To ease adjustment to this additional review process for TSD units at the INEL, a phased approach was used for implementing the RCRA permit compliance program. The basic goal of the phased approach was to maintain permit compliance while minimizing impacts and costs by using the existing infrastructure. Early compliance was made possible through a pilot phase to implement and evaluate trial-use procedures and training. Long-term compliance was made possible by issuing final procedures, distributing process and instrumentation diagrams showing hazardous waste equipment, and issuing RCRA document, instrument, and equipment lists on a controlled basis. Wherever possible, existing procedures and practices were adapted to implement the RCRA permit modification reviews.

Because a large number of changes are processed at the INEL, reviews for RCRA permit modifications need to be performed in accordance with the schedule for implementing the change and the overall priority of the change. After trained reviewers determine the need for RCRA permit or permit application modifications, permit applications can be updated in conjunction with implementation of the change, preventing any backtracking later. For modifications to issued permits, the permit modification process can be initiated as quickly as possible, preventing unnecessary delays in implementing the change.

BASIC STEPS FOR IDENTIFYING PERMIT MODIFICATIONS

The basic steps for determining whether a proposed change requires a permit modification are essentially the same for all types of changes.

1. Determine whether the change will impact any permit or permit application condition.
2. As applicable, determine the permit modification class.

The steps of the RCRA permit modification review are shown in Fig. 1.

Fig.1

IMPLEMENTING THE COMPLIANCE PROCESS

The initial steps to implement the program for RCRA permit compliance included 1) identifying permit conditions for compliance, 2) establishing procedures to implement the program, 3) developing a training program, and 4) developing the reviewer resources needed.

Identifying Permit Conditions for Compliance

Permit application writers reviewed the permit applications and the issued partial permits to identify the possible permit conditions for development of environmental requirements. The lists of conditions they developed included the application or partial permit, volume, section or module, revision, specific requirement, and implementing document for each identified condition.

As the final partial permits are issued, the lists will be revised to reflect changes.

Establishing Program Procedures

During the pilot phase, the trial-use procedures were based on current procedures for processing work orders, document changes, and projects. Supporting forms were developed from forms currently in use.

When the RCRA permit modification review program became effective, existing change control procedures were revised to include the permit

modification review, and supporting forms were revised to include a block for documenting review results.

A RCRA permit modification review flow diagram (Fig. 1) was developed to help the reviewing organizations decide if changes required permit modification. The review results are documented on the change proposal documents or a separate RCRA permit modification review form. Figure 2 shows the block used to record RCRA permit modification review results on INEL change forms.

Fig. 2

The only difference in the review and approval process for changes that do not impact permit conditions will be documentation to indicate that the change has been reviewed and found to have no impact.

For changes that do impact a permit condition, the reviewing organization will request that RCRA permitting personnel prepare the required permit modification notice or request. If the reviewing organization cannot determine the impact on permit conditions, RCRA permitting personnel may be asked to make the determination.

Training

Training was designed to be consolidated as much as possible to avoid duplication and to target the individuals who need to perform RCRA permit modification reviews. Two types of training were developed at the INEL: 1) performance training for reviewers who will determine if proposed changes impact RCRA permits or permit applications and 2) awareness training for individuals who need to know about RCRA permit modification reviews and the impacts on their work activities.

The 7-hour reviewer training includes a RCRA overview, study of the RCRA permit organization and the permit modification classes, a session to work through facility-specific examples, and written and performance tests. Personnel passing the class become qualified RCRA permit modification reviewers; personnel may exempt the class by challenging and passing both the written and performance tests. Reviewers will be retrained (or requalified by testing) every two years.

Awareness training was implemented by sending a letter of information sent to all TSD unit managers, document control, work control, and engineering personnel, project managers, and other personnel who could initiate or process changes that could be related to a RCRA permit or application. The letter addressed facility-specific change methods, provided awareness training in a question and answer format, and listed contacts for additional information or individualized training.

Reviewer Resources

A RCRA permit modification reviewer guide was developed and issued to each reviewer as an aid for determining if changes will impact permits or permit applications. The guide includes resources developed to assist reviewers in identifying permit-compliance items.

Copies of the issued partial permits and the permit applications prepared for TSD units were made available at convenient locations. In addition, electronic versions of the partial permits and permit applications were made available on an automated image management system and the Internet. Documents included in or referenced in a RCRA permit or permit application are listed by number on a document list. The list provides the specific volume and section in the permit or permit application where the documents are referenced or included. The document list is controlled and distributed to the reviewers.

Plant equipment and instruments identified in a RCRA permit or permit application may be located by number on equipment or instrument lists. Controlled copies of the equipment and instrument lists were issued to the reviewers in the reviewer guide.

Equipment and instrument lists are available through existing maintenance and engineering databases. The lists can be accessed in the equipment catalog under the main menu for each system. Equipment identified in a RCRA permit or permit application is indicated as "RCRA" in the environmental permit field.

Plant piping (waste lines) and large equipment (tank, vessels, etc.) identified in a RCRA permit or permit application are marked on applicable piping and instrumentation diagrams (P&IDs) with the following indications: see insert

Reviewers were instructed to assume that any equipment and instruments on the line, in addition to the equipment marked on the P&IDs (including pumps, valves, and jets), are also RCRA-identified equipment.

Regulatory interpretations and other information to clarify regulatory language or resolve problem areas in the review process were provided to reviewers as they were developed.

APPLICABILITY AT OTHER FACILITIES

This program could be adapted for use at other larger TSD facilities that will be operating under a RCRA permit. A formal program similar to the INEL program is necessary for larger TSD facilities. Small TSD facilities can use a single point of contact, familiar with the permit, to review all the change requests.

The key to success of developing such a program is the involvement of all the affected organizations: document control, maintenance, engineering, training, and RCRA permitting. The program is easier to implement if the facility has an effective change control or configuration management program in place. Each facility should balance the risk of non-compliance with the cost of the permit review program to be established for the facility.

BASIC ELEMENTS FOR AN EFFECTIVE PROGRAM

Evaluating the development and implementation of the RCRA permit compliance program at the INEL provides a list of basic steps and decisions that apply for similar programs.

1. Obtaining senior management approval. To obtain senior management approval for implementing the permit compliance program, the planned program must be demonstrated as workable, acceptable, and thorough.

2. Identifying permit requirements and compliance items at the facility. Specific requirements and references (RCRA permit or application, module or section) from the applicable partial permit or permit application should be identified. Structures, systems, equipment, equipment configurations, and documentation related to those permit requirements should be identified as compliance items, if changes to the items could affect the compliance status of the TSD unit. Corresponding implementing documents (procedures, drawings, databases, manuals) should be specified.

3. Identifying change methods in use at the facility. Using the permit compliance conditions identified from the permit or permit application, the methods used for making changes to those items can be identified. RCRA permit modification reviews should be incorporated into the change methods to ensure that all changes that could affect a permit or permit application are reviewed and tracked.

4. Establishing program procedures. Specific procedures for accomplishing RCRA permit modification reviews for facility changes should be established, with the following elements.

- Timely reviews: the RCRA permit compliance review should occur early enough in the process for any required notifications to be made.
- Documentation of reviews: the review for permit compliance should be documented on the change approval documents or attached forms or on electronic change documents.
- Implementing the program for different change methods: permit compliance reviews should be adapted for different change methods, including complex work orders and simple document revisions, which vary from facility to facility. Because of the complexity of the INEL, implementing the program and addressing site-wide change methods is presently in process.
- Implementation of class 1 modifications: because the regulating agency must be notified within 7 days after the changes are in effect, procedures for processing class 1 permit modifications must be specific.

5. Identifying and training reviewers. A pool of reviewers familiar with the RCRA permit or application should be established to evaluate proposed facility changes.

- Identifying the reviewers: personnel involved with management or change processes at RCRA-permitted facilities should be assigned and trained as RCRA permit modification reviewers. A listing of qualified reviewers should be available to personnel who normally make facility changes.
- Comprehensive training: training should be developed to accommodate personnel unfamiliar with RCRA and personnel with different levels of knowledge.

6. Providing reviewer resources. Resources to facilitate RCRA permit modification reviews of facility changes should be provided to the trained reviewers. Review resources include document and equipment lists and copies of the permit or permit application. Identifying RCRA equipment and instruments on P&ID's flags the RCRA-related items for reviewers and facility and engineering personnel.

7. Assessing program effectiveness. A built-in system for feedback and program assessment provides information about the review program and its effectiveness.

ABSTRACT

The Maralinga Nuclear Test Range, located in South Australia, is a former nuclear weapons test site that was used by the British in the 1950's and early 1960's. Both nuclear detonations (major trials) as well as chemical detonations of warheads (minor trials) resulted in extensive contamination of the site. At Taranaki, Maralinga's most heavily contaminated area, a series of minor trials involving the explosive dispersal of plutonium and uranium resulting in extensive contamination of surface soil and generated massive quantities of contaminated debris. The heavily contaminated debris from the trials was subsequently buried in a series of shallow pits at Taranaki.

The Commonwealth Government's Department of Primary Industries and Energy (DPIE) is undertaking a program to rehabilitate the most heavily contaminated areas at the site. A major part of the program is directed to reduce the risk presented by the contaminated debris buried in the pits at Taranaki. DPIE has identified the in situ vitrification (ISV) technology as the preferred technology for treatment of the Taranaki Pits. As part of this program, Geosafe recently completed two multi-ton radioactive demonstrations of the ISV technology at the site. The demonstrations involved preparing test pits which included 37 wt% steel, and other debris including lead, baryte shielding bricks and organic-based materials. Actual plutonium-contaminated debris originating from the original weapons tests was used in one demonstration and each demonstration involved the vitrification of one kg of uranium oxide. Results indicate that all demonstration objectives were met and that >99.999% of the radioactive materials were retained in the melt. No detectable activity was found inside the off-gas containment hood or on the insides of the off-gas piping. Preliminary radiochemistry analyses and X-Ray Fluorescence analyses indicate that the radioactive materials are uniformly distributed through the vitreous product. Leach tests of the vitrified product using the Product Consistency Test procedure at 7 and 28 day leaching intervals indicate that the normalized leach rates are extremely low (<0.1 g/m2) for all oxide species.

