkali and Radiochemical Inspectorate are the respective regulatory authorities.

Independent Monitoring

Operators are required to determine and record the radioactive content of waste disposals in accordance with conditions specified in authorizations.

In support of its regulatory function HMIP undertakes its own monitoring programmes to act as both a check on site operators' results and to provide independent data on the exposure of the public. These results are published annually (5). As part of these programmes HMIP carries out independent checks on solid LLW destined for land disposal. Consignments of waste are seized by HMIP Inspectors and sent to HMIP's Waste Quality Checking Laboratory (WQCL). The present paper focuses on this process and the subsequent checking procedure and describes how HMIP uses the results to obtain added assurance that disposals are in compliance with disposal Authorizations.

SOLID LLW ARISINGS AND DISPOSAL ROUTE

Low Level Radioactive Waste

In the UK, radioactive waste is classified under broad categories, according to its heat - generating and activity content. Low level waste (LLW) is regarded as waste containing radioactive materials other than those acceptable for disposal with ordinary refuse and with activity contents not exceeding 4 GBq/te of alpha emitting radionuclides or 12 Gbq/te of beta/gamma emitting radionuclides.

The largest volumes of solid LLW originate from the fuel cycle plants operated by British Nuclear Fuels plc (BNFL), the Magnox, AGR and PWR power stations operated by Nuclear Electric plc, and the research establishments of the UK Atomic Energy Authority and Ministry of Defence. More than 99% of the waste seized has originated from these nuclear sites and was destined for disposal at the landfill site in Drigg, Cumbria operated by BNFL for the disposal of solid LLW.

Drigg

The Drigg disposal site is located in West Cumbria about 6km south-east of BNFL's reprocessing facility at Sellafield. The site started operations in 1959. It receives waste mainly from Sellafield but also from other nuclear and non-nuclear establishments elsewhere in the UK. The site occupies about 120 hectares (300 acres) close to the Cumbrian coast.

Wastes were historically deposited by tumble tipping into trenches cut into clay to a depth of about 8 metres. This method of disposal ceased in 1994. Suitable wastes, mainly from Sellafield, are now compacted and placed in ISO-containers in a new facility at Sellafield. After transport to Drigg the wastes are fixed in a concrete grout prior to their orderly emplacement in a concrete lined vault.

The majority of the waste typically comprises discarded protective clothing (overalls, overshoes, gloves, paper hats etc.) and general trash from areas of low contamination. The waste is generally accumulated in 200 litre drums and the total activity of such a drum is typically 1 to 2 Mbq beta/gamma but can vary between 1 Kbq and 20 Mbq due to the inherent inhomogeneity of this type of waste.

At this stage the waste will be un-compacted and smaller items are likely to be in plastic bags within the drums. Waste generators are increasingly using compaction and there are also some sites which utilize super-compaction. It is HMIP policy to seize waste for independent monitoring before it has been super-compacted. The majority of consignments selected have been taken after they have been delivered to the Drigg site but as some waste may be compacted prior to delivery consignments are also seized from sites before despatch to Drigg.

WASTE QUALITY CHECKING LABORATORY

The independent monitoring or quality checking of solid low level radioactive waste is carried out at a laboratory established by HMIP for this purpose at the Winfrith Technology Centre in Dorset, England. The Waste Quality Checking Laboratory (WQCL) was first postulated in 1983 and a contract to build the laboratory was awarded to a consortium lead by Taylor Woodrow in 1985. During this first contract the design and construction of the facility were completed and the laboratory was equipped and staffed by scientists and technicians. The work took approximately three years to complete with the laboratory being commissioned in 1988.

From 1988 to 1991, the laboratory was contracted to perform research into the analytical methods required to identify and quantify the wide variety of radioisotopes which can potentially be found in LLW. During this period valuable foundation work on the quality system and quality checking techniques were completed.

The present contract to operate and staff the laboratory was awarded to Taywood Environmental Consultancy, one of the Taylor Woodrow group of companies in 1991. The main emphasis within this contract is the routine quality checking of solid low level radioactive waste consigned for disposal in England and Wales in support of HMIP's regulatory work.

Laboratory Description

The WQCL monitoring facility is located on the Winfrith nuclear licensed site operated by the UKAEA. This provides facilities for consignments of radioactive waste to be received at the laboratory and secondary waste arisings to be disposed of via site services. The laboratory also makes use of other site services such as health physics, dosimetry and site security. The facility is housed in part of a large building, once used for an experimental reactor, and consists of a suite of offices, laboratories, a workshop and waste receipt and storage areas.

Waste consignments can be transported to the laboratory in a variety of containers, these include full height and half height ISO freight containers, individual drums and loose or packaged waste in skips.

Following acceptance of the waste at Winfrith and receipt of the consignment at the WQCL, the transport container is moved to a suitable area for unloading. For most consignments this takes place at the WQCL waste receipt area, where the container undergoes a series of checks prior to opening and unloading. These are described in more detail under non-destructive testing. For drummed waste received in ISO freight containers the drums are unloaded and stored in this area. For loose or

packaged waste received in skips, a tented enclosure can be erected for repacking the waste into drums in preparation for non-destructive testing.

In addition to the waste receipt area the ground floor of the facility also houses the gamma spectrometry laboratories and a temporary X-radiography facility. The upper level of the facility comprises office accommodation and a suite of radiochemistry laboratories where the destructive testing and waste sampling is performed.

Quality Assurance

All the quality checking operations undertaken at the laboratory are carried out within a quality assurance system which was developed to ensure that all the work is performed to recognized and acceptable standards and that the results reported to HMIP are accurate and reliable. The quality system together with a number of key test methods were assessed by the National Measurement and Accreditation Service (NAMAS) in November 1993 and accreditation formally awarded to the laboratory in January 1994. Since then further test methods have been assessed and accredited by NAMAS as part of an ongoing programme to maintain and develop the laboratory's QA infrastructure. Formal accreditation provides assurance that the measurements made on the waste are accurate and traceable to national and international standards.

Non-destructive Testing

Upon receipt of a waste container at the laboratory, the consignment is given a unique identification number and each transport container is examined for evidence of damage or loss of integrity, any such findings are photographed and recorded. The labels attached to the transport container are photographed and the information on the labels also recorded. Seals placed on the container by HMIP are examined and photographed. The container is also checked for non fixed external contamination and radiation dose rate and finally the gross weight and external dimensions of the container and measured and recorded.

Following completion of the transport container checks, the waste consignment is opened and the contents unloaded. For drummed waste received in ISO containers the drums are unloaded directly into the waste receipt area of the laboratory and are logged into the QA system. Further checks are carried out on the waste drums at this stage, these include, radiation dose rate measurements, contamination checks, drum weight measurement and a note of the condition and integrity of the drum.

Since the non-destructive testing procedures carried out at the laboratory require the waste to be contained within 100 or 200 litre steel drums, any waste which is not received in this format such as loose waste in skips must first be repacked into drums. This requires direct handling of the waste by operators who must be suitably protected with the appropriate personal protective equipment. Repacking operations may also require a certain amount of size reduction in order to fit bulky items such as lengths of wood or pipe into the 200 litre drums.

Each drum received or packed at WQCL is given a unique identification number and a seal is placed on the lid to prevent tampering. The non-destructive testing is carried out on the whole of the waste consignment and involves two tests, these are X-radiography and Segmented Gamma Scanning (SGS).

Firstly each drum is X-radiographed to determine its contents. A total of nine X-radiographs are taken with three equally spaced around the circumference of the drum and at three equally spaced positions down the

height of the drum. Following processing, each X-radiograph is examined by trained staff to determine the contents of the drum. This is important for the identification of prohibited items as defined in Authorization Certificates and the BNFL's Conditions of Acceptance for wastes for disposal at Drigg. These include, free liquids, aerosol canisters, materials that are likely to cause fire or explosion hazards and large amounts of putrescible or rotable materials. The identity of any drum containing non-permitted items is noted for opening and more detailed examination and any non-permitted items found are removed from the waste. X-radiography is currently carried out for the laboratory under contract to a third party organization, however it is planned to construct a permanent X-radiography facility at the laboratory and to include this work in the WQCL repertoire of non-destructive testing.

The most important non-destructive technique used in waste quality checking is Segmented Gamma Scanning (SGS). Using this technique the gamma emitting radioisotopes within each drum can be identified and quantified. Each drum is placed in turn on a lifting turntable within the instrument which allows the radioactivity within defined segments of the drum to be determined. Up to 40 segments can be defined within a single drum. A schematic diagram of the SGS is shown in Fig. 1.

Fig. 1

The total radioactivity within the drum is then calculated by adding the results from each segment. A correction for the attenuating effect of the drums waste content is made by use of an external gamma emitting transmission source. The instrument is routinely calibrated and checked using reference radioactive sources traceable to national standards.

The wide range of waste material densities together with the large number of gamma emitting radioisotopes found in LLW can give rise to significant uncertainties in the radioactivities determined by the SGS. In an effort to reduce these uncertainties and achieve NAMAS accreditation for SGS measurements, an extensive research programme has been undertaken. Experimental measurements have been made using known reference sources with a wide range of gamma ray energies placed at different positions with a series of drums which have been filled with materials of differing densities. Analysis of the data collected from these experiments has enabled the laboratory to identify areas where improvements can be made. On completion of the non-destructive testing campaign the gamma emitting radioisotopes identified are listed and the total gamma emitting radioactivity for the waste consignment is calculated for comparison with the waste producer's declaration.

Destructive Testing

In order to determine the alpha and beta emitting radioisotopes within a consignment of LLW, destructive testing must be performed on a representative portion of it. In general approximately 5% of the packages or drums within a consignment are analyzed destructively for radiochemical content. The criteria used for the selection of drums for sampling is dependent on HMIP requirements and the nature of the waste being assessed. Examination of the X-radiographs for example, may reveal prohibited items such as aerosol canisters or free liquids which must be removed. The presence of dense objects seen on the X-radiographs may conceal sources of radioactivity which may not have been revealed by SGS monitoring. Drums may also be selected from examination of the gamma emitting radioisotope content as found by the SGS and by specific request from HMIP eg based on the origin of the waste within the producer's site.

Once a drum has been selected for destructive testing it is taken to the radiochemistry laboratory and attached to the waste receipt glove box. The lid of the drum is then removed from inside the glove box and the contents of the drum are examined. The waste receipt glove box is fitted with a fixed video camera and all drum opening operations are recorded on video tape. Any prohibited items found in the drum are photographed to provide evidence of the finding and segregated from the remainder of the waste which is then transferred to a second glove box. Here the waste is packaged if necessary and the contact radiation dose rate and weight of the package are measured and recorded. Representative sub-samples are then taken and transferred to a fumehood for radiochemical analysis.

Destructive testing begins with the preparation of an aqueous solution of the solid sample taken from the waste. This can be accomplished in a variety of ways depending on the type of waste material found. Methods such as acid dissolution, fusion, digestion or leaching, are commonly used, the principal objective being the extraction of all the radioactive species into solution. Once the primary solution has been prepared, aliquots are first taken for the determination of total alpha, total beta, total and individual gamma emitting radioisotopes.

The total alpha measurements are made by preparing a counting disc from the primary sample solution by evaporation onto a planchette. This is then analyzed in one of eight alpha spectrometer cells, counting times being calculated from count rate measurements. The results are used to identify the component alpha emitters and quantify the total alpha radioactivity of the sample.

Total beta determinations are made using Liquid Scintillation Analysis (LSA). An aliquot of the sample solution is added to a vial containing a scintillation medium and is then analyzed using a liquid scintillation counter. As for the alpha measurements the results are used to identify component beta emitters wherever possible and calculate the total beta radioactivity of the sample.

Component gamma emitting radioisotopes within the sample are determined by analyzing a 50ml aliquot of the primary solution in a fixed geometry on a gamma spectrometer. A separate low energy gamma spectrometer is used to determine low energy gamma emitting radioisotopes such as Fe-55, I-125 and I-129.

For all three of these techniques the chemical and radiochemical concentration of the solution must be controlled to optimize the counting characteristics and reduce interferences. All the analysis instruments used are regularly calibrated and checked using reference sources traceable to national and international standards. To ensure that the methods used and the results obtained from destructive testing are acceptable the laboratory participates in regular inter-laboratory comparison exercises organized by HMIP.

In addition to the total alpha, beta and gamma techniques described, the laboratory has a number of other specific radioisotopic methods which can be used for destructive testing.

The determination of specific radioisotopes by destructive testing first requires radiochemical separation from the other species found in the primary sample solution. The method adopted will depend on the chemistry of the element being isolated and may involve solvent extraction, distillation or ion exchange. The laboratory has analysis methods for most of the radioisotopes commonly found in low level radioactive waste.

REPORTING AND APPLICATION OF RESULTS

All the results produced by the laboratory from quality checking operations on waste consignments are reported to HMIP. Written reports are produced on the finding of the non-destructive and destructive testing campaigns, these are then forwarded to HMIP for review.
Some typical results obtained from the quality checking of a waste consignment are shown in Table I. The tables compare the results obtained by NDT and DT for 4 different drums taken from 3 separate waste streams within a single waste consignment. It can be seen that in general there is very good agreement between the two techniques.
Table I
From the regulatory point of view the results of the checking process may be considered as being in two distinct categories. Firstly, there are qualitative issues such as whether there was free liquid in the waste or whether the waste contained non-permitted items. Secondly, quantitative results can be compared with the activity as declared by the waste producer.
Results reports are always issued to the relevant HMIP site Inspector who makes the judgement as to what action, if any, should be taken against the waste producer. Qualitative issues are usually an indication that either the operator's procedures are deficient in some way, or that the procedures have not been complied with. These are concrete issues which the Inspector would take up formally with the operator and would ensure by subsequent site inspections that adequate corrective actions had been taken. Quantitative issues can be much more complex, particularly where the results are from destructive testing and analysis. Results from SGS analyses are not dependent on sampling as all drums in the consignment are analyzed whereas for chemical analyses a proportion (typically 5%) of the drums are selected and a further selection of material within a drum is sampled. Nevertheless the correlation of total activities calculated by the two methods is generally much better than might be expected. This increases confidence in the results. If the check analyses indicated that authorized or declared activities had been exceeded further samples or analyses would be carried out to confirm the results. In all cases the follow up action is taken by the Inspector for the appropriate site and in severe cases an operator would be liable to prosecution. Independent monitoring has so far given confidence that operators have taken a responsible and thorough approach to complying with disposal authorizations. Non-compliances found have been in the nature of qualitative breaches as described above and appropriate corrective actions have been undertaken by operators.
EUROPEAN NETWORK ACTIVITIES
Since October 1992 the laboratory has participated in the European Network of Testing Facilities for the Quality Checking of Radioactive Waste Packages. This network was formed to promote co-operation between laboratories within the European Union who are involved in quality checking activities. The countries represented in this network are: Belgium, Germany, France, Spain, Italy, The Netherlands, Austria and The United Kingdom. Each country has laboratory participants and regulatory observers represented on the Steering Committee and Executive board of the network and a number of working groups have been established to focus on important aspects of quality checking. There are currently 5 working groups whose remits are: gamma measurements, volatile releases from waste packages, quality assurance, neutron measurements and destructive testing.

The Steering Committee and Working Groups meet twice a year to discuss technical issues and matters of mutual interest. The network is currently involved in jointly submitting a number of research proposals to the European Commission as part of the fourth framework programme on nuclear fission safety. This research programme attracts joint funding from the European inter-laboratory comparison test for gamma measurements on 220 litre waste drums. This exercise will have obvious benefits to the quality assurance of SGS measurements performed at the WQCL.

CONCLUSIONS

Independent monitoring carried out by the Waste Quality Checking Laboratory is a key element of HMIP's regulatory work under the Radioactive Substances Act 1993. The quality and reliability of the laboratory's work is underpinned by formal accreditation of its test methods under the UK's National Measurement and Accreditation Service and its participation in the European Network of Testing Facilities for the Quality Checking of Radioactive Waste Packages.

ROUTINE QUALITY CHECKING OF LOW LEVEL WASTE PACKAGES BY DESTRUCTIVE AND NONDESTRUCTIVE METHODS

H.-J. Sanden

R. Odoj
Research Center Jlich (KFA)
Institute for Safety Research and Reactor Technology
Federal Republic of Germany

ABSTRACT

Nuclear waste packages have to comply with the specifications of interim storage facilities and have to meet the waste acceptance requirements for final repositories. In the FRG, the compliance with the acceptance criteria is preferably proved by process qualification of the waste treatment. However, the quality of waste packages originating from non-qualified processes has to be checked by control measurements.

On behalf of German nuclear regulatory authorities the Research Center Jlich (KFA) currently performs quality inspections on Low Level Waste (LLW) packages. Nondestructive assay methods as well as destructive analysis methods are used for quality checking. The routine inspection procedure consists of a fixed set of basic methods applied to all waste drums transported to KFA Jlich and a variable set of extended measurements applied to selected packages for which further information is desired.

Experience has been gained in the application of these methods over a wide range of waste types to be disposed of. The paper describes the current working program and gives a survey of the inspection procedures and quality checking methods applied routinely. Examples are discussed

where extended nondestructive testing methods (e.g. digital radiography and computerized tomography) are used to validate and improve the accuracy of activity determination.

INTRODUCTION

In the FRG all types of radioactive waste including low and intermediate level waste will be disposed of in deep geological underground repositories (salt or hard rock formations). Conditioned radioactive wastes have to meet the specifications and acceptance requirements defined by national regulatory and waste management authorities in the FRG. These requirements are specified depending on the type of waste, the waste form and the type of container (1). The fulfillment of the acceptance criteria for interim or final storage is preferably proved by the qualification of waste treatment and conditioning processes. In addition quality checking of waste packages is done on the basis of random sampling inspections (2).

The Research Centre KFA Jlich is engaged in R&D activities for the quality checking of nuclear waste packages since many years. Within national and European funded projects KFA has developed various nondestructive and partially destructive methods to characterize waste packages and to quantify the activity inventory. The nondestructive systems range from gamma scanning and neutron counting to transmission and emission computerized techniques (TCT, ECT, DR).

Many waste packages produced in the early 1980's and before originate from non-qualified waste treatment processes. As a consequence they do not generally meet the acceptance criteria without quality control actions. On behalf of German nuclear regulatory authorities KFA Jlich is currently responsible for the realization of quality control measurements on 1200 conditioned waste packages stored at the interim storage facility of Gorleben.

For waste characterization and quality checking nondestructive testing methods as well as destructive analysis methods are applied. The routine inspection consists of a fixed set of basic measurements applied to all waste drums and a variable set of extended measurements applied to selected packages when more information is desired. After the completion of the inspection procedure a report is produced for each individual waste package that forms the basis for the documentation of all necessary waste characteristics. The documentation of these drums is then checked by the German 'technical inspection agency' (Technischer berwachungsverein, TV) which operates on behalf of the radiation protection board BfS (Bundesamt fr Strahlenschutz). If the acceptance criteria are fulfilled the waste packages may be disposed of in the final repository Morsleben which will be operating until 30.06.2000. The disposal of the waste packages has to be accepted by the radiation protection board (BfS). For waste packages which do not fulfill the requirements specific waste treatment processes will be suggested (conditioning, drying etc.).

On the average the time spend to examine and handle one waste package amounts to half a day. This means that the current work program (1200 drums of which 400 have been examined up to now) will last roughly two and a half years. Therefore one major objective is to set up and optimize an inspection program for routine application while maintaining a high quality in performing the methods.

WASTE FORMS AND CHARACTERIZATION

Site specific acceptance criteria have been derived from radiation protection regulations and from the safety assessment of a repository. The waste acceptance requirements distinguish between several types of waste with respect to their chemical and physical composition and different types of containers. Concerning solid waste (waste category A1) to be disposed of in the German final repository of Morsleben requirements on the waste forms and activity limitations for certain radionuclides and nuclide groups must be fulfilled. Activity limitations have been derived for more than 150 nuclides depending on different considerations like normal operation, assessment of incidents, criticality and long-term radiological impacts. The inventory of at least sixty-four of those nuclides must be given in the documentation.

Acceptance Criteria for Waste Category A1 - Solid Waste

Solid waste to be disposed of in the repository of Morsleben has to fulfill the following basic requirements (1):

- solid waste form,
- no free liquids, not even in bottles,
- no internal canisters,
- no toxic materials,
- no chemical and biochemical reactivity (no corrosion, rotting or fermentation),
- no flammable substances,
- normal atmospheric pressure inside the drum (no gas production).

Activity Limitations

The waste category A1 is subdivided into five radiation protection groups (S1 to S5). Solid waste belonging to the lowest radiation protection group (S1) must fulfill the following limitations:

- dose rate near the surface D < 2 mSv/h
- total activity of a-emitters A < 0.4 GBq/m3
- total activity of b/g-emitters A < 4 GBq/m3
- surface contamination a < 0,5 Bq/cm2 , b/g < 5 Bq/cm2

For waste contained in standard 200 l drums some activity limits are listed in Table I for radioactive nuclides that can be detected by nondestructive assay. The second column gives typical detection limits for a real waste drum on the basis of nondestructive gamma scanning (measurement time: 40 minutes; weight of the matrix: 400 kg; 10 MBq of Co-60 and Cs-137 activity in the matrix).

Table I

The activity inventory is usually derived from quality checking of the waste treatment processes, random sampling inspections and calculations (enrichment of the nuclear fuel, burnup history, material activation, cooling time etc.). In fact, many relevant isotopes cannot be measured directly by nondestructive means because of their low concentration in the waste.

Therefore the concept of 'detection of key-nuclides' has been established for quality checking which is applied for instance within closed operational procedures at nuclear power plants. From the measurement of certain key-nuclides (mainly Co-60 and Cs-137) the activities of all other relevant isotopes are calculated on the basis of 'predefined' correlation factors. The correlation factors are derived from detailed radiochemical analysis of the respective waste streams. These correlation factors have to be approved by nuclear regulatory authorities.

Classification of the Types of Waste Encountered in the Program

Within the current quality checking program all waste packages result from nuclear power plants. Sometimes they may also contain cross-contaminants from fuel fabrication or research activities. Thus the activity is mainly due to fission and activation product activity. Nevertheless, it is necessary to assure the absence of a-emitting and fissile nuclides above certain limits. The type of waste examined so far can be subdivided in the following categories:

- unconditioned waste (scrap etc.) with low to medium density and low activity,
- cemented waste (density ca. 2g/ccm) with medium to high activity content,
- compacted waste - so called 'pellets' - (ashes, iron scrap etc.) with medium to high density (up to 3g/ccm) and medium to high activity,
- packages with internal shielding structures (weight more than 600 kg) and high activity content (up to more than 1 GBq),
- filter cartridges in special shielding containers,
- special items: packages containing free liquids, elevated pressure or containing radioactive gases (Rn-222 or tritium release from corrosion processes).

EQUIPMENT AND PROCEDURES

The routine inspection procedure consists of a fixed set of basic measurements applied to all waste items and a variable set of extended measurements applied to selected packages where more information is desired.

Basic Measurement Program

The basic measurement program is intended to characterize the waste according to the desired specification items (weight, dose rate, surface contamination, pressure, gas production rate, gas composition, integrity of the drum etc., integral gamma spectrum).

The basic measurement program involves the following methods and procedures:

- visual inspection of the surface of the drum,
- g-dose rate measurements in contact and in 1 m distance,
- a- and b/g-surface contamination,
- weighing the drum,
- measurement of the pressure inside the drum,
- gas sampling and gas analysis
- integral gamma scanning with a collimated HPGe-detector and evaluation of the total inventory of all detectable radionuclides,
- segmented gamma-scanning to analyze the spatial distribution of the prominent g-emitters,
- visual inspection of the drum filling by opening the drum.

The following gas components are analyzed by:

- standard organic and inorganic components by mass-spectrometry/gas-chromatography (MS/GC), thermal conductivity detection (TCD):
  H2, O2, N2, CH4, CO2, CO, FCKWs, other organics
- radioactive gas components by radioanalytical GC:
  H-3, C-14, Kr-85, Rn-222.

After the completion of the basic inspections and evaluation of the data the technical inspection agency decides whether further investigations have to be conducted. On the average about 90 percent of all drums can be released for final disposal without additional measurements.

Extended Measurement Program

The extended measurement program serves two purposes. One objective is to obtain more information on the internal structure of the drum (internal shielding, density or activity distribution). The other objective is to take samples for destructive analysis. Very often the first step helps to identify 'regions of interest' within the drum where representative samples can be taken.

The extended analysis procedure may involve the following methods:

- taking samples for radiochemical analysis,
- core drilling of cemented wastes,
- radiochemical analysis of samples by a- and g-spectrometry and by LSC techniques,
- transmission and emission computerized tomography (TCT, ECT),
- digital radiography (DR),
- passive neutron counting,
- correction techniques for internal shielding.

DETERMINATION OF THE ACTIVITY INVENTORY

Activity of the Key-Nuclides

Measurement of the activity of the key-nuclides in the drum is achieved by the well established method of gamma-scanning (4). A collimated HPGe-detector is moved along the drum axis, while the drum itself rotates on a turn table (Fig. 1). The standard measurement time is 40 minutes for a scan. The collimator has a diameter of 40 mm.

Fig. 1

The activity inventory is calculated for all detected nuclides from the evaluation of the integral gamma-spectrum according to the following relation between the measured net peak count rate Z and the activity concentration a = A/m (3) which is valid for homogeneous fillings of the drum:

Eq. 1

The above relation can be extended to situations where a homogeneous activity concentration is shielded by an additional inner shielding structure. For all undetected relevant isotopes the activity will be calculated in correlation to the measured key-nuclides (mainly Co-60 and Cs-137) using the specific isotope vector of the waste under consideration.

Activity of a- and b-Emitting Nuclides

If the inventory of a- and b-emitting nuclides has to be measured samples are taken for radiochemical analysis. This yields the isotopic composition of the waste in correlation to the prominent g-emitters. The a/b-inventory of the drum is then calculated by multiplying the activity of a key-nuclide with the relative abundance of each a/b-nuclide.

Problems Associated with Standard Procedures

The main difficulties associated with the standard methods of activity determination are well known. Uncertainties are mainly due to the following effects or difficulties:

- the activity of activation and fission isotopes generates a background in the gamma-
- spectrum so that the LLD for other nuclides is deteriorated,
- non uniform activity distributions and inhomogeneous matrix compositions may cause deviations between real and measured total activities,
- external shieldings must be identified to account for g-absorption,
- samples taken for destructive analysis may not be representative for the complete drum (more than one pellet per package).

To account for inhomogeneities of activity or matrix distribution more advanced nondestructive testing methods like computer tomography and digital radiography are used in addition to gamma-scanning. These techniques generate tomographic pictures of selected slices of the object or projected side views (6). Thus the opportunity is given to evaluate in detail the distribution of relevant gamma-emitting nuclides which yields more reliable values for the activity within a drum. The analysis is especially useful for the quality checking of radioactive waste packages resulting from non-qualified conditioning processes or with insufficient documentation. Figure 2 shows a simple sketch of the top view of the detection system to perform TCT/ECT- and DR-measurements (5).

Fig. 2

The tomographic scanning system developed with financial support of the European Union in the Institute for Safety Research and Reactor Technology (ISR) at KFA Juelich combines two detection systems. Three HPGe-detectors can be used for gamma scanning and spectroscopy simultaneously. For transmission measurements in computed tomography (TCT) or digital radiography (DR) four fast plastic scintillators are used. The transmission source is Co-60 with an activity of 7 Ci. The time for generation of a tomographic slice amounts to typically 15 minutes whereas radiographs are produced in 1-2 hours depending on the desired quality of the data. The system set-up and testing has been finished this summer.

SELECTED RESULTS AND DISCUSSION

In the final section of this paper some specific 'problems' encountered during the work program will be discussed. The intention is to introduce and discuss some of the extended nondestructive testing methods that have been developed to examine waste packages which cannot be investigated satisfactorily with the standard procedures.

Generation of Nuclide Specific Activity Distributions

The first example is a drum containing several waste 'pellets' (compacted canisters filled with waste). Some of these 'pellets' contain ashes produced by incineration and/or non-combustible waste coming mainly from nuclear power plants. In rare cases small quantities of a-contaminated waste can also be found originating from nuclear fuel fabrication.

The identification of a-contaminants like U-235 or Am-241 can be achieved by g-assay of the emission lines at 185.6 keV or 59.5 keV. These energies may be strongly affected by absorption in the waste matrix especially in the case of higher densities (> 2 g/ccm). The total a-activity inventory is calculated on the basis of destructive sampling and radiochemical analysis of the isotopic vector. The reliability of the determination of the isotopic vector is strongly affected by the representativeness of the samples taken out of the drum. In order to obtain 'representative samples' it is important to quickly identify which pellets contain a-contaminants and whether the activity is distributed homogeneously.

As an example Fig. 3 shows the two dimensional distribution of the count rate of the 185.6 keV peak of U-235 measured at the drum's surface. It is clearly visible that a-contaminants are located only in the upper pellet (the drum contained two of them). The angular profile at the circumference suggests that the material is not distributed homogeneously within the pellet.

Fig. 3

Due to the detailed analysis of the distribution of the a-contaminants samples could be taken of the hot spot regions of the upper pellet where

an activity concentration of approximately 20 Bq of U-235 per gram of waste was detected.

Density Correction by Transmission Mmeasurements

The second item is an example of a drum with a mass of more than 800 kg. This weight implies the existence of a heavy shielding structure. Another result of the basic inspection was that the Co-60 and Cs-137 were concentrated in the middle part of the drum (Fig. 4b). Thus it was necessary to perform shielding corrections for both key-nuclides. Therefore a digital radiograph of the drum and additional transmission and emission tomograms at 500 mm height above the bottom of the drum were produced. The results are shown in the Fig. 4 a-d).

Fig. 4 a-d

The radiograph clearly shows the existence of a massive cylindrical shielding structure (probably cast iron) with an inactive layer of cement at the bottom. From the visual inspection only a cement layer at the top can be identified.

The effective thickness of the shielding structure as well as the average density of the region filled with active material can be determined from the tomographic data. The correction factors for absorption are then calculated by computerized modeling of the shielding structure on the basis of the measured values. For the above mentioned drum the detected shielding amounts to an absorption factor of ca. 120 +/- 15 for of Co-60 and ca. 660 +/- 80 for Cs-137.

CONCLUSIONS

The effort to characterize waste originating from non-qualified waste treatment processes can be very time consuming and expensive if the waste producer has to proof the fulfillment of the requirements for interim storage or final disposal. Thus emphasis is given to the development of a comprehensive quality control system for all waste treatment and conditioning processes. In Germany there are roughly 60000 to 80000 waste packages with insufficient quality evidence concerning up to date requirements which have been produced before ca. 1980. Therefore, nuclear regulatory and management authorities have to define and initiate quality inspection programs before these waste packages can be disposed of in a final repository. Such programs should be routinely applicable with high throughput and high quality.

The work described in this paper has shown that quality control inspections for waste drums originating from non-qualified processes can be performed on a routine basis with sufficient quality. The application of state-of-the-art nondestructive assay techniques can help to reduce the time effort and costs spend for such inspections by decreasing the amount of destructive measurements. Another advantage is the validation and improvement of accuracy of the activity determination which is based on other techniques like gamma scanning. Furthermore such extended assay techniques can help to minimize the radiation exposure for the personal staff involved.

THE RETRIEVAL OF INTERMEDIATE LEVEL MAGNOX WASTE AT SELLAFIELD, UNITED KINGDOM A REGULATORY PERSPECTIVE

Peter Addison
Peter S. Watson
HSE Health & Safety Executive
HM Principal Inspectors
HSE Nuclear Safety Division
HM Nuclear Installations Inspectorate
St Peters House
Bootle
Merseyside L20 3LZ, UK

ABSTRACT
The safety of nuclear installations in the United Kingdom is regulated by Her Majesty's Nuclear Installations Inspectorate (NII), on behalf of the Health and Safety Executive (HSE), using a largely non-prescriptive licensing system. This paper summarizes the roles of these organizations and the way in which they exercise regulatory control. It also touches on the inspection and assessment which NII carries out to satisfy itself that a licensee's safety case is adequate. In particular it considers the application of regulatory control to projects associated with the retrieval of intermediate level Magnox waste at Sellafield, which is operated by British Nuclear Fuels plc.
Drawing on two examples of current projects, the paper analyses some safety aspects related to waste retrieval. Of central importance is the need to ensure that waste forms are chemically and physically stable, and so suitable for safe long term storage.
NII has gained valuable experience through its regulation of these projects. This paper sets out the key regulatory lessons learnt in the hope that this experience will benefit delegates to this conference.
Note: The views in this paper are those of the authors and do not necessarily represent those of Her Majesty's Nuclear Installations Inspectorate. Introduction
1. Since the 1950s, the reprocessing of irradiated Magnox (magnesium alloy clad) fuel at Sellafield, operated by British Nuclear Fuels plc (BNFL), has given rise to a considerable volume of intermediate level waste. The waste of special interest to this paper is the Magnox cladding which, when removed prior to reprocessing of the irradiated fuel rod, is known as swarf.
2. Until recently the stripped cladding was stored underwater in silos. One of the drawbacks of this is that, under certain conditions, Magnox

swarf corrodes under water giving rise to an essentially insoluble residue, referred to as sludge. Magnox sludge and swarf can be physically and chemically unstable, and have the potential for giving rise to a significant radiological release should an incident cause a breach of containment. Therefore, the form of the waste is a matter of regulatory concern.