This international application of the ISV technology on TRU-contaminated buried waste represents a major milestone in the deployment of the DOE-developed ISV technology. This paper will present a overview of the Maralinga Rehabilitation Program and discuss the two radioactive ISV demonstrations conducted at the site. In addition, plans for the remaining phases of work will be discussed.

THE MARALINGA SITE

Atomic weapons were developed and tested in Australia at Maralinga by the British Government from 1955 to 1963. Seven atomic explosions during 1956 and 1957 resulted in fission product fallout. Several hundred ancillary experiments were conducted, some of which involved explosive dispersion or burning of metallic plutonium, uranium and beryllium in the open environment. Weapons development ceased in 1963, following the Partial Test Ban Treaty. Several attempts at clean-up of the Maralinga site were made by Britain. The last was Operation Brumby in 1967, during which

contaminated areas of soil were plowed to mix and dilute the level of surface contamination, and debris pits containing plutonium were capped with concrete. The site then reverted to Australian control. Details of the operations at Maralinga were summarized by Symonds (1). Interest in rehabilitation of the site was revived in 1984 by the Australian Royal Commission into British Nuclear Tests in Australia. The recommendations of the Commissioner (2) included a further clean-up to permit unrestricted access of Aboriginal people to the former test sites.
Maralinga is situated in the State of South Australia, between the Nullarbor Plain and the Great Victorian Desert, 40 km north of Watson siding on the Trans Australia Indian Pacific Railway (Fig. 1). The area of the site is 3,210 km2. Maralinga has a semi-arid environment with an average of 200-mm annual rainfall. Average temperatures range from 33C in January to 18C in July, with summer temperatures frequently in excess of 40C. The weapons development tests were conducted on Tietkens Plain, an outcrop of limestone and dolomite, partly covered by sand and bordered by vegetated sand hills.
Fig. 1
THE MARALINGA REHABILITATION PROGRAM
The Technical Assessment Group (TAG) was established by the Australian Government in February, 1986, to conduct scientific and engineering field studies, laboratory research and pilot operations necessary to define a range of realistic and cost-effective rehabilitation options. The scientific studies commenced with an aerial radiological survey of the former test sites, and included field and laboratory work to assess concentrations of residual radioactive isotopes in native foodstuffs, soils and inhalable dusts at Maralinga.
Dosimetric modelling of potential radiological dose through the pathways of ingestion, inhalation and wound contamination during the activities of a semi-traditional Aboriginal lifestyle led the TAG to conclude that the current radiological hazard at Maralinga resulted from the dispersal by chemical explosive of about twenty two kilograms of metallic plutonium in twelve Vixen "B" one-shot minor trials at the Taranaki test site between August 1960 and April 1963. In these trials, each nuclear device was detonated by chemical explosive on an exposed "featherbed" structure. The "featherbed" consisted of massive steel plates and walls of lead and barytes bricks mounted on rolled steel joists. The detonation of the devices produced a measurable, but negligible, nuclear energy yield in most shots. Plutonium was dispersed as fine oxide dusts, as sub-millimeter particles, and as surface contamination on larger fragments of debris from the destruction of the "featherbed". Engineering studies by the TAG defined a series of engineering work packages using established technologies for treatment of contaminated land and debris pits.
REMEDIATION OPTIONS
The report by TAG (3) to the Australian Government contained nine rehabilitation options and about 29 sub-options. The options ranged from low cost/resource/risk (e.g., fencing and exclusion of contaminated areas) to high cost/resource/risk (e.g., collection and disposal of contaminated soil and the contents of debris pits). The scope of rehabilitation covered access by semi-traditional Aboriginal Communities, primarily the residents of Oak Valley, ranging from casual access to fully unrestricted habitation.
Data from safety trials conducted at the Nevada Test Site (4) indicated that about twenty percent of the plutonium detonated (i.e., about four

kilograms of plutonium) might have been deposited in the near field of the detonations. Twenty one numbered shallow debris pits in a fenced area at Taranaki have been reported to contain about 820 tonnes of debris and 1150 tonnes of soil contaminated with plutonium from the Vixen "B" trials. Pending further evidence, the pits have been assumed to contain between four and twenty kilograms of plutonium. This paper is focused on the stabilization of the contents of these debris pits.

STABILIZATION OF DEBRIS PITS

TAG (3) considered three options for stabilization of the plutonium debris pits: exhumation and reburial of the pit contents, stabilization by concrete grouting, and stabilization by in situ vitrification. Exhumation processes considered involved excavation of debris and contaminated soil into rectangular steel boxes, for disposal either in deep boreholes, or in a lined and capped sub-trench below the trench for disposal of collected contaminated surface soil. Exhumation would require intensive radiological protection of personnel against inhalation of plutonium dusts.

Grouting procedures assessed included a combination of in-pit grouting, grouting of adjacent rock and soil, with concrete capping, cut-off walls and tumuli over the grouted pits. A major problem in the grouting option was the uncertain degree of void filling and consequent doubtful degree of improvement in long-term safety.

In situ vitrification (ISV) is a U. S. Department of Energy developed process being commercially applied by Geosafe Corporationa. The process involves electric melting of contaminated soil and debris and/or other earthen materials for purposes of permanently destroying, removing, and/or immobilizing hazardous and radioactive contaminants. Melt temperatures typically reach 1400-2000C by passage of (typically) 3 to 4 MW of electrical power with a square array of four electrodes. Off-gases are collected for treatment in a steel containment hood that spans the area being processed. When electrical power is shut off, the molten mass solidifies into a vitrified monolith with unequalled physical, chemical, and weathering properties compared to alternative solidification/stabilization technologies. For the Maralinga application, the ISV process would melt the soil and debris contained in the pits. The plutonium oxide would be incorporated into a stable leach resistant vitreous/ceramic block, with steel debris melting to form an encapsulated steel ingot.

The ISV process appeared to have advantages of improved occupational, public, and environmental safety together with greatly improved containment of the radioactive materials in the vitrified product that would be much more durable compared with alternative stabilization methods. This conclusion was subject to the proviso that the presence of limestone and the contents of the pits did not adversely affect process efficiency and that the logistics for operation of the process at Maralinga could be resolved. The Australian Government decided to proceed on the basis of an option which involved collection and trench burial of the more highly contaminated surface soil, and determination of the applicability of ISV for stabilization of the contents of the debris pits.

DESCRIPTION OF THE MARALINGA ISV PROJECT

The ISV project was structured as a four phase project. Phase 1, conducted in 1993 and 1994, involved an initial study to determine if the ISV process was suitable for the application. The study included a site

visit to evaluate the site conditions and involved engineering-scale ISV tests and crucible melt studies using debris and uncontaminated soils from the site. Phase 1 results indicated that the ISV process could be applied to the soil and debris combinations at the site.

Phase 2, conducted in 1995, involved a series of ten on-site engineering-scale tests and three intermediate-scale demonstrations to obtain site-specific process data. Two of the intermediate-scale demonstrations used radioactive materials, including blast debris from the original weapons tests. These two radioactive demonstrations are the subject of this paper. The principal goal for the intermediate-scale radioactive ISV demonstrations was to collect sufficient data to determine if the ISV process could be expected to effectively treat the contaminated soil and debris in the Taranaki pits and to obtain data to confirm the behavior of plutonium in the process. Data from the tests and demonstrations were also gathered to support the design of a full-scale ISV process machine that will be tailored for the site-specific conditions and to develop a remedial design plan which will define the approach and logistics associated with the full-scale treatment at the site. Specific objectives were established for each demonstration so that the performance of the ISV process and the resulting vitrified product could be evaluated against the performance criteria established for the project.

Science and engineering advisors representing the Commonwealth helped determine ISV process performance criteria for the application and were present to observe activities during key stages of the demonstration project.

The demonstrations were configured in a manner that was thought to best represent the configuration of the actual pits as well as the actual types and amounts of debris buried in the pits. Standard scaling relationships established for the ISV process were used in conjunction with historical data that describes the pits and the pit contents to develop scale mock-ups of a typical Taranaki pit.

An intermediate-scale (85 kW) system capable of producing melts up to 4,500 kg (5 tons) was constructed for the project. Figure 2 is a photograph of the ISV equipment as positioned for the second radioactive demonstration involving plutonium. This size of system provides cost effective data that can be directly scaled to the full-size application. The off-gas treatment system was designed specifically to handle the higher off-gas generation rates and higher off-gas temperatures expected to result from processing buried wastes. In addition to the steel and radioactive materials, the pits contained significant amounts of gas generating materials such as sulfates, carbonates, and organics.

Fig. 2

RADIOACTIVE ISV DEMONSTRATIONS

The two radioactive demonstrations involved the treatment of soil, 37 wt% steel debris, and other debris including bitumen-stabilized soil, lead, plastic, electrical cable and barytes bricks. The barytes bricks were originally used as radiation shielding material and are composed of barium sulfate. Figure 3 is a photograph of one of the pits being filled with debris and soil. One kilogram of uranium oxide was buried in each pit to serve as a surrogate for plutonium. For each demonstration melt, the uranium oxide was contained in a plastic bag and located in the center of the pit to serve as a highly localized area of contamination. The second radioactive demonstration included a steel plate, originating from the weapons tests, that was contaminated with approximately 0.5

grams of plutonium oxide (predominantly 239Pu with about 3% being 241Pu). About 90% of the 241Pu originally on the plate had decayed to 241Am.
Fig. 3
Each demonstration melt was conducted at opposite ends of a trench. In order to best represent the geochemistry of the limestone-based soil surrounding the Taranaki pits, the tests were conducted in the Taranaki area adjacent to two of the larger waste burial pits.
The two demonstrations were conducted in September and October of 1995. The first demonstration occurred over an 84 hour time period while the second demonstration occurred over a 96 hour time period. During the operations, process-related data, such as electrical power and off-gas related data, was collected to support the design process for a full-scale ISV machine that will be tailored specifically for the site.
Following the two demonstrations, the resulting vitrified monoliths were excavated for examination, weighing, and sampling. The mass of the first demonstration monolith was determined to be 3,766 kg (4.15 tons). The mass of the second demonstration monolith was determined to be 4,292 kg (4.73 tons). Figure 4 is a photograph of the second demonstration monolith being weighed.
Fig. 4
RESULTS AND OBSERVATIONS
Both demonstrations were completed successfully. Physical characterization of the vitrified blocks and preliminary radiochemical analyses have been completed. Additional analyses, including a variety of leach tests, are currently underway. Based on the available data, the following observations and conclusions can be made concerning the demonstrations:

The ISV process was demonstrated to be capable of melting the soil and debris combinations in the pit including the 37 wt% steel. In addition, the non-steel debris in the pit (barytes bricks, cable, lead, bitumen stabilized soil, and plastic) did not pose any processing difficulties.

The voids and gas generating materials in the pits (carbonates, sulfates, and organics) did not pose any processing difficulties with respect to off-gas containment. The off-gas treatment system's high off-gas flow rate was fully sufficient to accommodate the high steady state off-gas generation rates and transient off-gas surges that resulted from processing the gas generating materials and voids.

The volume reduction for the soil and debris treated was 47% for the first demonstration melt and 55% for the second demonstration melt.

Based on isokinetic off-gas sampling, the amount of uranium oxide retained in the first demonstration melt was 99.99987% and the amount retained in the second demonstration melt was 99.99968%. Using the same isokinetic off-gas sampling methods, the amount of plutonium retained in the second demonstration melt was determined to be in excess of 99.99999%.

Following the demonstrations, health physics-related surveys of the equipment established that the insides of the off-gas containment hood, off-gas piping, and primary HEPA filters were free of detectable contamination above background levels (less than 0.25 Bq alpha and beta combined per 100 cm2 surface area). Consequently, decontamination of the equipment was not required.

The plutonium, uranium, and americium in the vitreous phase are not smearable. Significant intrusive sampling activities resulted in the creation and handling of many small fragments of vitrified product,

including dusts, but did not result in the transfer of any detectable contamination to tools or personnel.

Based on X-Ray Fluorescence analyses and alpha spectrometry analyses of samples, the plutonium and uranium oxides were found to be uniformly distributed throughout the vitreous phase. Table I provides a summary of the data for several samples from the plutonium demonstration.

The metal phase at the base of each melt was determined to be free of plutonium and uranium based on qualitative analyses. Quantitative analyses of the metal phase have not yet been completed. (Earlier Phase 2 tests involving cerium as a plutonium surrogate established that the cerium did not partition to the metal phase.)

Leach tests of six samples of vitrified product, conducted in triplicate, using the Product Consistency Test Procedure at intervals of 7 and 28 days indicate that the normalized leach rates for all oxides in the vitrified product are less than 0.1 g/m2. The leach tests included standard PCT tests as well as modified leach tests using leachants with pH values of 5, 7 and 10.

Table I

CONCLUSIONS

The data and observations resulting from the radioactive ISV demonstrations conducted at the Maralinga site support the following primary conclusions concerning the likely performance of the ISV process on the Taranaki pits:

The ISV process, at full-scale, can be expected to effectively treat the soil and debris combinations in the Taranaki pits.

The data indicates that an ISV process machine designed specifically for this application will be capable of handling the higher off-gas temperatures and transient off-gas flows associated with the treatment of the buried wastes.

The vast majority (>99.999%) of the plutonium and uranium will be retained in the melt and will be uniformly distributed throughout the vitreous phase.

The vitrified product will be a uniform, dense, hard product of high strength with exceptional leach resistance.

Plutonium will not be distributed to any significant extent to other phases in the melt.

The ISV process can be safely applied to the materials present at the Taranaki site.

PLANS FOR SUBSEQUENT PHASES OF WORK

The two radioactive demonstrations provided an opportunity to obtain site-specific process performance data to evaluate the ISV process for this application. The data will be used to develop a remedial design plan for the full-scale application to determine the most efficient, safe and economical approach to treat the Taranaki pits with the ISV technology. In addition, the data is being used to design a full-scale ISV process machine that is being tailored to accommodate the specific characteristics and treatment requirements of the site. Phase 3 will involve the construction of the full-scale ISV machine. Phase 3 is expected to commence in 1996. Phase 4 involves the actual treatment of the Taranaki pits. Phase 4 is expected to commence in 1997.

ABSTRACT

In the framework of a cooperation agreement between SIA "Radon" (Russia) and SGN (France), the cold crucible technology developed by Radon has been tested with two different simulated wastes. These surrogates are representative of VVER (nuclear reactor of water-water type used at Nuclear Power Plants) and Radon waste respectively. The operating conditions, the performance of the cold crucible, the off-gas treatment, and properties of the produced glass have been determined.

Moreover, joint vitrification of low-level liquid wastes with solid wastes and crushed lead-containing cathode ray tubes (CRT) glass were conducted. Glasses produced from sodium nitrate or sodium borate based wastes and lead-containing waste can be melted at 1200-1300oC and these are high chemically durable. Their viscosity range is between 2 and 7 Pa s. These glasses, with resistivity 0.02-0.05 Wm, are able to be produced by induction melting in a "cold crucible". When a "yellow phase" forms, it may be dispersed in molten glass by high active agitation followed by a rapid temperature decrease to solidify the "yellow phase" (sulfates) in the glassy matrix. Vitrification tests in the experimental plant based on cold crucible were performed and the operating conditions and the glass properties were determined.

Experimental results have shown that lead glass is a suitable additive for radwaste vitrification. Joint vitrification of radwaste with lead-containing waste yields glass or glass-composite material with low leach rate both alkali cations and lead.

The next milestone of the joint development program to reach industrial scale-up are also described.

INTRODUCTION

Successful application of the cold crucible technology at SIA "Radon" for intermediate-level waste vitrification (1) stimulated a search of new applications, including the use of the cold crucible for lead-containing toxic waste immobilization (2). In the frame of a cooperation agreement between SIA "Radon" (Russia) and SGN (France), the cold crucible technology developed by Radon has been tested with two different simulated wastes. These surrogates are representative VVER and RBMK (channel-type uranium-graphite reactor) wastes.

The tests were conducted in an experimental plant based on coreless induction melter - cold crucible with industrial-scale dimensions.

The main aims of these tests are characterization of this technology with simulated intermediate-level Radon and SGN specified wastes, determination of basic process parameters, heat and mass balance, product, off-gas and secondary waste characterization and determination of the ability of cold crucible to maintain an underpressure at operation.

Glasses prepared were analyzed for chemical composition, viscosity, resistivity, chemical durability, and homogeneity. Aerosol concentration and chemical composition, gas specific activity, components volatility and gas concentration (HCl, SOx, COx, NOx) have been determined from off-gas analysis. The estimation of sleeve filter workability (operation efficiency and regenerability) was carried out as well.

Experiments on the joint vitrification of low-level liquid and solid wastes and crushed lead-containing CRT glass were also conducted. The same cold crucible based plant was used. Glass properties, lead volatilization and leaching were studied.

EXPERIMENTAL

Plant Description

The basic unit of the plant design (Fig. 1) is an induction melter - a cold crucible (IMCC). The melter was manufactured from water cooled stainless steel pipes. It has a water-cooled lid. An agitator may be installed in the lid if necessary.

Fig. 1

The crucible was installed in a protective access box, equipped with exhaust ventilation and filter. The cold crucible dimensions during test No. 1 and 2 were 590 mm in length, 300 mm in width, 655 mm in height and 10.18 dm2 in melt surface area. The crucible was surrounded by a two-turn inductor energized from a high-frequency (HF) generator. The generator' s power and operating frequency were 160 kW and 1.76 MHz respectively. The plant is equipped with water flow rate indicators. Generator's lamp was cooled with distilled water.

Tests No. 3-5 with lead glass were performed with small cylindrical cold crucible (100 mm in diameter) energized from HF generator operated at 1.76 MHz with 60 kW of power.

Batch preparation was carried out manually in containers. The batch prepared was charged in a mixer followed by feeding into the melter. Glass melt was poured into metallic container (measures 400x400x150 mm). Off-gas was purified on coarse (sleeve) filter and cooled in a heat-exchanger.

Experimental Procedure

Five vitrification tests were performed. During the first test a simulated SGN waste was vitrified and during the second test a simulated "Radon" waste was treated with borosilicate additives. The salts were crushed previously to be undersized of 10 mm and dry blended to glass forming additives. SGN and Radon waste compositions are presented in Table I.

Table I

The glass-forming additive compositions including loam clay and CRT glass are given in Table II.

Table II

Dry batches compositions for the resulting glasses are shown in Table III. Before the first and the second tests water was admixed to batch to produce a paste with moisture of about 20 wt.%. The prepared paste was fed into the mixer in 20-22 kg batches. The batch capacity was evaluated by change of level in mixer taking into account its density.

Table III

Initiating of melting in the cold crucible was produced by means of heating a short-circuited loop (titanium ring) in an electromagnetic field followed by the titanium ring oxidation and incorporation of titania in the glass.