3. This paper outlines the work carried out by Her Majesty's Nuclear Installations Inspectorate (NII), part of the Nuclear Safety Division of the Health and Safety Executive (HSE), to regulate projects associated with the post operational clean out and decommissioning of intermediate level Magnox waste storage facilities at Sellafield. In particular it refers to projects currently in progress, or planned, to retrieve this waste.

4. The first part of the paper describes the UK's regulatory framework for the control of safety on nuclear licensed sites; briefly discusses the HSE's publication 'Tolerability of Risk' and how the philosophy described therein is applied through the 'Safety Assessment Principles for Nuclear Plants'; and relates this to the specific regulatory assessment of licensee's safety cases insofar as they relate to radioactive waste. The paper then summarizes the UK policy on radioactive waste management and decommissioning, and goes on to describe the regulation of work carried out by BNFL to retrieve Magnox waste. From this, the paper discusses the safety significance of waste retrieval and draws out several significant regulatory lessons learnt, each of which has generic application.

5. BNFL's paper to this conference (1) deals with waste retrieval from the operator's view point and contains more details of plants and processes at Sellafield.

UK NUCLEAR REGULATORY SYSTEM

6. All civil nuclear installations in the UK are subject to the Health and Safety at Work etc. Act 1974 (2). Amongst the relevant statutory provisions of this Act are those parts of the Nuclear Installations Act 1965 (3) which refer to issues of safety. Under the Nuclear Installations Act, no site may be used for the purposes of installing or operating any prescribed nuclear installation unless a nuclear site license has been granted by the HSE and is, for the time being, in force. The HSE has delegated responsibility for administering this licensing function to NII.

The Licensing Regime

7. The licensing regime is established by NII through powers under the Nuclear Installations Act to attach conditions to the site license which are enforceable in a court of law. In addition there are the powers available under the Health and Safety at Work etc. Act, for example to issue enforcement notices. This regulatory regime has been successfully applied to a wide variety of nuclear installations within UK over many years and has been shown to provide a powerful yet flexible system of control capable of being matched to the degree of hazard involved. The licensing regime covers a nuclear installation through its full life cycle from design to decommissioning and takes into account the need to regulate and control the management of radioactive waste.

8. The site license is predominantly non-prescriptive and most conditions attached to it require the licensee, who has the sole responsibility for ensuring safety, to make and implement adequate arrangements to take

account of specified requirements. An example of this for Accumulation of Radioactive Waste (License Condition 32) is:

The licensee shall make and implement adequate arrangements for minimizing so far as is reasonably practicable the rate of production and total quantity of radioactive waste accumulated on the site at any time and for recording the waste so accumulated.

This Condition also gives the HSE the power to formally approve the arrangements, to specify any limitations to the arrangements or, if it wishes, to specify the place and manner of waste accumulation.

9. A similar Condition gives the HSE the powers to direct the licensee to dispose of the accumulated or stored waste in accordance with an authorization, issued by the appropriate Authorizing Department, under the relevant legislation. Other Conditions relating to the control of nuclear matter on the site include monitoring, record keeping, radiological protection, training, documentation, emergency arrangements, quality assurance and, in particular, the requirement for the licensee to produce a safety case to justify safety during all stages of the installation's life. Safety aspects of the movement of radioactive matter within, onto and from the site and the keeping of radioactive material on site are also regulated by NII under the provisions of the Ionizing Radiations Regulations 1985, made under the Health and Safety at Work etc. Act.

The Regulators

10. The aim of the NII is to secure the maintenance and improvement of standards of safety at civil nuclear installations and to protect workers and members of the public from ionizing radiation. To achieve this aim the NII is structured to enable priorities to be decided centrally; to respond rapidly to technical innovation and operational experience; to be consistent in the development and application of standards; and to apply the regulatory requirements consistently and coherently across the whole nuclear industry.

11. The NII is divided into inspection, assessment and policy branches. The inspection branches, as their name would suggest, are primarily involved in carrying out site inspection activities to confirm that licensees are complying with their legal obligations. The assessment branches provide specialist technical advice on the adequacy of the licensee's safety cases. The policy branches co-ordinate the setting of NII policy on a range of issues, making sure that it accords with that set by other government departments and agencies.

12. A licensee's safety case must include reference to radioactive waste management and accumulation facilities on the site. In addition the licensee has to obtain authorization for discharges from the site. These discharges are regulated by authorizations issued under the Radioactive Substances Act 1993 by the Authorizing Departments (Department of the Environment - principally HM Inspectorate of Pollution - the Welsh Office and the Ministry of Agriculture, Fisheries and Food or the Scottish Office, as appropriate). In order to ensure consistency within the UK national policy on radioactive waste, and to ensure a minimum of duplication of work between government bodies, a memorandum of understanding clarifies the responsibilities of the various government departments and agencies involved.

Tolerability of Risk

13. In response to a recommendation by Sir Frank Layfield in his 1986 report of the Sizewell Inquiry into the UK's first commercial pressurized

water reactor HSE produced 'Tolerability of Risk' which, after consultation and revision, was republished in 1992 (4). The document is a straightforward account of risk written for the general public. It discusses how people normally approach risk, shows how industrial risks (and nuclear risks in particular) are regulated, the nature of risk from radiation and how risks are calculated.

14. Three levels of risk are identified:

a. a risk which is so great or the outcome so unacceptable that it must be refused altogether - the 'unacceptable' or 'intolerable' risk. These cannot be justified except in extraordinary circumstances;

b. a risk which is or has been made so small that no further precaution is necessary - the 'broadly acceptable' region where no detailed working is needed to show that risks are as low as reasonably practicable;

c. risks that fall between these two states, that have been reduced to the lowest level reasonably practicable bearing in mind the benefits flowing from its acceptance and taking into account the cost of further risk reduction. The Health and Safety at Work etc. Act requires that such risks must be reduced so far as is reasonably practicable - the 'Tolerable' region.

The document goes on to quantify these regions which, in turn, form the basis for the quantitative guidance to NII assessors developed in NII's Safety Assessment Principles.

Safety Assessment Principles

15. The NII's Safety Assessment Principles (5) are used as guidance by NII assessors in their examination of licensees' safety cases for all licensed installations including nuclear chemical plant. The Principles are not 'standards' imposed on licensees but nonetheless they have been published so that anyone can be aware of the criteria against which safety cases are judged. They are intended primarily for use with new plant and major modifications, but are also used when reviewing older plant in comparison with modern standards.

16. The majority of the Principles reflect good engineering practice which can be regarded as the basis of safe design. However, they also contain overall risk targets (derived directly from Tolerability of Risk) which NII uses to assess whether the licensee's probabilistic analysis demonstrates that the risks from its plant are balanced and not dominated by a single failure or fault sequence. Tolerability for risks associated with normal operation and accident conditions are separately addressed, each having defined levels of tolerability denoted by a Basic Safety Limit, and a broadly acceptable level by a Basic Safety Objective.

17. In the UK's non-prescriptive regime the licensee is free to propose any means to achieve an appropriate level of safety but must demonstrate in a clear and unambiguous fashion that the proposals are adequate. This is achieved through the safety case which demonstrates, in an objective and traceable manner, the safety adequacy of the proposed operation from the design through commissioning and operation to the end of plant life and decommissioning. In particular it must link the underlying safety concepts, supporting research and development to the design criteria. From this the safety case identifies the operational limits and constraints for safe operation of the plant throughout its lifetime. It will be appreciated that not all this information is available from the very start and so the safety case is usually developed in a phased fashion.

18. The involvement of the regulator does not remove the licensees' responsibility for safety. NII's assessment of a safety case is carried out using its experience and expertise on a sampling basis to establish confidence in the arguments put forward and to determine whether the licensee has, as a minimum, met their own criteria. The assessment is carried out in a probing manner, using the Principles as the framework, to test the licensee's claims and assumptions - taking into account the safety significance of the chosen aspects. Dialogue between the assessors and the licensee is maintained until NII is satisfied with the safety arguments.

19. In pressing for the licensee to meet acceptable standards the test of 'reasonable practicability' is always an argument open to the licensee to limit their obligations. As a result much depends on the magnitude of the potential hazard. For example, the qualitative engineering Principles are more likely to be liberally interpreted where the potential hazard is low. The underlying rationale for the NII's assessor is to ensure that the licensee has avoided, or adequately contained, all identifiable potential hazards within the bounds of reasonable practicability.

UK POLICY ON RADIOACTIVE WASTE MANAGEMENT AND DECOMMISSIONING

20. The UK national policy on radioactive waste management was reviewed in 1994/95 and the conclusions of that review were set out in 'Review of Radioactive Waste Management Policy' (6). From this, NII has derived policy statements on radioactive waste management and decommissioning to ensure that UK policy is properly implemented, taking due notice of best international practice. In summary, the policy statements cover amongst other things the need for the licensee to:

- undertake strategic and site/plant specific planning of radioactive waste management and decommissioning;
- prepare programs and arrangements for decommissioning, and commence decommissioning at a time acceptable to NII;
- demonstrate a systematic and progressive reduction of hazards presented by the site or plant;
- take a balanced account of radiological risks to workers, the public and the environment;
- demonstrate that wastes are not unnecessarily created, and that generation and accumulation has been reduced as far as reasonably practicable;
- segregate and characterize radioactive wastes, where practical and cost effective;
- store wastes in a passive and retrievable form and, where appropriate facilities are available, dispose of the wastes as soon as reasonably practicable;
- have a valid safety case for waste storage facilities, including maintenance and surveillance programs and periodic safety reviews.

The two examples of waste retrieval projects which follow show how NII applies UK policy in practice.

RETRIEVAL OF INTERMEDIATE LEVEL MAGNOX WASTE

21. Historically, NII were concerned that certain facilities for the storage of potentially high hazard waste were being operated for longer than first envisaged. Over a period of time NII encouraged BNFL to develop a strategy for safe long term storage; and BNFL themselves realized the need to take action, for both safety and commercial reasons. An acceptable overall strategy is being developed, and considerable progress has been made. Central to the strategy is that the waste should

be retrieved, and then immobilized to render it safe for long term storage and disposal. The remainder of this paper concentrates on the first step of waste retrieval. To illustrate some of the generic nuclear safety issues and regulatory lessons learnt, two examples of current waste retrieval projects have been chosen:

Example 1 - Sludge Retrieval from Magnox Pond and Decanning Plant

22. The Magnox pond and decanning plant was commissioned in 1959/60 for the purpose of receiving and decanning Magnox fuel, and for exporting irradiated fuel rods for reprocessing on site. It operated until 1986, when its function was taken over by a new building. Spent Magnox fuel rods were placed in skips in a pond for a period of cooling, to allow shorter lived isotopes to decay to acceptable levels, and to provide a shielded environment.

23. BNFL opted for storage of Magnox clad fuel under water to minimize the likelihood of fire if Magnox and irradiated uranium were exposed to air. However, Magnox cladding corrodes in untreated water to form an essentially insoluble residue mostly made up of magnesium hydroxide, commonly referred to as 'sludge', and this corrosion reaction evolves hydrogen. Overtime the amount of sludge in the Magnox pond and decanning plant built up so that by 1986 the plant had accumulated around 1800 cubic meters of sludge. The levels of radiation in the building and of airborne activity started to rise, and the potential existed for personnel to exceed statutory dose limits unless special preventive measures were applied.

24. BNFL have since embarked on a series of plant improvements (particularly the addition of new ventilation systems) and post operational clean out projects, with the objective of removing all fuel, sludge and debris and so reduce local levels of radiation, to enable further decommissioning to proceed safely. Although this work is scheduled to continue well into the next century, conditions within the plant have already improved significantly.

25. NII has reviewed the overall program of post operational clean out activities and has decided to carry out a detailed examination of a sample of projects, of which the most significant is the retrieval of sludge from one of the five original wet bays. BNFL has designed the bay sludge retrieval facility to transfer this sludge to settling tanks as custom-built interim storage. Facilities are now being planned to enable treatment and immobilization of this sludge at a future date.

26. The facility has been developed from commercially available units, though with the addition of specialist control equipment. The real area of difficulty in this project lies in the requirement to install and commission the facility safely in an area where the levels of radiation and contamination are high and where access is restricted. This called for a thorough study of possible options and methods of work to ensure that dose uptake is as low as reasonably practicable. These studies required a knowledge of the working environment, and a precise breakdown of specific operations. The culmination of this work is a series of BNFL documents which lay down the steps to be taken and identifying those responsible for specific actions.

27. The facility was tested extensively, using a scale model and a full size off-site rig. Off-site commissioning enabled operating and maintenance personnel to gain a first hand experience of the facility in totally inactive conditions, whilst at the same time proving the equipment and demonstrating the correct operation of safety systems. The

use of off-site commissioning to eliminate dose uptake during inactive commissioning has been a prominent feature of the Sellafield waste retrieval projects, one which NII wholeheartedly supports.

28. Active commissioning of the facility is underway and quantities of sludge have been transferred to settling tanks. A review of early commissioning results was carried out to gain a better understanding of the physical and chemical processes involved during sludge retrieval, and so to make sure that the levels of conservatism were sufficiently high given the uncertainties inherent in work of this type. The review confirmed that commissioning could proceed on a careful, step by step, approach; and that at each step commissioning results need to be compared to expectations and any deviations properly justified.

Example 2 - Swarf Retrieval from Solid Active Waste Storage Facility

29. Swarf from the decanning process has been stored underwater in concrete compartments at the Solid Active Waste Storage Facility from 1964 until recently, when the Magnox Encapsulation Plant started receiving swarf directly from the fuel handling plant for encapsulation. The risk of a fire due to the generation of hydrogen as a result of swarf corrosion is a dominant feature of the safety case for the building. The corrosion reaction is exothermic, and so cooling and inerting capabilities have been fitted.

30. The other significant aspect is the potential for leakage of water from the compartments, and indeed a major leak occurred in 1976. NII carried out an investigation of this leak, and published their findings (7). The incident helped clarify the position with respect to interim storage: further storage capacity was limited, and the strategy of retrieval, immobilization and safe long term storage adopted.

31. It was agreed that BNFL would first retrieve the more recently deposited and essentially intact swarf, because it represents the greatest risk of hydrogen generation. No equipment existed at the time to fulfil this objective, and BNFL commissioned the swarf retrieval facility, a plant novel to the company. In essence, the design principles of this facility were that it should be able to work within the same physical envelope as those existing machines which service the compartments, be capable of retrieving swarf and keep it under water for export using a standard flask, and to effect a seal so that inerting of a compartment could be carried out in the event of detection of significant levels of hydrogen.

32. The basis of the facility is a simple petal grab which is lowered into a compartment, collects a quantity of swarf, and then deposits the swarf into a water-filled bin which is raised into a flask and transported for later encapsulation. It was designed in a modular form to accommodate existing crane capacity. Its substantial weight (around 170 tonnes) represents a significant additional load for the building to support and necessitated verification that the building could support the facility. The seismic capability of the building also had to be re-examined to make sure that the facility did not affect it significantly.

33. The facility was fabricated, and subjected to a thorough inactive commissioning program, before being brought on-site. This was done by BNFL to iron out any operational problems without attracting any dose detriment, and also for training operators and maintenance personnel. 34. BNFL has drawn up a strategy to empty the building, and waste retrieval has started. At present, recovery of swarf from one compartment is complete, and retrieval from another compartment is underway. In the near

future, we expect BNFL to present to NII its plans for post operational clean out of the remaining eighteen compartments in the building, which will be developed from experiences gained to date.

REGULATORY LESSONS LEARNED

35. Several issues have emerged which are common to other waste retrieval projects, and their identification will aid the assessment of future post operational clean out and decommissioning activities:

i) Waste Retrieval and Immobilization. The regulator's aim is to ensure that the licensee renders any potential hazardous waste safe at source. However, Magnox sludge and swarf has existed for some years mainly in a form which presents a potential threat due to its physical and chemical characteristics. Clearly the top priority for dealing with such waste is to retrieve and immobilize the waste as soon as reasonably practicable, and so render it suitable for safe long term storage or disposal. BNFL has recognized the importance of this work, and retrieval of the waste is well underway.

ii) Understanding the processes. The removal of sludge from the Magnox pond and decanning plant exemplified the need for operator and regulator to fully understand the processes involved in waste retrieval. The uncertainties inherent in work of this type call for high levels of conservatisms which can only be refined through experience gained from predictable and consistent commissioning results. The regulator should look for the licensee's commissioning plan to proceed on a careful, step by step, approach; and at each step commissioning results should be compared to expectations and any deviations properly justified.

iii) The Role of the Regulator. Once the NII had accepted BNFL's strategy for the treatment and safe long term storage of intermediate level waste, BNFL displayed firm commitment to hazard reduction by cleaning out the plants and encapsulating the waste on a reasonable timescale. It can take time for the regulator and licensee to reach agreement about the long-term strategy for such activities, but it is an essential first step in that it provides the necessary framework. Thereafter, provided the licensee maintains adequate progress and demonstrates adequate control of the safety of its work, regulation is relatively straightforward.

iv) Regulatory Standards. For the two waste retrieval projects described earlier, the buildings did not represent satisfactory long term storage arrangements, and there was a need for action to prevent further deterioration. In such situations, there may not be sufficient time available to allow the licensee to develop ideal improvements - it may be better to adopt a solution which is fit for purpose and is available quickly. Hence there is a need for a balanced approach to regulation, wherein the regulator should apply appropriate standards, although modern standards remain as a benchmark against which to base these regulatory judgements.

v) Risks associated with modifications. The regulator should ensure that the licensee has demonstrated that there is an overall net benefit to be gained by modifying plant to effect waste retrieval. But the regulator should also bear in mind that a short term increase in risk may be necessary to secure real long term improvements to safety.

vi) Safety during Installation and Commissioning. Regulation of waste retrieval projects has reinforced the need to consider the risks to the work force associated with performing a modification in a hazardous environment. The regulator needs to ensure that the operator has carried

out a systematic study of all potential hazards (nuclear and non-nuclear) and that they have in place effective managerial controls.

vii) Design Safety Case. The plant buildings described above were mostly constructed around 30 to 40 years ago. They were not designed to cope with the additional loads associated with waste retrieval, and in general they were not specifically designed to resist earthquakes. In such situations, the regulator should ensure that structural capability has been assessed retrospectively, and that the integrity of the structures is sufficient to sustain waste retrieval over a given period of time.

viii) Off-Site Commissioning. Waste retrieval equipment at Sellafield often has had to be installed in areas of complex layout and with high background radiation, making working conditions difficult. This has necessitated remote handling, extensive use of off-site facilities for testing and training, and special attention to the need to keep doses as low as reasonably practicable, which called for a thorough identification of safe working practices and effective administrative controls. Off-site commissioning has come to be regarded as an essential component of the safety case of a waste retrieval project. Therefore the regulator has to be involved in the off-site activities of the licensee.

ix) Novel Plant. The use of plant novel to the nuclear industry to effect waste retrieval is often unavoidable, in which case the licensee must pay more attention to design proving studies, model testing and full scale mock-ups. It also means that the regulator should pay special attention to the assessment of the adequacy of the plant and its ability to fulfil its function without undue risk.

CONCLUSIONS

36. This paper has outlined some of the ways in which the NII has used and continues to use its regulatory influence to improve the safety of projects associated with the retrieval of Magnox waste. Progress has been possible through the co-operation of BNFL, who have responded positively and responsibly in the course of dialogue with NII inspectors and assessors to the regulatory requirements of the NII.

37. The NII has gained valuable experience through its regulation of waste retrieval projects at Sellafield, experience which we hope will be of interest to delegates at this conference.

ANNEX 1

UK Classification of Radioactive Wastes

The reader should note that Magnox sludge and swarf are classed as Intermediate Level Waste, in accordance with the classification system set out by the UK's Radioactive Waste Management Advisory Committee, Ref 8.
The categories adopted by the Committee are :
High-level or Heat Generating Wastes
Wastes in which the temperature may rise significantly as a result of their radioactivity, so that this factor has to be taken into account in designing storage or disposal facilities.
Intermediate-Level Wastes
Wastes with radioactivity exceeding the boundaries for low-level waste, but which do not require the generation of heat to be taken into account in the design of storage or disposal facilities.
Low-level Wastes
Wastes containing radioactive materials other than those acceptable for dustbin disposal, but not exceeding 4 GBq/te alpha or 12 GBq/te beta/gamma.
Very low-level Wastes
Wastes which can be safely disposed of with ordinary refuse (dust-bin disposal), each 0.1m3 of material containing less that 400 kBq of beta/gamma or single items less than 40 kBq of beta/gamma.

ABSTRACT
A comprehensive program is currently in progress at several laboratories for the development of sensitive, practical, non destructive assay techniques for the quantification of low- level transuranics (TRU) in bulk solid wastes.
This paper describes the method being developed to assay high density TRU waste packages using photon interrogation. The system uses a pulsed electron beam from a linear accelerator (LINAC) to produce high-energy photon bursts from a metallic converter. The photons induce fissions in TRU waste package which is inside an original Neutron Separating and Counting Cavity (NS2C). When fission is induced in trace amounts of TRU contaminants in waste material, it provides "signatures" from fission products that can be used to assay the material before disposal. We give here the results from counting photofission-induced delayed neutrons from 239Pu, 235U and 238U in sample matrices. We counted delayed neutrons

emitted after each pulse of the LINAC by using the Sequential Photon Interrogation and Neutron Counting Signatures -SPHINCS- technique which had been developed in the present framework. The SPHINCS method enhances the available counts by a factor about 20 compared with the counting of delayed neutrons only after the irradiation period. Furthermore, the use of SPHINCS measurement technique coupled with NS2C facility improves the signal to noise ratio by a factor about 30. This decreases the detection limit.The electron linear accelerator operates at 15 MeV, 140 mA, and 2.5 ms wide pulse at a 50. and 6.25 Hz rate. The dynamics of photofission and delayed neutron production, NS2C advantages and performances, use of an electron linear accelerator as a particle source, experimental and electronics details, and a future experimental works are discussed.

INTRODUCTION

Radioactive waste management is an issue in every country with a civil and/or military nuclear program. Thus, assaying waste contaminated by alpha emitters with long half-lifea is vital for both safety and long-term waste management. The wide variety of materials and contaminants, the low concentrations and large volumes involved mean that such type of assay is a complicated matter. In France, actinide concentrations in surface-stored waste packages are limited to a maximum 100 nCi[a]/g . The average value on storage sites must be below 10 nCi[a]/g.

Over the last few years, considerable progress has been made in the field of assay techniques for low-level a contaminated waste. References (1) and (2) contain a wide survey of these developments.

This document presents an active detection method for radioactive waste embedded in high-density matrices, mainly concrete packages. The high density of the packages, as well as their high water content (up to 20%), means that only high-energy neutrons or gamma particles have an enough high range to activate the enclosed actinides. Our aims were to evaluate the feasibility of dosing transuranians by induced photofission, and to optimize an experimental system with a view to improving detection limits.

The experimental process described below (SPHINCS) coupled with the NS2C irradiating cavity is one of the first to use a LINAC assay method combined with sequential detection using delayed neutrons.

PRINCIPLE OF THE METHOD

The induced photofission assay method consists of irradiating radioactive matter with high-energy photon bursts in order to produce (,fission) reactions in the enclosed transuranics. Measurement is based on detecting prompt and delayed photofission neutrons to establish the quantity of "photofissile"b material present. Two measuring methods can be used:

i) irradiation at low levels of photon energy followed by counting the prompt photofission signal,

ii) high energy irradiation followed by counting of delayed neutrons.

The first method has the advantage of being statistically satisfactory. The number of prompts neutrons emitted in fission is approximately 100 times greater than the number of delayed neutrons emitted after fission. But the (,n) reactions on different materials other than TRUs produce signal interference that increases proportionally to the energy of the incident photons. Consequently, we have to use relatively weak levels of gamma energy. Since the photofission cross-section increases in proportion to the energy of the photons, this reduces the number of useful reactions. It should also be noted that the interrogation photons may "blind" the measurement system for a period of about one millisecond

(the "gamma flash") (3). This limits the counting of the prompt signal, which population decreases within a few hundred microseconds.
The chief drawback of the second method, i.e. counting the delayed signal, is the small proportion of delayed neutrons. This results in increasing measurement uncertainly. However, the method has the advantage of being unaffected by photoneutron interference and the "gamma flash". Thus using high energy photons increases the photofission reaction rate without affecting the background noise during counting.
Our investigations led us to opt for a pulsed irradiation and counting of the delayed signal between the LINAC pulses which is called Sequential Photon Interrogation and Neutron Counting Signatures ; the SPHINCS technique. This method enables us to increase sensitivity at least ten times.

PHOTOFISSION AND DELAYED NEUTRONS PRODUCTION

The production of delayed neutrons resulting from the decrease in radioactivity of fission fragments is directly linked to the photofission rate T. This is given by:
Eq. 1
The number of delayed neutrons emitted by group i during time tc, after a pulse is:
Eq. 2
Since the detection follows each pulse, the total number of delayed neutrons for all the groups (i=1,...6) emitted during the n counting periods will therefore be:
Eq. 3
If counting is only carried out after n pulses, the total number of delayed neutrons is:
Eq. 4
With:
Eq. 5
Counting the delayed neutrons signal between the LINAC pulses (SPHINCS) increases significantly the sensitivity.
As Eq. 1 shows, the photofission rate is in proportion to the integral on the energy of the product of the effective cross-section s[g,F](E) and the Bremsstrahlung spectrum S(E). This integral increases as a function of the electrons energy (see Fig. 1).
Fig. 1
The choice of this energy is limited by the thresholdc of the reaction
Reaction
equal to 15.9 MeV. It is also limited by the rate of photoneutrons that increases with the energy. These photoneutrons can interfere with the delayed signal when counting between pulses.

EXPERIMENTS

Photon Source

Our series of experiments was carried out using the linear accelerator (LINAC) of the DGA/ETCA/DPN at Arcueil. this accelerator has the following characteristics: pulse width 2.5 ms, repetition frequency ranging from 6.25 Hz to 400 Hz, electron energy ranging from 15 MeV to 30 MeV and a peak current intensity of 140 mA. The tungsten braking target is 3 mm thick. When the electron beam strikes the target, photons are emitted following the deceleration of the electrons in the nuclei coulomb field. This is the Bremsstrahlung radiation phenomena.

Experimental Setup

Figure 2 is a diagram of the experimental setup used. The distance between the target and the element to be irradiated is approximately 120 cm. Neutron counting is carried out using proportional counters with a useful length of 100. cm and a diameter of 2.55 cm. The counters are filled with at a pressure of 4 atmospheres. These counters are covered in cadmium-coated polyethylene and are placed approximately 40 cm away from the beam axis. Neutron detectors around the outside of the waste package are then used to detect neutrons from the photofissions. Fission neutrons passing through the cadmium barrier (the cadmium energy cut off is approximately 0.417 eV) are thermalized in the polyethylene before being detected by the 3He counters. We use the end point energy (electron energy) of 15 MeV. The duration of irradiation pulse is 2.5 ms.
Fig. 2
Electronics
Four 3He counters are arranged as in Fig. 2. The counters are linked by 40 m cable to a signal amplifier operating in current collection mode (drawer type TADS manufactured by the French Eurisys Mesures company). Pulses transmitted by this setup are used by a multiscale board operating in multisweep mode Counting synchronization versus time is performed by the start pulse of the LINAC.
Detection efficiency is measured for a single counter using an Am-Li source (without any matrix) with an energy spectrum close to that of the delayed neutrons and located approximately 40 cm from the detector unit.
Insert A
Due the large size of the accelerator hall, the photoneutrons produced instantaneously on the components of the embedding matrix or the braking target, persist as thermal neutrons long after the gamma flash. Their half-life is of the order of 4.80 ms. Hence the need for the cadmium shielding. Figure 3 shows a recording versus time of neutrons (g,n) made by a counter unit with and without cadmium shielding.
Fig. 3
NS2C IRRADIATION CAVITY
As shown in Fig. 3, the surrounding cadmium of the detection system absorbs the majority of the photoneutron background noise. However, the experimental results obtained with and without cadmium cover are not in agreement with our predictions. This could be explained either:
- by "leakage" of the cadmium shielding,
- or by a non-thermal neutronic component which still active during the counting time.

The first reason is, to our knowledge, not significant due to the high quality of the cadmium shielding manufacturing.
A contrary to, the second possibility appears more probable. This could be explained by the "huge" size of the experimental cell (13m x 13m x 3m) which leads to a greater thermalization time for he photoneutrons (about 20 ms). Consequently, during the useful counting time (12 ms after photon burst) a significant amount of background noise coming from this origin still exists.
In order to reduce the life time of such neutrons, we build a specific cell which surrounded the sample and it matrix (see Fig. 4). This new cell, called NS2C (Neutron Separating and Counting Cavity) allows us to cut both external photoneutrons (coming from the bremsstrahlung target and cell walls) and internal photoneutrons (coming from photon interactions on matrix and on NS2C walls). Moreover, the NS2C leads us to

detect, with low background noise, the delayed neutrons from photofission reactions (useful signal).
Experimental results using the NS2C are very satisfactory: The corresponding signal to noise ratio is about 200. compared to the one obtained without such new cell which is about 30. (see Table I)
Table I
Fig. 4
EXPERIMENTAL RESULTS
Samples of UPu (weight 3.83 g) , 238U (weight 100g, 194g and 292g) and 235U (weight 1.90 g) are used (see Table II). They are placed in blocks of polyethylene (diameter 10 cm and height 20 cm), glass (diameter 10 cm and height 9 cm) and concrete (diameter 56 cm and height 110 cm) with respective densities of 0.95, 1.70 and 2.35 g/cm3. The background radiation level is obtained by irradiating the blocks devoid of all TRU matter. The foreground is obtained by subtracting the background from the global signal ("photofissile" matter + package).
Table II
Figure 5 shows a global recording for 100 g 238U sample without matrix - inside the NS2C casemate- and the corresponding recording without the NS2C casemate.
Fig. 5
Neutron counts versus time for 100 g 238U inside the NS2C casemate and the corresponding recording without the NS2C casemate
DETECTION LIMITS
The samples shown above are contained in three different matrices (except for the 238U).
Measurements are taken using two counting units.
The number of delayed neutrons emitted by the 1980-pulse cycle for the UPu pellet and the 235U sample placed at the centre of the matrix are 2.36 106 and 7.23 105 neutrons respectively.
The detection limits are calculated taking the false alarm and non-detection risks to be equal to 5%. Background and useful signal count times are approximately 294 s. We shall consider the least favorable situation where all the fissile material is concentrated at the centre of the package.
Table III gives the detection limits in grams for an "irradiation-counting" time of 300 s and electron energy of 15 MeV. The irradiation occurs on the TRU sample which is inside the NS2C cavity.
Table III
Extrapolating for Entire Concrete Container
The diameter of the photon beam at 1 m from the Bremsstrahlung target is taken to be around 10 cm. The photon-irradiated section has a volume of 4.4 liters. The least favorable situation is considered where the fissile material is situated along the longitudinal axis of the container. Measurement is taken by axial scanning of the package. It consists of 10 reading each at a height of 10 cm during 100 s (the height of the package being around 1 m). Detection limits for each section are used to approximate the one of the whole package. The respective detection limits in counts CmD for the whole package CmD1 and for a section are related by:
Eq. 6
Where:
t = counting time for the whole package
t1 = counting time for a single section.

The mass detection limits are related by:
Eq. 7
Where:
Esp1 = Recording in counts per gram of TRU in the case of the section
Esp = Recording in counts per gram of TRU in the case of the package.
For our hypothesis this gives:
Eq. 8
We therefore obtain:
Eq. 9
For the hypothesis above (i.e. TRU matter along the container axis and signal and background measurement time of 300s) the detection limits in grams of actinides per gram of matrix for the UPu and the 235U samples are 8.94 10-7 g/g and 1.77 10-6 g/g. These values correspond to 3.24 10-6 Ci[a]/t and 4.10-2 Ci[a]/t for 235U and UPu respectively.