After the melt formation the batch was fed into the cold crucible in batches of 0.5-1 kg. A need for charge was determined visually by measure of melt surface opening in the crucible. An average melt capacity was evaluated by measuring the weight of the containers filled with glass. The current, voltage of feeding supply line, generator's electric parameters, flow rate and temperature of cooling water, underpressure in the cold crucible and filter resistance were checked every 20 minutes during the experiment. The glass samples were taken at the cold crucible discharge as well as from the containers after cooling. The condensate after heat-exchanger was drained and studied. During the first test the vitrification of SGN waste vitrification. The experiment was carried out for 16 h. Sampling was started after the operation conditions hit and was carried out in accord with feed cycle.

During the second test the batch contained simulated "Radon" waste. The experiment was conducted for 7 h. Two hours of this time a batch containing the radionuclide 137Cs with total activity of 5.5 MBq was vitrified. Off-gas sampling was carried out at filter outlet to exclude the effect of water soluble constituents of aerosols.

The next three experiments were performed to determine a feasibility and conditions of lead-containing toxic waste vitrification. At first, broken CRT glass without additives was remelted. Then, joint vitrification of Radon waste and lead glass was performed. Finally, joint vitrification of SGN waste, soil and lead glass was carried out.

During all of the experiments the underpressure of 15-20 mm H2O was maintained, the off-gas flow rate was checked and filter inlet and outlet temperatures were recorded. Simultaneously the gas flow rate and the filter resistance were recorded. A filter regeneration was carried out by transitory (0.2 s) pulse air feed in every sleeve by turns in two cases: when filter resistance reached 1.5 kPa and at instant of glass pouring. Glasses, off-gas deposits and condensates produced were analyzed for constituents by atomic absorption spectroscopy (S-115 spectrophotometer, Russia) and emission spectral analysis techniques (unit based on ISP-30 spectrograph). A glass resistivity and viscosity were measured with Institute of Glass (Russia) unit modified in Radon. Leach rates of sodium

and potassium ions and 137Cs were measured by IAEA technique (MCC-1 test) (3).
Specific activity of glasses containing 137Cs was measured by counter SI-8B supplied with device PSO-2/4 in comparison with standard source.
Incorporation of Simulated SGN and Radon Wastes in Borosilicate Glass
Before the first test the melter was filled with glass that remained from the previous experiments. Before and after the operation the glass level was set the same this level, corresponded to the minimum possible level of glass left after the glass pouring. Average process variables are shown in Table IV.
Table IV
The generator power was elevated as far as glass level in melter was elevated. Glass properties are given in Tables V.
Table V
In the middle of the first test some problems occurred with the glass sampling due to a change in glass composition that resulted in the increase of glass resistivity (4). "Yellow phase" formation due to high sulfate content was also observed. An attempt to disperse the "yellow phase" by means of agitation before pouring was not successful because of low melt viscosity.
No problems were encountered with Radon waste vitrification. Glass compositions are given in Table V. These are similar to common Radon waste glass (5).
At 1200-1300oC both melts had a suitable viscosity and fluidity, which all the melt pouring to be implemented for 2-3 minutes.
The effect of melt agitation on melter capacity was estimated during Radon waste vitrification. Melt agitation was carried out by blade stirrer installed at an angle to melt surface. A 10 kg batch was fed in the mixer and the time for every batch treatment was determined. Two batches were doped with 137Cs. According to preliminary data, agitation increased glass productivity by approximately 15-20%.
The glasses prepared had a low specific activity. Therefore a significant error occurs at 137Cs volatilization and leach rate measurements. Volatilization and chemical durability of glasses have been evaluated more precisely from volatilization and leaching of sodium and potassium cations. It is seen from data shown in Table IV that volatilization during melting and leach rate of these cations from glasses are similar to other known borosilicate glasses. Approximate measurements showed cesium leach rate has the same order of magnitude as sodium and potassium.
Solubility of SGN and Radon waste glasses in HF indicating vitreous phase fraction is 90% and higher (Table V).
Incorporation of Mixed Waste in Glass
Melting of broken CRT glass yielded a homogeneous melt containing minor inclusions of metallic contacts. Their low content did not result in an accumulation of molten metal phase at the crucible bottom. Process variables are represented in Table IV.
Glass compositions of the joint vitrification were determined from a laboratory study (2). Two of the mixtures (Table III) were fully melted at 1200oC. Melt resistivity at this temperature ranged between 0.02 and 0.05 Wm. This range is suitable for electric melting in the cold crucible. Sodium, potassium, lead and boron losses were measured (Table IV). Glasses (Table V) contained about 30% of Radon and SGN waste respectively. No problems were encountered during melting. Lead-

containing glasses were able to dissolve an increased quantity of sulfate and chloride ions (6) and "yellow phase" formation was not observed. Homogeneous glasses with good chemical durability were produced. Sodium, potassium and lead leaching was insignificant (Table V).

Off-gas Analysis

Cesium and other components losses from the melter were determined from off-gas specific activity and dust content taking into account the off-gas flow rate.

After the first run with simulated SGN waste, 3.1 kg of dust was collected in sleeve filter as well as 200 g of dust was deposited on off-gas pipe walls. Chemical composition of off-gas pipe and sleeve filter deposits are given in Table VI.

Table VI

Relative fraction of insoluble compounds (calcium, magnesium, aluminum and iron silicates and sulfates) from the off-gas pipe was higher compared to the product discharged from the collector and filter sleeves.

A sleeve filter was charged with filter cloth from carbon fiber with a filter surface area 2.8 m2. An average off-gas flow rate during the test time was 50 m3/h (recalculated to normal condition). Inlet temperature was maintained at the level 130-160oC and filter outlet temperature was 90-120oC. Gas filtration flow rate at filter operation was 0.8-1.0 cm/s. Filter resistance ranged between 0.3 and 1.5-2 kPa. Reverse blow-out decreased the resistance to 0.5-1.2 kPa. After sleeve filter parameters at SGN and Radon waste vitrification aerosol concentration was decreased from 930 to 22 and from 1500-2000 to 15-30 mg/m3 respectively. Off-gas specific activity at Radon waste treatment was decreased from 7.25 to 0.16 Bq/m3. Trapping efficiency of aerosols and 137Cs was 97.52.0 and 96.20.7% respectively.

During simulated liquid waste treatment the gas constituents concentrations were measured. Average HCl and SO2 concentrations were 11 and 6 mg/m3 respectively during batch feeding and 14 and 4 mg/m3 respectively during glass pouring. Nitrogen oxides concentration ranged between 27 and 38 (averaged -31) g/m3. Carbon monoxide in the off-gas had not been revealed. Oxygen concentration was found to range within conventional values (19.5-21 vol.%). During simulated waste vitrification without agitation the off-gas dust content ranged between 0.3 at the end of batch portion melting and 4.8 g/l immediately after the next batch portion feeding.

A test run conducted to determine material loss from the melter during batch feeding of 10 kg portions has shown that melt agitation increases the solid aerosols losses by factor of 2-3: from 0.27% without agitation to 0.87% with agitation. A dust content in off-gas in the latter case increased to 9.7 g/m3. An increase of solid entrainment at melt agitation resulted in greater dust deposition in off-gas tube (480 g per 1300 g of free-flowing bulk material from collector and filter sleeves. Overall dust entrainment has achieved of 1.9% from produced bulk glass.

At the end of the experiment two runs of batch feeding spiked with 137Cs were carried out. Overall batch activity of 4.45 MBq was fed into melter. Average off-gas specific activity at sleeve filter inlet was 7.3 Bq/l (maximal value - 14.3 Bq/l). Radioactive cesium loss from melter (with respect to off-gas specific activity) was 12.6% from loaded activity. These data should be considered as preliminary due to very short time of the test.

Condensate compositions obtained after the heat-exchanger contained mainly nitric acid. Moreover minor chloride and sulfate ions were detected (up to 2.5 and 0.1 g/l respectively). Average specific activity of the condensate at simulated "Radon" waste operation was 520 Bq/l.

CONCLUSION

Simulated SGN and Radon waste vitrification tests in a "cold crucible" have demonstrated the good workability, reliability and high productivity, and ability of the cold crucible to maintain an underpressure during the operation. Cold crucible capacity can be increased by additional melt agitation. The quality of glasses produced is also high. Lead-containing broken CRT glass can be remelted with formation of chemically durable glass. Common vitrification of lead glass and intermediate-level waste also yields homogeneous glass. Leach rates of sodium, potassium cations and cesium radionuclides were low and they were found to be on the level of good borosilicate glasses.

ABSTRACT

Induction-heated cold crucible melting is increasingly seen as a promising technique by the international scientific and technical community. It is capable of achieving high temperatures and power densities with virtually no melter corrosion, making it an ideal solution for many applications ranging from simple melting of metals, molten salts or glass, to complex processes involving chemical reactions in molten baths, or even to the incineration of combustible waste or ion exchange resins.

This technique has been developed by the Commissariat l'Energie Atomique (CEA) for many years, and is now reaching maturity in many sectors of activity.

Metals. A prototype melter has been built in France to ensure the containment of irradiated fuel cladding scraps. The unit produces ingots 20 cm in diameter and 1 m high weighing 200 kg each, with a volume reduction factor of nearly 6.

Molten salts or glass. The CEA operates several prototype units primarily intended to vitrify fission product solutions. They routinely achieve glass production rates of 50 kg per hour, and may be coupled with a calciner to evaporate and calcine the feed solution. Similar units can be used to obtain metals from their oxides by reduction in a molten bath; metal alloys have also been produced.

Waste treatment. Cold crucible melters are used today for simultaneous incineration and containment of combustible wastes including plastics or resins; the latter are burned directly on the surface of the glass melt in which the residue is directly confined, and which may be cast into a container for direct disposal.