CONCLUSION AND FUTURE PHOTOFISSION EXPERIMENTS

Several important conclusions can be drawn from these studies. First, LINAC operation in the bremsstrahlung mode can produce sufficient photons in each burst to assay TRU with high sensitivity. Second, the use of pulsed irradiation and counting between pulses (SPHINCS technique) enhances the available counts by a non negligible factor. Furthermore, using the NS2C cavity improves the signal to noise ratio considerably. Following this way, the systems used here offer important advantages in waste management applications. First of all, they are compatible with passive counting systems. They can use the same or similar detection systems and electronic processing, since most passive systems assaying large containers will also utilize neutron detection. Secondly, they have energy variability and control of beam current. Both can be important in shorting assay time. Thirdly, they can assay large packages of waste barrels. or large crates. This is due to the high intensity available from the interrogating beam and to the potential for sweeping the beam across the package. Fourthly, the beam sweeping can be used to scan containers to locate contaminated portions of the volume that can sometimes be removed for recycling or to reduce the overall volume to below 10 nCi/g. Fifthly, the photon interrogation assay, will minimize the effects of the waste matrix on the assay.

In the future, we will concentrate on three areas of importance for application of the present technique to waste assay. First, we will determine the yields of photoneutrons for various matrices and the ratio of prompt to delayed events when TRU references are included. From these determinations, we can set the limits of practicability in counting prompt fission signatures. Second, we will build and evaluate a prototype assay system scaled up to large sample volumes and based on our experimental setup. With higher efficiency, better neutron gamma discrimination and a uniform mixture of matrix and TRU in a sample, we would expect to decrease the detection limit.

Finally, we will study the background problems that occur when radioactive isotopes that emit beta and gamma radiation are introduced into the sample matrices. For 3He detector systems, photon-induced pulses are lower in amplitude, but they can "pile up" to signal amplitudes above the counting threshold and result in false counts. Shielding materials and thickness ones and detector operating conditions are the important areas to explore.

ABSTRACT
The problem of radioactive waste management is both scientifically and technically complex and also deeply emotional issue. In the last twenty years the first two aspects have been mostly resolved up to the point of safe implementation. In the Republic of Slovenia, certain fundamentalist approaches in politics and the use of radioactive waste problem as a political marketing tool, brought the final radioactive repository siting effort to a stop. Although small amounts of radioactive waste are produced in research institutes, hospitals and industry, major source of radioactive waste in Slovenia is the Nuclear Power Plant Krko. When Krko NPP was originally built, plans were made to construct a permanent radioactive waste disposal facility. This facility was supposed to be available to receive waste from the plant long before the on site storage facility was full. However, the permanent disposal facility is not yet available, and it became necessary to retain the wastes produced at the plant in the on-site storage facility for an extended period of time. Temporary radioactive storage capacity at the plant site has limited capacity and having no other options available NPP Krko is undertaking major efforts to reduce waste volume generated to allow normal operation. This article describes the Radioactive Waste Compaction Campaign performed from November, 1994 through November, 1995 at Krko NPP, to enhance the efficiency and safety of storage of radioactive waste. The campaign involved the retrieval, segmented gamma-spectrum measurement, dose rate measurement, compaction, re-packaging, and systematic storage of radioactive wastes which had been stored in the NPP radioactive waste storage building since plant commissioning.

INTRODUCTION

The Krko Nuclear Power Plant is a 2 loop Westinghouse-designed PWR nuclear electric generating station located by the Savariver, just outside the town of Krko in the Republic of Slovenia. Krko NPP, since startup in 1981, has supplied electric power to the republics of Slovenia and Croatia providing 15 to 20 % of total electricity generation. As a normal byproduct of the generation of electric power by a nuclear power plant, wastes from plant processes are generated. Some of these wastes contain radioactive materials resulting from the normal operations of a nuclear steam supply system, and must be stored in a safe and efficient manner in order to protect the public and plant staff from exposure to radioactive materials.

The Krko project was originally supposed to be the beginning of a very ambitious Yugoslav nuclear program. At that time, during the seventies, the radioactive waste management policy was also of general Yugoslav interest, concern and responsibility. When the construction of nuclear facilities was banned in 1987, the radioactive waste policy became a problem of republics of Slovenia and Croatia because these two republics owned the only nuclear power plant. According to the agreement between the governments of Croatia and Slovenia, a Project team, responsible for preliminary activities and preparation of all necessary documents and licences for the construction of final repository for low and intermediate activity waste, was established within the organization of NPP Krko. During six years of Project team existence a conceptual design for shallow ground and tunnel type repository was prepared, together with preliminary safety assessments for both types of repository - to name just a few among more than ninety documents produced. Preliminary screening was performed, based on available geological, seismic, hydrogeological and other relevant data defining suitable candidate macro locations for the final repository according to recommendations of the International Atomic Energy Agency combined with methods successfully implemented elsewhere. Preliminary results have indicated that suitable locations for final repository are available in both Republics.

In January 1991, the Slovenian Republic Administration for Nuclear Safety issued "Guidelines for the Low and Intermediate Level Radwaste Repository Site Selection in Slovenia". According to the Guidelines, the site selection procedure is executed in four steps taking into consideration forty three criteria. In February 1993 the second step results were reviewed and public announcement was made for thirty-six potential locations covering the total area of 896 hectares situated in eastern and north-eastern parts of Slovenia. It should be noted that the public reaction after the announcement was much milder as compared to the reaction after the presentation of the first step results in June 1990. Despite considerable effort the Project team was never publicly accepted. Unfortunately, radioactive waste management was understood in Slovenia as an exclusive problem of the nuclear power plant, instead of being discussed and resolved within the scope of waste management at the state level. For this reason in 1993 the Slovenian government founded the Radioactive Waste Management Agency, reporting directly to the government. As a result of the third step of the selection process, five most suitable locations were identified and presented to the public provoking strong disapproval within the local communities where the locations have been identified. At that point the siting process was stopped and it is not expected to resume any activities in the near future. When the level of ecological consciousness of Slovenian people

becomes high enough to understand the obligation to dispose of waste, including the radioactive waste, in a controlled manner, the process will continue with detailed investigations of candidate sites. The direct prerequisite for such a development is the clear standpoint of the Slovenian Government, Assembly and ecologists, indicating the firm intention to build the repository as a part of changing the attitude towards surroundings. Temporary radioactive storage capacity at the plant site has limited capacity and having no other options available, NPP Krko is undertaking major efforts to reduce waste to allow normal operation. Among many other activities, supercompaction of existing waste was one of viable options.

KRKO RADIOACTIVE WASTE SUPERCOMPACTION CAMPAIGN

Waste Types and Quantities

The types of wastes stored at NPP Krko include the concentrate from evaporation of plant process waste liquids (EB); used process filter cartridges (F); used protective clothing, gloves, and rags-compressible wastes (CW); depleted ion exchanger resins used in water purification systems (SR) and previously supercompacted waste (SC). Continuous operation since the commissioning of the plant had, by November 1995, resulted in the production of 9924 55-gallon and 617 85-gallon storage drums containing radioactive wastes.

Table I

Krko Radioactive Waste Storage Facility

The Krko Radioactive Waste Storage Facility is a seismically qualified 1470 m2 building located within the protected area of Krko NPP (Fig. 1). Construction is of steel-reinforced concrete, with 1 meter thick outer walls and 60 centimeter thick inner dividing walls. The roof slab is 1 meter thick except for the slabs above the entrance compartment, which are 60 centimeters thick. The facility is built on a reinforced concrete base pad, and is designed to withstand predicted potential earthquakes and extreme weather conditions. The waste storage areas interior to the building consist of six corridors 4.17 meters wide and in excess of 7 meters high. A second level of storage area is provided, supported on steel beams which are in turn supported on steel plates bolted to the dividing walls spaced at 0.5 meter intervals. The facility is continuously monitored for airborne radioactivity, and contamination surveys are regularly performed in accordance with the Krko site radiological control program. Prior to performance of the compaction campaign, the existing 55-gallon waste drums were stored, in two tiers 5 layers deep, horizontally on the concrete floor and on steel shelving. The steel shelving was supported by steel plates bolted to interior walls. Access for inspection and monitoring within the storage matrix was difficult.

Modifications to the Storage Facility

The storage facility was modified to accept the new TTC (overpack container) and an overhead crane added to transport them. The saddles used in the old storage configuration to support horizontally placed drums were removed since the new containers specially designed for the supercompaction campaign are stored in a vertical position. For the second level of waste container storage, the steel support structure required only minor modifications to accommodate the additional weight of the compacted wastes. Steel grating was installed on the steel support beams, and horizontal steel restraint structures were added in each compartment to provide additional stability for the new containers. Steel

ribs were added to the support beams to prevent sliding of the grating during any seismic event.

Fig.1

Extended Storage Requirements

Construction of a new radioactive waste storage facility, in addition to the existing one, was considered, but the licensing process for construction of a new building would take considerable time, and the new facility would thus not be available before the current facility was completely full. Thus, NEK decided to explore techniques for more efficiently utilizing the available space in the existing storage facility.

In addition, the drums in use were not suitable for long-term storage in a temporary facility, and were also not suitable for off-site transportation or for permanent disposal. Thus, it was decided to repackage the existing filled drums into superior, specially designed containers or "overpacks". These containers had to be suitable for extended temporary storage, transportation to the final waste repository, and to facilitate handling for permanent disposal.

By 1995, the Radioactive Waste contained in the storage building occupied approximately 94% of the available storage space. With the plant designed to operate until the year 2023, the remaining storage space would be inadequate. However, it was determined that by supercompacting and repackaging the 8600 drums containing solidified evaporator concentrated compressible waste, it would be possible to gain enough space for 3000 additional drums.

Waste Volume Reduction

In 1988 and 1989, a quantity of 1924 standard 55 gallon storage drums containing compressible wastes were supercompacted using a large mobile "supercompactor" owned by Westinghouse Electric Corporation.. The compressed drums, referred to as "pucks" were placed into 617 overpacks (85 gallon steel drums) and returned to storage in the storage building. Additionally, tests were performed in order to determine the efficiency of the supercompactor when used to compact drums containing evaporator concentrates solidified in vermiculite cement. Due to the porous nature of the vermiculite cement, and the high compaction power of the mobile supercompactor, the tests showed that these drums could be reduced in volume by up to 50%. Thus, it was decided by NEK management to use waste compaction technology to address the lack of storage space and to meet the requirements of volume reduction.

Tube Type Containers (TTCs)

Use of the 85-gallon overpacks, which were used for storage of the compacted waste drums resulting from the 1988-89 compaction tests, was determined to be impractical. These overpacks are not qualified to contain weight greater than 500 kg. The Tube Type Containers (TTCs) were thus specially designed for use in the Krko radioactive waste facility, and were produced on the basis of NEK specifications. The TTCs are qualified as IP-2 transportation package per IAEA Safety Series No. 6, "Regulations for the Safe Transport of Radioactive Wastes" (IAEA, 1985, amended 1990). The TTCs are made of steel, 2700 mm high, with an internal diameter 640 mm, wall thickness of 2 mm, bottom and top closure cap thickness 2.5 mm, and total weight, including waste, of 2500 kg. The height of the TTCs was chosen to optimize their placement in the storage building, and to contain from 4 to 10 pucks depending on the type of waste and the volume reduction achieved or 3 standard 55 gallon waste

drums if repackaging is needed. Calculations addressing different types of overpacks showed that the use of these specially designed overpacks would dramatically reduce the volume of the stored wastes following the supercompaction campaign.

The TTCs are qualified for use for extended temporary storage, and for later transportation to a final disposal site. As part of the qualification procedure, they were subjected to a severe regime of stacking and drop tests. Each TTC is coated, interior and exterior, with qualified primer and paint. These coatings ensure that moisture from outside cannot enter the container, and that any trace corrosive material (boric acid) will not corrode and degrade the container walls. In addition, these coatings provide a high degree of fire resistance.

Before the start of the TTC filling operation, a measured quantity of desiccant material was added to the bottom of the TTC. The same desiccant material was also used to fill the voids during the filling process and to cap off the remaining empty space on the top of the TTC. This ensures that the pucks inside the TTC's are securely immobilized, while at the same time absorbing any residual moisture. After a TTC has been filled with pucks of compacted waste, the closure lid is welded to the body of the TTC. Welding of the closure lid of filled TTCs was performed on a specially designed base table, which turns on interior ball-bearings. The welder stands behind lead shielding to minimize the radiological dose received while welding the closure lid, and the TTC turns in place, allowing the welding to be performed in minimum time and with minimum manipulation by personnel.

SUPER COMPACTION CAMPAIGN EQUIPMENT

The Westinghouse/Scientific Ecology Group (SEG) Mobile Supercompactor used for the campaign is a 1000 ton hydraulically operated press contained in one standard 12 m truck trailer, along with its equipment: a hydraulic power unit, a waste drum loading system, an air filtration system, a liquid collection system, and a compacted drum unloading crane.

To facilitate handling of the overpacks used for the compaction campaign, a 4 Ton Electric Overhead Traveling Crane was provided. This crane conforms to FEM 1.001 (3rd Edition 1987) rules for hoisting appliances. Crane rails to support the equipment were installed permanently in the 6 storage cell ceilings. The crane itself is constructed and installed so that it can be removed from one storage cell, and then installed in another. This provides the capability to quickly recover any overpack or drum which may be damaged, and to facilitate repackaging and replacement within the new storage configuration.

In order to facilitate the loading of the overpacks and prevent dropping the overpack or contents, a loading platform was built for the campaign. The platform was designed to accommodate six (6) overpacks, thereby allowing the platform operator to select an overpack based on partial fill and compacted drum size. The platform was equipped with a hoist capable of picking up a compacted drum at the compactor exit conveyor and lift them to the top of the platform, there to be lowered into the selected TTC. Sufficient working space is available to permit the lowering of uncompacted drums into the overpacks should that be desirable.

A conveyor system specially designed for use with the platform was also installed. This included a loading conveyor where the drums to be compacted were deposited by the forklift, to be fed by gravity to the compactor loading arm. A special interlock built into the system allowed

only one drum at a time to roll into the loading arm, allowing the next drum to take its loading position once the loading arm was lowered. At the exit end of the compactor, a gravity type conveyor system was installed. This conveyor, completely enclosed to prevent the spread of airborne contamination, ran from the compactor unloading chute to just below the overpack loading platform where the compacted drums were picked up by the platform lifting hoist. A system of drip pans was also provided to prevent spills of liquids onto the compacting area floor when drums containing liquids were ejected from the compactor.

COMPACTION CAMPAIGN ACTIVITIES

In order to ensure proper identification of the contents of the existing drums prior to compaction, drums were inspected, weighed, and scanned using a segmented gamma spectrometer. The segmented gamma spectrometer was chosen for use in the supercompaction campaign in order to provide state-of-the-art measurement technology, capable of categorizing the wastes much more accurately than the standard external dose rate measurements employed at most commercial nuclear stations. The gamma spectrometer was used on all but a few drums during the campaign, and scanning of each drum took approximately fifteen (15) minutes. The remaining drums were above the weight limit for the scanning equipment, and so were measured using the standard practice of external dose measurement.

Using the segmented gamma spectrometer, the radiological (isotopic) content of each drum and dose rate measurements were taken, and the data from each drum recorded. These measurements provide a detailed record of the contents of each TTC, and the data necessary to calculate, in advance, the dose rate which will result when several pucks are placed into a TTC. Once the weight, activity and dose measurements had been determined and recorded, drums were sorted by these criteria for compaction. Drums identified as containing spent ion exchanger resins or filters were separated and not compacted. The scanning of all waste drums handled during the campaign was performed by NEK personnel in accordance with the NEK Radiological Protection Procedures.

The first radioactive waste storage drum was compacted, with representatives of the Slovenian Safety Authorities present, on November 3, 1994. The compaction operation was interrupted due to a hydraulic system failure in the supercompactor, which was returned to the Westinghouse European Service Center in Belgium for repairs. Repair work was completed on March 21, and the unit was immediately returned to Krko. Operations resumed on March 27, 1995. At the end of the campaign, a total of 8770 drums had been compacted. These include 7135 drums containing evaporator concentrates, and 1635 Compressible Wastes drums. In addition, 387 drums containing filters and spent ion exchanger resins were repackaged into TTC overpacks without being compacted, and 766 of these were relocated to shielded storage positions without being repackaged. A total of 1745 TTC's were used for the campaign. The final volume reduction achieved was 27% of the original volume. Refer to Fig. 2 for an illustration of volume reduction achieved for different waste types. Figure 3 illustrates the type and number of drums compacted, repackaged, and stored during the performance of the campaign.

Fig. 2

Fig. 3

Radiological Controls

Health Physics coverage was performed by the NEK Health Physics department. Monitoring, dose assessment, and radiological controls were performed in accordance with Krko radiological control procedures. An ALARA study was performed prior to the start of the campaign, which provided estimates of doses expected for each member of the campaign staff. Due to extra measures taken by Krko Health Physics and the campaign staff the actual total dose accumulated during the campaign (238.81 mManSv) was substantially lower than originally estimated dose (514.31 mManSv).

Each member of the campaign crew was provided with presentations and instruction prior to the start of the project. Each member's responsibilities and duties were explained, along with requirements of site procedures for radiological control and personnel monitoring. By systematically storing the drums within the storage matrix, dose rates resulting from handling were reduced, and the remaining resin/filter drums could be stored separately in cell D where they are shielded by filled TTC's. TTCs containing waste with higher dose rates were placed interior to the storage matrix, so that high activity TTCs are surrounded by the lower activity TTCs which provide additional shielding. This resulted in a considerably reduced dose rate at the boundaries of the storage matrix in keeping with ALARA principles. The dose rate in the access areas of the radioactive waste storage building varies from zero to 50 (Sv per hour). In the accessible areas in front of the storage cells, the highest dose rate in any area accessible by personnel is 150 (Sv per hour).

Records Keeping and Traceability

Project records were kept on printed paper and in a computerized data base. These records show the exact number of drums compacted, their type, weight, dose rate, final TTC location, and the TTC location in the storage building. Records were kept during the performance of the campaign by the QC/Record Keeper, who recorded each drum location in the TTCs, the drum and TTC numbers, and ensured documented TTC desiccant fill and lid welding verification. The location of each closed TTC within the storage building was recorded, as were dose rate measurements on contact, at 1 meter, and at 2 meters.

Gamma spectrometer data were used to calculate predicted dose rates from filled TTCs. When the fill was complete, predicted and actual dose rates were compared to ensure accuracy. Logs were kept of the activities on each shift.

CONCLUSION

The Radioactive Waste Compaction Campaign was performed from November, 1994 through November, 1995 at Krko NPP, to enhance the efficiency and safety of storage of radioactive waste. The campaign involved the retrieval, segmented gamma-spectrum measurement, dose rate measurement, compaction, re-packaging, and systematic storage of radioactive waste which had been stored in the NPP radioactive waste storage building since plant commissioning. The final volume reduction achieved was 30% of the original volume. Additional storage space was provided for at least five years of normal plant operation.

In addition to the reduction in volume, the compaction campaign brought additional benefits. By placing the supercompacted drums into new type container with thicker walls, superior stability is achieved, which diminishes the probability of handling accidents during storage, transportation and final disposal activities. During the supercompaction

campaign a more precise estimate of types and quantities of radionuclides contained in wastes was achieved using a direct segmented gamma-spectrum measurement, and by a combination of external dose and gamma-spectrum measurements.

ABSTRACT

A systematic implementation of a radiological protection program at the GTS Duratek (GTSD) Vendor Treatment Facility (VTF) at the Savannah River Site. The project is unique in that it incorporates a turnkey approach to operation and control of a waste treatment facility by a single subcontractor at a DOE site. It should be of specific interest to those DOE M&O and ERMC prime contractors who subcontract waste treatment, radiological control, and industrial safety technologies and services.

INTRODUCTION

The purpose of this project was to implement a radiological protection program at the GTS Duratek (GTSD) Vendor Treatment Facility (VTF) at the Savannah River Site (SRS). The VTF is a temporary installation in the M-Area of SRS consisting of buildings 341-1M and 341-8M and tanks 100-7, 100-8, and 100-10. The objective of the VTF is to convert approximately 660,000 gallons of mixed (radioactive/hazardous) waste in sludge form to a durable, stable glass wasteform. The scope of the VTF project also includes RCRA clean closure of the tanks following removal of the sludge. Facility-specific radiological controls for the VTF are necessary to minimize safety and health risks to occupational workers, as well as members of the general public. The Radiation Protection Program (RPP) establishes radiological requirements for all VTF operations and support activities.

DESCRIPTION OF THE M-AREA VENDOR TREATMENT FACILITY PROCESS

Mixed wastes (hazardous and radioactive) were originally stored in nine tanks of the Interim Treatment/Storage Facility and in the Mixed Waste Storage Shed by the Reactor Materials Department (M Area) of SRS. The tank waste has been transferred to tanks 100-7 and 100-8 for mixing prior to vitrification. The wastes are aqueous based sludges from a wastewater treatment facility supporting an electroplating operation containing nickel and uranium, which classify them as hazardous and radioactive respectively. The wastes partially occupy three 500,000 gallon tanks, six 35,000 gallon tanks, and one-hundred twenty-five 55 gallon drums. GTSD

has coupled a single stage treatment unit to these tanks and, with the addition of common glass forming chemicals, convert these wastes into a smaller volume of chemically durable glass, with a total waste volume reduction of 83.7%. At the conclusion of the vitrification process, the storage tanks will be decontaminated to RCRA clean closure standards. A conceptual process flow diagram of this operation is given in Fig. 1.
Fig. 1
Operation
The DuraMelter 5000 will be operational 7 d wk-1, 24 h d-1, 52 wk y-1 producing glass at a nominal rate of 5 tons d-1, with a maximum production rate of 7.5 tons d-1. The system will operate continuously until all of the waste has been processed. At this rate, it will take less than one year to vitrify all 660,000 gallons of waste.
Vitrification Melter
The waste feed slurry mixture is pumped to a single stage vitrification unit (DuraMelterTM 5000). Here, the slurry is deposited on the surface of a molten glass bath. Heat from the glass bath is transferred vertically through the accumulated feed pile and evaporates free water from the slurry, calcines inorganic salts to metal oxides, and fuses the resultant mixture into a uniform melt which mixes with the molten glass inventory. Any organic species in the feed are oxidized to carbon dioxide and water.
Vitrification Off-Gas Treatment
The melter is coupled to a multistage off-gas treatment system, which maintains the melter at a constant slightly negative pressure and treats emissions. The reactions that occur when the slurry enters the melter generate steam, a variety of gases (NOx, SOx, CO2, and trace halides), and particulate. The front end of the off-gas system is composed of a water spray quencher followed by two aqueous based packed bed towers connected in series. Following the packed bed scrubbers is a mist eliminator and a dry filtration process which assures the absence of particulate radionuclides (uranium) in the final process exhaust. These filtration units are baghouses and high efficiency particulate air (HEPA) filters. A sampling port is provided after the HEPA filters for air monitoring.
Vitrified Glass Waste Form
The waste glass produced is a borosilicate glass designed to meet TCLP release rate requirements while maintaining a high waste loading (large waste volume reduction). The glass will be transformed into flat, marble-shaped objects called "gems," and loaded into 71 gallon steel drums. The 71 gallon drum has a square cross section which allows for a higher drum packing density.
Radionuclide Inventory
The Curie balance for all systems is schematically shown in Fig. 1. The radionuclide emission from the off-gas system, post-HEPA, is calculated to be 1.67 x 10-9 Curies d-1.
RPP DEVELOPMENT
The contracting organization for the VTF, Westinghouse Savannah River Company (WSRC), recognized that the successful operation of the facility was dependent upon a dedicated workforce of not only operations personnel, but a health and safety staff, as well. The ability of the contractor to provide qualified radiological control personnel to the project at significantly less cost to WSRC was an added benefit of a contracted health and safety staff. The WSRC Site Technical Representative (STR) for the VTF communicated these concepts well

throughout the technical and contractual decision-making processes at WSRC, resulting in a dedicated VTF Radiological Control Organization.
The RPP was developed in accordance with the requirements of three primary source documents: WSRC Manual 5Q, Radiological Control; the DOE's Radiological Control Manual, DOE/EH-0256T; and WSRC-SCD-4, Operational Readiness Functional Area Requirements for Radiation Protection; as well as contractual commitments between GTSD and WSRC. In late 1995, the RPP was reviewed and revised to incorporate requirements of 10 CFR 835, Occupational Radiation Protection. Through the use of a requirement matrix, a Project Instruction was developed which defined the RPP. It was then necessary to develop specific Implementing Procedures to meet the requirements of the developed RPP. A total of forty-two (42) procedures were developed under the following groupings: Organization and Administration, Internal Audits and Investigations, Radiological Protection Procedures and Posting, External Radiation Control Program, External Radiation Dosimetry, Internal Radiation Exposure Control Program, Internal Radiation Dosimetry, Fixed and Portable Instrumentation, Air Monitoring, Radiation Monitoring/Contamination Control, ALARA Program, Records, and Training.
Development of the RPP Project Instruction and Implementing Procedures was initiated in January, 1995. After addressing minor comments from WSRC, the completed program met all requirements of the source documents and contract. The program was accepted in full by WSRC in early May, with the concurrence of the SRS DOE site representative and the GTSD Quality Assurance organization. Program development time, including the review process, was approximately three months. The review and revision process for 10 CFR 835 compliance was completed in approximately three weeks in late 1995.

RADIOLOGICAL CONTROL ORGANIZATION AND RESPONSIBILITIES

One of the challenges that GTSD faced in providing its own dedicated radiological control staff was to maintain the important delineation of the operations and health and safety organizations. A Radiological Control Organization (RCO), consisting of a Radiation Protection Manager, Radiation/Safety Supervisor, and five (5) Radiological Control Technicians was formed to establish and conduct radiological control operations at the VTF. No member of the RCO holds an operational position in the VTF organization, although RCO personnel are often called upon to "pitch in" on tasks such as decontamination, housekeeping, and general labor. Each member of the RCO is empowered to stop work or mitigate the effect of an activity if he/she suspects that the activity will result in the violation of VTF RPP implementing procedures or result in imminent danger or unacceptable risk. The relationship of the RCO to the overall VTF organization is shown in Fig. 2.
Fig. 2
The Radiation Protection Manager (RPM) is the corporate manager with overall responsibility for the successful development and implementation of the VTF RPP. In this capacity, the RPM provides program direction and assistance to the Radiation/Safety Supervisor (RSS). The VTF RPM is empowered with final authority for resolving radiological issues and concerns. For the purposes of the VTF project, he reports functionally to the VTF Program Director.
The Radiation/Safety Supervisor (RSS) is the individual primarily responsible for the daily management of the radiation protection, occupational health & safety, and industrial hygiene programs for the

VTF. In that capacity, the shift Radiological Control Technicians report to him and he in turn reports to the Director of Operations. The RSS receives technical direction and assistance in the implementation of the RPP from the RPM. The primary duties and responsibilities of the RSS are to:

Work closely with the Facility Operations Manager to ensure that radiological control support is available for VTF operations and maintenance, as appropriate.

Implement methods to ensure that personnel exposure, contamination of areas, equipment, and personnel, and solid radioactive waste volume are minimized.

Review radiological surveys, sample results, logs, deficiency reports, and incident reports as specified in VTF RPP implementing procedures.

Ensure that the appropriate radiological data are forwarded to the WSRC STR for assessment of RPP effectiveness.

Act in the capacity of VTF RPM, as specified in VTF RPP implementing procedures.

The Radiological Control Technician (RCT) is responsible for routine and non-routine monitoring of radiological conditions within the VTF, and for assisting and guiding VTF personnel in the radiological aspects of their jobs. VTF RCTs report directly to the RSS, and may receive direction in operational aspects of their jobs from the Shift Supervisor or the Facility Operations Manager. The primary duties and responsibilities of the RCT are to:

Perform routine and non-routine monitoring of radiological conditions within the VTF, including airborne radioactivity, contamination levels, and external radiation fields.

Operate and perform calibration checks on all radiological monitoring and detection equipment in use at the VTF.

Install, verify, and maintain radiological postings at the VTF.

Install, verify, and maintain radiological engineering controls at the VTF.

Monitor access and egress from radiological areas at the VTF.

Generate radiological documents (such as Radiation Work Permits and Radiological Incident Reports) and maintain radiological records.

Assist and guide VTF personnel in the radiological aspects of their jobs.

In addition to RCO personnel, all on-site VTF personnel are qualified as Radiological Workers. Each radiological worker must understand that proper radiological control is an integral part of their daily duties. Radiological workers are trained to recognize that their actions directly affect contamination control, personnel radiation exposure and the overall radiological environment associated with their work.

RPP IMPLEMENTATION

The RPP development and implementation schedule, relative to the operational schedule of the VTF, is shown in Fig. 3.

Fig. 3

The first step in implementing the RPP was the selection of the RSS and one RCT to set up radiological control facilities and equipment during the construction phase. Two additional RCTs were added at the beginning of the sludge transfer phase. A fourth RCT was added at the mid-point of sludge transfer, and the full complement of one RSS and five RCTs was present on site prior to startup. Prior to startup, the onsite RCO typically worked five eight-to-ten hour dayshifts per week. From startup

through operation, the RSS typically works straight dayshifts, not including off-shift tours and inspections, with one RCT assigned to each of five rotating operational shifts. For the tank closure phase, RCO staff will be reduced to the RSS and two RCTs. During the sludge transfer phase, and prior to assignment to rotating shifts, each of three RCTs was assigned to a dedicated duty area: sludge transfer operations, tank modifications, and count room. Defined work scope and RCT familiarity associated with each particular duty area maximized RCO efficiency in supporting VTF operations. To minimize front-end qualification time, RSS and RCT candidates were selected from applicants with current training qualifications, including DOE RCT Core Academics, SRS Site Radworker II, SRS Respiratory Protection qualification, and OSHA 40-hour HAZWOPER. The willingness and ability of the RSS to perform RCT duties on an as-needed basis further added to the cost and time savings realized on the VTF project.

Since the uranium mixture described in Fig. 1 is the sole radiological component of hazards present at the VTF, the bulk of radiological control activities address contamination and airborne radioactivity, rather than external radiation fields. Due to the low enrichment in U235 of the uranium mixture, criticality control was determined to be unnecessary. Industrial hazard monitoring and control, though not addressed in this text, required a substantial manpower commitment from the RCO. All industrial hazard monitoring and control at the VTF, including that for heat stress, noise, chemical hazards, combustible gas, oxygen levels, and confined space entry is conducted by the RCO under the guidance of a Certified Industrial Hygienist. Consolidation of radiological control and industrial safety duties significantly reduced the cost of the VTF health and safety programs.

The RCO facility at the VTF consists of a dedicated mobile office trailer with desk space for three, records files, a single computer and printer, and the radiological count room. The count room is equipped with a stationary phoswich detector and scaler for alpha/beta/gamma counting of airborne and surface contamination samples, a GM detector and rate meter for personnel monitoring, storage space for all field monitoring instruments, and a set of check sources for all radiological instrumentation. Field monitoring instruments include additional "friskers" for personnel monitoring, portable alpha, beta, and gamma contamination and dose rate meters, and stationary and portable air samplers. Instrumentation is calibrated at an offsite calibration facility, also owned and operated by GTSD. Since instrument needs "ramp up" toward the end of sludge transfer and into startup, Instruments are added to inventory on a "just-in-time" basis. Instruments are also provided by the GTSD Instrument Services group, so no downtime is experienced in using the just-in-time approach. Posting materials, protective clothing, and respiratory protection equipment at the VTF is provided by WSRC.

Currently (post-construction/start-up testing), there are several radiologically posted areas at the VTF. The 341-1M Building is posted as a Radiological Buffer Area (RBA) with the area around tanks 100-3, 4, and 5 posted as Contamination Areas (CA). All open tanks which have not been decontaminated internally (100-7,8) are posted CA and Airborne Radioactivity Area (ARA). All remaining tanks have been decontaminated and deposted. Maximum loose surface contamination inside any tank is approximately 10,000 d min-1 100 cm-2 beta-gamma, and 1000 d min-1 100

cm-2 alpha. Airborne radioactivity in any tank has not exceeded 2 DAC total, and respiratory protection is routinely used inside the tanks. Tank 100-10 RCRA clean closure is completed. The radiological count room is currently posted RBA. No area at the VTF currently requires Radiation Area (RA) posting, and the need for this posting is not anticipated for the duration of the project. The maximum external exposure rate recorded at the VTF has been 0.7 mR hr-1 at contact in a sump used for sample storage in Building 341-1M.

RESULTS

To date (11/30/95) one Radiological Incident has been recorded at the facility. The incident consisted of a contaminated system opening for valve maintenance, without appropriate RCO notification. The incident did not result in any release of radioactive contamination or personnel contamination. The incident was promptly discovered by RCO personnel, with appropriate notification of the RSS and WSRC, and follow up actions in accordance with the RPP. No personnel contaminations have yet occurred at the facility. External radiation doses by thermoluminescent dosimeter have not been detected (self-reading dosimeters are not required since no RAs exist at the facility). No bioassay trigger levels have been reached, so no internal radiation dose has been recorded.

CONCLUSIONS

The following items are noted as strengths of this project which resulted in cost and time savings:

Dedicated health and safety staff provided to the project at significantly less cost to WSRC.

Support of the dedicated health and safety staff concept by the WSRC Site Technical Representative (STR).

Abbreviated RPP and Implementing Procedure development time.