As a result of these developments, induction-heated cold crucible melting has reached a level of maturity that makes it a feasible alternative for practically all high-temperature waste treatment processes.

INTRODUCTION

The ever more pressing need to develop a satisfactory solution to the problem of radioactive waste, for lack of a means of eliminating the radioactivity entirely, has led to efforts to confine and contain the waste in increasingly small material volumes. This represents an implementation of the "2C" principle - containment and concentration - as opposed to the "2D" principle - dilution and dispersion.

Three decades of work in this area have shown that this objective requires the use of high-temperature processes, which destroy any organic matter and produce radioactive waste in metallic or generally in oxide form, stabilized within a suitable matrix (1). In France, these principles are implemented by the Commissariat l'Energie Atomique (CEA) and its subsidiaries, COGEMA and SGN; the exemplary operating record of the fission product solution vitrification facilities at Marcoule (since 1978) and La Hague (since 1989) clearly demonstrate the benefits of this technique (2).

Nevertheless, the CEA is continuing to develop increasingly effective processes applicable to an increasingly wide range of waste materials. This is the impetus behind the induction-heated cold crucible melting technique (3) described here.

PRINCIPLE

The technique is based on the use of a water-cooled structure that is transparent to the electric field produced by an induction coil surrounding it; this allows currents to be generated inside the material contained in the structure. The upper diagram in Fig. 1 shows a closed,

water-cooled cylindrical metal structure forming a Faraday cage: the electric field inside is nil, as the current flows only around the periphery. The second diagram in Fig. 1 shows a sectorized metal structure that allows currents to flow in each sector - notably on the inner face, creating a nonzero electric field that induces currents in the material and thus heats it by Joule effect. The process material is thus molten at the core, and solidified on contact with the cooled melter wall.

Fig. 1

Schematically, the current penetration depth p (cf. Fig. 1b) depends primarily on the resistivity r of the material and on the current frequency F:

Eq. 1

where k is a constant depending on the units used. The penetration depth should be roughly equal to the crucible radius for maximum efficiency.

FEATURES AND ADVANTAGES OF COLD CRUCIBLE MELTING

The salient feature of the process lies in the fact that all the equipment components may be cooled. The molten material at the center of the crucible thus solidifies near the melter walls, which never exceed temperatures of about 200C. This has a number of implications:

The crucible is protected against any risk of corrosion, ensuring a very long operating lifetime and allowing it to be used to process a wide range of materials containing even highly corrosive elements: glass with high P_2O_5 and even SO_3^{2-} concentrations may be produced without difficulty. A glass melter has been used at Marcoule for more than a decade, during which it has produced a broad spectrum of glass compositions and highly corrosive molten salts, and yet it still appears virtually new today.

Extremely high - practically unlimited - core temperatures may be reached in the process material. Crucibles of this type have been used to melt uranium and zirconium oxides at temperatures exceeding 2500C, as well as zirconium metal at 1800C and even hafnium at over 2200C.

A cold-crucible melter may be easily dismantled. Neither glass nor metal adheres to the cooled wall, which is therefore never subject to strong contamination.

The melter is highly compact, considering its ability to generate extremely high power densities in the glass - much higher than in an electrode furnace, where the power density is limited by electrode wear. Cold crucible melters are thus particularly well suited for obtaining high throughput in a small volume, and extend the range of potential compositions for solidifying fission product solutions or any other type of waste for which this type of treatment is applicable.

COLD CRUCIBLE MELTING OF METALS

Hull Melting

Metal melting applications mainly involve metal waste consisting of irradiated fuel cladding "hulls" (4) produced by reprocessing spent fuel from different types of reactors. After the fuel subassemblies are cut up and the fuel is dissolved in a nitric acid solution, the waste consists primarily of short cladding tube scraps made of zircaloy in pressurized water reactors, or of stainless steel in fast reactors. The hulls are both alpha and high-level beta-gamma wastes, as they may contain transuranic nuclides in residual undissolved fuel as well as high-level fission or activation products.

The melting process is illustrated schematically in Fig. 2. The water-cooled copper crucible is surrounded by an inductor. A water-cooled mobile bed is initially positioned so that its top face is level with the bottom of the inductor. The hulls are then placed in the crucible and melting occurs in the presence of oxide or fluoride flux that fills the gap formed by magnetic striction between the molten metal and the cold crucible. Hulls are fed continuously to the melter with a suitable percentage of slag. When the molten metal bath reaches a predetermined level, the bed begins to move downward continuously to maintain a constant level in the crucible. The metal solidifies as it exits the inductor, allowing the extraction of an ingot with the diameter of the crucible and with any desired length, surrounded by a thin layer of solidified slag. Most of the slag detaches naturally from the ingot during cooling, and is suitable for further treatment. The flux is important in digesting the oxides formed during melting, as well as any residual (e.g. uranium and plutonium) oxides still contaminating the hulls after fuel dissolution.

Fig. 2

A full-scale prototype unit implementing this process has been built by the CEA. The facility includes the following major components:

the melter assembly comprising a 20 cm ID cold crucible surrounded by an inductor supplied with 10 kHz current from a 300 kW motor generator; a conical manifold above the crucible provides for process inlet and outlet flows (hulls, flux, argon, off-gas); the complete assembly is cooled with demineralized water;

the hull feed system, including a feed hopper and a rotating disk distributor;

the flux feed system installed in a glove box and connected to the cold crucible via a series of shutoff valves;

the off-gas treatment system, comprising a particle separator, a scrubbing column and a HEPA filter stage;

the ingot drawing machine.

Melting is performed automatically using a centralized control system to produce ingots 200 mm in diameter and 1000 mm long. Tens of metric tons of nonradioactive zircaloy and stainless steel hulls have been melted in this prototype unit.

Development work on this project is temporarily suspended, as COGEMA is now considering a compaction process to handle such wastes in its reprocessing plant at LaHague.

Other Applications

A cold crucible melter is not limited to merely remelting metals. It may also be used to implement chemical reactions, for example to produce metals - including uranium. Uranium metal is generally produced by metallothermic reactions between UF_4 or U_3O_8 and reactant metals such as calcium, magnesium or aluminum. A cold crucible reaction process would present a number of advantages: high-frequency induction melting of raw materials creates suitable reaction conditions; magnetodynamic phenomena created by the electric fields may favor coalescence of the metal and improve the uranium ingot quality; the cold structure is capable of removing the heat generated by the exothermic reaction, and thus shorting the fabrication cycle; the process is well suited to continuous production. The feasibility of the method has been demonstrated by calciothermic tests with UF_4 and U_3O_8.

Cold crucible induction calciothermy may also be applied to other metals. Tests with neodymium fluoride to produce Nd-Fe alloys have yielded promising results.

COLD CRUCIBLE MELTING OF MOLTEN SALTS AND GLASS

Molten salt processes will only be mentioned here as a potential application for which work is only is only beginning, i.e. the interactive chemistry involving molten salts and metals, with possible applications in reprocessing. The advantages of the cold crucible are obvious in this context, where the extent of the corrosion problems encountered has hamperered the design a suitable contact reactor; today this is no longer an obstacle and a new avenue of research has been opened.

The following discussion covers glass melting, beginning with the solidification of fission product solutions. Direct induction is possible in molten glass (5), which is slightly conductive with an electrical resistivity ranging from 1 to 50 Wm. The required induction frequency is inversely proportional to the crucible radius, between 200 and 300 kHz for a melter a few tens of centimeters diameter.

Figure 3 shows a cold-crucible melter of the type used today at Marcoule, ranging from 30 to 55 cm in diameter and from 30 to 70 cm high. Several units are in use, and have logged a cumulative total of several thousand hours in operation, supplied either directly with glass or with a calcine and frit mixture from a calciner similar to the ones used in the R7 and T7 vitrification facilities at LaHague.

Fig. 3

Melting may be initiated using a microwave system by incorporating a few hundred grams of a suitable glass composition, or by placing an annular aluminum, titanium or zirconium starter element that burns in air when induction heated, melting the surrounding glass and allowing induction currents to develop in the melt.

The capacity of this type of melter depends on both the surface area and the operating temperature. The actual value is roughly proportional to the surface area and to the fourth power of the temperature: melting occurs by radiation from the molten glass to the surface. Table I indicates the rates extrapolated from a throughput rate of 30 kgh-1 for a melter 55 cm in diameter operating at 1200C, as demonstrated with the R7 glass used at LaHague. In fact, these values are underestimated, as they do not allow for the effects of stirring the melt (which could easily be obtained either by sparging or mechanically using a cooled stirring device), which would increase the capacity by at least 50% - assuming the generator is powerful enough to maintain the glass in the molten state under these conditions.

Table I

A new melter 1 meter in diameter has been built at Marcoule and is now being tested with a 160 kW transistor generator at a frequency of 100-200 kHz. This unit opens the way to a new generation of large melters that have been thoroughly modeled by the CEA, and which will probably constitute the most suitable means for vitrifying the very large backlog of high-level fission product solutions now in interim storage throughout the world. This potential was not lost on the international experts called together by WHC at Hanford in mid-1994 to select a melting process for vitrification of the high-level waste at the site: the cold crucible melter tied for first place with the liquid-fed ceramic melter.

Similarly, COGEMA has undertaken a program to nuclearize the cold

crucible melter for testing in one of the vitrification facilities at LaHague.

Low- and medium-level radioactive waste produced in variable quantities by power reactors - VVERs in the East and PWRs in the West - could also be vitrified in cold crucible melters. The feasibility of this application has been demonstrated in France using a two-step process of calcination in a rotating kiln followed by melting in a 50 cm diameter cold crucible supplied with both calcine and a natural aluminosilicate mineral, clinoptinolite. This operation was conducted to substantiate the potential for vitrifying liquid waste with high boron and soda content from the Czech power plant at Temelin; several cubic meters of simulated solution were vitrified in a few hundred kilograms of glass (6).