Consolidation of radiological control and industrial safety duties.

RCO personnel participating in tasks such as decontamination, housekeeping, and general labor.

Willingness and ability of the RSS to perform RCT duties on an as-needed basis.

Ramp-up and ramp-down of personnel and material resources commensurate with project evolutions.

Defined work scope and RCT familiarity associated with dedicated, assigned duty areas.

RSS and RCT candidates selected from applicants with current training and qualification.

Just-in-time instrument supply and calibration resources.

Continuous assessment of the adequacy of allocated RCO personnel and material resources to VTF operations must be conducted to ensure that the VTF RPP and RCO continues to support the mission of the VTF in a cost and time-efficient manner.

Session 25 -- FIFTY YEARS OF NUCLEAR WASTE MANAGEMENT POLICY AND PRACTICE II

Co-chairs: Ted Gado, Foster Wheeler Environmental Corp.

25-1

HIGH-LEVEL WASTE MANAGEMENT: A PERSPECTIVE EXTENDED TO THE 1996 STATUS

Milton H. Campbell
MACTEC

ABSTRACT

A 1974 symposium on High-Level Radioactive Waste Management is revisited. The early year plans for waste management are briefly reviewed. A selected chronology traces progress on programs for commercial, defense, and foreign High-Level Waste Management from that symposium to date. The emergence of a glass waste form produced in vitrification plant as an industry norm is apparent.

INTRODUCTION

This paper revisits the symposium on High-Level Radioactive Waste Management organized by this author in 1974. The symposium was sponsored by the American Chemical Society (ACS) Division of Nuclear Chemistry and Technology at the 167th national ACS meeting. The symposium papers were collected and published in the Advances in Chemistry Series No. 153 (1). Early on, it was recognized in the US Atomic Energy Commission that radioactive waste management covered a broad area of federal government and commercial activities in the nuclear fuel cycle. Two simultaneous sources for radioactive waste were perceived; 1) national defense plans that required plutonium generated radioactive waste of several unique types, and 2) commercial use of nuclear reactors to produce electric power generated quite another set of radioactive waste forms. One common product of both courses was (and is) high-level radioactive waste. However, even within a single generation source, the waste takes multiple forms and has no conveniently simple definition.

By 1974 high-level radioactive waste management had become a topic of discussion in the scientific and engineering communities, a subject for the nation's newspapers to interpret for the lay public, and a major issue for activist groups. The purpose for this symposium was to present a 1974 overview of high-level waste management activities. The invited papers fell into three categories: 1) Commercial High-Level Waste; 2) Defense High-Level Waste; 3) Environmental and Decontamination.

COMMERCIAL HIGH-LEVEL WASTE

In his overview of this category, Dr. Pitman, then director of the Division of Waste Management and Transportation, US Atomic Energy Commission made the following points about solidified high-level commercial waste (2).

> "The AEC's program will provide retrievable storage for these solidified wastes in carefully maintained and monitored engineered facilities for the next several decades."
>
> "During this period investigation and demonstration of waste disposal in deep, stable, geologic formation will continue."
>
> "After completion of an extensive testing and demonstration program establishing the acceptability of permanent disposal, the radioactive waste will be removed from the retrievable surface storage facility and disposed of permanently."

High-level waste management at the first, and only, commercial fuel reprocessing facility in the U.S. (Nuclear Fuel Services at West Valley, N.Y.) was summarized (3). Purex processing type high-level and intermediate level wastes were neutralized and stored in multi-confined mild steel tanks.

An Oak Ridge National Laboratory study (4) projected commercial waste generation through year 2000 indicating that it would, "portend a problem of impressive size and complexity, but one that could be handled within the framework of current and planned investigative programs." Natural salt formations were believed to offer the best prospects for high-level

waste disposal, although other promising geologic formations were being considered.

Solidified waste forms for the immobilization of high-level radioactive wastes from the commercial reprocessing of power reactor fuels and processes for the reliable production of the waste forms were being developed at Battelle Pacific Northwest Laboratories (5). The development program had begun on nonradioactive laboratory and pilot scales and was planned to be carried out through fully radioactive engineering scale demonstrations of the processes. Development emphasized silicate glass or glass-ceramic forms produced in a two step calcination-melting process.

Radioactive waste management in Europe was summarized (6). At that time, Germany, England and France were vigorously developing technology and methodology for incorporating high-level radioactive waste into silicate glass. Germany was concentrating on a spray calcination vitrification system. England had selected a rising level glass process in which evaporation, calcination, and borosilicate glass vitrification all took place in a heated pot. France was operating a small-scale batch pot calcination - batch vitrification system and developing a new continuous system using a rotary calciner and melter with a batchwise draw-off.

DEFENSE HIGH-LEVEL WASTE

Reprocessing defense fuels to recover plutonium values resulted in site specific waste forms closely related to the chemical processes employed. Consequently, high-level waste management strategy varied somewhat from site to site.

Methods were being considered to immobilize Savannah River Plant (SRP) wastes (7) in solid forms such a cement, asphalt, and glass. 137Cs and 90Sr were recognized as the major biological hazards and heat producers in the alkaline wastes prepared at SRP. In the conceptual processes studied, 137Cs removed from the alkaline supernates together with sludges that contained 90Sr were to be incorporated into solid waste forms of high integrity and low volume suitable for storage in a retrievable surface storage facility for about 100 years and for eventual shipment to an off-site repository. Mineralization of 137Cs or its fixation on a zeolite prior to incorporations into solid forms was being studied. Methods for removal of sludge from the waste tanks were under study.

A status report was given on high-level waste management at the irradiated fuel reprocessing plant (ICPP) at the National Reactor Testing Station (INEL) (8). Interim storage of an acidic high-level liquid waste in stainless steel tanks was followed by calcination of the liquid waste in a fluid bed calciner and storage of the calcine in bins. Conversion of the granular calcine to cermet, glass-ceramic, and ceramic forms was being carried out to test for alternative long-term storage requirements.

The Hanford Waste Management Program was to complete evaporation of liquid tank wastes to prepare a solid radioactive salt cake to be stored in mild steel tanks for the interim (9). Additionally, megacuries of 137Cs and 90Sr previously removed from the liquid tank wastes were converted into solid 137CsCl and 90SrF to be stored under water in doubly encapsulated metallic containers. Several alternative modes for long-term storage/disposal of these high-level liquid wastes were being evaluated. For some of these modes, conversion of the solids to immobile silicates of low water solubility would be desirable. Low (10) and high temperature process development for preparation of silicate minerals was in process.

ENVIRONMENTAL AND DECONTAMINATION

Although it was not an exhaustive treatment, concern for radioisotope containment and a clean environment was highlighted by several papers. Studies on migration of plutonium (11) in limestone and basalt indicated that the absorption coefficients were dependent on the types and amounts of other ions present in the solution. Migration coefficients were for flow along the surface of fissures and through the porus stone.

Spent fuel from nuclear reactors is stored under water at the Idaho Chemical Processing Facility. The fuel storage basin becomes contaminated with 137Cs and 90Sr from fuel elements that leak and from cut pieces of fuel. Both 137Cs and 90Sr were removed from the coolant by ion exchange (12).

One requirement for any nuclear facility is to monitor the effluent waste water to show compliance with existing standards. A sequential procedure was described for the separation of the transuranic elements from up to 60 l of water sample (13).

FOLLOW-UP CHRONOLOGIES

This concise view of the approach to Radioactive Waste Management can be opened like a time capsule some twenty years later to validate our vision of the seventies. I'll now address three of the categories adding some interim chronology to see how the predictions fared. It is not possible in the time available to make an in-depth coverage on the chronological progress for each discussion item; rather, the speaker has taken the liberty of selecting his version of key events or status points. Members of the audience should feel free to overlay this presentation with their own perceptions.

Commercial High-Level Waste Chronology

A chronology for the Commercial High-Level Waste category is shown in Fig. 1. The column under 1974 reflects the positions taken in the symposium. Author selected entries are inserted under the appropriate year and opposite the appropriate 1974 entry. The Nuclear Waste Policy Act (NWPA) of 1982 and its subsequent amendments have played an important part in this chronology. For instance, even though an interim storage facility was originally envisioned and the thought was reinforced via NWPA, no such facility is in sight. Permanent geologic storage, seemingly on the fast track in the eighties has been loosing steam this decade much to the dismay of the utilities. Activities to develop commercial high-level waste forms have been virtually discontinued in the U.S. due to the demise of fuel reprocessing. There is more action on that in the foreign high-level waste category, however. Nuclear Fuel Services at West Valley is the only commercial reprocessing waste in the U.S. A vitrification facility has been constructed and demonstrated in the cold mode at that location. Hot start-up for a 30 month campaign is planned in March, 1996. The waste filled canisters will be temporarily stored in the decontaminated process cells.

Fig. 1

Defense High-Level Waste Chronology

Defense High-Level Waste Chronology is displayed if Fig. 2 with a format similar to the previous figure. In this case, the three DOE sites where fuel reprocessing was conducted were considered. With a number of alternative waste forms under consideration in 1974, the first obvious move was to select a single reference waste form. There was not enough space on the figure in the early eighties to record all of the independent studies conducted by independent peer groups, the National Academy of Engineering, etc., etc. Fortunately, these thoughts were

collected by Ray Walton et al in 1982, reporting the decision that borosilicate glass was to be the reference waste form for DOE with crystalline ceramic as the alternative waste form. The Defense Waste Processing Facility, DWPF, was designed and constructed at SRP in the 1980's; it has gone through waste qualification tests with 75 full sized canisters of simulated waste being produced. A number of these canisters were cut open to assess the glass quality and the compositional homogeneity. The results were suitable for qualifying the waste form and vitrification process. Hot feed start-up is anticipated early in 1996. At ICCP, the calcined waste form with a high calcium, alumina, zirconia, borate, and fluoride can be best solidified into a ceramic waste form. At Hanford, the initial plans for a vitrification facility, the Hanford Waste Vitrification Plant, HWVP, that would convert the double-shell tank wastes to borosilicate glass was abandoned in 1992. Since then an RFP has been prepared for early 1996 issue on the subject of privatization of the vitrification process. To summarize, a substantial technical evaluation established borosilicate glass as being the reference waste form for Defense Wastes. Only one vitrification facility has been put on line to date. Addition of future facilities in the DOE complex is a long way off.

Fig. 2

Foreign High-Level Waste Chronology

The Chronology presented in Fig. 3 for Foreign High-Level Waste is impressively far ahead of the U.S. position. First, it is clear that the glass waste form option was widely accepted early on. With vitrification plants that have operated since the 1980's, the high-level waste management programs outside the U.S. are an outstanding reflection of what was envisioned at the 1974 symposium.

Fig. 3

SUGGESTIONS FOR THE FUTURE

High-Level Waste Management in the United States will be best served by staying the course and completing vitrification of Defense High-Level Waste materials as expeditiously as possible. A substantial experience base will be forthcoming from the Savannah River Defense Waste Processing Facility operation and from the West Valley Demonstration Project. Implementation of these experiences with modifications that accommodate feed type variations should assure a safe, timely completion of this challenging task.

ABSTRACT

Irradiated nuclear fuel has been reprocessed at the Idaho Chemical Processing Plant (ICPP), which is a part of the Idaho National Engineering Laboratory (INEL); formerly the National Reactor Testing Station (NRTS), since 1953 to recover uranium-235 and krypton-85 for the U.S. Department of Energy (DOE); formerly US Atomic Energy Commission (AEC) and US Energy Research and Development Administration (ERDA). The resulting acidic high-level liquid radioactive waste (HLLW) is stored in stainless-steel, 1,100-m3, single-shell tanks in underground concrete vaults. A solidification process was developed during the 1950s to form a granular calcine solid from the acidic HLLW with a seven-fold volume reduction. An engineering-scale demonstration, the Waste Calcining Facility (WCF) was constructed and operated in 1963. After the successful demonstration of the process, the WCF was continued as a production facility through 1980, calcining 15,000 m3 of HLLW to 2,160 m3 calcine.

The New Waste Calcining Facility was designed and constructed based on the operating experience of the WCF and began operation starting in 1982. The calcined waste is stored near-surface in stainless-steel bins within concrete vaults. The bin sizes are approximately 4-m diameter by 12.5 to 18.5-m high. Some of the bins are cylindrical and others are of an annular configuration. Currently, there is an inventory of 3,800 m3 HLW calcine at ICPP consisting primarily of alumina and zirconia-based calcines, resulting from dissolution of aluminum and zirconium fuels, respectively, and zirconia-sodium blends. The amount of alumina, zirconia, and zirconia-Na calcines is approximately 560, 1250, and 1750 m3, respectively. An additional 240 m3 calcine inventory consists of calcines from processing other minor fuels and start-up bed material. Several technologies have been identified to date that could immobilize calcine; these include vitrification and glass-ceramic processing. Preliminary scoping tests were run in the 1960s, and laboratory testing was started in the 1970s to develop glass formulations for ICPP calcines. In the 1980s, glass ceramic formulations were tested to produce a high waste loading waste form with a nearly three-fold lower volume than the equivalent glass waste forms. For alumina calcine, waste loadings of up to 29 wt% and 24 wt% could be obtained in a borophosphate and borosilicate glass, respectively. For zirconia calcines, waste loadings of 33 wt% were observed using a borosilicate frit. Nonradioactive laboratory- and pilot-scale and radioactive laboratory-scale tests were run using the borosilicate frit 127, and MCC-1 and MCC-2 leach tests indicated that there did not appear to be significant differences in the glasses formed using simulated zirconia calcine at laboratory or pilot scale and using radioactive zirconia calcine at laboratory scale. This paper focuses on some of the history and early experience which has helped the ICPP successfully accomplish its mission safely and with minimal impact on the environment.

INTRODUCTION AND PURPOSE

Irradiated nuclear fuel has been reprocessed at the Idaho Chemical Processing Plant (ICPP), which is a part of the Idaho National Engineering Laboratory (INEL); formerly the National Reactor Testing Station (NRTS), since 1953 to recover uranium-235 and krypton-85 for the U.S. Department of Energy (DOE); formerly US Atomic Energy Commission (AEC) and US Energy Research and Development Administration (ERDA). A decision was made at the start of reprocessing to store the resulting acidic high-level liquid radioactive waste (HLLW) in stainless-steel 1100 m3 single-shell tanks in underground concrete vaults, rather than continue the practice at that time of HLLW neutralization and storage in carbon steel tanks. In another innovation in the waste management practice, a solidification process was developed during the 1950s to form a granular calcine solid from the acidic HLLW with a seven-fold volume reduction. A pilot-scale demonstration, the Waste Calcining Facility (WCF) was constructed and operated in 1963. After the successful demonstration of the process, the WCF was continued as a production facility through 1980, calcining 15,000 m3 of HLLW to 2,160 m3 calcine. The New Waste Calcining Facility was designed and constructed based on the operating experience of the WCF and began operation starting in 1982.The calcined waste is stored near-surface in stainless-steel bins within concrete vaults. The bin sizes are approximately 4-m diameter by 12.5 to 18.5-m high. Some of the bins are cylindrical and others are of an annular configuration. Currently, there is an inventory of 3,800 m3

HLW calcine at ICPP with compositions shown in Table I. Not shown in Table I is zirconia-Na calcine, which has a similar composition to Fluorinel-Na calcine. The amount of alumina, zirconia, zirconia-Na, and fluorinel-Na calcines is approximately 560, 1250, 950, and 800 m3, respectively. The remaining 240 m3 calcine inventory consists of calcines from processing other minor fuels and start-up bed material with compositions shown in Table I.

Table I

Several technologies have been identified to date that could immobilize calcine; these include vitrification and glass-ceramic processing. Preliminary scoping tests were run in the 1960s, and laboratory testing was started in the 1970s to develop glass formulations for ICPP calcines. In the 1980s, glass ceramic formulations were tested to produce a high waste loading waste form with a nearly three-fold lower volume than the equivalent glass waste forms. For alumina calcine, waste loadings of up to 29 wt% and 24 wt% could be obtained in a borophosphate and borosilicate glass, respectively. For zirconia calcines, waste loadings of 33 wt% were observed using a borosilicate frit. Nonradioactive laboratory- and pilot-scale and radioactive laboratory-scale tests were run using the borosilicate frit 127, and MCC-1 and MCC-2 leach tests indicated that there did not appear to be significant differences in the glasses formed using simulated zirconia calcine at laboratory or pilot scale and using radioactive zirconia calcine at laboratory scale.

This paper focuses on some of the history and early experience which has helped the ICPP successfully accomplish its mission safely and with minimal impact on the environment.

EARLY ICPP DEVELOPMENT

The ICPP was purposely located on an arid tract of withdrawn public land previously used by the U. S. Navy for testing guns and munitions. The sparsely populated surrounding area and its remote location were particularly suitable for processing spent and irradiated nuclear fuel , then in its infancy. The ICPP was originally designed to process a widely-varying load of enriched production reactor fuel material as well as uranium and uranium-aluminum alloy fuel elements from a number of experimental reactors. The original design also provided space for the addition of processing facilities for stainless steel and zirconium fuel elements, and for other radio-chemical processes.

The development of the initial plant processes and the initial design scoping of the plant were carried out by Oak Ridge National Laboratory (ORNL). After completion of the design studies the AEC Processing Advisory Committee recommended in April 1950 that the plant be built at the NRTS in Idaho. In June, 1950 the Foster Wheeler Corporation was selected as the architect-engineer with responsibility for all detailed plant design except for the processing equipment. The American Cyanamid Company was selected as the operating contractor in late 1950. About this time Bechtel Corporation was selected as the construction contractor and excavation started.

Construction was essentially complete by mid 1952. After a preliminary test, cold run, and low radiation level run period, the plant was placed in routine production in March 1953. Late in 1953 Phillips Petroleum Company (Phillips) assumed responsibility for plant operation. Extended periods of high efficiency operation demonstrated the worth and dependability of the ICPP for processing a variety of irradiated reactor fuel (1).

Increasing liquid waste volumes were projected as more and more fuel was committed for reprocessing. A process for waste volume reduction was desired and pyrochemical processes were evaluated (2). Eventually development of a fluidized-bed calciner reduced waste volume by 7-fold and converted the liquid waste to a less mobile solid-granular form. This work was initiated in about 1953. The calciner development, based on a concept and testing by ANL, used a 15-cm (6-inch) diameter pilot plant (3). Positive results of the early development tests convinced the AEC, in 1956, to build a demonstration facility, The Demonstration Waste Calcining Facility (DWCF), at the ICPP. Construction began in 1958, at a cost of $6 million, and was completed in 1961. Phillips assigned a special section of its Technical Branch the responsibility to begin testing and to prepare to start the facility. Cold testing began in 1961 by Operations personnel and continued for one and one half years. In November 1962 , operation of the DWCF was demonstrated. The "D" was dropped from the acronym and the facility became known as the WCF. Radioactive feed was introduced on December 8, l963. The first run lasted 11 months, until October 15, 1964, when the first Calcined Solids Storage Facility (CSSF) was filled. More than 1800 m3 (500,000 gallons) of radioactive liquid waste from three waste tanks were converted to 2100 m3 (7,500 ft3) of solids. The net output exceeded the design rate by 15% and the process operated at 99% efficiency. Figure 1 is a photograph of the WCF and CSSFs 1-3 after construction.

Fig. 1

As fuel shipments to ICPP increased additional CSSF's were built and the WCF was modified for higher feed rates. The facility operated until March 1981, calcining about 15,000 m3 (4 million gallon) of liquid radioactive waste. The WCF was then replaced by the New Waste Calcining Facility (NWCF) which began hot operations in September 1982. The ICPP fuel storage and dissolution and remote analytical facilities were also subsequently replaced by state of the art facilities to improve operational safety and allow throughputs consistent with the demand of fuel receipts. Figure 2 is a 1985 photo of the NWCF and additional CSSFs 4-6. Note the relative size of the WCF and location of the subsurface HLW liquid tanks.

Fig. 2

ICPP WASTE MANAGEMENT CONSIDERATIONS AND DESIGN DECISIONS

Basic decisions and considerations had a direct bearing on the future of reprocessing. Specific issues included whether or not to neutralize acid wastes from the process, selection of a calcination method, design of waste tanks, number of waste tanks required, and design of CSSF's.

Acidic Raffinates Storage: A decision was made not to neutralize raffinates with sodium hydroxide as was commonly practiced in those days. This was possible due to implementation of improvements in extraction technology. Neutralization would have significantly increased the volume of high-level liquid waste generated and complicated its use as an isotope feed stock for ORNL's expanding isotope recovery operations. A decision to neutralize would have precluded continuous fluidized-bed waste calcining because of the inability of the process to handle high concentrations of alkali nitrates present in the solid product.

Design and Number of Liquid Storage Vessels: A decision was made to construct a limited number of 1,100 m3 (300,000 gallon) waste tanks of stainless steel. Stainless steel was available after the end of WW II and was necessary because the waste was acidic. The initial tanks were

constructed of type 348 stainless steel. Corrosion testing was used to justify the substitution of more economical 304L stainless steel in future tank construction. Tanks planned for use with high-level waste were equipped with in-tank cooling system to maintain the solution at low temperature which minimized material corrosion. Acidic waste with no precipitates minimized the formation of galvanic corrosion cells between solution precipitates and the tank material. Today the ICPP has only 11 major waste tanks because the tankage space as the tanks have been emptied using the calcining process. Also, no tank failures have been experienced, even for tanks used to store aluminum-complexed-fluoride solutions.

Selection of Calcination Process: Initially the design liquid extraction raffinate was aluminum nitrate based. Candidate solidification processes included pot calcination, spray calcination and rotary kiln calcination (2). Later the fluidized bed process was chosen because it was continuous, was readily adaptable to remote operations, had no moving parts to wear out, had adequate throughput capacity to meet ICPP requirements, and was adequately developed for the demonstration (4).

Design and Construction of Calcined Solids Storage Bin Sets: A decision was made that the calcined solids would be stored in stainless steel bins with extended design life. The vessel design was based on a critical centerline temperature that would prevent the radionuclide migration. The first CSSF was conservatively designed and constructed of annular bins; subsequent CSSF's incorporated observed heat transfer experience and employed a more economical cylindrical bin design . In addition, after CSSF #1, subsequent CSSF's were designed with retrieval ports to accommodate any future desire to retrieve the calcine for subsequent processing.

ANL CALCINATION TECHNOLOGY DEVELOPMENT

The concept of calcining radioactive liquid waste by atomizing the liquid in a heated bed of inert particles was originated by ANL. Initial calcination development was then accomplished jointly between ANL and Phillips Atomic Energy Division through 1961.

Early development by ANL (5) consisted of brief feasibility studies using a 7.5-cm (3-inch) diameter calciner and additional more extensive studies using both unshielded and shielded 15-cm (6-inch) diameter calciners. Tests with the 7.5-cm diameter calciner were all with cold feed. Subsequent tests with the 15-cm diameter calciners were both cold and up to 12% spiked, hot, as-produced feed from the ICPP. Initial development was based on testing acidic aluminum nitrate solution but ANL later extended the work to include Hanford type PUREX waste. ANL development with aluminum nitrate waste consisted primarily of testing the behavior and treatment of fission products in the calcination process using the six-inch-diameter calciner. Radioactive feed consisted of ICPP first-cycle raffinate diluted with simulated cold aluminum nitrate raffinate in a dilution ratio which ranged from 1:1000 to 1:8. Basically ANL pilot plant experience indicated the fluidized bed process was feasible from the operating viewpoint and that ruthenium was the only volatile fission product. The tests showed that virtually all activity except ruthenium remained in the solid product over the temperature range of 350 to 550C. The ruthenium volatility was determined to be very temperature sensitive. At 350 degrees operating temperature about 88% of the ruthenium was volatilized. Whereas at 550C less than l% volatilized. Partial condensation of the off-gas removed 99.8% of the entrained non-volatile

activity. Later use of a venturi scrubber and silica gel bed prior to partial condensation resulted in decontamination factors of 1,000 to 10,000 for ruthenium and 100,000 for non-volatile fission products.
Both bayonet and convoluted filters were tested for calciner off gas cleanup. The bayonet sintered metal filters proved highly efficient for removal of particulate from calciner off-gases. The filters were especially effective when coated with a dust layer. They were so effective that analysis of condensate and gas samples detected no radioactivity other than ruthenium. Failure of the sintered metal filters after being subjected to extreme temperatures (700C) was caused by embrittlement. Additional tests indicated that if operating tests did not exceed 400C no embrittlement would occur. Convoluted metal filters were tested and found to be unsatisfactory. Breakthrough of non volatile activity was 10-fold greater than with bayonet filters.
Since sintered metal filters required much development, venturi scrubbers were studied as an alternative for cleaning the off-gas. The use of silica gel adsorbers were studied for removal of volatile ruthenium. A primary advantage of these devices was low waste volume generation. The scrub solution from the venturi could be recycled to calciner feed and the regenerating solution from the adsorber was very small. Both scrubber and adsorbers were then added to the ANL 15-cm (6-inch) calciner to study particulate removal in parallel with ICPP studies. Venturi scrubbers were very effective in removing particulate from the off-gas, and silica gel adsorbers were very effective in removing volatile ruthenium. Tests also showed that the silica gel could be readily regenerated.

ICPP CALCINATION TECHNOLOGY DEVELOPMENT

Development at ICPP in support of a DWCF was the responsibility of Phillips, the operating contractor at ICPP from the fall of 1953 until 1967. Calcination of acidic aluminum nitrate waste using fluidized bed technology reported by ANL in 1955 was based on conceptual studies. A 15-cm (6-inch) diameter pilot plant calciner patterned after the one used by ANL but with a number of changes to help solve operability problems reported by ANL was then built and operated by Phillips personnel at the NRTS (6). The purpose of this pilot plant testing was to provide equipment and process scale up data and to define process parameters for designing the DWCF. The 15-cm diameter calciner pilot plant as reported by Grimmett in 1957 (7) was fed simulated cold aluminum nitrate waste at rates ranging from 20 to 110 ml/min, at fluidized bed operating temperatures ranging from 180C to 500C, and at operating period durations of 8 to 336 hours.
The 15-cm diameter calciner vessel was 1.7 m (5.5 feet) long and contained a charging tube, a thermowell and off-gas tube at the top of the vessel. The fluidizing air distributor consisted of a flat plate with twelve 1.3-cm (0.5-inch) diameter holes, spaced on a 4.3-cm (1-11/16 inch) triangular pitch with 1.3-cm (0.5-inch) tubes welded to the top of the plate to extend 0.6 cm (1/4 inch) above the plate. The top of the tubes were capped with 1.4-cm (3/4-inch) discs and 0.3-cm (1/8-inch) holes were drilled at 90 degree intervals. Air was introduced to the bottom of the distributor through a 1.4-cm (3/4-inch) pipe. The calcined product was removed continuously by means of a one-inch draw-off line extending 61 cm (2 feet) above the distributor plate. Heat was supplied by 18 internal electric heaters with 15-cm (6-inch) heated lengths located horizontally inside the calciner bed. Liquid feed was introduced under pressure through commercially available pneumatic atomizing spray

nozzles. To provide operating data, pressure taps and thermocouples were located throughout the bed. Calciner auxiliary equipment included a cyclone, a spray scrubber, condenser, and fluidizing gas preheater. Operating variables studied were feed rate, bed temperature, fluidizing velocity, feed nozzle air-to-feed ratio, product draw off, and liquid feed composition. A problem with size distribution not reaching steady state made it difficult to determine various effects of operating variables on the product.

Feed Rate. It was generally determined that feed rate influenced particle size distribution and possibly bulk density. Low feed rates generally produced smaller particles than runs at higher rates. The effect of feed rate on bulk density was not conclusive.

Bed Temperature. The data showed decreasing bulk density with increasing bed temperature throughout the temperature range studied. The bed temperature also had a profound effect on particle-size generation. Low bed temperatures (300C) produced large mass mean particle diameters, whereas, 500C tended to produce fines.

Fluidizing Velocity. Changing fluidizing velocity appeared to change particle size distribution.

Feed Nozzle Air-to-Feed Ratio. Runs were made at constant air to feed rates, but low atomizing air flow rates possibly caused agglomeration tendencies.

Product Draw Off. A relatively small amount of air is passed countercurrent to product overflow. The air is an effective means of controlling particle size withdrawal.

Feed Characterization. The concentration and composition of feed to the calciner was not studied but was expected to have a strong effect on calcine structure and size distribution. Although most runs were made with aluminum fuel, some exploratory runs were made with stainless steel and zirconium type fuel raffinates.

The results of the pilot plant tests verified the feasibility of calcining aluminum type waste. The advantages of the technology include independence from complicated moving parts, excellent control of bed temperature with uniform high heat transfer rates, reduction in corrosion potential of stored product, adaptability to remote operation, and excellent control of particle size and properties.

ICPP CALCINATION DEMONSTRATION AND HOT OPERATIONS

Pilot plant tests established target ranges of principal operating values for the full scale demonstration. The ranges for the variables was 1) calciner bed temperatures of 400 to 500C, 2) fluidizing air velocities of 23 to 40 cm/sec (0.75 to 1.3 feet/second), and 3) air to liquid feed nozzle ratios of 500 to 750. The facility was operated on cold simulated feed for more than 4500 hours to establish that the equipment was adequately reliable and safe for hot remote operations. Prior to "hot" startup of the WCF an extensive safety analysis was conducted to assure no surprise hazard existed. Through 1973, the WCF and ICPP reprocessing facilities were operated alternately with common crews during campaigns that lasted several months each. This provided maximum use of both maintenance and operation personnel. In order to increase ICPP throughput separate dedicated crews were provided to allow concurrent operation of the WCF and reprocessing facility. Ultimately, the WCF operated until March 1981, calcining nearly 15,100 m3 (4.0 million gallons) of liquid radioactive waste.

A simplified flow diagram of the WCF process is given in Fig. 3. A major portion of the equipment, ~70%, is for off-gas cleanup. The cleanup equipment includes a cyclone, a quench tower, a venturi scrubber, entrainment separators, silica gel adsorbers, and HEPA filters.

Fig. 3

The WCF calciner vessel was four-feet in diameter. Radioactive feed was introduced into the bed through pneumatic atomizing nozzles. The feed was sprayed through three nozzles equally spaced in a horizontal plane at a total rate of 320 to 530 L/hr (85 to 140 gallons/hour) including waste, additives, and scrub recycle. During the first three campaigns and until June 1969, heat was supplied by an in-bed heat exchanger bundle using sodium-potassium alloy which operated at a bundle temperature of up to 760C. The NaK was pumped by an electromagnetic pump and heated in an oil fired furnace. Preheated fluidizing air was introduced through 14 capped orifices equally spaced on a distributor plate. Operation at superficial fluidizing velocities between 25 and 40 cm/sec (1.0 and 1.3 feet/second) was satisfactory with average bed particle size ranging from 0.6 to 0.75 mm.

To allow increased WCF capacity and reliability, an in-bed combustion system using oxygen-atomized kerosene was installed in 1970 (8). The use of in-bed combustion resulted in increased heat transfer rates, a change in the behavior of fission product ruthenium, and lower metal wall temperatures. A less volatile ruthenium species reduced concentrations in the off-gas by a factor of 100 to 200. However, decontamination on WCF internal surfaces became more difficult.

Boric acid was added batchwise to aluminum nitrate feed solution to suppress the formation of alpha alumina and insure the product remains in the amorphous rather than crystalline form. The addition of boric acid is essential to provide particle size control, minimize decontamination problems, and reduce erosion of pumps, valves, and piping by making the aluminum specie soluble in the nitric acid scrub solution.

Calcium nitrate is added to fluoride bearing zirconium type waste to complex free fluoride. This is necessary to reduce corrosion on downstream process equipment and piping and to control fluoride volatility.

The granular calcined solids product is pneumatically transferred to and stored in vented stainless steel bins located in concrete vaults.

NWCF DESIGN, CONSTRUCTION, AND OPERATION

The WCF was retired in 1981, to be replaced by a state-of-the-art NWCF. Anticipated increasing fuel receipts coupled with excessive wear and the desire to reduce exposure to personnel during the operation/maintenance cycle called for a replacement calcining facility.

Wear and tear on the WCF equipment after many years of operation result in increased delays for maintenance refurbishment. This coupled with a need to increase throughput to accommodate increased fuel shipments prompted the need for a replacement. Design of the NWCF was initiated in 1974 (9) and construction started in 1976. The facility incorporated the newest fluidized bed calcination, off-gas cleanup, remote operations and maintenance, and decontamination technologies. The design throughput was increased to 11,300 L/day (3,000 gallons/day).

The calcination process didn't change significantly with the new facility. The construct incorporated many improvements. The calciner vessel active bed region was increased to a 1.5-m (5-ft) diameter with a 2.1-m (7-ft) diameter expanded upper section fabricated from 347

stainless steel. Downstream vessel sizes correspondingly sized. Also more corrosion resistant Nitronic 50 was used to handle more hostile (trace fluoride and chloride) chemical environments and higher operating temperatures. WCF experience identified high wear and exposure areas. To greatly reduce or eliminate such problems, high maintenance equipment (pumps, valves, flanges, electrical connections, and off-gas filters) was placed in readily accessible corridors for remote replacement using master-slave and electro-mechanical manipulators and cranes. The remote capabilities installed at NWCF were tested in a full-scale mock up facility at the INEL and positioned for easy removal and replacement without lengthy shut downs or high radiation exposures to personnel. Failed equipment was transferred directly to integral shielded facilities for remote decontamination and subsequent repair or disposal. NWCF operating experience has demonstrated the effectiveness of this concept and design.

The NWCF began hot operations in September 1982, after extensive system operability and cold testing, and calcined 6,000 m3 (1.6 million gallon) of waste before shutting down in March 1984 when all available liquid waste feed was processed. During the down period a new Distributive Control System was installed. The NWCF was restarted on September 30, 1987 and has operated successfully on various feeds and combinations of feed such as Fluorinel, zirconium, and blended Fluorinel-Na waste feeds. To date the NWCF has calcined over 13,600 m3 (3.2 million gallon) of radioactive liquid waste to 1,670 m3 (5,900 ft3) of calcined solids. Successful operation of the NWCF and WCF have combined have to eliminated the need to build twenty-six 1,100-m3 (300,000-gallon) waste tanks,

EARLY HLW IMMOBILIZATION TECHNOLOGY DEVELOPMENT

As calcining of acidic liquid high-level waste became a reality it became readily apparent that methods for final disposal of the calcined waste most be developed. The calcine, although physically and thermally stable, was leachable for several of its radioactive constituents, most notably cesium.

Scoping experiments were therefore started in the 1960s to evaluate potential final chemically-stable waste forms. Many possibilities were examined including glass, sulfur encapsulation, concrete, and ceramics (10). Final disposal of reprocessed nuclear-fuel waste was not of high priority during the sixties in the then current DOE structure and research on these aspects languished to the end of the decade.

By the early 1970s a reawakening occurred and research funds on some scale became available to all of the DOE sites managing high-level waste, but most notably at the Savannah River site because DuPont was committed to solidifying and disposing of its liquid waste prior to passing its operating contract on to someone else.

At the ICPP a small program was started by the mid 1970s to evaluate immobilization of its calcined waste for final disposal. The reprocessed high-level waste at the ICPP consists of varied nuclear-fuel compositions and is also different from that of either the Hanford or Savannah River high-level waste. The major differences are 1) the liquid waste is acidic as opposed to neutralized (basic) and 2) the ICPP waste compositions are totally different. The ICPP calcined waste are mostly cladding material. Wastes from the early 1960s consists mostly of aluminum, whereas later reprocessed waste consists mostly of zirconia, calcium fluoride and alumina and just for good measure stainless-steel fuels and sodium containing calcined waste is also present.

Although early waste immobilization experiments revisited such possibilities as encapsulation of the calcine in concrete, and explored sintered glass-ceramics (11), metal matrices (12), pelletizing (13), it became obvious more practical processes were needed. Hanford had done extensive experiments on conversion of their waste to glass but those glass formulations were not suitable for vitrifying the high-alumina and zirconia calcines at the ICPP.

Glass waste-form development at the ICPP proceeded rather efficiently because of the meager funding allocations available at the time. Calcination was very successful and engineered storage of the calcine was planned for many years. Therefore, there was no apparent urgency to immobilize the ICPP high-level waste for final disposal. Nevertheless an efficient glass composition was demonstrated for the high-alumina waste (14). Another glass composition was developed for the zirconia-calcium fluoride calcine (15). For alumina calcine, waste loadings of up to 29 wt% and 24 wt% could be obtained in a borophosphate and borosilicate glass, respectively. For zirconia calcines, waste loadings of 33 wt% were observed using a borosilicate frit. Glass from this waste has turned out to be of extraordinary leach resistance. In fact current Savannah River glass contains a small percentage of added zirconia to provide improved stability. Laboratory and pilot-scale melter experiments showed that the high zirconia-calcium fluoride glass can be produced at practical melter temperatures, and very durable melter refractories are required because of fluoride corrosiveness (16, 17, 18). Nonradioactive laboratory- and pilot-scale and radioactive laboratory-scale tests were run using the borosilicate frit 127, and MCC-1 and MCC-2 leach tests indicated that there did not appear to be significant differences in the glasses formed using simulated zirconia calcine at laboratory or pilot scale and using radioactive zirconia calcine at laboratory scale.

Because the calcines at the ICPP are of varied composition, a practical and simple computer code was developed to not only predict glass stability but also determine a practical glass composition for a proposed waste composition. The code has worked effectively to determine aspects of permissible waste loading, immobilized waste durability, and amount and type of additives needed.

Waste volume reduction became the byword during the 1980s. The volume of a glass waste form required to immobilize the ICPP calcined waste was considered large mostly because of requirements to add calcium to the waste during calcining to stabilize the fluorides present in the liquid waste. This addition is required even if the liquid is directly vitrified. Direct liquid vitrification does not save on glass volume and is very corrosive to melter electrodes.

Waste volume reduction efforts resulted in the development of a glass-ceramic waste form during the 1980s for the ICPP calcined high-level waste (19, 20). A glass-ceramic can accommodate up to about 70 wt% calcine whereas a glass can only accommodate about 30 wt% calcine. In addition the glass-ceramic is about 50% more dense. Therefore final volume reduction is greatly reduced and the glass-ceramic is equally as durable, if not more so. Processing a ceramic waste form is more sophisticated, ideally requiring an isostatic pressing process and special particle and containment handling technology.

Recent evaluations have proposed dissolution of calcine and separation of a small high-activity waste fraction, followed by a significantly smaller-scale vitrification process (21). The low activity waste would be

disposed on site as a grout. Evaluations are continuing with a full-scale facility projected to process all of the calcine by 2035 in order to meet a legal agreement with the State of Idaho.

CONCLUSIONS

The ICPP fuel reprocessing operation that began in 1953 has resulted in approximately 3800 m3 of solid calcined HLW which is stored safely in stainless steel bins with a long design life and is scheduled for immobilization for shipment of the glass off-site by 2035.

A set of decisions and focused development activities during the early history of the ICPP has resulted in these current relatively safe conditions, with no major waste leaks to the environment compared to some of the other DOE sites. This paper describes some of these developments which illustrate successful application of an innovative technology including development through radioactive pilot scale and pilot demonstration to result in full-scale waste processing that is unique in the DOE complex. As a result, the HLW storage at the ICPP is currently under a relatively minimal environmental risk compared to other comparable DOE sites.

RADIOACTIVE WASTE DISPOSAL - THE EARLY YEARS (1943 - 1970)

Frank L. Parker
Vanderbilt University
Nashville, TN 37235

ABSTRACT
Though there were early concerns about the fate of the radioactive materials discharged to the environment (Arthur Compton's 1943 letter concerning the likely fate of materials that would be discharged to the Clinch River when the Manhattan Project moved to Oak Ridge), there was no major public disclosure until the control of atomic energy was put under civilian control in 1954 and the first International Conference on Peaceful Uses of Atomic Energy in Geneva, Switzerland by the United Nations. The first International Conference on Radioactive Waste Disposal organized by the International Atomic Energy Agency was held in 1959 and the first congressional hearings on radioactive waste disposal were held in the same year. The end of innocence began in 1970 with the start of the environmental movement triggered by Silent Spring by Rachel Carson but implemented by the National Environmental Policy Act but really gained full momentum with 1984 law suit which put the hazardous wastes of the Department of Energy under the legal jurisdiction of the U.S. Environmental Protection Agency. Disposal practices at the major sites will be reviewed with particular emphasis on practices at Oak Ridge where the author was head of radioactive waste disposal research. International aspects will also be presented and compared to U.S. practices from the perspective of the author who was head of radioactive waste disposal at the International Atomic Energy Agency from 1960-1961. Recent, since perestroica, information about early Soviet practices will also be

discussed. Despite revisionist views of the early days, it is clear that in the U.S. the majority of the practices were the industrial norm or the tools for better information were not available (neither the alpha nor the gamma spectrometer had yet been invented) or the general scientific ignorance (discharge of wastes to the ground was considered standard practice). Speculation about future disposal practices will be presented.

INTRODUCTION

Some highlights of the USA Radioactive Waste Policy - Past, Present and the Future as seen through my own clouded lens will be presented. My views are prejudiced because I have been a participant in many of the activities I will describe. While the present day situation is known to many of you, I am always amazed that in the USA, due to rapid turnover of civil servants engaged in these tasks and the almost as rapid turnover in the operating contractors of the DOE sites and the somewhat slower turnover in the personnel at the DOE National Laboratories that the corporate memory of what took place has faded. This is vividly shown in the revisionist history of Radioactive Waste Disposal in the USA. (1) I hardly recognized some of the events described there. Even the polemical book Nuclear Imperatives and Public Trust by Luther Carter gives a better insight into the program. (2)

The present situation is clouded by the election of a new congress this last year that has little knowledge or interest in the topic unless the budgets can be cut. Nor can we expect much resistance to this juggernaught from the executive and judicial branches because as Finley Peter Dunne, a noted political satirist at the turn of the century, had his cartoon character Mr. Dooley say "No matter whether th' constitution follows th' flag or not, th' supreme coort follows th' iliction return."(3) With the President promising to veto many of the Congress' Budget Bills because of the most egregious parts of the bills, none of the major fights are about nuclear energy or radioactive waste disposal. In fact, the Department of Energy's budget passed the Congress and was signed into law on the first try. Where this will all end, is still uncertain. In any case, it will not be what was before. Finally, I would like to make some guesstimates and recommendations about future policy. This is the safest part of the presentation because none can dispute the factual content and as Abraham Lincoln said, "The world will little note, nor long remember, what we say here" (4) so I do not expect to hear from any of you in the next century to say "Frank, you were dead wrong."

The comments will be divided into three time periods as 1943 to 1990 (past), 1990 to 1995 (present) and post 1995 as the future. Because of the time limitations, only a few topics will be discussed of the major categories of wastes: high level wastes, and low and intermediate level wastes and their environmental impact, and the governmental policy and regulatory framework and public involvement that prevailed during these time periods.

HIGH LEVEL WASTES

Till ownership of nuclear reactors was allowed in the civilian sector in 1954, McMahon Bill (5) and President Eisenhower announced the Atoms for Peace Initiative (6), all U.S. fuel was reprocessed after short irradiation times to maximize plutonium-239 production for bomb purposes. A similar concept, short storage times after removal from reactors, was carried over to irradiated civilian reactor fuel. In fact, this was mandated in the regulations that the solidified waste from reprocessing would be transferred to a federal repository no later than 10 years after

separation. (7) This was the legal policy of the USA for many years, even after President Carter indefinitely suspended reprocessing of spent fuel derived from the production of civilian nuclear power in 1977 because of fears of nuclear proliferation (8) despite the fact that the INFCE studies (9) and the OTA study (10) indicated that spent fuel and reprocessing wastes would not be the preferred routes for terrorists groups to obtain nuclear weapons. This also has relevance today with heavy political pressure to transmute the plutonium in high level wastes to reduce proliferation threats. With the world now awash with surplus plutonium from dismantled weapons, it seems silly to oppose reprocessing on proliferation grounds. Because of this concern, the United States has attempted to maintain a rigid separation of materials from weapons production and those from civilian use. President Reagan weakened this rigid separation when he authorized the burial of spent fuel from civilian reactors in the same repository as high level waste from weapons production. (11) Since the U.S. is the only nation that will not allow reprocessing and commingling of civilian and weapons nuclear material, the net deterrent is not great. This is true, particularly, if it is kept in mind that the USA has only 1/4 of the world's nuclear power reactors and that together these power plants produce 20 tons per year of new plutonium. Though this plutonium is not weapon grade, this does not mean that explosive devices cannot be made from this material. The decision of what to do with the 50 tons of surplus U.S. weapons grade plutonium already available has not yet been decided but some indication of the options available can be had in the recent NAS/NRC report. (12) It may be thought that this is too much emphasis on nuclear weapons and civilian power plutonium problems. It should be remembered from the consequences of Chernobyl, that one terrorist detonation of a nuclear device would doom nuclear power and any rational discussion of radioactive waste disposal for many, many years. One of the first lectures given to new employees at Oak Ridge, contained the sentence, "You can get away with most anything here except a criticality accident." (13)

Discussion of high-level waste disposal had already appeared in government documents as early as 1944, (14) and in reviews by the NAS/NRC as early as 1956. (15) However, it was not until the NAS Committee meeting in 1955 that a recommendation was made for deep geological disposal with emphasis on rock salt as the medium of choice. (16) This decision by a non-governmental group resulted in the start of experimental investigations on deep geological disposal in salt in 1957 at the Oak Ridge National Laboratory with a first publication on the progress in 1958. (17) The initial experiments were simulated high-level liquid wastes in the operating Hutchinson, Kansas Salt Mine of the Carey Salt Company. Despite assurances by geologists that salt was impermeable, it was quickly found that the simulated waste moved rapidly along the interfaces of bedding planes of anhydrite and polyhalite and salt. However, the success of the laboratory work on stability of rock salt under high irradiation and the theoretical studies on the heating of the salt from high level wastes prompted a move to the inactive Carey Salt Mine in Lyons, Kansas. In today's gridlocked bureaucratic environment, it is useful to recall how the Lyons mine was chosen. Four of us, Joe Lieberman, head of the Sanitary Engineering Section of the AEC (see paper by Walter G. Belter this meeting), Ed Struxness, Associate Director of the Health Physics Division at ORNL, myself and Bill Heroy, one of the most distinguished geologists of the time, met in a room at the Cosmos

Club in Washington. The Cosmos Club, a private institution, was then the informal headquarters of the scientific elite in the U.S. and particularly for the earth sciences. Bill Heroy and I had visited all of the operating and accessible salt mines in the U.S., as well as a number of other mines to help determine the location of these first tests of a geological repository for high level wastes. In an afternoon, we did an impromptu, informal multiattribute utility analysis of potential sites with a sensitivity analysis of the weightings of the attributes (note, I have put what we did into present day jargon) and the choice of Lyons, Kansas was robust. Therefore, at the end of the meeting, Lieberman said to me "go ahead and do it Frank." That was it, the authorization and the appropriation. As an aside, I do not believe our budget ever came close to a million dollars per year. For local transportation, we had a shopworn panel truck from the government car pool in Kansas City. Yet despite this, the first set of Engineering Test Reactor fuel assemblies (thermal flux of 1.5 x 1014 n/cm2sec and irradiation times of 23 days with an initial loading of 400 gm of 235U resulting in a curie content of 240,000 curies per canister at time of emplacement) were placed in the test facility during November 17-19, 1965. After having reached the design objectives of a total dose to salt of 5.3 x 108 rads and a peak temperature of 200C, the third and final set of irradiated fuel assemblies were removed on June 26-27, 1967. (18) Basically all of the equipment and procedures being used in test facilities today are based on designs developed then. What has been going on in the last 30 years? The results were so satisfactory that in June 1970, the AEC tentatively selected a full scale high level waste repository site in the bedded salt at Lyons, Kansas, pending confirmation tests, that would be completed in 1978 at a total cost of 25 million dollars. (19) With the political climate prevailing at that time, it would have been possible to do that. However, that site was found to be inadequate. Instead of utilizing an eminently suitable site (Naval Air Station) only 10s of miles from Lyons, there have been a long series of failed attempts to establish a centralized above ground surface interim storage facility for spent fuel and a repository. They have failed for complex reasons, both technical and political. After the abandonment of the Lyons site, the AEC in 1973, while making a centralized surface storage facility the "near-term objective," reaffirmed that the "major effort" was to be a Federal Repository "to be ready in the early 1980s." (20) In 1974, the new Chairperson of AEC, Dixy Lee Ray, downgraded geological disposal to a separate objective. (21) In 1977, the Department of Energy in the course of announcing a new centralized storage facility (away from a reactor) also noted that a geologic repository was still required. (22) The Interagency Review Group on Nuclear Waste Management in March 1979 called for a "stepwise approach to the development of HLW repository." (23) In February 1980, President Carter made the first Presidential Announcement on Nuclear Waste Policy (24) and said that the goal was permanent geologic disposal of nuclear waste. The Nuclear Waste Policy Act of 1982 favored permanently disposing of high-level radioactive waste in a geologic repository and provided a mechanism for narrowing the choices to three sites which would be examined simultaneously. (25) The repository would only be allowed to dispose of 70,000 MTU, less than the expected wastes from presently existing nuclear power plants excluding the vitrified wastes from defense activities, which could potentially be greater than that from civilian wastes. In May 1986 in a blatant

political move DOE announced the cessation of the search for the site for the second repository. (26) The Nuclear Waste Policy Amendments Act of 1987 directed DOE to terminate all site specific activities at all repository sites except Yucca Mountain. (27) Needless to say, no centralized facility for spent fuel storage is available today and defense high level wastes continue to be stored as liquids in tanks at Hanford, Savannah River, Idaho Falls and West Valley (the only commercial reprocessing plants to operate in the U.S.) and as calcined material in bins at Idaho National Laboratory. Civilian spent fuel is stored in pools at nuclear power plants. Where there is insufficient space in pools, dry storage on site in silos and "roach motels" is practiced.

Because of the concern that there would be insufficient space at civilian nuclear power plants for spent fuel and that a geological repository would not be available in time to receive this spent fuel, the Congress established a Monitored Retrievable Storage Review Commission to advise them on what should be done about a centralized storage facility. (27) As can be seen from Table I by 2025 most existing nuclear power plants will have reached the end of their licensed lifetimes and the problem will grow more acute. The MRS Review Commission after an extensive study recommended:

1) Construct Federal Emergency Storage Facility of 2000 MTU
2) Construct a User-Funded Interim Facility of 5000 MTU
3) Congress should reconsider interim storage by the year 2000, taking into account uncertainties that have been resolved in the meantime, new developments and experience with the facilities recommended in 1 and 2. (28)

Table I

Though almost universally declared a superior technical document, it was rejected by those who wanted a centralized storage facility with a much larger storage capacity and those who wanted no centralized facility at all, and the report disappeared into a black hole, but has recently been resurrected. Preparations for a user-funded facility (Mescalero Indians) are proceeding rapidly. Because of delays in the construction of a repository, the DOE is again attempting to site a centralized interim storage facility. Some members of Congress, including the influential Senator Bennett Johnson, formerly Chairman of the Senate Energy Committee, have become so discouraged by the slow pace and high cost of determining whether Yucca Mountain is suitable for a final repository, that he presented a bill to halt further studies of Yucca Mountain in favor of a centralized storage facility at that site. (29) That portion of the bill has been defeated. So where does that leave us with respect to high-level waste? Bluntly, a behind schedule program to vitrify defense wastes for the repository with no agreement in place that the wastes will be acceptable when and if they are vitrified, and no guarantee that the Federal Government will pay its fair share of the repository costs. For the civilian spent fuel program, producers feel betrayed because in 1970 Federal Regulations AEC required high level wastes at reprocessing plants to be converted to solid form within 5 years of its generation and transferred to a Federal Repository within 10 years after the irradiated fuel is reprocessed. (30) In the 1982 Waste Policy Act, the Congress seemed to promise that in exchange for the $0.001/ kwhr of nuclear energy sold, the DOE would take title to spent fuel no later than January 1998 and dispose of it in a geologic repository. Because of the 1970 regulations the utilities did not build

large spent fuel pools as the government would take the spent fuel within a few years after discharge and in 1982 guaranteed a date certain of January 31, 1998. Government lawyers do not agree with that interpretation of the law so the utilities are left with building their own on-site out of reactor spent fuel storage facilities with increasing likelihood that the State Public Utility Commissions will not allow both costs as direct pass through to the consumers. With the increasing competitiveness of the electrical generation and supply business in the United States, even if both costs were allowed, the nuclear utilities may not be able to recoup their costs and still remain competitive. So if there is progress such as starting up the Defense Waste Processing Facility (DWPF), it will be only token. Despite the accelerated schedule for making a decision about the suitability of the Yucca Mountain, it is highly unlikely that those dates will be met, as EPA has not yet issued its final regulations. The new regulations, required by court remand, (31) need to take into account the study of the requirements by the National Academy of Sciences/National Research Council (NAS/NRC) mandated by the Congress. (32) Even if they do adopt the NAS/NRC recommendations, (33) there are likely to be court challenges to the regulations. So despite the US's early successes 30 years ago in showing that it was possible to successfully emplace and retrieve spent fuel from deep geological facilities, we are likely to see a Belgian or Swedish attempt to pass the United States and become the first nation to construct a geological repository and place wastes in it just as the French overcame the early U.S. lead in reprocessing to become the first nation to successfully commercialize the process.

The Waste Isolation Pilot Plant, first authorized in 1980, (34) and completed in 1990 is still waiting to open.

LOW LEVEL SOLID WASTE DISPOSAL

In some ways the saga of low level radioactive waste disposal is even more fascinating than that of high-level waste disposal, because it is so widely dispersed and affects far more individuals and institutions. Consequently, there are a plethora of books dealing with the subject, but I shall only sketch in the historical background and complexities so as to reach some conclusions. From 1942 to 1950, all burial (almost entirely weapons connected wastes) was done nearby onsite, as though they were municipal wastes, which were largely unregulated at the time (I shall deal with liquid wastes as an environmental problem). As the amount of radioactive wastes from the civilian sector, power, industry, research etc., increased and it became apparent that the defense work would continue and grow, it became necessary to centralize and control the disposal of both the defense and civilian wastes at AEC sites during the 1950s. As the 1960s began, it became apparent that though the volume of waste was so substantial that commercial sites should be established. As a consequence, six commercial sites were licensed. Within a few years, three, all in the humid region, had closed. The reason for the closures have been administrative, regulatory, perception, and failure to achieve the containment that was promised even though the public health and environmental impact was low. Since then a fourth has closed and only Barnwell, South Carolina and Hanford, Washington are still open.

Once the shortcomings of municipal waste type disposal were recognized, enhanced containment and shielding of wastes with higher external radiation was practiced both at AEC's and commercial sites. The burial sites were still open to precipitation during disposal operation and

stabilization of wastes was not mandated or practiced. Only after the French developed the surface tumulus method involving stabilization and engineered containment did the U.S. begin to move in that direction. Most proposed compact designs are some variant of the French system though none of the sites presently operating in the U.S. use that system for all disposal at their sites. Some other countries, e.g., Sweden, United Kingdom and Germany have gone to deep underground geological disposal for greater containment.

Without going through the vicissitudes of low level waste compact formation allowed by the Low Level Waste Policy Act of 1980, (35) and the subsequent amendments, (36) no new sites have yet been licensed. Suffice to say that South Carolina has temporarily shattered the system by opening its site to anyone, except North Carolina, who can afford their fancy prices. How long this will continue is entirely problematical. The price of disposal has risen astronomically from $1/ft3 in 1975 (Class A wastes) to more than $300/ft3 at Barnwell at present. The failure to site new facilities has been due to a variety of causes which many English in her book on the topic has labeled Trust, Justice, Risk, Authority and the Quest for Legitimacy.

ENVIRONMENTAL

It would be inappropriate to conclude this retrospective view without some mention of the environmental impact of all of these developments. At one level the cost of remediation is at least on order of magnitude greater than the high level waste disposal program and much greater than that of the low level waste program. (38) More important, the environment in its broadest sense is where this impact on humans and the natural environment (humans, of course, are part of the natural environment) takes place. Though the early practice followed what was standard at the time, utilize the dilution capacity of the environment and the cleansing power of the soils, there was far less fundamental knowledge of these processes than there is today and the environmental standards were far different than they are today. Even as avid a proponent of restriction of radioactive dosages to humans as K.Z. Morgan was willing to accept geologists' views that shale was impermeable and allow low level liquid wastes to be discharged to open basins to evaporate because the potential evaporation was greater than precipitation. We quickly learned from the leakage from these open basins about heterogeneities and anisotrophy and kinetics and the stochastic nature of precipitation and evaporation. We also learned about the "bathtub effect." However, the practice continued with covering of the basins or trenches to reduce the worker dosages from the radiation from the nuclides which had sorbed to the sides of the basins.

Despite claims to the contrary, there was environmental awareness. The Clinch River Study, carried out in 1960-1964, showed that even with practices of that time, no one downstream from the Oak Ridge Reservation was subjected to doses greater than the permissible levels. (39) The objective after that study was to maintain Strontium-90 releases to less than two curies per year. Sadly, this is not true at some sites in the former Soviet Union where greater than permissible doses are received by the downstream population and the releases of Strontium-90 to the river per year range from 20 to 100 curies per year, with a projected increase to as much as 1000 curies per year into the Techa River, which has an average flow one two hundredth that of the Clinch. (40)

CONCLUSIONS

While we have obviously become more sophisticated and knowledgeable since those early days, it has not enabled us to forecast the future any better. Despite that, I will take a flyer on where we will be. For a solution of the high-level waste problem, it is clear that further refining of models to reduce projected doses for time periods up to a million years from the releases from deep geological repositories from their current 10-6 to 10-16 Sr/yr to even lower levels will win no new adherents. If these calculations are robust, then research to establish a repository should be carried out only to the degree necessary to obtain a license. There are still may fundamental scientific questions raised by the repository investigations. Resolution of these questions should compete for funding with other basic research questions.

For low level wastes, where the wastes will decay to innocuous levels in short time periods, less than 300 years, then solidification (vitrification) and engineered containment should be carried out to prove, by extrapolation, that the hazardous substances can be safely kept from the environment for that period of time.

For remediation of the polluted environment, as can already be seen, the funds available will dictate the degree of cleanup. For the most part the risks are not imminent, except to workers. However, there are still unstabilized, potentially mobile wastes, e.g., high-level waste in tanks, that must be immobilized. (41) The degree of cleanup needs to be related to the risk and this will necessitate more attention to future land use. Not mentioned at all in this paper, is perhaps the most important topic of all, i.e., to prevent future contamination of the environment, i.e., pollution prevention. This is, perhaps, a reflection of the lack of emphasis given the topic in the early days till now. All these decisions will be dependent upon public involvement, trust, political will, and good fortune, a tall order.

USNRC*

ABSTRACT

For over 40 years, the country has been pursuing a goal of developing a practical system which would provide for the control and permanent isolation of the quantities of waste generated in the civilian power program. Today, despite the expenditure of hundreds of millions of dollars and the efforts of many skilled scientists, we seem no closer to realizing that goal than we were when the AEC's civilian waste management program began in the early fifties. Reflecting on the history of the development of the AEC's civilian waste management program and the experiences at Lyons, KS it should be quite clear that neither the presentation of data on waste form stability, geologic stability, the verification and validation of environmental transport models or geochemical relationships, bio-chemical interactions or health effects can, over the periods of time in question, be incontrovertibly demonstrated to the satisfaction of serious critics.

We are dealing with a largely political problem which cannot be resolved by purely technical arguments; it is a problem which exists now, which cannot be avoided and one which may be resolved only through the legislative process. If, from a purely political perspective, spent fuel can not be left on the reactor site under the close scrutiny of national, state and local regulators, the DOE must build a monitored, retrievable surface storage facility. Irrespective of the outcome of the Yucca Mt. studies, construction and operation of an RSSF should not be delayed any longer if we wish to keep any semblance of a national nuclear power program alive.

INTRODUCTION

In the early days of the AEC's civilian power program, most papers on the subject of civilian waste management seemed to be introduced with the phrase "as nuclear power assumes an ever increasing role in meeting our nation's energy demand, the quantities of radioactive waste will grow proportionately...." Some growth! In 1970, we were projecting nuclear power production to be on the order of 1000Gwe by the year 2000. There would be, in that year, one reactor brought on line each week and every shipyard in the world would be busy fabricating reactor pressure vessels! Today, we may be on the verge of losing our nuclear power option and, in the near future, we may find ourselves buying from other countries the very technology we developed.

One of the major objections to the increased use of nuclear power in this country has been waste disposal. There is no better example of the politico-technical dilemmas which face our nation in many areas than the issue of radioactive waste disposal. For over 40 years, the country has been pursuing a goal of developing a practical system which would provide for the control and permanent isolation of the quantities of waste generated in the civilian power program. Today, despite the expenditure of hundreds of millions of dollars and the efforts of many skilled scientists, we seem no closer to realizing that goal than we were when the AEC's civilian waste management program began in the early fifties. As early as 1953, in an article in "American Scientist", Dick Hatch of Brookhaven wrote:

"..if the atomic energy program is to grow and become worldwide, as seems highly probable, much will depend on the development and maintenance of a high sense of responsibility to future generations in regard to the disposal of waste from that industry. Meanwhile, if we are to anticipate the need of disposing of large quantities of longer-lived radioactive waste products on a permanent basis for our own benefit, we must face up to a new kind of responsibility, that is, setting up for our own use a system of standards and practices under which this generation would not be the principal beneficiaries."

At the time that article was written, the highly radioactive liquid wastes produced during the recovery of plutonium were being stored in tanks at the AEC's Hanford and Savannah River production sites. Outside of the production groups, the rest of the AEC community had only a limited picture of the scope and magnitude of the waste management practices at these sites. Even then, it was clearly recognized, as Hatch noted in his article, that total reliance the indefinite storage of highly mobile, highly radioactive liquid waste in tanks was not a very good idea.

"..Certainly it would be unimaginative, uneconomic and eventually downright dangerous to continue to pursue the same course in the management of (civilian) waste disposal affairs...Thus it is quite generally recognized that any stored waste should be reduced to the least practical volume, possibly to the solid state..."

By the early 50's, the AEC's civilian waste management research program had already taken shape. Lab-scale studies at Brookhaven, Oak Ridge, Hanford and Idaho were showing great promise in converting liquid waste to stable, solid forms. Perhaps recognizing the potential magnitude of the problem and the need to get advice from the scientific community, the AEC requested the National Academy of Sciences to carry out an examination of the problem. They were to review current research efforts and to make recommendations on the future direction of the AEC's waste

management program. That Committee, made up of some rather eminent personages, met in Princeton NJ in 1955 and arrived at a number of conclusions:

1) Safety is a primary concern, taking precedence over cost and

2) Radioactive wastes should be isolated as permanently as possible from the biosphere

More importantly, the Committee suggested a number of possibilities for future work which included 1) disposal in salt 2) deep-well disposal in permeable formations and 3) conversion of liquid wastes to solids

Supported by these recommendations, work began in earnest to develop improved techniques for converting liquid wastes to stable solids and for examining various methods for their "disposal".

By the early sixties, studies on the fluidized bed solidification of fuel reprocessing waste generated at the Idaho Chemical Processing Plant (ICPP), on the "pot calcination" and rising level glass processes at Oak Ridge, the phosphate glass and rotary kiln processes at Brookhaven and on the spray calcination process at Hanford had all reached the point of successful cold engineering demonstration. Indeed, so successful was the fluid bed calciner project at the ICPP that the pilot plant was converted to a production unit which became fully operational in 1963.

These cold pilot plant engineering studies had clearly demonstrated the feasibility of converting wastes to a variety of stable, solid forms and the advantages of solidification became obvious to all:

- Large reductions in waste volumes
- Rendered waste less soluble and relatively immobile
- Lowered storage costs
- Permitted safe transportation of waste and the development of practical methods of disposal

Accordingly, the AEC decided to take the next logical step in this development effort: a hot pilot plant demonstration. Thus began the Waste Solidification Engineering Prototype (WSEP) demonstration project at PNL. Approved in 1962, this project was designed to demonstrate, using full levels of radioactivity, the solidification of liquid waste with compositions representative of those expected to be produced in several commercial fuel reprocessing flowsheets. Three individual processes were to be tested: the ORNL pot calcination process, the Brookhaven phosphate glass process and the PNL spray solidification process. A follow-on product evaluation was also planned to be carried out to characterize the long-term behavior of the solidified products in simulated storage environments.

Fig. 1

The WSEP program was nothing short of a remarkable success. Highly radioactive strontium and cesium concentrate, graciously donated by the AEC Production Division's B-Plant at Hanford, were shipped over to the WSEP facility to produce synthetic waste solutions with representative levels of self-heating and radiation. Interchangeable modular units for each process were designed, tested, installed and operated without a hitch. Hot operations began in 1966. Fantastic engineering by the boys of Battelle. It should be pointed out that the WSEP program was solid proof-of-principle. WSEP demonstrated the basic feasibility and practicality of several solidification technologies, applicable to a variety of reprocessing flowsheets. With the data from this program, the industry could readily adapt this technology to meet their own specific needs. Remember that, at this time, the industry had some very explicit and

singular responsibilities for demonstrating the safety of their plant designs and processes.