The possibility of feeding the process solution directly to the molten glass in a cold crucible has been investigated and tests have been conducted. This procedure significantly diminishes the melter capacity, especially with dilute feed solutions. Russian scientists routinely use this method in cold crucible melters by first concentrating the solution and its additives (7). The advantage of this approach is to eliminate the prior calcining step, and is most appreciable in the case of solutions that are difficult to calcine, e.g. those containing large amounts of sodium, as with low- and medium-level waste solutions. A drawback, however, is the increased entrainment of particle material, which complicates the design of the off-gas treatment system.

Incinerator ashes are another waste form that can easily be melted in a cold crucible. Whether produced by a or bg incinerators, they contain mainly silica (SiO_2) and other oxides (CaO, MgO, etc.). The refractory nature of their components makes them generally difficult to melt as is; simply adding basalt or a small amount of sodium carbonate flux largely facilitates the process. This is a simple operation that today routinely yields several tens of kgh^{-1} of a glass or vitrocrystalline material with potentially very good containment properties, and allowing volume reduction by at least a factor of five.

NEW DEVELOPMENTS AND APPLICATIONS FOR COLD-CRUCIBLE MELTING

New Developments and Applications for Cold-Crucible Melting

In addition to increasing the capacity - an experimental unit 1 m in diameter has already been demonstrated with a capacity of 100 kgh^{-1} - the CEA is now orienting its research program toward an increasingly wide range of wastes, and notably incinerable waste. The objective is to achieve incineration (i.e. thermal decomposition of the organic structure) and vitrification of the inorganic residue simultaneously and directly in the molten glass. This process is of particular interest for plastic and cellulosic wastes - as well as ion exchange resins, which are currently conditioned in cement of polymer matrices representing a significant waste volume for disposal. A number of difficulties must be overcome before incineration-vitrification becomes a viable process:

The combustion off-gases are generally chlorinated in the case of plastic wastes such as polyvinyl chloride, and generally sulfated in the case of resins, many of which are sulfonated. The CEA has acquired considerable experience in incinerating highly chlorinated plastic wastes, and has developed an incineration process for a-bearing waste (8,9) now implemented in industrial facilities at two French nuclear centers and which could be of interest to the world nuclear community. Virtually all the chlorine from the feed material enters the off-gas stream and is eventually converted to hydrochloric acid from which all

the radioactivity must be eliminated. Similarly, the sulfur contained in sulfonated resins will most likely be recovered in sulfuric acid or sulfate form.

A second difficulty involves the actual formulation of the glass or vitrocrystalline material used to confine the inorganic residue and thus the radioactivity. It is virtually impossible to include chlorine or sulfur in significant amounts in vitreous or vitrocrystalline materials with good containment properties. The advantage of the cold crucible technique in this area is that it obviates all the corrosion problems attributable to chlorine and especially sulfur, which at very high temperatures, and often as a molten salt, is incompatible with the use of conventional refractory or metal materials.

Laboratory tests are in progress at the CEA's Marcoule center, and a small-scale pilot facility is now under construction with a 30 cm diameter cold crucible and a suitable off-gas treatment system.

Another potential application of cold crucible technology has also been investigated: the incineration of graphite. Under a CEA research and development program to recover plutonium from the graphite at a French defense site, the feasibility of this approach was demonstrated using a cold crucible 30 cm in diameter together with a post-combustion chamber. The problem here, of course, is not to burn the graphite, but to control its combustion. The nonradioactive tests completed to date have been conclusive, and the process will be implemented to burn plutonium-contaminated graphite in French defense centers.

CONCLUSION

Vitrification today is gradually supplanting other waste conditioning and containment processes. It is clearly of economic interest in that it provides for a very significant volume reduction - unlike the other available processes, which increase the volume of the final waste form. It is also of ecologic interest, by creating a high quality containment matrix with excellent long-term behavior.

Cold crucible melting will continue to advance as simple, relatively inexpensive techniques that generate no secondary waste are demonstrated and proven industrially. High-level waste has been vitrified by COGEMA in France for more than 15 years; low-level waste will one day be vitrified - and followed by other liquid and solid waste forms.

The cold crucible melter is unrivaled for its flexible operation, for the extremely high temperatures it allows, for its high specific capacity and compact size, for its operating lifetime and virtual absence of secondary waste, and for its potential to "digest" practically any form of liquid or solid waste including both metals and combustible materials.

It is now necessary to develop units with higher capacities and to conclusively demonstrate the possibility not only of melting but also of incinerating liquids as well as solids. Considerable work remains to be done, but the future of cold crucible melting is extremely promising.

ABSTRACT
In order to obtain yearly generation volume and composition data for low- and medium-Level radioactive waste, we investigated the characteristics and generation trends for each waste which has been produced at nuclear power plants in Korea. The data were utilized for technical and economical assessment. For technical assessment, four promising melters, which were the cold crucible heated by direct induction (CCM), the cold crucible melter heated by vertical electrodes (CCVE), the quantum catalytic extraction process (QCEP), and the plasma torch melter (PT), were selected to determine the best available melter in the view point from Korean situation. Four melters were evaluated according to evaluation factors such as waste feeding, melter life, replacement materials during melter life, throughput, entrainment of volatile Cs and toxic material, and recycle potential of spent scrubbing solution to melter itself. Economical assessment was carried out for four treatment strategies with the melters selected in the technical assessment. For each strategy, the capital and the operation cost were estimated and the

disposal volume was calculated with reasonably estimated volume reduction factors with respect to the waste type and the treatment concept. Then the disposal costs were calculated according to the several unit disposal costs. The treatment and disposal cost were plotted for several unit disposal costs from 2,500 to 20,000 US$/m3. The results showed that the strategies adopting the CCM and/or the PT were more economical than the current treatment system for overall unit disposal cost range if the waste treatment system is newly constructed according to the strategies, and they were more economical only for the unit disposal cost of 6,250 US$/m3 and more in case that the current system is modified with the CCM and/or the PT.

INTRODUCTION

In Korea, new treatment technology development of Low-Level radioactive waste (LLW) is necessary due to high concern for the protection of environment, the difficulty in disposal site selection, and the disposal cost increase. The vitrification technology is considered as the most promising one of new LLW treatment technologies and it is a world-wide trend to apply it for the treatment of LLW. Korea Electric Power Research Institute (KEPRI) has already launched a feasibility study on LLW vitrification to determine whether or not vitrification technology is adopted to treat LLW from domestic nuclear power plant and to suggest a reasonable development strategy in the case that its adoption turns out to be reasonable. Therefore, the objectives of this study are focused on the technical and the economical assessment of vitrification for LLW from nuclear power plant in Korea.

For the study, waste generation trends are first analyzed to determine the yearly generation volume and characteristics for each waste stream. Secondly, we will compare and analyze the characteristics of glass melters which are being developed and studied in the world, including melter type, operation temperature, expected life time, waste feed, throughput, pre-treatment method, off-gas system, etc.. In order to select melters being utilized for economical assessment, detailed technical assessment is going to be conducted for four promising melters. Then the economics for four LLW treatment strategies with the melters selected is to be evaluated in detail, considering comparison of treatment and disposal cost for each strategy.

WASTE CHARACTERISTICS AND GENERATION VOLUME

LLW generated at nuclear power plant could be categorized as combustible and non-combustible dry active waste (DAW), spent resin, spent liquid filter, and evaporator bottom products (borated liquid waste concentrate). In order to obtain yearly generation volume and composition data for low- and medium-Level radioactive waste, we investigated the characteristics and generation trend for each waste which has been produced at nuclear power plants in Korea (1-4). Table I shows the waste characteristics and the maximum volume generated at a site having two 1,000 MWe PWR. Total generation volume turned out to be 346.5 m3 (216.97 TON) and was composed of combustible DAW of 200 m3 (40 TON), non-combustible DAW of 50 m3 (75 TON), evaporator bottom products of 80 m3 (88 TON), spent resin of 14 m3 (10.22 TON), and spent liquid filter of 2.5 m3 (3.75 TON). Radiological data in Table I were quoted from EPRI report (5) in which main nuclides were Fe-55, Co-60, Ni-63, and Cs-137 and specific activity for each waste stream was increased as order of spent resin - spent filter - DAW - evaporator concentrate.

Table I

In Korea, combustible and non-combustible DAW have been drummed after sorting according to four classification categories. In other words, combustible waste has been classified as vinyl seats & shoes cover, protection clothes & shoes, paper & wood, and sponge, etc., and in the case of non-combustible DAW as concrete & asbestos, air filters, glass & metallic, and sand, etc.. Table II and III show, respectively, composition and ingredients for each DAW. As shown in Table I to III, LLW was composed of very complex ingredients which would generate various types of chemicals if DAW was pyrolysed or incinerated (6).

Table II

Table III

TECHNICAL ASSESSMENTS FOR FOUR PROMISING MELTERS

For the technical assessment, we chose four types of melters such as the cold crucible heated by direct induction (CCM), the cold crucible melter heated by vertical electrodes (CCVE), the quantum catalytic extraction process (QCEP), and the plasma torch (PT). Table IV shows the characteristics for each melter such as melter life, throughput, operation temperature, and waste feeding & volume reduction factor, etc. which were drawn from materials provided by companies (7-9). As shown in Table V, important items were selected as evaluation factors, which have scoring range of 1 to 5, and weighting multiplier with respect to importance for cost benefit of operation and maintenance. The assessment items include the throughput, the maintainability, the off-gas entrainment for volatile material like Cs nuclide, the melter life, and the waste feeds. Evaluation criterion for throughput, 150 Kg/h was calculated based on the assumption that a vitrification facility could deal with all waste in Table I and was operated for 2,080 hours per year.