We mentioned `commercial fuel reprocessing'. Now, the story of civilian radioactive waste management cannot be separated from the story of spent fuel reprocessing. In the sixties, you may recall, there was a system that we referred to as the nuclear fuel cycle, wherein the large quantities of unfissioned uranium and the plutonium bred in the fuel during power production would be chemically separated from the highly radioactive fission products and recycled for re-use. That separation process produced a waste stream that used to be called high-level waste. In the AEC/Congressional blueprint for the civilian power program, the reprocessing of spent reactor fuel would be carried out as a commercial operation, since the fuel was, in fact, the property of the individual power reactor operators. The unfissioned uranium and plutonium would be sold back to the AEC. Remember the $10/gm plutonium buy-back policy? Based on the power growth curve, the quantities of spent fuel discharged from the civilian reactors were expected to increase dramatically. By 1966, the AEC was in the process of issuing an operating license for the first commercial fuel processing facility, the 1MT/da. Nuclear Fuel Services (NFS) facility at West Valley, N.Y. That facility design was based on the successful PUREX reprocessing plant which has been in operation at Hanford for some time; like PUREX, that facility had provisions for tank storage of liquid waste. At that time also, GE had submitted its application for their 1 MT/da Midwest Fuel Recovery Plant (MFRP) adjacent to the Dresden Nuclear Power Station. What later became the Allied-Gulf Nuclear Services corporation was also involved in discussions with the licensing arm of the AEC on their plans for the construction of a 5 MT/da plant adjacent to the AEC's Savannah River plant at Barnwell, S.C. Such a high throughput facility, it was believed, would lead to dramatically lower processing costs and thus would AGNS could attract substantial business from the utilities since lower fuel cycle costs would, at that time, increase the utilities profitability. The Atlantic Richfield Hanford Company (ARCHO) also expressed an interest in getting into this business as did National Lead, purveyor of fuel shipping casks. So the commercial fuel reprocessing business was shaping up as expected.

Fig. 2

Meanwhile, back on the waste disposal front, the success of the waste solidification program now allowed for the real possibility of disposing of high level waste at sites other than at the site where the fuel was reprocessed. This made the concept of storage in bedded salt (suggested by the NAS) feasible. Project Salt Vault, which was carried out by the ORNL during the period from 1963 to 1967, followed up on some earlier experiments on the storage of simulated liquid and solidified wastes in an abandoned salt mine at Lyons Kansas. Project Salt Vault was an engineering demonstration of techniques for the handling and emplacement of wastes in bedded salt and for determining the response of salt to the effects of heat and radiation. Fully radioactive spent fuel elements from the MTR (or was it the ETR?) at Idaho were buried in an abandoned mine in Lyons Kansas in 1963 and, over a period of three years, data was obtained on the behavior of salt under such adverse environmental conditions. Following completion of the project, the fuel was successfully removed from the mine and sent safely back to Idaho. Salt Vault clearly demonstrated that there were no serious adverse effects on the salt from

heat and radiation, that conventional mining techniques were adequate for dealing with structural problems in a disposal facility and that wastes could be transferred to and handled safely in a underground environment. The success of the waste solidification program and the results of the Project Salt Vault demonstration provided encouragement that a solution to the civilian high-level waste disposal problem was well in hand.

Again, the AEC looked to the NAS for approbation of its overall waste management program. Another NAS committee was formed, reviewing the progress made in solidification and "disposal" since the last study. That Committee issued its report in 1966 and noted, among other things:

"The containment of fission products in an inert solid is still the manner of waste disposal the Committee most favors"

and:

" Continuation of the studies toward ultimate disposal of high level solid waste in salt was recommended by the Committee...the use of caverns in salt beds as permanent storage sites for high level radioactive solids has promise of being successful and satisfactory".

That report came close on the heels of another study carried out in 1964 by the American Association of Petroleum Geologists which identified, among other sites, the salt beds of Kansas as a promising site for waste disposal.

While all this was going on, the Commission was reviewing developments in the licensing of commercial fuel processing plants. As noted, NFS, GE, AGNS, ARCHO and National Lead were all, in some fashion, getting heavily involved in the fuel processing business. At one Commission briefing by the staff, Commissioner Jim Ramey asked, not altogether rhetorically, whether the Commission, as a matter of policy, should continue to permit the random siting of fuel processing plants with their related waste storage facilities or whether these plants should be restricted to pre-defined sites, more suitable from the waste storage perspective. This question may have been triggered by a comment in the 1966 NAS report that no current Commission site was acceptable from the standpoint of long term waste storage.

This humble but incisive question begat the monumental Fuel Reprocessing Plant Siting Study. That study, which focused exclusively on the civilian sector, considered nuclear power growth, the reactor mix (as defined by the Systems Analysis Task Force, SATF, study for the year 2000), fuel reprocessing technology, the status of solidification and waste disposal technology. The results of that study, supported by the magnificent ORNL-4451 "The Siting of Fuel Reprocessing Plants and Related Waste Management Facilities" (to which many, many experts contributed), led the Commission to a number of conclusions, among which was the belief that fuel reprocessing plants could be located in most places provided the site was not going to be used as a site for a permanent waste disposal and that, importantly, disposal of the high level reprocessing waste should not be permitted on privately owned land with federal (rather than state) ownership indicated.

This study provided the bases for the Commission approving the issuance of the landmark Appendix F to 10CFR50 in August, 1970 which established, for the first time, the responsibility of the Federal Government to provide for the long-term management of high level waste generated in this country. That policy stated that:

> reprocessing plants may be located on privately owned land

high level liquid waste inventories must be limited in volume to the quantity produced in the prior five years

all high level wastes must be transferred in AEC-approved dry, stable, solid form to a federal repository no later than ten years following separation of fission products from irradiated fuel

the Federal government will assume permanent custody for these wastes when it accepts the wastes and a single payment from industry which would cover all costs of disposal

repositories will be on land owned and controlled by the federal government

a design objective for reprocessing plants shall be to facilitate decontamination and removal of wastes from temporary storage at the time of decommissioning

Parenthetically, there were some state officials who took umbrage at Federal preemption of this activity. Today, that's hard to believe but in fact, some officials in Louisiana, South Carolina and New Mexico were all, at one time or another, interested in playing host to the federal repository.

Today, we hear much about acceptance criteria for the form of the waste and the long term performance of the multiple barriers designed to prevent release to the environment. Interestingly, it may be recalled that in formulating this policy, the question of the acceptability of the waste form was given every consideration by the AEC staff since such] criteria would have a direct impact on fuel reprocessing plant designs. Given interment in a geologic repository, AEC staff believed, and the Commission agreed, that the form of the waste was of importance only during the period of interim storage, transportation and emplacement in the repository. The staff held to the belief, correctly I think, that the very long term integrity of either the waste form or its packaging could never be convincingly demonstrated over the periods of time involved. Ultimate reliance was therefore being placed on the stability and long term integrity of the geologic disposal environment to isolate the waste from man's biosphere. Here, the geologic record would, we believed, provide a more convincing and demonstrable argument for assurance of long-term isolation.

At that point in time, everything seemed to be coalescing. The technologies of reprocessing, waste solidification and disposal were coming together and we saw that the nuclear fuel cycle could, and would, we thought, be closed in a way envisioned by the pioneers in the field. After numerous endorsements by the NAS, bedded salt was clearly the disposal environment of choice for the federal repository and, at this point, the Commission felt confident it could proceed with the systematic and disciplined development of the first Federal Waste Repository.

Then we had the fire at the Rocky Flats weapons plant. Without going into details, the Rocky fire produced some rather large volumes of plutonium contaminated wastes which could not, as a practical matter, be stored on the Rocky site. Plans were made to ship these wastes to the NRTS in Idaho. Frank Church, who was then Senator from Idaho, objected and asked the Commission in effect `why Idaho? Why, if these wastes couldn't be stored safely in Colorado, would it be acceptable to store them in Idaho?' The Commission clearly needed a solution to this dilemma. One of the Assistant General Managers asked his program managers whether the salt repository could accept plutonium wastes. When the answer was "yes", the Commission committed to removing the plutonium wastes from Idaho by

some definite future date (20yrs) and put the repository project on the fast track; in hindsight, perhaps too fast.

In 1971, ORNL was charged with developing criteria which would allow us to evaluate potential salt disposal sites and to proceed with the development of a conceptual design and cost estimate for such a repository. That information would be used to support a FY 1972 Congressional budget request for construction of the repository. Based on the criteria developed by ORNL and our knowledge about Kansas geology, the Lyons site was selected. Preparation of the required Environmental Impact Statement was begun. It was anticipated that, if funding was received, the Lyons facility could become operational sometime in 1974, barring unforeseen problems. Incidentally, the estimated costs for the Lyons facility was on the order of $25-30 million. It must be noted that the Commission staff considered the selection of Lyons as tentative. There were clearly many questions that we, and our USGS consultants, felt needed to be answered before we started digging. Lyons was, however, a good bet for many reasons. There was, in the abandoned portion of the old Lyons mine, a place for the disposal of the mined salt as well as facilities for marketing what we didn't put back in the ground. Lyons was located on three railroads, the salt had been stable for several millions of years and its thickness was more than adequate for heat dissipation. Because of their experience with Project Salt Vault, there was, at the local level, general public acceptance of a repository.

Fig. 3

Again, the Commission went back to the NAS to solicit their views on this tentative, but monumental decision. NAS reviewed the plans for the Lyons repository project and gave its blessing to the site subject to the completion of certain additional studies which it felt were necessary to provide assurance of long term geologic and hydrologic stability.

During October of 1970 amid much fanfare, briefings on the AEC plans were provided to state and local officials as well as representatives of the local scientific community . Little did we realize what was in store. New technical issues requiring resolution were raised (e.g., the Wigner effect: energy storage in crystals). There were almost blackmail-like demands from various researchers and other interested parties for AEC support to carry out a variety of geologic and environmental studies in the area. Following publication of the Lyons Environmental Impact Statement and the receipt of many comments, Congressional hearings were held in March of 1971. At those hearings, testimony and serious opposition in principle to the project was expressed formally for the first time. A member of the U.S. House of Representatives, Joe Skubitz by name, was the first, I believe, to raise the NIMBY question at Joint Committee hearing on Lyons. Congressman Skubitz said to us, in effect, he didn't care how safe the facility was, it wasn't going to be in Kansas! He was, as I recall, supported by Senator John Pastore who, years earlier, had objected to federal plans to build a Hoof and Mouth Disease laboratory in his state of Rhode Island.

Subsequently, the anti-Lyons fervor rose and the repository became a hot political issue. Many technical issues, real and imagined were raised. Ultimately, as a result of many meetings with interested and affected parties, the many technical issues and red-herrings raised during the EIS review process had been boiled down to a few reasonable questions upon which all parties agreed: 1) the ability to find and plug boreholes left over from earlier oil exploration activities in the area, 2) the ability

to quantify the rock mechanics properties of overlying formations (which protected the salt from dissolution) to ensure that, under conditions of repository operation, their integrity would be maintained and 3) that retrievability of wastes be demonstrated and maintained until some period of confirmation had been completed. A proposed plan was developed to provide this information jointly by the US Geological Survey, the Kansas Geological Survey and the ORNL. These studies followed closely the NAS recommendations.

Subsequent to, or almost concurrent with, the 1971 Congressional hearings, rather serious questions on site suitability were raised following the disclosure of solution mining activities in a salt mine adjacent to the Lyons mine. These questions ultimately led to the abandonment of the Lyons project, even though the Kansas Geologic Survey indicated its support for a disposal project in the Kansas salt beds at a site other than Lyons. We were now on the run. Then-AEC Chairman Schlesinger wanted to withhold announcement of the decision to leave Lyons until Democratic Governor Docking could be replaced by a Republican in the election of 1972, This would clearly show the clout a Republican governor had with the White House. I don't believe the AEC ever openly acknowledged abandoning Lyons, they sort of walked away from it, focusing attention elsewhere. Although exploratory work was initiated at a few other sites in Kansas, ultimately, none of these proved to be as good as Lyons.

The Commission management was finally beginning to see the need to develop contingency plans. The USGS had earlier identified a small area in New Mexico which appeared to have many features which would make it a suitable repository site. The Commission decided to follow up on this suggestion and do some exploratory work while at the same time, identifying other bedded salt sites for further examination.

Sensing the obvious weaknesses in the Commission's waste program, the flood gates were opened for new suggestions and it seemed everyone and his brother joined what became a feeding frenzy. A new cast of characters entered onto the waste management stage, the Joint Committee was neutered, the NRC was split off from the Commission, the residue became ERDA and nuclear power relegated to a lesser role in the national energy plan. There was renewed interest by these newcomers in old suggestions for disposal,e.g., space disposal, disposal in antarctic icecaps, tossing wastes into the subduction zone of drifting continental plates, disposal of wastes into cavities specially created by nuclear weapons, transmutation, sealed casks at Hanford, seabed disposal. Much time and not an insignificant amount of money was spent chasing these old ideas and, aside from the sealed cask concept, none went anywhere. I often wonder how much money was spent on these pipe-dreams. Certainly, their pursuit resulted in deferring needed decisions on the development of more practical waste management solutions based on our Lyons experiences.

Because of the favorable initial findings at the New Mexico site and reflecting on the continued problems of public acceptance in Kansas (which appeared to be due, in large measure, to the precipitous action on our part), the Commission made a decision in December of 1971 to proceed with the development of a "Bedded Salt Pilot Plant" wherein all civilian wastes stored would be easily retrievable by proven means and in which an experimental program to demonstrate the analytical techniques used to assure safety could be carried out concurrently. Later, that facility would be expanded to accept plutonium wastes which were being safely

stored in "20-year retrievable" storage facilities in Idaho. In 1973, a `Governor's Committee' was formed in New Mexico to ensure competent, objective evaluations of the complex technical problems involved and to preclude the political grandstanding and research blackmail evident in the Kansas exercise.

Since the delay in the development of a full scale repository would require extended storage of waste at the fuel reprocessing plants, intervenors were then beginning to use the absence of a repository as a reason for blocking the construction of nuclear power plants. For this reason, the Commission, in 1972, made a decision to proceed with plans to store high-level reprocessing plant waste in a retrievable surface storage facility (RSSF) for a period not to exceed 100 years, thus allowing it to meet its commitment to the nuclear industry to accept 10 year old solidified fuel reprocessing waste. This activity would be carried out concurrently with the BSPP development and other work to identify and evaluate alternate repository sites.

Once again, the NAS was asked to form a panel to comment on the plans for the interim storage of the high-level reprocessing plant wastes. That Committee issued a report in 1975 which stated, among other things, the following:

1) retrievable surface storage is an acceptable interim stage in a comprehensive system for managing high level radioactive wastes

2) the Panel recommended an optimized version of the sealed storage cask concept

3) recommended a number of additional research tasks which needed to be carried out, including optimization of the form and containerization of the waste (providing for multiple barriers)

4) precautions should be taken in siting and design of a sealed storage cask facility to minimize the risks of earthquakes, tornados, "sabotage, act of war, accidental air crash, etc"

5) the facility should be made unattractive to plants and animals

6) noted that retrievable surface storage is not a substitute for ultimate disposal and recommended an immediate and comprehensive assessment of sites in "salt, shale, or other suitable geologic media" for the disposal of high-level waste followed by a demonstration repository at the earliest possible time, and

7) increased research on processes for economically separating and disposing of, or using, long-lived actinides.

Whatever happened to the RSSF is not altogether clear to me. It seems to have evaporated. The NRC staff even went as far as developing regulatory guides for licensing as "ISFSI" (independent spent fuel storage installation), but then nothing happened. Somewhere along the line, I think the Bedded Salt Pilot Plant turned into the Waste Isolation Pilot Plant (WIPP) designed solely for the receipt of low activity plutonium waste, a facility which has yet to accept any real waste.

In retrospect, we have, since the mid-seventies, created an Office of Nuclear Waste Isolation, a Center for Nuclear Waste Regulatory Analysis; we have asked the American Physical Society and National Academy of Sciences to carry out thorough and independent reviews of the nuclear waste program; we have prepared plans, schedules, PERT charts, established time limits, issued extensive regulations, conducted site examinations (Hanford, Deaf Smith e.g.) and held "waste confidence" hearings. We have revisited already demonstrated waste solidification technology. Hundreds, if not thousands of millions of dollars have been

spent on testing, model development, lab experiments, field work on natural analogs, all of which seem to have helped the decision-makers not at all. We are perhaps worse off than we were in 1972 since the public and the Congress have been witness to paralysis in the waste management area. In its frustration, the Congress has enacted various pieces of legislation to try to move the process along. While well intentioned, some elements of the legislation were clearly misguided. Perhaps the most visible example were some elements of the Waste Management Act of 1982. This act not only provided a golden trough (through mandatory utility contributions to a waste management superfund) at which all waste management practitioners could feed but also provided essentially veto power to a wide variety of diverse interests: states, localities, Indian tribes, all of whom, while acting with the purest of motives, could effectively block any attempt to establish any sort of waste management facility anywhere.

As we know, the Carter administration killed the fuel cycle as we once knew it in the interests of non-proliferation. We no longer have the problem of disposing of wastes from the reprocessing of civilian reactor fuels. Now we have spent fuel piling up at reactor sites around the country. Whether solely to continue the feeding frenzy at the trough of the waste fund or for other reasons, spent fuel is now considered as waste, despite the tremendous economic value of the resources contained therein.

Many of those who labored so brilliantly in the early days of the waste management program feel this whole situation is regrettable, to say the least. Fifty years should have been enough time to bring this matter to some form of closure. No one in authority seems to be able to make a decision, probably because any decision in this area is considered potentially damaging politically. It is almost embarrassing to look at the progress of the European nuclear programs, all developed as a result of pioneering work done in the U.S.: Granite disposal in Sweden, salt disposal in Germany, glassification in Belgium and France. Why we, in this country, have not proceeded more expeditiously is truly puzzling to the international community.

The lessons of Lyons and subsequent happenings should be clear if anyone chooses to look back. Years ago, Alvin Weinberg wrote an article titled "Science and Transcience" in which he identified part of our current dilemma. We are still trying to make political decisions with technical information. We wrap a political issue in a white lab coat and say "look at this data, the answer is crystal clear". The data we have developed o'er these many years doesn't seem to convince anyone who feels potentially adversely impacted; our pure scientists will never be convinced we can, with acceptable levels of uncertainty, predict very far into the future. So we, like Sisyphus, may be doomed to pushing that rock up the hill, only to have it roll back to the bottom each time we get near the top.

As a recent example, the NAS has again reviewed the waste disposal problem from the standpoint of our regulatory posture and has come up with some recommendations, among which, if I understand it correctly, is that the time frame over which we need to demonstrate waste isolation should be during the period of maximum hazard and this examination should consider a period on the order of 1 million years; further, that during the period of maximum hazard the radiation dose to a maximally exposed individual should be on the order of 15 mrem. That study has, it would

appear, raised some other virtually intractable issues (such as future population distribution, land use, maintenance of human control) which, in combination, can only serve to further delay the decisions that need to be made.

If history is any teacher, it should be quite clear that neither data on waste form stability, geologic stability, the verification and validation of environmental transport models or geochemical relationships, bio-chemical interactions or health effects can, over the periods of time in question, be incontrovertibly demonstrated to the satisfaction of serious critics. One needs to question the continued pursuit of these ghosts. Interesting science but of little help to those who need to make the decisions and those who have waste which requires "disposal".

It may be that the only way out of this maze may be for the Congress or the courts, to force the issue through legislation or court order, forcing implementation of some plan, any plan, thereby taking the political heat off those responsible. I would note that a decision in the current court fight between the DOE and a group of utilities on DOE's contractual obligations to take responsibility for spent fuel by January, 1998 may do more to get this program back on track than anything our poor scientists can do.

It is clearly time for the country to get on with the job of moving fuel away from reactor sites where it was never meant to be for very long. But what to do with it? We all know really! If, from a purely political perspective, spent fuel can not be left on the reactor site under the close scrutiny of national, state and local regulators, the DOE must build a monitored, retrievable surface storage facility. The next question is "where". The most likely prospect is at the Nevada Test Site. Since weapons testing is in a period of suspension, the impact of an RSSF should not be a problem from the standpoint of our national security. Since retrievability is assured, public acceptance may be easier to secure. Moreover, it is unlikely that that site, given its past history, could be used for other purposes. Assuring the long term protection of that site from human intrusion is not a rhetorical question to be endlessly debated. At that site, among others, long term site control is a fact of life which can not be avoided. There are other sites which may be just as acceptable: Hanford for one, the INEL for another. With the cancellation of the new production reactor and potential reductions in almost all of DOE's facilities and operations, the presence of an interim repository for spent fuel might prove quite attractive from the point of view of the local economy.

While the RSSF is being built and operated, efforts could continue at a more leisurely pace (if that's possible) on resolving the transcientific problem of how to demonstrate long-term isolation. The issue seems to be one of HOW to demonstrate, not the demonstration of a specific site itself. With regard to current attempts to demonstrate the acceptability of Yucca Mt., one ought to review the 1966 NAS reports and the EPA's comments on the bedrock storage concept at Savannah River to see what may lie in store for the unsuspecting at a public hearing.

If construction of one or more RSSF's is to be pursued, one of the major considerations that must be dealt with in terms of public acceptance is the issue of transportation. The Lyons exercise demonstrated that this topic is not, in the eyes of the public, an insignificant issue. The numbers of shipments, the condition of rights-of-way, container testing, inspections, notification of routings and emergency action plans are all

elements of a system that must be developed and documented before an RSSF can get off the ground.

In an altogether different vein, I have often wondered if this waste management problem might be viewed from another perspective. It would seem that, other than heavy metal poisoning, the only demonstrable hazard presented by either spent fuel or high level reprocessing waste is the induction of some form of cancer, production of genetic abnormalities, or irreversible damage to sensitive biota. Ought we not, once again, go back to the NAS and ask that they conduct a study or survey to estimate the likelihood of developing a cure for cancers and genetic abnormalities over the next 100, 200, or 500 yrs. Such a survey might prove enlightening in terms of helping us view the problems of radioactive waste storage in a more balanced light. If the NAS really believes that it is possible to predict, with acceptable levels of uncertainty, events 1,000,000 years into the future, or to confidently assess radiological doses over comparable periods, it should certainly be possible, with even greater confidence, to project when a cancer cure will be developed or when genetic engineering will advance to the point that genetic abnormalities can be reversed. From that perspective, the waste management problem might degenerate to a 1000 year problem, one for which there is a much more reliable basis for predicting future impacts and thus a more solid base upon which to secure public acceptance. That acceptance is, in the final analysis, the key ingredient in this stew.

To summarize, the lesson of Lyons and subsequent events suggest that we are dealing with a largely political problem which cannot be resolved by purely technical arguments; it is a problem which exists now, which cannot be avoided and which must be addressed through the legislative process. The Congress came very close to legislating what would seem a prudent solution: i.e., to mandate the construction of an RSSF. Surprisingly, last October the current administration came out against such a proposal. However, the Congress and the courts may yet force this issue. While a decision to continue work on the Yucca Mt. repository can be debated, it seems unlikely that, based on past experience, the results of this work could ever develop the sort of incontrovertible proof of long term integrity that the various opponents seems to require. In any event, the development of an RSSF can not and should not await the outcome of the Yucca Mt. studies.

A HISTORICAL LOOK AT WASTE MANAGEMENT IN SELECTED PARTS OF THE NUCLEAR FUEL CYCLE--THE PRACTICES, DECISION POINTS AND THEIR EFFECTS

Richard L. Philippone
Bechtel Environmental Inc.

ABSTRACT

A historical look at the waste management practices in three segments of the nuclear fuel cycle--uranium ore mining and milling, reprocessing of spent fuel from power reactors and high level waste handling, and disposal methods is presented. The technical and political decisions that affected these practices are also presented. The initial practices of the mining and milling segment came from the mining industry. These practices were changed because of studies showing adverse health effects leading to public pressure to change or through legislation. Reprocessing technology was based on technology developed under U. S. government defense programs. While safely containing the reprocessing waste streams,

improvements have been made to reduce the volume of waste generated and reduce plant operating costs and personnel exposures. The decision of the U. S. not to reprocess spent fuel while many other countries continue to do so has led to quite different approaches to high level waste handling and disposal between these nations. The U. S. is trying to find a permanent repository for storage of the spent fuel while the other countries are reprocessing and thus significantly reducing the volume of waste, vitrifying the waste and temporarily storing it for up to 50 years. At the same time these countries are studying the best underground geological formations for a permanent repository. Which approach will lead to the most economical and best solution to problem is yet to be determined.

INTRODUCTION

This paper will present a historical review of the practices, significant decision points and the effects of these decisions on selected parts of the nuclear fuel cycle. The elements of the fuel cycle presented will be uranium ore mining and milling, reprocessing of spent fuel from commercial nuclear reactors, and high level waste handling and disposal. Eight segments constitute the nuclear fuel cycle. The three selected segments represent the beginning, one of the intermediate segments, and one of final elements of the cycle. While I have worked in all parts of the fuel cycle and there is value in examining the entire fuel cycle, time restraints and my much greater personal involvement in the selected segments led to restricting the paper to the above subjects.

The objective of the paper is to preserve some of the history and the lessons learned so we can continue to improve and hopefully expand the use of nuclear energy.For each of the fuel cycle segments, the paper will describe the process and the waste streams generated, give some background on their history, state any decision points that caused a change in practices, along with some of the factors that influenced the decision, reflect on the actual effects of the decision, and if applicable, describe what may have happened if alternatives under consideration at the time had been chosen.

URANIUM MINING AND MILLING

The Atomic Energy Act of 1947 authorized the Atomic Energy Commission (AEC) to purchase uranium ores and concentrates. The carnotite and roscolite ores of the Colorado Plateau had previously been mined and concentrated for the recovery of radium, uranium and vanadium. The radium was used for painting watch dials so they would be visible in the dark and for some limited use in medicine. The vanadium was used to increase the strength of steel, and the uranium was used as a coloring agent in a glaze on crockery. Most of material for the Manhattan Engineering Project came from the Belgium Congo's very high grade pitchblende deposits assaying 30-70% U_3O_8. Some came from the Vanadium Corporation of America's government funded mill at Monticello, Utah, which produced a uranium- vanadium sludge. These Colorado Plateau ores were much lower grade, normally 0.2 to 0.3% U_3O_8 (1). After World War II, the U. S. almost immediately entered the cold war with the USSR and wanted to develop an indigenous supply of uranium; therefore, the U. S. began an aggressive effort under the AEC's Division of Raw Materials to explore for uranium , develop mines , build uranium processing mills, and encourage companies to do likewise. The AEC reopened and operated the war time built uranium-vanadium mill at Monticello, Utah from 1948 until 1960 (1). Its purpose was to produce needed products but was also used to

determine actual milling costs. This information was used in contract negotiations with private companies such as Union Carbide, Vanadium Corporation of America and later with Anaconda and Kerr McGee to buy their production. The practices adopted in this new industry were those of the mining industry. Some had been in use since the gold rush days of late 1870's. Although a government agency, the AEC's Division of Raw Materials personnel were largely from the mining industry so their technology and their management policies were akin to the mining industry rather than other parts of AEC or the Government in general.

Fig. 1

Figure 1 shows the main elements of mining and milling and the various waste streams produced. Many of the early mines were small underground mines. Most were dry mines, so there was not the problem of acidic water discharges that are prevalent in the eastern U.S. coal mining regions. Relatively little of the material removed from this type of mine was dumped at the site. By the late 1960s, 70 percent of uranium production came from underground mines that were larger in size and produced more waste rock. Some of these mines contained water (3). In wet mines, mining costs were about 30 percent higher (3). At about the same time, the much larger open pit mining operations, ranging in depth up to 400 feet, were begun in New Mexico and Wyoming. Large amounts of overburden and waste mixed with ore were removed (15-150 percent more) and left at the mine site. Some of this was voluntarily returned to old open pits but most was not. Still,because of the arid conditions in the western U. S., these open pit mines did not pose the same ecological problems of erosion and acid water pollution that similar mining practices caused in Appalachia. The other major operating problem for the underground mines was providing adequate ventilation. Inadequate ventilation could adversely affect personnel in the form of radon and dust exposures, which could result in silicosis to the lungs of the miners.

The milling operation required dust collection equipment to contain the dust from crushing the ore. This was particularly true of the limestone ores that fed the Anaconda plant. The dust from these systems was captured and in most cases injected back into the system to recover any values. In the early 1950s, five of seven plants recovered vanadium and uranium. This was done by mixing the ore with 7-15 percent salt (NaCl) in a hearth roaster at a temperatures of ~850F. The fumes and any dust rising from the operation were passed through scrubbers and/or a "bag-house" of filters before exiting up a stack. This operation improved over the years. The roasted product was then dissolved in sulfuric acid (H_2SO_4) by most of the mills; but a few mills used sodium carbonate (Na_2CO_3) as a dissolvent. Ores not containing vanadium could be dissolved directly. The mills separated the solids from the pregnant liquors by thickeners and filtration. Later the mills added a step to increase the concentration of the uranium and remove more impurities by using either solvent extraction or ion exchange processes to recover the uranium (4). Two of the primary waste streams from the milling operation were: 1) A fine material left after the uranium and vanadium were extracted, called tailings. Tailings were usually impounded and stacked in tailing piles; and 2) waste liquors streams, which consist of contained liquors in the tailings and other plant discharges. The chemical composition of these liquors was dependent on the treatment rendered and could be either acidic or basic in nature and could contain varying quantities of H_2SO_4, $NaClO_3$, NH_4SO_4, and small amounts of cyanide.

Significant Decisions

There have been several significant decisions that have effected the waste management practices of uranium mining and milling industry. These were: 1) a series of laws and regulations which forced further treatment of the waste and effluents from the mines and plants; and 2) public pressure to change practices.

These laws included the establishment of the Environmental Protection Agency (EPA) in 1970 but more importantly, the Resource Conservation and Recovery Act (RCRA) of 1976 and the Comprehensive Environmental Response Compensation and Liability Act (CERCLA) in 1980 which implemented hazardous and waste management practices in this and other industries. The Uranium Mill Tailings Radiation Control Act (UMTRA) in 1978 was specifically directed to the industry. These laws plus the Clean Air Act of 1970 and the Clean Water Act of 1972 imposed further restrictions (5). Examples of these effects are as follows: Efforts were made to impound the liquids and allow them to evaporate in the tailings ponds. However, the ponds would eventually dry out. These were the same methods used in other parts of the industry and produce the same results. When the piles dried out, the winds would blow the fine tailings as dust clouds over the surrounding landscapes. This was not considered a problem and only if the tailings were near populated areas, (i.e.,the old tailings pond from gold milling operations at Colorado Springs, Colorado) was it even considered a nuisance. For many years nothing was done about it but problems arose in the uranium industry when the residents around Grand Junction began using the tailings from the Climax Uranium Mill. The first use was for mulch and fertilizer for rose beds and gardens. The retained chemicals made things grow wonderfully. It wasn't until they decided that tailings would also make good building material and cement and concrete blocks that were used to build houses, buildings, sidewalks etc. that problems developed. Radiation levels began to climb from this use and under UMTRA and CERCLA legislation a massive program to remove the material and reconstruct the buildings was instituted. The program also included the remediation of the milling sites and contaminated private properties in the vicinity. These programs returned the overburden back into the mines, moved certain tailings to more remote locations, placed multilayer coverings over the tailings piles, and treated any aqueous waste residues or soils, not only at the mill site, but in private properties surrounding the mills (5).

Liquid Waste Streams

In regard to the liquid waste streams, the State of Colorado accused Union Carbide of polluting the Colorado River from their Rifle, Colorado Plant. However, Carbide won the argument when they showed that the river was cleaner after it left the plant than upstream. It seems that the hot springs at Glenwood Springs about 10 miles upstream had considerable radioactivity. Rifle Creek, a pure mountain stream, also ran through the plant and discharged into the Colorado River. Dilution was sufficient to mask any discharges from the plant and even lowered the initial radioactivity content of the Colorado River

In the Grants, New Mexico area the results were different when the uranium mills decided to inject their waste solutions into deep wells in the desert near the mills. This was practiced for several years but then the Indians living on the nearby desert detected these chemicals in their well water. The practice was halted because of strong public pressure.

REPROCESSING OF SPENT NUCLEAR FUEL

This section addresses the reprocessing of spent fuel from nuclear power plants and the disposition of waste streams it generates. This will include the early reprocessing at Nuclear Fuels Services West Valley plant, the only plant in the U. S. to actually operate in a commercial mode (6,7). It will also discuss the efforts of General Electric at Morris, Illinois (8,9) and Allied General Nuclear Service at Barnwell, South Carolina (10) to operate their plants. Both plants were built and began pretesting, but neither were actually ever in production mode. Exxon Nuclear at Oak Ridge, Tennessee (11), only got to the detailed design stage before it was stopped. The paper will also discuss practices outside the U. S., where countries such as France, the UK, and Japan consider reprocessing an integral part of the fuel cycle. In many cases the technology is the same as reprocessing fuel from the defense program reactors. However, each industry faced some unique problems. I refer readers to Mr. William McVey's WM-96 paper "Evolution of Spent Nuclear Fuel Technology and High Level Waste Management" for a discussion of the technology in the defense plants.

Fig. 2

Figure 2 shows the main elements of reprocessing and the waste streams it generates. These waste streams have been numbered for easy identification.

The reprocessing of light water reactor (LWR) spent fuels throughout the world has the same basic flowsheet. However, there are a number of gas cooled reactors, particularly in the UK for which the head end of the process must be altered. The spent fuel from the reactors is generally placed in fuel storage pools. The pools are filled with very high purity water. The French at their UP-3 plant have now introduced a new dry storage facility which does not require the extensive water treatment required in pond storage and eliminates waste stream-1 (WS-1). The removal of the fuel element-end pieces generates WS-2. These pieces are compacted and packaged. Shearing the fuel bundles into 1.27 cm to 7.62 cm (0.5" to 3.0") segments produces WS-3 from the release of off gases from the fuel elements plenum section and dust fragments which are captured in a dust collection system. The ceramic material containing uranium, plutonium and fission products in the sheared pieces are dissolved away with nitric acid from the zircaloy or stainless steel metal casing. The radioactive metal hulls, WS-4, are washed and placed in containers. The resultant nitrate solutions are clarified and the solids, WS-5, are combined with other streams and treated. The uranium, plutonium and americium, if present, are separated from the fission products using a solvent, tributlyl phosphate (TBP) in a diluent (i.e. kerosene) in a process called PUREX. These fission products become WS-6, a high-level waste (HLW). NFS only evaporated, sampled, and stored this WS-6 (HLW) as a solution. The other U. S. mills had plans to vitrify these waste. The French and the UK vitrify the HLW and Belgium has successfully vitrified HLW from Germany. The second stage of the PUREX process then separates the uranium from the plutonium. These products are then solidified as oxides. The second stage of solvent extraction and the product purification and solidification steps waste streams produces two waste streams that have always been processed to recover the nitric acid and clean the solvent. WS-7 resulted from acid recycle. This system uses evaporation and acid fractionating towers to recover the acid and remove the contaminants. These processes are primarily to reduce waste volumes rather than recover the monetary value of the acid. These acid wastes

require neutralization. It was common practice in these early reprocessing plants to use ferrous sulfamate as a plutonium reduction agent. However, this created a large amount of waste when it was neutralized. As a result, current plants use combinations of N_2O_4, hydrazine and hydroxyl ammonium nitrate (HAN) for this purpose which significantly reduces the waste. The Barnwell plant planned to use an electropulse column for this reduction (10). WS-8 is created from the solvent recovery operation. This process involves removal of heavy metal and fission products in chemical complexes and solvent degradation products. The cleanup consists of alternate carbonate and acid washes with the waste products either being sent to an intermediate level waste storage or to rework. NFS stored most of these waste as liquids but the later plants concentrated and solidified these waste.

These operations also generate off-gases. The usual practice was to treat vessel off gases separate from the dissolver off-gases. The off-gas from the plants contain iodine, krypton, and tritium. From the earliest days, processes were in place to contain and remove the iodine through a series of iodine strippers, absorbers and passage through silver zeolite beds. These off-gas systems also employed high efficiency particulate filters (HEPA) before the off-gas exited through a stack. The replacement of HEPA filters add to the HLW waste volume. The French and UK plants also recover krypton. Although considerable R&D has been performed and pilot operations conducted, no reprocessing plant is recovering the small quantities of tritium in these off-gases. Failed equipment will be another increasing waste stream as plants age.

Significant Decisions

The first significant decision effecting reprocessing occurred in 1973 when the AEC's Regulatory Division [now the Nuclear Regulatory Commission (NRC)] banned shipments of liquid plutonium. This caused U. S. plants to include plutonium solidification circuits to their flowsheets. The imposition of much stricter seismic criteria by this same regulatory body led NFS to abandoned plans to enlarge their plant. Since they believed their 1 MTU/day plant could not compete with the larger plants being built at Barnwell and being designed by Exxon at Oak Ridge, the existing plant was closed. General Electric also ceased trying to operate the Midwest Plant in Illinois. However, their reasons were due to technical difficulties. The plant's different flowsheet, using a uranium denitration-fluorination purification circuit (9), did not scale up from pilot runs. This coupled with difficulties in maintaining certain equipment led them to close the plant before it got into production. The most significant decision was President Carter's declaration of a moratorium on reprocessing in the U. S. and to simply store the spent fuel. This was done because of the fear of nuclear proliferation and to set an example that we hoped other countries would follow. The Carter decision forced the cessation of operation of Barnwell and Exxon to stop all work at the Oak Ridge facility. At about the same time, the NRC stopped any further consideration of a plan to utilize mixed uranium and plutonium oxides in either breeders or LWRs. This decision led to intense studies of whether some modification of the fuel cycle would have greater proliferation protection than the conventional PUREX process. Both international and domestic teams made these studies and the results showed that there were just marginal differences in the proliferation risks of the processes. None of the foreign countries followed our lead except, several years later, the West Germans because of strong pressure

from their "Green Party" abandoned plans to build the Wackersdorf Reprocessing Plant. President Reagan lifted the U. S. moratorium in 1981, stating that the policy was to support private investment in reprocessing of LWR spent fuel by removing unnecessary regulations and creating stable long-term conditions under which commercial reprocessing would be viable. As a result, interest was shown by Bechtel in buying and operating the Barnwell plant. However, because of decreased demand for uranium and no market for plutonium, the sale did not proceed. Meanwhile, the French have built and are operating major additions to their facilities at La Hague (UP-3 & UP-2-800) and the UK has completed and are operating the THORP Plant at Sellafield. The Japanese are building the JNFL plant at Rokkasho-Mura, and the Russians, other Eastern Bloc countries and India continue reprocessing. These countries lack the natural resources the U. S. has and as result of the 1974 oil embargo, have a strong commitment to ensure an indigenous energy supply which they can control.

U. S. Government sponsored R&D, as well as R&D sponsored by other nations and through cooperative programs between nations, was motivated in early years to develop processes that would increase recovery of uranium and plutonium and to reduce personnel exposures. There was fear in those days that we would run out of uranium and it would become so costly that nuclear energy growth would end. There was also early recognition that reprocessing dealt with very high radiation levels so worker protection was essential. While little R&D is being done in the U. S., it is still being done abroad. Today the driving force is to reduce operating and maintenance costs and the above objectives are still valid as they are viewed as a means to that end. This has meant that waste quantities are being reduced and improvements made in the vitrification process for high level waste.

HIGH LEVEL WASTE HANDLING AND DISPOSAL

The handling and disposal of high level waste (HLW) has been studied, practiced and argued about for the past 50 years. The U. S. has always followed the path of proceeding as rapidly as possible to entomb the HLW in a permanent storage repository. The Europeans, United Kingdom and Japanese have a different strategy. They store the HLW in a temporary repository for 50 years while they decide which is the best permanent disposal method to use and where these repositories should be. The first U. S. attempt to build a permanent repository was at Lyons, Kansas (13). In the 1960s it was planned that the LWR spent fuel would be reprocessed and vitrified waste canisters would be the principal item to be stored. Studies by the National Academy of Science indicated that the salt beds underlying Lyons would make a safe storage media. The Oak Ridge National Laboratory (ORNL) had conducted many measurements using fully irradiated fuel elements from a test reactor to simulate waste canisters in an abandoned Carey Salt Company mine. By ORNL moving employees and their families to Lyons, the local townspeople accepted such a facility. They believed that ORNL engineers would not endanger their own families by placing them in an dangerous location. Therefore, the operation would be a safe one and they welcomed the jobs it would produce.

Significant Decisions

The support for the Lyons repository was not shared by people in the rest of the state, especially not by Congressman Skubitz. His first objection was to the trucks and railcars which would cross Kansas and the fear they would have accidents and contaminate the area. Even though these casks which would contain the waste had been subjected to extensive and

demanding test conditions, I doubt if he and his supporters ever changed their minds. However, that was not a deciding factor in the fate of the Lyons repository. Adjacent to the Lyons mine was the American Salt Company's mine. The mine had employed solution mining techniques in an effort to reduce costs. This practice was perceived to endanger the Lyons mine and probably was the final factor that caused AEC to abandon the Lyons site and became the first significant decision affecting the HLW program. I do not know if the AEC ever seriously considered buying the American Salt Mine and closing it. It was reported that the American Company's salt was uncompetitive in nearby Kansas City with salt from the Gulf of Mexico barged up the Mississippi and Missouri Rivers so the sale price of the mine would be low. Had that occurred it would have removed a serious obstacle in locating a repository at that time. Additional details and perspectives of the operations at Lyons can be found in C. R. Barlett's, Dr. Frank Parker's and W. G. Belter's papers given at this conference.

As discussed in the previous section, the second major decision was that U. S. chose to store spent fuel elements rather than vitrified waste from reprocessing. Opponents of reprocessing cite proliferation risks and claim that reprocessing is not economical compared to disposing of spent fuel. Proponents of reprocessing state that reprocessing is not that great a proliferation risk, that storing fuel elements in effect creates a plutonium mine because the fuel elements can be reclaimed and converted to plutonium if a nation desired. Furthermore, with the collapse of the Soviet Union, the far greater threat is from some terrorist group or nation stealing a bomb from one of countries that have been created since the Soviet break-up. Proponents also state it is impossible at this time to determine which route is more economical because while reprocessing costs are known and some information is available on temporary storage of both spent fuel and vitrified waste, there is no information available on the permanent storage of either spent fuel or vitrified waste.

With the decision to store spent fuel and the abandonment of Lyons, the U. S. turned its search elsewhere, (i.e.,. Yucca Mountain, Nevada, Hanford, Washington and Deaf Smith, Texas). The strategy at that time foresaw the possibility that a permanent repository may not be ready before the reactor spent fuel pools were filled to overflowing, so provisions were made to build a monitored retrievable storage (MRS) facility at Oak Ridge. Again the host location was receptive to this facility but the Tennessee state officials waged a successful campaign to kill the project at Oak Ridge based on perceived threats of major contamination from transportation accidents and the fear that a permanent repository would never be built and the waste would remain permanently in Oak Ridge. To pay for the storage, the utilities with nuclear plants were accessed a charge of 1 mill/kwhr of electricity sold. Congress then decided to only consider the Yucca Mountain site so all efforts have been focused there. With no reprocessing, the site will store spent fuel elements and is trying to decide if they can be retrievable.

Despite the many millions of dollars spent on the Nevada repository, the U. S. is still a long ways from an operating storage facility. Instead most utilities have been required to build additional on-site storage for their spent fuel besides paying 1 mill/kwhr of electricity generated for the government to store the fuel.

In contrast, reprocessing has significantly reduced the quantities to be stored in the UK and Europe and temporary HLW storage vaults are being

built (14). The plan is for the containers of vitrified waste to be stored for up to 50 years. Concurrently, an intensive program of investigating three different underground host rock formations for a permanent storage facility is underway. This program includes underground laboratories at Mol, Belgium to study clay formations, at Gorleben, Germany to study salt formations, and near Marcoule, France to study granite formations.

OVERALL SUMMARY AND CONCLUSIONS

The waste management practices of uranium mining and milling industry in the early 1950s through the 1960s were based on those of the mining industry and were accepted by the public. Health studies, changing public attitudes and legislation resulting from conditions in Grand Junction, Colorado and in the Grants, New Mexico area resulted in major changes being made. This includes returning overburden and waste rock back into the mines, the covering of mill tailings ponds, remediation of contaminated soils both at the mills and at surrounding properties and the cessation of injecting waste solutions deep into the ground. This again was another example of the failure of waste injection into the ground as being a safe method of waste disposal.

The technology used in reprocessing power reactor spent fuels is based on the PUREX technology developed at ORNL and used in U. S. government-owned plants. Although the early U. S. plants did a reasonable job in containing the waste streams generated particularly for iodine, the major shortcoming was that many of the waste streams had large volumes and were stored in the liquid state. Efforts through the years have focused on reducing the volume of these wastes and then solidifying the high level waste. This is now done routinely in France and the UK and has been done in Belgium. The U. S. decision to forego reprocessing and curtail practically all R &D has left this development to other countries. Their programs have resulted in lowering reprocessing costs, reducing waste volumes and lowering worker and the public's radiation exposure.

There are marked differences in the approach of the U. S. from other countries such as the UK, France and Japan in handling and disposal of high level waste. The U. S. continues to follow the path of entombing the spent fuel and other HLW in a permanent storage repository. In contrast, the above named countries, vitrify the reprocessed liquid HLW, place them in temporary storage for up to 50 years and are conducting an intensive study of the best way to permanently store the waste through testing in underground laboratories in different geological formations. Arguments are made for each approach that revolve on whether one is a greater proliferation risk than another and whether it is more economical to permanently store vitrified reprocessing waste or spent fuel. Neither approach addresses the problem that the most serious proliferation risk may come from the stealing of nuclear weapons. While we have obtained costs on reprocessing and some initial costs on the temporary storage of spent fuel and vitrified waste it is still impossible at this time to determine which route is more economical since no one knows what the respective costs are for permanently storing either product will be. While Europe and Japan have allocated up to 50 years to find a solution, the U. S does not have a specific time table but is trying to do it as soon as soon as possible. The Yucca Mountain site has not as yet been proven to be an acceptable site. There is no centralized temporary storage location so the spent fuel is being stored at the over 50 reactor locations in the U. S. and the rate payers continue to pay the 1

mill/kwhr charge for permanent storage. Who will arrive at the final solution to problem first and at what cost is still to be decided.

ABSTRACT

The Waste Management Programmatic Environmental Impact Statement (WM PEIS) is a nationwide study examining the environmental impacts of managing five types of radioactive and hazardous wastes that result primarily from nuclear defense activitiesthe development, production, and testing of nuclear weapons at a variety of U.S. Department of Energy (DOE) sites located around the United States. The five waste types are low-level mixed waste (LLMW), low-level waste (LLW), transuranic waste (TRUW), high-level waste (HLW), and hazardous waste (HW). The waste types are described, and the major sites are identified. The range of decisions and various alternatives for treating, storing, and disposing of wastes are discussed. The analysis process and major results and insights are summarized. Finally, preferred alternatives are discussed.

INTRODUCTION AND OVERVIEW

The management of both current and anticipated volumes of low-level mixed waste (LLMW), low-level waste (LLW), transuranic waste (TRUW), high-level waste (HLW), and hazardous waste (HW) require safe and efficient handling and disposition of these wastes, compliance with all applicable Federal and State laws, and protection of public health and safety. Each waste type has unique physical and regulatory requirements (see Table I) and accordingly is managed separately. For each waste-type system, facilities are needed to treat, store, and dispose of the waste. For the first time, the U.S. Department of Energy (DOE) has attempted not only to examine in an integrated fashion the impacts of complex-wide waste management decisions for each waste type but also the specific cumulative impacts for all the waste facilities at a given site. In this context, management of these wastes includes:

- Modifying existing waste management facilities or constructing new facilities at particular sites;
- Operating modified or new waste management facilities at those sites;
- Transporting waste among waste management facilities, as necessary; and
- Sampling and analyzing waste constituents as necessary.

Table I

The Waste Management Programmatic Environmental Impact Statement (WMPEIS) provides information on the impacts of various siting alternatives that DOE will use in deciding where to locate additional treatment, storage, and disposal facilities for each waste type. However, the location of a facility at a selected site will not be decided until completion of a subsequent sitewide or project-specific environmental impact analysis. To assist DOE in making decisions regarding the sites at which it should locate waste management facilities, the WMPEIS considers four categories of alternatives for each waste type: a no action alternative that is generally consistent with current practice; a decentralized alternative that would, in general, result in wastes being managed where they are generated or stored currently; a regionalized alternative that would locate waste management facilities at a lesser number of sites throughout the nation; and a centralized alternative that would locate large waste management facilities at only one or two sites. For certain waste types, DOE considers more than one regionalized or centralized alternative to present a wide variety of options on the number and location of sites having major waste management facilities and the sites at which the facilities could be located.

Figure 1 identifies the sites where wastes are generated or stored for one or more of the types of waste evaluated in the WM PEIS. "Major" sites, as shown in the figure, are those candidate locations identified

under the WMPEIS alternatives that may receive wastes generated off-site and/or host disposal facilities. These sites received detailed evaluation in the WM PEIS.

Fig. 1

Table II summarizes the range of decisions that DOE needs to make with respect to the treatment, storage, and disposal of the waste types discussed. The location of waste management facilities to implement these decisions is addressed in the alternatives.

Finally, DOE has conducted a significant outreach program to obtain public input on the Draft WMPEIS. The public comment period was extended from its initial duration of 90 days beginning September 21, 1995 to 150 days, now ending February 19, 1996, several times the normal time provided by DOE for other major impact statements. In addition to receiving written comments for this period, DOE conducted 14 public hearings at 18 locations throughout the nation, selected in accordance with the management and siting alternatives analyzed in the WM PEIS. All of these hearings, which were attended by approximately 600 people, were conducted via interactive televideo conferencing. This innovative method saved DOE more than $400,000 compared with the normal procedure for hearings.

Table II

DOE will consider the public comments as part of an evaluation of the alternatives during the course of the decision process. Table III illustrates examples of the factors and criteria DOE may use to screen, evaluate, and narrow the current alternatives to select a preferred alternative for each waste type considered in the WM PEIS.

Table III

DOE will identify all of its preferred management alternatives by waste type in the Final WMPEIS, which is expected to be issued by late summer 1996. After issuance of the Final WMPEIS, DOE is considering holding another public comment period to receive input on the Department's preferred alternatives before Records of Decision are issued. DOE is also working with site-specific advisory boards and the DOE Environmental Management Advisory Board to develop appropriate processes for reaching consensus. Specific decisions regarding Department wide management of each waste type may be staggered over the coming years upon consideration of all appropriate information, including but not necessarily limited to the findings of the Final WMPEIS.

ALTERNATIVES

In the WM PEIS, an alternative is defined as a configuration of sites for treating, storing, or disposing of a specific waste type. The alternatives for each waste type fall within the aforementioned categories: the no action alternative, and decentralized, regionalized, and centralized alternatives. These four broad categories of alternatives encompass the range of reasonable alternatives available to DOE for siting of facilities for the management of the five waste types that are considered in the WM PEIS. However, under each category of alternatives, there are many possible combinations for the number and location of DOE sites for treatment, storage, and disposal facilities. In addition, there is more than one option for treatment of some waste types. To narrow these combinations to a level permitting meaningful analysis, DOE selected a total of 36 representative configurations to be ultimately analyzed over all the waste types considered in the WM PEIS.

To identify reasonable proposed sites for waste management facilities, DOE determined where the largest waste volumes were located and where transportation requirements would be minimized. The characteristics of the waste, specialized treatment requirements, and existing facilities were also taken into consideration in site selection. For example, some wastes that require special treatment were analyzed separately, and treatment sites were selected for analysis based on the volumes requiring special treatment rather than on total volumes. In some cases, treatment facilities could be used for more than one waste type. Therefore, some sites were evaluated as candidate sites even where the volume of a particular waste type was not among the largest. Table IV presents details by site for the alternatives evaluated in the WM PEIS. On-site LLMW wastewater treatment and minimum LLW treatment facilities would occur under all the alternatives.

Table IV

Table IV con't.

To illustrate the alternative selection process, consider the case of LLMW. The no-action alternative is to continue treatment at existing facilities. However, this alternative does not address disposal or comply with the Resource Conservation and Recovery Act. The decentralized alternative considers treatment at the 37 sites now generating or storing LLMW and considers disposal at 16 sites. Four regionalized alternatives were defined with treatment considered at from 4 to 11 sites and disposal considered at from 1 to 12 sites. The centralized alternative only considers 1 site, Hanford, for treatment and disposal of all LLMW.

ANALYSIS AND KEY RESULTS

To evaluate the potential environmental impacts of the alternatives, DOE first identified the type, characteristics, quantity, and special requirements (e.g., handling requirements) of each waste type. To frame the analysis within reasonable bounds and to make the analytical process more manageable, DOE developed and applied specific assumptions. DOE then determined the health risks, environmental impacts, and costs of waste treatment, transport, storage, and disposal as applicable for each waste type. Figure 2 graphically depicts this framework. Key results will be discussed in four areas: human health effects, transportation, the environment, and program costs and benefits.

Fig. 2

The human health analysis yielded four major results: First, in general, the human health impacts from constructing and operating waste management facilities would be low. Second, waste management activities would generally result in greater risks to waste management workers than to the off-site public. These risks would be primarily due to physical hazards, which could include construction accidents or other accidents related to typical industrial activity. Third, the incineration of transuranic waste requires special technologies or considerations to avoid adverse effects in the off-site population. Fourth, safe disposal of low-level waste and low-level mixed waste at certain facilities may require limitations on the type or quantity of radionuclides. Without imposing such limitations as needed on a site-specific basis, groundwater contamination could exceed standards for drinking water. The analysis of transporting wastes between sites yielded three major insights: First, transportation poses a greater risk to the general public than the construction and operation of waste management facilities. This risk is primarily related to traffic accidents rather than exposure to radiation or chemicals. Second,

transporting waste by rail generally poses less risk to the public than transporting by truck. Based on highway accident statistics, shipping high-level waste over 40 years and other wastes over 20 years by truck could potentially result in from 12 to 69 fatalities. The majority of these fatalities would be from traffic accidents. Shipping all wastes except hazardous by rail over this same time period could result in 2 to 6 fatalities. Third, transporting wastes to consolidation facilities would generally be less expensive than building facilities at many DOE sites, but could result in increased air emissions and traffic fatalities. This situation is a very clear example of the tradeoffs that DOE must consider and the decisions it must make.

The primary environmental impact areas examined were air and water quality. The following sites, RFETS, Hanford, NTS, LANL, WIPP, and ORR could have air quality impacts under some of the regionalized and centralized alternatives. (See Table IV for full site names.) Regulatory standards for air may be exceeded as a result of increases in emissions from on-site construction equipment and vehicles, and from thermal treatment of transuranic or hazardous waste. In addition, the groundwater analysis shows that using a generic disposal facility, Hanford, SRS, FEMP, SNL-NM, and PGDP could experience groundwater impacts under one or more of the PEIS alternatives. However, steps can be taken to avoid air and water impacts. The potential impacts identified can be reduced or eliminated by carefully choosing the technology to be used, facility location, method of vehicular transport, or other mitigating measures. For example, predicted impacts could be avoided or reduced by the use of rail instead of truck transport for some types of waste, or by avoiding certain types of treatment for particularly toxic wastes.

The social and economic impacts of these decisions will be very important to DOE, as illustrated in three major findings. First, using commercial facilities to treat DOE hazardous waste could result in lower costs than building new DOE facilities. Generally, DOE treats its wastewater at the DOE sites and uses commercial facilities to treat and dispose of its remaining hazardous waste. According to the WMPEIS analysis, this approach may be more cost effective and result in fewer impacts than constructing new DOE facilities. Second, the cost to manage all five waste types over 20 years could range from $20 to $45 billion. Costs depend on which alternatives are chosen and tend to decrease as the number of treatment and disposal sites decrease (for example, under the centralized alternatives). Third, socioeconomic impacts would be relatively small, with the maximum increase in jobs generated in the economies around any site being in the range of one to three percent. On a national basis, the largest economic benefits would result from decentralized alternatives and generally would decrease as alternatives become more centralized. Of course, a site chosen for a centralized alternative would experience the maximum economic benefit.

It should be emphasized that the WMPEIS analyses were based on generic assumptions appropriate for a programmatic document. Before any new large waste management facilities are built at a site, more detailed and site-specific analyses would be conducted. Therefore, the results presented provide early indications of where problem areas may be encountered and are not the basis for construction and operation of new facilities.

SUMMARY AND PRELIMINARY CONCLUSIONS

Many lessons have been learned from the evaluations of the treatment, storage, and disposal of the waste types. The key points for each waste

type are as follows. For LLMW, the highest risks are to waste management workers associated with construction activities, although some individual site environmental impacts occur under the Centralized Alternative, which utilizes the lowest number of workers. Costs range from $8 billion for the Centralized Alternative to $13 billion for the Decentralized Alternative. Radionuclide- and/or chemical-specific limits will be required for disposal at most sites.

For LLW at the national level, costs, risks, and impacts are greater for volume reduction than minimum treatment. Transportation poses the highest risks to the public. Centralized disposal results in a large transportation volume with commensurately greater transport risk from both traffic accidents and radiation exposure. Rail transport has significantly lower risks than truck transport. As for LLMW, radionuclide-specific limits will be required for disposal at most sites.

For TRUW, the LDR treatment of TRUW poses greater risks, air quality impacts, and costs than lesser levels of treatment. Transportation risks and costs were roughly equivalent for all alternatives involving shipping to WIPP. For HLW, costs and risks are slightly higher for centralized storage at Hanford, but the differences are not significant. Alternatives are roughly equivalent from the standpoint of environmental impacts and costs. The acceptance rate at the candidate repository controls length of storage time. For HW, risks and impacts are similar for each alternative and the costs favor commercial treatment.

As part of the preparation of the WM PEIS, DOE has identified the following preferred alternatives for treatment or storage of the five waste types. These preferences are based on the lessons learned as cited above, on continued use of effective or proven DOE practices, and in part on the DOE's proposed site treatment plans for LLMW:

The No Action (status quo) Alternative is preferred for treatment of non-wastewater hazardous wastes, which continues use of commercial facilities. Treatment of hazardous wastewater would continue at DOE sites.

DOE prefers to continue to store HLW on-site at the Hanford Site, INEL, and SRS pending disposal in a geologic repository. This arrangement can be accommodated under the No Action, Decentralized, or Regionalized alternatives. DOE does not yet have a preference on where to store West Valley HLW pending disposal in a geologic repository.

The Regionalized Alternatives are preferred for LLMW treatment because they most closely approximate DOE's Proposed Site Treatment plans developed under the Federal Facilities Compliance Act. However, negotiations are underway with regulatory authorities regarding the proposed plans, and DOE's preference for LLMW treatment may be affected by these negotiations.

At the time of this report, DOE had not yet identified a preferred alternative for management of LLW and TRUW.

Finally, DOE is now reviewing the public comments. The most significant issues raised were the relationship and integration of the WMPEIS with other significant DOE proposed actions; currency of waste inventory data used in the analysis; long-term storage of wastes versus disposal; the effect of the analysis if the WIPP and Yucca Mountain facilities do not become available; privatization of WM facilities versus DOE ownership and operation; relationship of environmental restoration activities to WM; transportation planning, risks and emergency preparedness; and "not-in-my-backyard" concerns, particularly for disposal of wastes. Other issues

frequently mentioned involved environmental justice, groundwater contamination in sensitive areas, and adverse economic impacts such as decreased land value near sites chosen for WM facilities. All these issues will be addressed in the preparation of the Final WMPEIS.

ABSTRACT

Past practices at U.S.Department of Energy (DOE) field facilities may have resulted in the presence of minute amounts of radioactive contamination in some hazardous wastes shipped from these facilities. In May 1991, the DOE Office of Waste Operations issued a nationwide moratorium on shipping potentially mixed waste from DOE facilities to commercial treatment, storage, and disposal (TSD) facilities. A potential waste-clearance strategy was developed to address the DOE mixed-waste moratorium issues, which had resulted from a lack of existing regulations regarding volume contamination. A radiological assessment model was developed on the basis of the detailed radiological assessment performed for eight commercial hazardous waste TSD facilities. The model incorporates waste- and site-specific data to estimate potential radiological doses to on-site workers and the off-site public from waste-handling operations at a TSD facility. The described waste-clearance strategy would provide both DOE and commercial TSD facilities with a rapid and cost-effective methodology for assessing potential human exposures from the processing of chemical wastes contaminated with trace amounts of radionuclides. This strategy also has important potential applications for establishing site clearance limits to ensure that worker and public risks would remain well below regulatory limits. The clearance strategy issues pertaining to current free-release practice, dose limits, data requirements, and conservatism are discussed.

INTRODUCTION

U.S.Department of Energy (DOE) facilities have historically disposed of their radioactive waste at DOE-owned radioactive waste disposal sites. The nonradioactive but hazardous chemical component of the DOE wastes has been treated and disposed of at permitted commercial treatment, storage, and disposal (TSD) facilities. However, past practices at DOE field

facilities may have resulted in the presence of minute amounts of radioactive contamination in some hazardous wastes shipped from DOE facilities to commercial TSD facilities.

In May 1991, the DOE Office of Waste Operations issued a nationwide moratorium on shipping potentially mixed waste from DOE facilities to commercial facilities. The moratorium is to remain in effect until procedures are approved and implemented to ensure that hazardous wastes contain no radioactive materials added by DOE operations (i.e., the "no-rad added" policy). The "no-rad added" policy was imposed because of the lack of existing policy and regulations on the release of slightly contaminated bulk materials. Assessment of previous DOE wastes at TSD processing facilities revealed extremely low radiological risks to both TSD workers and members of the public (1).

Strategies for clearance of radioactive materials based on low-risk criteria have been prescribed by international organizations (2). A potential waste-clearance strategy is discussed in this paper for addressing the DOE mixed-waste moratorium issues, which resulted from a lack of existing regulations regarding volume contamination. The radiological doses evaluated from waste processing at eight TSD facilities are orders of magnitude below federal limits and guidelines, as well as the average dose from natural background radiation in the United States (discussed in the section "Comparison of Doses and Risks"). This leads to the potential establishment of "authorized limits for release" as an interim measure, according to current DOE guidance, and ultimately leads to waste clearance based on risk (the section "Strategy towards Waste Clearance" describes this process). A radiological assessment methodology was developed as part of the clearance strategy on the basis of detailed radiological assessment of these TSD facilities (described in the "Development of Dose Assessment Model" section). This methodology provides a simplified physical concept of the potential human exposure associated with the radioactive contents of hazardous chemical wastes.

COMPARISON OF DOSES AND RISKS

On-site worker and off-site public doses were calculated for the eight commercial TSD facilities. The preliminary results are discussed below.

Estimated Doses to Workers and the General Public from Waste-Handling Operations at TSD Facilities

The worker doses include the external exposure as well as the inhalation dose. Maximum annual worker doses were extremely low, ranging from 210-5 to 710-2 mrem. In the absence of more specific data, cumulative worker doses were calculated on a conservative basis, i.e.,assuming that each worker was engaged in the same operations for every year the DOE wastes were received on-site. These cumulative doses ranged from 210-5 to 810-2 mrem.

Two types of workers, inspection/sampling workers and incinerator workers, received the highest annual and cumulative doses. Doses to these workers were dominated by internal doses. Doses to inspection/sampling workers were mostly due to sampling of solid materials (i.e., dirt), which can result in the generation of airborne respirable particulates. Doses to incinerator workers were mostly due to incinerator maintenance. Because of the greater uncertainty, the estimation of internal doses was based on more conservative assumptions than that of external doses, resulting in relatively higher internal doses. For example, resulting data were not available to directly evaluate airborne concentrations

during incinerator maintenance and sampling of solid materials; therefore, a relatively conservative airborne dust concentration of 10 mg/m3 was employed to model these doses. Based on both the likely particle distribution and our experience, it is probable that these values exceeded the actual respirable concentrations by 10- to 100-fold. The potential radiological doses to the general public residing in the vicinity (within 50 mi [80 km]) of the TSD facilities were assessed. Based on an examination of the operations and disposition of the wastes, no credible off-site release of radioactive material to the atmosphere were identified at two facilities (1). At the remaining six facilities, for which population doses were evaluated, maximum annual individual doses ranged from 110-7mrem to 610-3 mrem. Cumulative maximum individual doses, calculated for the entire period that DOE wastes were shipped to commercial TSD facilities, ranged from 210-7 to 610-3 mrem (1). The maximum annual collective population doses ranged from 410-7 to 310-1 person-rem. The total population dose was 0.4 person-rem for all DOE wastes sent to TSD facilities.

Comparison with Federal Standards and Regulations

Federal radiation protection limits differ for members of the public and those exposed as a result of their occupation. The calculated maximum individual public radiation doses are less than 0.1% of the air pathway limit of 10 mrem/yr established by the U.S.Environmental Protection Agency (EPA) for protection of the public (3). The calculated public radiation doses are less than 0.01% of 100 mrem/yr, which is the DOE limit (4)for protection of the public from all sources and all pathways combined. Maximum annual doses to workers are less than 0.1% of the 100-mrem/yr DOE guideline for the general public, such as the unmonitored workers who might have been exposed at the TSD facilities. In addition, DOE has issued guidance establishing a collective dose limit of 10 person-rem/yr (5). The calculated total population dose from all pathways combined is less than 5% of the established guidance. Figure 1 lists some of these standards, their applications, and sources (3-4, 6-12).

Fig. 1

Comparison with Background Radiation

To provide some perspective, the calculated doses to workers and the public were compared with those derived from natural background radiation. In the United States, the average annual dose from natural background radiation is about 300 mrem to an individual (9). In comparison, the estimated dose in any one year to the maximally exposed worker does not exceed 0.03% of the average annual dose from background radiation. The estimated dose in any one year to a maximally exposed member of the off-site public does not exceed 0.002% of the average annual dose from background radiation. For the entire population within 80 km (50 mi) of the various sites, the estimated maximum population dose in one particular year does not exceed 0.00001% of the average dose from natural background radiation received by a similar population.