Table IV

Table V

The technical assessment resulted in Table VI in which the CCM was the most promising system from the viewpoint of Korean situation. It is also desirable that both the CCM and the PT are applied to LLW treatment for two reasons such that 1) The molten glass of CCM has good retaining capability for nuclides and toxic materials having low boiling point (10), and the spent scrubbing solution can be recycled to the CCM. However, there is a limit on the content of metallics for input into the CCM; 2) The PT can treat all kinds of waste without any pre-treatment, but the PT has disadvantages that lots of radioactive Cs might be volatilized to increase the shielding cost for off-gas treatment system and the generation volume of spent scrubbing solution which can not be recycled to the PT. Therefore the PT might generate a lot of secondary wastes.

Table VI

ECONOMICAL ASSESSMENT FOR FOUR TREATMENT STRATEGIES

The economical assessment was conducted for four treatment strategies as follows:

Strategy I: the current treatment concept adopted in Korea. Currently, the DAW is compacted by super compactor. The spent resin is solidified with cement by the in-line mixing system and spent liquid filter is drummed into cement lined container. The liquid radwaste has been concentrated with the evaporator and then solidified with cement. In the near future, evaporator bottoms will be dried and solidified with paraffin if the dryer installation is completed.

Strategy II:

1) the metallic waste and the air filter of non-combustible DAW: super compacting,
2) the liquid filter: drumming into cement lined container,
3) the evaporator bottoms: vitrification (CCM: 200 Kg/h throughput) after drying.
4) the non-combustible DAW excluding metal and the air filter, the combustible DAW, and the spent resin: direct vitrification (CCM) without incinerator,

Strategy III:
1) the non-combustible DAW and the liquid filter: treatment with plasma torch melter (PT: PACT-2 throughput(see Table VIII)),
2) the spent scrubbing solution and the evaporator bottoms: vitrification (CCM: 200 Kg/h throughput) after drying,
3) the others: direct vitrification (CCM) without incinerator.

Strategy IV:
1) the spent scrubbing solution: vitrification (CCM: 10 Kg/h throughput) after drying,
2) the others: treatment with plasma torch melter (PT: PACT-6 throughput).

Table VII shows the reasonable estimated volume reduction factors (VRF) with respect to the waste type and the treatment concept, final volume, and treatment cost for each strategy. Treatment costs were calculated with data of Table VIII in which almost all data were provided by companies and a few data were taken from EPRI (11) and EPA (12) report. This data was recalculated considering escalation rate.

Table VII

Table VIII

For strategies II to IV, both minimum and maximum VRF were applied to combustible DAW, spent resin, and evaporator concentrate which were likely to have very wide range of VRF. Because all VRF data for the plasma torch could not be found. So we determined somewhat larger values than those of vitrification. If spent resin is treated by plasma torch melter without considering radiological aspect, maximum VRF for spent resin is likely to be around 150. However, it was determined as 30 because 1) it is desirable that nuclides contents in glass/slag waste forms do not exceed class C; 2) SEG (U.S.A) suggested that maximum VRF for spent resins was about 30 if they were treated by QCEP which had capability to obtain similar VRF as a plasma torch melter. We also assumed that 1) generation volume of spent scrubbing solution from plasma torch melter (PT) and cold crucible (CCM) were about 1.0 and 0.3 m3/TON of waste, respectively; 2) only air filter of noncombustibles contributed to generation of spent scrubbing solution; 3) all sand and glass of noncombustibles were used as glass/slag former. This resulted in abnormal high VRF for noncombustibles.

For treatment cost calculation, all equipment costs utilized for a strategy were summed and divided by the amortization period (15 years). Then operation costs were added to them. Total treatment costs for strategy II to IV have lower and upper values. Upper values includes the capital and operation cost per year in case that the waste treatment system is newly constructed in accordance with the strategies, and lower value means in case that the current system is modified with plasma torch and/or vitrification melter. For strategy IV, TCY= 730.7 and 343.3 represent treatment cost with evaporator and vitrification melter, respectively.

As compared with strategy I, Strategy II to IV reduce the disposal volume by 70 - 92 %. Disposal costs were calculated with respect to the several unit disposal costs from 2,500 to 20,000 US$/m3. Figure 1 and 2 show that treatment and disposal cost for each strategy with respect to construction type (new or modification) of waste treatment system when minimum VRF is applied. From the figures, it can be shown that the strategies adopting the CCM and/or the PT are more economical than the current treatment system for overall unit disposal cost range if the waste treatment system is newly constructed according to the strategies, and they are more economical only for the unit disposal cost of 6,250 US$/m3, which is lower than the disposal cost of Barnwell site (8,300 $/m3), and more in case that the current system is modified with the CCM and/or the PT.

Fig. 1

Fig. 2

CONCLUSIONS

In Korea, the maximum volume generated at a site having two 1,000 MWe PWR turned out to be 346.5 m3 (216.97 TON) and was composed of combustible DAW of 200 m3 (40 TON), non-combustible DAW of 50 m3 (75 TON), evaporator bottom products of 80 m3 (88 TON), spent resin of 14 m3 (10.22 TON), and spent liquid filter of 2.5 m3 (3.75 TON).In order that these all wastes are economically encapsulated into glass/slag waste forms, it is desirable that both the direct induction heated cold crucible and the plasma torch hearth are adopted. From the viewpoint of technical and economical aspects, it might be concluded that strategy (III) is the best concept in which noncombustibles and spent liquid filter are treated by the plasma torch hearth and the others by the cold crucible.

The vitrification facility to be constructed by strategy (III), which has enough throughput of 250 kg/hr (CCM: 200 kg/hr, PT: 50 kg/hr) to deal with all wastes from a site having four 1,000 MWe PWRs, will have the average volume reduction factor of 12.63 - 24.87. The number of glass/slag waste forms generated from 12 units (1,000 MWe PWR) for 30 years will be 12,060 - 23,580 drums (200 liter size).

ABSTRACT

This paper describes the redirection of the Tank Waste Storage Program. The redirection will allow placement of all tanks in a well-defined safety envelop and will prepare the tanks for treatment and long-term disposal of tank waste.

This paper will present the new directions and associated accomplishments. The redirections are the result of Tank Waste Remediation System (TWRS) fiscal constraints, changes in U.S. Department of Energy management philosophies, and changing regulatory and oversight requirements - quantum changes from past business practices.

INTRODUCTION

The federal government established the Hanford Site in South-Eastern Washington near the City of Richland in 1943 to produce plutonium for national defense purposes. The Hanford Site occupies approximately 1,450 square kilometers (560 square miles) of land North of the City of Richland. The production mission ended in 1988, transforming the Hanford Site mission to waste management, environmental restoration, and waste disposal. Thus the primary site mission has shifted from production to the management and disposal of radioactive, hazardous, and mixed waste that exist at the Hanford Site.

This paper describes the focus and challenges facing the Tank Waste Remediation System (TWRS) Program related to the dual and parallel missions of interim safe storage and disposal of the tank associated waste. These wastes are presently stored in 2.08E+05 liters (55,000) to 4.16E+06 liters (1,100,000) gallon low-carbon steel tanks. There are 149 single- and 28 double-shell radioactive underground storage tanks, as well as approximately 40 inactive miscellaneous underground storage tanks. In addition, the TWRS mission includes the storage and disposal of the inventory of 1,929 cesium and strontium capsules created as part of waste management efforts.

Tank waste was a by-product of producing plutonium and other defense related materials. From 1944 through 1990, four (4) different major chemical processing facilities at the Hanford Site processed irradiated (spent) fuel from defense reactors to separate and recover plutonium for weapons production. As new and improved processes were developed over the last 50 years, the processing efficiency improved and the waste compositions sent to the tanks for storage changed both chemically and radiologically. The earliest separation processes (e.g.,bismuth phosphate coprecipitation) carried out in TPlant (1944-1956) and BPlant (1945-1952) recovered only plutonium. All remaining dissolved fuel elements, including enriched uranium, were sent to the tanks as alkaline waste. Later processes, such as the Reduction Oxidation Plant Process (REDOX) and Plutonium Uranium Extraction (PUREX) flowsheets were developed to also recover uranium which was then recycled back into making reactor fuel. The process of purification of both plutonium (ZPlant) and uranium (BPlant) also lead to the creation of waste streams which, after neutralization to a pH10, were added to the tanks.

Most processes associated with plutonium recovery from spent fuel involved dissolving the material in nitric acid. After extensive acid side chemical separations to recover plutonium, uranium, and often neptunium, the waste streams were made alkaline by addition of sodium hydroxide and/or calcium carbonate prior to their transfer to the low-carbon steel waste tanks. Making waste alkaline produced large quantities of metal oxyhydroxides, which along with solids from the bismuth phosphate process formed the sludge found in the bottom of the tanks. The waste composition in tanks was complicated further by the recovery of uranium by sluicing during 1952-1958. The waste was made alkaline to prevent corrosion of the low-carbon steel tanks, thereby introducing large volumes of sodium nitrate and other sodium salts into the waste tanks. Sodium nickel ferrocyanide was added to 20 of the tanks during the 1950s in order to precipitate solids and create additional space in the tanks.

To increase useful storage capacity, volume reduction methods (e.g., in-tank and external evaporation), and recovery of heat producing cesium and strontium in BPlant (1968-1985) were carried out. The concentration of the originally soluble sodium salt-rich waste led to the production of the saltcake, which is often found overlying the sludge waste in the tanks. Most of the hazardous chemicals and radionuclides are found in the sludge. Only radio-cesium, -iodine and -technetium are significantly soluble in alkaline salt solutions.