Comparison with Potential Release Levels

Although no international or U.S.standard exists for the release of bulk materials contaminated with radioactivity, there are principles or examples with which the derived TSD dose (or risk) levels can be compared. In Safety Series No.89 (2), the International Atomic Energy Agency (IAEA) states the principles for exemption of radiation sources and practices from regulatory control. The IAEA recommends that an individual dose of 1 mrem/yr (annual risk level of 10-6 to 10-7) to a

"critical group" of the general public would offer sufficient protection for exemption purposes. The level of 1 mrem/yr represents only 1% of the current recommended limit of 100 mrem/yr to the general public. In comparison with the IAEA exemption level of 1 mrem/yr, the calculated TSD doses are lower by a factor of 10 or more.

Comparison was also made with environmental assessments (11,12) of specific cases that have been (or are in the process of being) prepared for the release of radioactively contaminated metals. The calculated TSD dose levels in these cases are quite comparable with the other dose values.

STRATEGY TOWARD WASTE CLEARANCE

Numerical guidance exists for the unrestricted release of surface-contaminated materials, such as that found in Regulatory Guide 1.86 (13) of the U.S.Nuclear Regulatory Commission (NRC) and equivalent guidance in DOE Order 5400.5 (4). However, equivalent guidance for the unrestricted release of volume-contaminated materials does not exist. Generic guidance on release of bulk contamination is contained in DOE Order 5400.5 (and also in the proposed DOE 10 CFR Part 834 ruling), which allows establishment of "authorized limits for release" based on as low as reasonably achievable (ALARA) analysis.

Interim guidance on ALARA has been issued by DOE (14). Essentially, compliance with ALARA incorporates the following factors: objective, options, cost-benefit analysis, and control. Although the objective for hazardous waste is release, the options may consist of disposal as low-level radioactive waste or off-site shipment for treatment and/or disposal. Costs would be incurred for the activities associated with the options. Release for off-site treatment or disposal would require further activities of surveying, monitoring, and control prior to the release. Weighing costs against risks is certainly the most important element of ALARA and, therefore, for the entire release strategy. Estimating costs, however, is not the subject of this paper. This paper focuses instead on the potential risks incurred in the release of waste for off-site treatment or disposal. As discussed earlier, potential individual risks from release of DOE wastes have been found to be very low, generally below 510-8. For this reason, it would be feasible to establish a waste-clearance process based on risks. This can be accomplished by establishing the "authorized limits for release." How to characterize risks, therefore, becomes a crucial element in this process.

Although it would be feasible to establish a clearance approach for the release of DOE wastes to the commercial TSD facilities, it is important that such releases would also meet state or local regulations. In general, state regulations are tied to existing federal statutes. However, because no federal statutes exist regarding the clearance (unrestricted release) of radioactively contaminated wastes, most states do not have regulations, although some have established release limits of their own. As a result, the stakeholder's acceptance of DOE wastes becomes an integral component of the waste-clearance strategy. In this regard, DOE needs to establish a clear communication and consensus with state regulators, as well as with commercial TSD site operators. Also, as an input to the ALARA analysis, a baseline cost estimate should be established. Achieving such consensus is not a trivial matter; past experience, however, supports the feasibility of such an approach (11).

Aside from the licensed radioactive disposal cost, cost elements associated with waste characterization, surveying, instrumentation,

decontamination, packaging, interim storage, transportation, and so forth are also important in reaching an ALARA decision.

The authorized limits are intended as an interim measure before a universal unrestricted standard is developed. The authorized limits are basically intended for site- or region-specific concerns, with each limit based on specific cost and risk information as input to ALARA practice. It is possible that as time evolves, commonalities can be identified among sites and the wastes generated such that a complex-wide standard can be developed. Furthermore, international agencies such as the IAEA and the Commission of the European Communities are in the process of developing an unconditional clearance standard for slightly contaminated radioactive materials.

DEVELOPMENT OF DOSE ASSESSMENT MODEL

A computer dose model has been developed to support the waste-clearance strategy for DOE wastes. The dose assessment model considers exposure to two groups: on-site workers and off-site members of the public. This model, depicted in Fig. 2, was developed in the following steps on the basis of previous detailed analysis of the TSD facilities studied.

Fig. 2

Identification of Major Receptors and Major Operations

The receptors identified for the TSD facilities include four classifications of on-site workers, an off-site individual, and the general population. Operations are carried out in the same sequence as those for waste processing, including the following:

- Transport of wastes from DOE generator sites and transport of incineration residues off-site;
- Acceptance of waste at TSD facility including unloading, sampling, check-in, and storage;
- Waste incineration, which involves incineration, transport of incineration residues on-site, and incinerator maintenance;
- On-site landfilling of incineration residues.

Incineration and landfilling operations contribute to the off-site public dose.

Selection of Isotopes

The radionuclides incorporated in the model were based on previous DOE waste inventories at TSD sites. Additionally, the model also incorporates the radionuclides regulated under 10 CFR Part 61. The model currently can be applied to wastes containing uranium (U-232, U-234, U-235, U-236, U-238), plutonium (Pu-238, Pu-239, Pu-240, Pu-241, Pu-242), americium (Am-241), carbon (C-14), cesium (Cs-137), cobalt (Co-60), curium (Cm-242), iodine (I-129), nickel (Ni-59, Ni-63), niobium (Nb-94), strontium (Sr-90), technetium (Tc-99), and tritium (H-3).

Selection of Pathways

External exposure, inhalation, and ingestion were considered for all receptors. To extend the model to a broader range of radionuclides and site conditions, simplified groundshine and ingestion pathways were added to the plume-based inhalation.

Calculation of Doses

Simplified formulas were derived to calculate doses to on-site workers and off-site members of the public for each reference operation. By using conservative parameter values derived from the eight TSD facilities, bounding dose calculations were performed on the basis of unit activity. On-site worker external doses were based on scaling of microshield calculations. On-site worker internal doses were dependent on mass

loading factors to determine the quantity inhaled and ingested. Off-site receptor doses were based on the CAP88-PC gaussian plume exposure model (15).

Development of Graphical User Interface

A Windows graphical user interface was developed to estimate the worker and off-site public doses (both external and internal) for a specific TSD. The model enables the user to:

- Easily adjust key parameters for a site-specific assessment;
- View context-specific help;
- View results in tabular or graphical form;
- Save site-specific data to retrievable files;
- Access data forms through multiple means: menu, icons, and command buttons;
- Easily select applicable radionuclides;
- Discriminate site-specific values from default values;
- Easily identify maximally exposed receptors; and
- Compare resultant doses with regulatory limits.

SUMMARY

In summary, it is feasible to establish a DOE waste-clearance strategy for TSD facilities on the basis of existing guidance on ALARA. A risk tool in dose assessment is being developed as an important component of the clearance strategy. Other requirements for successful implementation of such a strategy include acceptance by states and stakeholders, as well as other logistics that include cost estimates and implementation of details to be identified later.

SCOPING ANALYSIS OF TOXIC METAL PERFORMANCE IN DOE LOW-LEVEL WASTE DISPOSAL FACILITIES*

Robert D. Waters
Dmitri A. Bougai
Phillip I. Pohl
Sandia National Laboratories
Albuquerque, New Mexico 87185-0734

ABSTRACT

This study provides a scoping safety assessment for disposal of toxic metals contained in Department of Energy (DOE) mixed low-level waste (MLLW) at six DOE sites that currently have low-level waste (LLW) disposal facilities - Savannah River Site, Oak Ridge Reservation, Los Alamos National Laboratory, Hanford Reservation, Nevada Test Site, and Idaho National Engineering Laboratory. The study has focused on the groundwater contaminant pathway, which is considered to be the dominant human exposure pathway from shallow land MLLW disposal. A simple and conservative transport analysis has been performed using site hydrological data to calculate site-specific "permissible" concentrations of toxic metals in grout-immobilized waste. These concentrations are calculated such that, when toxic metals are leached from the disposal facility by infiltrating water and attenuated in local ground-water system, the toxic metal concentrations in groundwater below the disposal facility do not exceed the Maximum Contaminant Levels as stated in the National Primary Drinking Water Regulation. The analysis shows that arid sites allow about 100 times higher toxic metal concentrations in stabilized waste leachate than humid sites. From the limited available data on toxic metal concentrations in DOE MLLW, a margin of protection appears to exist in most cases when stabilized wastes containing toxic metals are disposed of at the DOE sites under analysis. Possible exceptions to this conclusion are arsenic, chromium, selenium, and mercury when disposed of at some humid sites such as the Oak Ridge Reservation. This analysis also demonstrates that the U.S. Environmental Protection Agency's prescriptive regulatory approach that defines rigid waste treatment standards does not inherently account for the variety of disposal environments encountered nationwide and may result in either underprotection of groundwater resources (at humid sites) or an excessive margin of protection (at arid sites).

INTRODUCTION

Six DOE sites - Savannah River Site (SRS), Oak Ridge Reservation (ORR), Los Alamos National Laboratory (LANL), Hanford Reservation (HR), Nevada Test Site (NTS), and Idaho National Engineering Laboratory (INEL) currently dispose of low-level waste (LLW), and each is planning to dispose of mixed low-level waste (MLLW) (1). This study has focused on the groundwater contaminant pathway, which is generally considered to be the dominant human exposure pathway from shallow land disposal facilities such as these (2). A simple and conservative transport analysis has been performed to estimate site-specific "permissible" toxic metal concentrations in stabilized waste. Toxic metals present in MLLW were identified and the permissible toxic metal concentrations in groundwater at the site performance boundary (MCLs)were defined. From these concentrations the disposal facility "permissible" toxic metal concentrations in stabilized waste for the disposal facility were derived based on the estimated concentration attenuation provided by the waste form and on environmental transport from the disposal facility to the performance boundary using the conceptual groundwater pathway model described below. These "permissible" stabilized waste concentrations were then compared with data on toxic metal concentrations in DOE MLLW to assess the feasibility of disposal of toxic metal contaminated wastes in DOE LLW disposal facilities. The results of the analysis are used to discuss the U.S. Environmental Protection Agency (EPA) regulation related to disposal of chemotoxic wastes.

Requirements for managing DOE LLW are established in DOE Order 5820.2A (3). While the Order does not give specific guidance on toxic components of mixed waste, it requires that the hazardous component of DOE MLLW be managed to conform to the Resource Conservation and Recovery Act (RCRA) requirements of appropriate regional authorities. The list of toxic metals regulated under the RCRA (commonly referred to as RCRA metals) is given in Table I. The toxicity of waste is determined by the Toxicity Characteristic Leaching Procedure (TCLP), a test of the leachability of solids containing any one of a list of specific contaminants. A concentration of RCRA metal in the extract above its regulatory level (column 2 of Table I) renders the waste hazardous.

Table I

The Hazardous and Solid Waste Amendments (HSWA) to the RCRA prohibit land disposal of untreated hazardous wastes. This portion of the HSWA is referred to as the Land Disposal Restrictions (LDR). Treatment standards for wastes containing toxic metals have been established by EPA in the form of maximum permissible hazardous constituent concentrations in waste TCLP extracts. Corresponding concentrations are listed in column 3 (LDRs for characteristic wastes) and column 4 (universal treatment standards (UTS) for listed wastes) of Table I. EPA has recently proposed that the metal UTS replace LDR treatment standards for characteristic metal wastes in order to reduce confusion and make compliance easier (60 FR 43654, August 22, 1995). This proposed rule is not yet finalized.

TECHNICAL APPROACH

Model Assumptions

In accordance with performance assessment guidelines established by the DOE Performance Assessment Task Team (4): 1) a buffer zone of 100 m is used in assessing compliance with the performance objective for protection of groundwater resources, and 2) the requirement in 5820.2A to "protect groundwater resources consistent with federal, state, and local requirements" is taken to mean that the human exposure benchmarks are

Maximum Contamination Levels (MCLs) based on 40 CFR 141, the National Primary Drinking Water Regulations. The same document recommends a 10,000-year period of compliance for the performance objectives for groundwater protection.

The MCL values for RCRA metals that are used as human exposure benchmarks in the analysis are listed in column 5 of Table I. Arsenic (As), lead (Pb) and silver (Ag) do not currently have MCLs. The MCL values promulgated in 40 CFR 141.11, which were effective until December 7, 1992, were used for As and Pb. Silver is not considered in the analysis because it does not have an MCL, and the only potential adverse effect from exposure to Ag in drinking water is argyria (a discoloration of the skin), considered a cosmetic effect which does not impair health (56 FR 3526, January 30, 1991).

Immobilization/solidification techniques using cement-based grouts are considered the most common and universal option for the treatment and ultimate disposal of MLLW for variety of waste matrices (5,6). In particular, this stabilization technique is likely to be applied to the majority of MLLW streams containing toxic metals (i.e., inorganic solids and aqueous liquids (7)). Therefore, the analysis considers cement-based grout as a reference waste form for stabilization of the MLLW.

Because the uncertainty in hydrogeologic and geochemical parameters is frequently large even at well characterized sites, a simple and conservative groundwater pathway model (6), shown in Fig. 1, has been used in this analysis. The following major assumptions were used (6):

Source Term Assumptions. 1) The waste form was grout-stabilized. 2) Effects of contaminant solubility limits were neglected. 3) Performance of the disposal facility's engineered barriers is limited in time. After failure of the engineered barriers, the infiltration through the disposal facility is equal to the natural infiltration through local soils. 4) A continuous contaminant source was assumed for the transport calculations.

Environmental Transport Assumptions. 1) A one-dimensional analysis was performed. 2) Leachate dilution with groundwater was the only concentration attenuation mechanism accounted for. The contaminant-plume mixing depth in the saturated zone used in the "mixing cell" dilution model was estimated from either a) constraining hydrogeology (e.g., thin aquifers, sequences of units of high and low permeability) or b) vertical transverse solute dispersion. The last method was based on a one-dimensional flow, three-dimensional transport model (8). 3) Effects of longitudinal dispersion were neglected. (Once a continuous source model is assumed, this assumption is of minor importance.) 4) Fractured flow in the vadose zone was addressed by removing the fractured section from the stratigraphic column, implying complete and instantaneous transport through the fractured zone. 5) Fracture flow in the saturated zone was treated as an equivalent matrix porosity.

Calculations

The contaminant concentration attenuation in the groundwater pathway was calculated by assuming a mixing cell beneath the disposal facility in which contaminated leachate is mixed with clean groundwater (Fig. 1). The resulting concentration in the groundwater is calculated based on mass balance with the following formula:

Fig. 1

Eq. 1

where Cl is the leachate concentration (M/L3), Ql is the leachate volumetric flux (L3/T), Qgw is the groundwater volumetric flux (L3/T), a

is the length of the disposal facility parallel to the groundwater flow (L), b is the width of the disposal facility perpendicular to groundwater flow (L), ql is the infiltration rate through the disposal facility (L/T), dm is the mixing depth in the aquifer (L), and qgw is the groundwater Darcy velocity (L/T). The parameters a and b were assumed to be 50 m (6). Attenuation caused by environmental transport was represented by a dimensionless concentration reduction factor (CRFDW)

Eq. 2

The contaminant arrival time at the 100-m performance boundary was calculated as the sum of the retarded contaminant travel time in the vadose (tv) and saturated zones (ts):

Eq. 3

where lv is the depth from the disposal facility to the saturated zone (L), ls=100 m is the distance between the disposal facility and performance boundary, the qv and n are the volumetric moisture content in the vadose zone and the porosity in the saturated zone, respectively (dimensionless), and the retardation factors Rv and Rs (dimensionless) for the vadose and saturated zones are given by

Eq. 4

where Kd,v and Kd,s are the metal-soil distribution coefficients (L3/M) (discussed in the next section), and rb,v and rb,s are the soil bulk densities (M/L3) for the vadose and saturated zones, respectively. Similar to the attenuation for environmental transport, the toxic metal concentration attenuation provided by the waste form is represented by the source concentration reduction factor, CRFS. The CRFS was estimated based on the assumption that the toxic metal concentration in the waste form leachate is determined by desorption into infiltrating water (6):

Eq. 5

where Cw is the toxic metal concentration in the grouted waste form averaged over the entire volume of waste in the disposal facility (M/L3), qG is the volumetric water content of the grouted waste form (dimensionless), Kd,G is the distribution coefficient of the toxic metal in the grout (L3/M), rG is the bulk density of the grout waste form (M/L3), and fm is the mixing fraction, defined as the ratio of the volume of disposed waste in a unit volume of the facility (dimensionless). The following parameter values have been used in the calculations for equation (5) (6): qG =0.3, rG = 1.76 g/cm3, fm = 0.66.

Once the CRFDW and CRFS are calculated for each site and each toxic metal, the permissible waste form leachate concentrations (Cpl) and permissible concentrations in stabilized waste (Cpw) were calculated for the toxic metals as

Eq. 6

Eq. 7

Sorption Parameters for Toxic Metals

The RCRA toxic metals can be divided into three broad classes: 1) cationic elements (Ba, Cd, Pb, Hg), 2) anionic elements (As), and 3) redox-sensitive elements (Cr, Se) (9). In most cases, adsorption and precipitation cause very low mobility of cationic species in subsurface environments. For anionic species, adsorption and ion exchange will cause relatively little retardation in the subsurface, though oxyanions (e.g., AsO33-, CrO42-, SeO32-) are adsorbed specifically by mineralogical surfaces which carry a positive charge. Chemical speciation and mobility of the redox sensitive elements are strongly dependent on specific hydrochemical conditions.

Whenever site-specific RCRA metal sorption parameters were available, these were used in transport calculations. However, for a number of metals, site-specific sorption data were lacking. To provide the model with input parameters in the latter case, a generic toxic metal distribution coefficient (Kd) list was compiled (Table II). Literature review revealed applicable quantitative sorption data for some RCRA metals that are very limited for soils and especially for grout matrixes. In the latter case, values for sorption parameters have been assigned based on modeling or empirical relationships. The mercury (Hg) geosphere and grout Kd values are based on predictions of the MINTEQA2 geochemical model for the "medium pH of solution, medium in iron oxides and natural organic content matrix" conditions and "high pH of solution, low in iron oxides and natural organic content matrix" conditions respectively (13). As and Cr were assigned grout Kd values based on empirical pH-dependent "metal-sediment" partitioning relationships (15) assuming pH=12.5. Grout Kd values for the toxic metals are rounded to the nearest order of magnitude so as not to imply more precision in estimated values than is justified (6).

Table II

RESULTS AND DISCUSSION

Toxic Metal Concentrations in DOE MLLW

Very limited data are available on actual concentrations of toxic metals in DOE MLLW. Waste concentrations of RCRA toxic metals in several Oak Ridge Reservation MLLW waste streams are presented in Table III. Whether these data are representative of the entire DOE MLLW inventory is unknown, although similar processes should provide similar waste streams. The final column of Table III gives the weighted averages of all the waste streams.

Table III

Site-Specific Analyses

The summary (6) of the site-specific models and data for the six DOE sites considered in this analysis is presented in Table IV. Due to the extremely arid nature of the Nevada Test Site hydrogeological environment, a groundwater pathway is not believed to exist, implying total groundwater protection at this site (6). Therefore, no water pathway analysis was included in this work for the NTS. Calculated site-specific concentration reduction factors due to waste leachate mixing with groundwater (Table IV) show that leachate dilution provided by arid sites (INEL and LANL) is about two orders of magnitude greater than for the humid sites (ORR and SRS). The semi-arid Hanford Site has an intermediate dilution value. Estimated site-specific CRFDW (Table IV) and CRFS (Table II) were multiplied by the RCRA metal MCLs (Eqs. 6 and 7) to produce site-specific permissible leachate concentrations and stabilized waste concentrations for the RCRA metals (Table V). Values in Table V can be used as the basis for guidance to establish site-specific waste form performance criteria and waste acceptance criteria.

Table IV

The travel time calculations (Table V) show that, except for a few estimates (e.g., Ba and Se travel times for the Hanford Site), characteristic RCRA metal travel times for the arid and semi-arid sites exceed the DOE recommended LLW disposal compliance period of 10,000 years (4). For humid sites, the contaminant arrival times at the performance boundary will occur at least 500 years beyond the assumed performance of

engineered barriers, with most of the contaminant travel times falling within the higher range of thousands and tens of thousands years.

The last column of Table V shows estimated toxic metal concentrations in the example stabilized ORR waste. These estimates are based on data in Table II, assuming that the grout to MLLW mixing ratio is 1:1 and that the stabilized waste density is the same as the grout density. Assuming that RCRA metal concentrations in these example waste streams are typical for DOE sites, the data in Table V show that disposal of MLLW at the sites under analysis will satisfy or nearly satisfy groundwater protection requirements for most toxic metals. Exceptions are the anionic and redox-sensitive elements As, Cr and Se, and Hg. The concentrations of these metals are approximately an order of magnitude higher than the estimated permissible concentrations at some humid sites (e.g., ORR). Although this analysis is conservative, it indicates that care must be taken when disposing of As, Cr, Se, and Hg in humid environments. Waste streams containing a large amount of these elements may require enhanced stabilization (other than grout stabilization) prior to disposal, or even relocation for disposal to a semi-arid or arid environment. However, more detailed analyses that take credit for additional attenuation factors may provide higher permissible waste concentrations.

Table V

Implications for Regulation of Chemotoxic Waste Disposal

The rationale for the EPA TCLP-based TC, LDR, and UTS standards (Table I) is that corresponding concentration levels in the TCLP waste extract are considered to be an upper bound of contaminant concentrations in the disposed waste leachate under field conditions (55 FR 11862, March 22, 1990). The TC levels for toxic metals have been established as 100 times the MCLs which were in effect at the time of the rulemaking, with a generic 100-fold dilution/attenuation factor estimating attenuation of the toxic constituent leachate concentration in groundwater during subsurface transport from the disposal facility to the point of human exposure (45 FR 33084, May 19, 1980; 55 FR 1862, March 22, 1990). The LDR and UTS standards are also based on technology (i.e., based on performance of the Best Demonstrated Available Technology [BDAT] for hazardous waste treatment) (55 FR 22689, June 1, 1990; 59 FR 47982, September 19, 1994). However, the health risk considerations are implicit in the EPA rulemaking, because, with the exception of Se, the LDR standards for toxic metals are exactly the same as the TC levels.

Comparison of the site-specific permissible leachate concentrations estimated in this study (Table V) with TC, LDR and UTS standards (Table I) shows that, except for a few species (e.g., As), the UTS standards compare well with the estimates of permissible leachate concentrations for humid sites and will therefore ensure groundwater protection for most disposal environments, including humid ones; the LDR and TC standards will provide adequate protection at semi-arid and arid sites only. At the same time, the UTS waste treatment standards provide unnecessarily large margins of groundwater protection in arid disposal environments. Thus, the current EPA regulatory approach of setting a single waste treatment standard inherently does not account for a variety of hydrogeological disposal environments encountered nationwide. The result of such regulatory action is either potential underprotection of humid environments or unnecessarily high protection of arid sites. A performance-based regulatory approach, consisting of setting a performance objective to be fulfilled in every regulatory action, would

provide a much more consistent, flexible, and cost-effective way of protecting human health and the environment (2).

CONCLUSIONS

Arid sites appear to provide a greater degree of groundwater protection from land disposal of toxic metals because of higher attenuation and longer contaminant travel times. Arid sites also allow about 100 times greater leachate concentrations for stabilized waste compared to humid sites (e.g., Los Alamos National Laboratory vs. Oak Ridge Reservation). Most RCRA toxic metals are, in general, immobile in the subsurface environment, even at relatively humid sites. Exceptions to this conclusion are anionic species (e.g., arsenic and selenium), which tend to have lower Kd values. However, more specific analyses are needed to better determine the environmental fate of these and other metals.

From the limited available data on toxic metal concentrations in DOE MLLW and the estimated performance of grout-stabilized process waste, a margin of protection appears to be present in most cases when wastes containing RCRA toxic metals are disposed of at the evaluated DOE sites. Exceptions to this conclusion are As, Se, Cr and Hg when disposed at some humid sites. Waste streams containing large amounts of these elements may require enhanced stabilization (other than grout stabilization) prior to disposal, or relocation for disposal to semi-arid or arid sites.

The EPA's prescriptive approach of explicitly defining regulatory levels for toxic waste does not inherently account for the variety of disposal environments encountered nationwide, and may potentially result in either underprotection of groundwater resources at humid sites (e.g., TC levels) or an unnecessarily large margin of protection at arid sites (e.g., UTS levels).

A STRATEGY FOR RCRA PERMIT COMPLIANCE

Elizabeth C. Thiel
Michael D. Jorgensen
Lockheed Idaho Technologies

ABSTRACT

The Resource Conservation and Recovery Act (RCRA) of 1976 established national requirements for safe management of hazardous wastes. All generators and transporters of hazardous waste and all operators of treatment, storage, and disposal (TSD) facilities, including federal facilities, are responsible for handling and disposing of that waste as prescribed by the act and its implementing regulations.

The objective of one program established by RCRA, under Subtitle C, is to ensure that hazardous waste is handled in a manner that protects human health and the environment. Under Subtitle C, any facility that treats, stores, or disposes of hazardous waste must obtain an operating permit. As part of the permit conditions, configuration and operating conditions cannot be changed without notification of or approval from the regulator. A change to a permitted facility requires a permit modification if it affects a specific permit condition.

Because of the large number and wide differences in the hazardous and mixed waste units managed at the U.S. Department of Energy's Idaho National Engineering Laboratory, it was necessary to develop and implement a new business practice to maintain compliance with its RCRA permit.

The new business practice, reviewing TSD facility changes for RCRA permit modifications, applies a six-step process to ensure permit compliance at INEL facilities. The review process includes permit applications under regulator review, as well as issued permits. Lessons learned from problems encountered during implementation have been used to refine the process, which can be applied to other permitted facilities.

The key to success in developing such a program is the involvement of all the affected organizations: document control, maintenance, engineering, training, and RCRA permitting. The program is easier to implement if the facility has an effective change control or configuration management program in place. Each facility should balance the risk of non-compliance with the cost of the permit review program to be established for the facility.

BACKGROUND

The INEL was established in 1949 as a center where nuclear power reactors and support facilities could be built, tested, and operated with maximum safety. The INEL site covers 890 square miles and is 22 miles west of Idaho Falls. Fifty-two reactors have been built at the INEL, and 12 are still operable. The primary mission of the INEL is to utilize its engineering and scientific capabilities, site, and facilities to support national defense and energy programs. Current major programs at the INEL include water reactor safety, materials and fuels testing, nuclear fuel storage, high-level waste calcining, breeder reactor operation and research, manufacturing of tank armor, and management of hazardous, low-level, transuranic, and radioactive mixed waste. A total of 53 hazardous or mixed waste units will be permitted. These units include container storage areas, tank treatment and storage systems, incinerators, and other facilities.

REQUIREMENTS FOR PERMIT MODIFICATION

At facilities operating under a RCRA permit, operating conditions and documents and equipment related to the permit cannot be changed without notification of or approval from the regulating agency. Changes at permitted facilities require permit modifications if conditions specified in the permit are affected.

The Environmental Protection Agency (EPA) developed regulations for permit modification to help owners and operators of TSD facilities comply with the regulations and to reduce the possibility of fines or civil or criminal prosecution for environmental compliance failures. Consistent identification of needed permit modifications is essential for permit compliance.

The process developed at the INEL to review facility changes for possible permit modification was designed to accomplish the following goals.

- maintaining configuration control of all items related to RCRA permits or permit applications
- processing RCRA permit or application modifications to meet regulatory time frames
- providing training and information, including identification of RCRA permit compliance items, to facilitate reviews

The review process included permit applications under review by the regulating agency as well as issued partial permits.

Owners or operators of facilities that treat, store, or dispose of hazardous waste are required to submit a comprehensive, two-part permit application that covers all aspects of the design, operation, and maintenance of the facility. Based on the application, the regulating

agency determines if the facility is in compliance with Subtitle C regulations and develops a facility-specific operating permit. The review by the regulating agency may take from one to three years.

During the term of a permit (usually 10 years), situations may arise that justify modifying, revoking and reissuing, or terminating the permit. The regulating agency may initiate revocation (and reissuance) or termination of a permit for noncompliance with the permit. The owner (or operator) or the regulating agency may initiate a permit modification to prevent noncompliance. Permit applications are modified during the review period to reflect any facility changes that occur before the permit is issued. The most common conditions requiring modifications to permits or permit applications are listed below.

Substantial alterations or additions are made to the facility.

New information about the facility becomes available.

New statutory or regulatory requirements affect existing permitted activities.

Regulations for modifying a permit, established in 40 CFR 270.40-43, provide a permit modification classification system and administrative procedures for permit modification, including interactions with the regulating agency and the public. In addition, the regulations authorize the regulating agency to grant temporary permits to allow facilities to respond promptly to changing conditions.

Within the state of Idaho, RCRA permits are administered and enforced by the Idaho Department of Health and Welfare (IDHW). The RCRA permit modification provisions are established in the Idaho Administrative Procedures Act (IDAPA) 16.01.05012, which adopts the EPA permit modification regulations.

RCRA permits, as defined in the federal regulations and IDAPA requirements, are issued by facility, and the IDHW has identified the INEL as a single facility, owned and operated by the Department of Energy Idaho Operations Office (DOE-ID). In practice, however, the permit requirements are applied to specific TSD units (also called facilities). TSD units may include containers, tank systems, surface impoundments, waste piles, land treatment units, landfills, incinerators, and miscellaneous units. At the INEL, a single permit is issued for the INEL as a facility, with partial permits issued for the individual TSD units. The partial permits are issued to DOE-ID, as the facility owner and operator, with the specific contractor for the TSD unit identified as co-operator.

RCRA PERMIT MODIFICATION CLASSES

To facilitate classifying RCRA permit modifications, the EPA identified foreseeable changes at a facility that would require a permit modification and designated a modification class for each. The identified changes and their designated classes are incorporated into the regulations at 40 CFR 270.42, Appendix I, Classification of Permit Modification.

If the proposed change is not listed, the reviewer may propose a modification class based on established class definitions and similarity of the proposed modification to previously classified modifications. The modification may be submitted as a Class 3 modification or a request for the IDHW to determine the modification class based on the proposed class. The regulations classify modifications into four types: class 1, class 1 requiring approval (class*1), class 2, and class 3, as shown in Table I.

Temporary modifications may be allowed for class 2 or 3 permit modifications for 180 days or less. The advantage to temporary modifications is that public interaction is not required.

Table I

TYPES OF FACILITY CHANGES

During the operation of TSD facilities at the INEL, waste management practices will be adapted, as needed, to keep pace with both technological and regulatory developments. Many of these adaptations will require changes to conditions specified or material incorporated by reference in a RCRA partial permit or permit application.

The following conditions require a RCRA permit or permit application modification.

- changing TSD unit design, operation, capacity, or waste types processed if RCRA permit or permit application specified conditions are affected
- transferring the TSD unit to a different owner or operator
- managing newly regulated wastes or waste management units

Changes associated with the TSD unit ownership or waste management regulations are unusual and can be anticipated by personnel managing RCRA permit compliance. Changes associated with the TSD unit design, operation, capacity, or waste type processed are the target of the RCRA permit modification review process. Although each facility has its own mechanisms for initiating changes, three types of change methods apply to most permitted facilities: 1) work orders for maintenance and modifications, 2) document changes, and 3) projects.

Work Orders

Work orders are used at the INEL to implement physical changes to TSD units or waste management processes. As part of the review and approval process, work orders are reviewed for needed RCRA permit or permit application modifications. Permit modifications originating from work orders will most likely be class 1 changes.

Document Changes

Document changes, used to implement changes to operating practices or designs for a TSD unit, may include generation of new documents or revisions to or cancellation of existing documents (procedures, manuals, lesson plans, process run plans, databases, forms, plant drawings). Reviews for RCRA permit or permit application modifications are part of the normal review and approval process for document changes at the INEL.

Project Changes

Projects are used to implement large-scale physical changes at a TSD unit, including construction of a new TSD unit. New projects or modifications to existing projects are reviewed for RCRA permit or permit application modifications as part of the development of the environmental checklist required for federal facilities by the National Environmental Policy Act. Project changes are the most likely to require class 2 or higher permit modification requiring approval from the regulating agency.

GENERAL APPROACH TO PERMIT COMPLIANCE

Any change at a TSD unit that affects specified conditions or referenced information in a RCRA permit or permit application requires a modification to the permit or application. Some changes may not affect compliance with applicable RCRA permits or permit applications. For example, an item of equipment whose manufacturer name and model number is specified in a RCRA permit or permit application can be replaced with an identical item (the same manufacturer name and model number) without affecting compliance with permit or permit application conditions.

However, if the same item of equipment is replaced with an item from a different manufacturer, a permit or permit application modification will be required. Permit modifications, which can be both time-consuming and costly, should be requested only when necessary or when they can be considered with another modification. The RCRA permit modification review process is used to confirm that modifications will be necessary.