The single-shell tanks were taken out of active service in 1980, and no new waste has been added to these tanks since then. Sixty-seven (67) of these tanks are assumed or confirmed leakers. Removal of drainable liquid by saltwell pumping (interim stabilization), waste sampling in support of characterization, installation of new monitoring equipment, and/or any mitigation or remediation deemed necessary to assure interim safe storage of the waste are the only significant intrusive activities into these tanks. Drainable liquid removed from the single-shell tanks, as well as dilute waste resulting from decontamination of production facilities are added to the double-shell tanks after due consideration of waste compatibility concerns. There are approximately 2.12E+08 liters (55 million gallons) of waste in the TWRS single- and double-shell tank system.

THE TWRS MISSION

The TWRS Program is the largest environmental clean-up program in the United States.

The purpose of the TWRS interim safe storage mission is to place all tanks in a safety envelope and prepare for long-term disposal of tank waste.

Mission Related Activities Include:

1. Continuation of the current program of tank monitoring and maintenance including any enhancements needed to assure interim safe waste storage (see the discussion of controlled, clean, and stable below);
2. Resolution of safety issues related to interim safe storage and/or disposal of the waste in the tanks;
3. Removal and transfer of pumpable liquids from single-shell tanks by saltwell pumping (interim stabilization);
4. Performing waste and tank characterization to the extent needed to either resolve tank safety issues or to support safe retrieval, transfer, processing (pretreatment) and disposal of the waste;
5. Continuation of receipt and storage of newly generated waste in double-shell tanks; and
6. Concentration of waste to the maximum extent safely practical in the 242-A Evaporator.

These activities form the basis for assuring that the tank contents and the farms themselves are maintained in a controlled, clean, and stable mode until the waste is retrieved and processed for disposal.

In addition, major resources are being expended on:

1. Development and application of systems engineering to assure integration of the overall TWRS mission activities;
2. Preparation for phased waste retrieval, treatment and waste vitrification efforts that form DOEs first major step in demonstrating waste disposal utilizing private sector resources (privatization); and
3. Achieving an integrated and responsive authorization basis to assure continued safe operation of the tank farms as the mission changes from storage to disposal.
4. Gaining knowledge of tank waste.

The remainder of this paper will highlight recent achievements in the areas of resolution of tank waste safety issues, progress toward putting the tank farms into a controlled - clean - stable mode, and transition to an operating mode in which privatization is a key operating factor.

TANK WASTE SAFETY ISSUES

All U.S. Department of Energy (DOE) facilities that store hazardous or radioactive materials have documented safety analyses, which establish a range of operating parameters (e.g., temperature, pressure, concentration) within which routine operations are conducted. These safety analyses also evaluate the effects of potential accidents, abnormal events, and natural disasters. The DOE has a formal program which requires identifying any known or suspected conditions that have not been analyzed or fall outside of the observed safety range as an Unreviewed Safety Question (USQ). Following identification of a USQ, a review takes place that may result in a change to the safety documentation or a change in operations. Following the review process, the USQ may be closed from an administrative standpoint when conditions surrounding the safety issue have been reviewed and their effects bounded. However, the safety issue may still exist and may require operational constraints, ongoing monitoring or mitigation. [In that fashion, safety issues, and USQs are related but not identical]

Concern over waste tanks having the potential for releasing high-level radioactive wastes to the environment resulted in the passing of Public Law 101-510, section 3137, "Safety Measures for Waste Tanks at Hanford Nuclear Reservation," also known as the Wyden Amendment. In response, DOE has developed a set of criteria to identify tanks with potential safety concerns as "watch list" tanks. There are currently 54 "watch list" tanks, with 10 tanks that are listed in more than one (1) of four (4) different categories based on the specific safety concerns described below.

Over 50 years of fuel reprocessing at Hanford has resulted in the accumulation of nearly 2.12E+08 liters (55 million gallons) of waste in the single- and double-shell tanks. Prior to the 1990s, it was generally believed that the stored wastes were chemically unreactive under both the present storage conditions and plausible accident scenarios, as well as being chemically stable. This paradigm was proven wrong when detailed evaluation of tank contents and behavior discovered that:

1. Twenty-five (25) of the stored single- and double-shell tanks waste tanks were generating, storing, and releasing hydrogen in quantities that might lead to flammable gas concentrations above the safety margin of 25% of their lower flammability safety limit (The Flammable Gas Issue). Recent measurements have shown that changes in atmospheric pressure may cause changes in liquid levels in some of these and other waste tanks. This may indicate a greater amount of gas stored in the waste than previously believed, and 25 additional tanks may be added to the flammable gas watch list until this issue is resolved. Screening of all waste tanks for potential flammable gas accumulation has been initiated.
2. Twenty (20) single-shell tanks contain organic materials in the presence of excess sodium nitrate and sodium nitrite oxidizing agents that could lead to a potential propagating reaction, and ensuing release of radioactive and hazardous materials to the environment, if the waste was dried and heated to threshold temperatures above 200C. (The Organic Safety Issue)
3. Eighteen (18) single-shell tanks contained sodium nickel ferrocyanide which could similarly pose a threat of a propagating reaction, if dried and heated to above 250C. Ferrocyanide based deflagration represents the bounding "worse case" accident scenario previously identified in the Hanford Environmental Impact Statement. (The Ferrocyanide Safety Issue)
4. A single-shell tank (241-C-106) contains sufficient heat producing radio-strontium that it requires addition of cooling water to prevent tank failure from structural damage, if its temperature is allowed to fall outside of safe operating criteria. (The High Heat Issue)

The Waste Tank Safety Program was chartered in 1990 to address the four (4) safety issues discussed above. If risks were high, relative to interim safe storage of the wastes until they could be retrieved and permanently disposed, then the safety program assured that either adequate controls were in place to prevent the condition of risk from occurring, or if that were not possible, mitigation or remediation of the condition was initiated to actively remove the cause at the tank farms. Until such data were collected and interpreted to assure continued safety, the tanks associated with safety concerns were placed under stringent operating controls.

Extensive work and increased knowledge over the last few years has led to the demonstration and documentation of a significantly lower-risk condition with the tank waste. This will allow us to close some of the

safety issues discussed above. For example, laboratory studies with simulants and analyses of actual waste samples have bounded the energetics of the fuel-rich materials added to the tanks. In addition, storage of the wastes over the last 30 to 40 years resulted in degradation of the organics and ferrocyanide significantly reducing the potential for explosive reactions.

Key Understandings Leading to Safety Issue Resolution Include the Following:

Demonstration that radiolytically or chemically induced waste aging processes have destroyed or significantly lowered the energy content of a vast majority of organic materials added to the tanks. Therefore, conditions exist which can no longer have the potential for a propagating reaction in even a dry tank. Furthermore, the exploration of waste species energetics, waste species solubility, and waste tank chemistry demonstrate that the organic rich tanks contain a sufficient amount of moisture to preclude a risk from propagation under even the bounding "worse case" accident scenario. A combination of experimental work and waste characterization is continuing to provide data to substantiate these findings of waste safety.

Results of extensive tank monitoring and surveillance show that most of the tanks on the Flammable Gas Safety Watch List pose little potential for exceeding 25% of the lower flammability limits for generated gases, or if such gas accumulation potential exists, it can be mitigated by installing a low-flow ventilation system on the tank.

PROGRESS TOWARD PLACING THE SINGLE-SHELL TANK FARMS INTO A CONTROLLED - CLEAN - STABLE MODE

An essential element of the strategy for meeting the TWRS mission is achieving a Controlled, Clean, and Stable condition in the Tank Farms. This strategy is essential in achieving an interim, safe, low-cost status until retrieval and disposal operations commence in the tanks.

The definition of controlled, clean, and stable is as follows:

1. Controlled

a) All necessary (as determined by safety analysis) active and passive safety systems are in place.

b) Resolution of any safety issues related to interim safe storage and/or disposal of the waste stored in watch list tanks.

c) All controls necessary to provide assurance of meeting risk acceptance criteria for current operations associated with these USQs are in place. Continuous, remote, on-line monitoring of key parameters, such as waste volume and temperature is in place to adequately control the Hanford Site high-level waste tanks. This includes continuation of the current program of remote tank monitoring and maintenance, including any enhancements needed to assure interim safe waste storage.

2. Clean

a) Surface contamination areas are cleaned and reduced to radiological control areas or even less controls.

b) Unused contaminated equipment is removed from the tank farm.

c) Reusable equipment is stored, if not in use.
3. Stable
a) Removal and transfer of pumpable liquids from single-shell tanks by saltwell pumping (interim stabilization);
b) All penetrations where liquids could intrude into the tanks are sealed.

Controlled, Clean, and Stable Strategy

The controlled, clean, and stable strategy has the following four (4) elements, which are discussed below: 1) reduce the mortgage; 2) provide safe storage; 3) reduce worker exposure to hazards; and 4) maintain compliance with regulatory requirements.

1. Reduce the Tank Farm "mortgage." - The "mortgage" is the current operational costs to monitor the tanks and their waste. This task is currently a high labor-intensive effort that includes a large number of tank farms and tank entries. The procedures for single-shell tank farm entries will be modified to:
a) Require tank farm entry only on a non-routine basis.
b) Provide remote monitoring of all essential parameters.
c) Allow access for waste sampling and characterization, if required.
2. Provide safe storage prior to retrieval. - This task includes updates to safety analyses as well as specification of necessary engineering design features, and operational and administrative controls. It also includes any equipment modifications and development of procedures and training for the equipment.
3. Reduce worker exposure to hazards. - Every time a worker enters a tank farm, or operates equipment in or near a tank, there is some level of potential exposure to radiological and chemical hazards. The reduction of the areas specified as either radiological controlled areas (RCAs) or surface contamination areas (SCAs) reduces worker exposure to these hazards.
4. Maintain compliance with regulatory requirements. - The Hanford Site Tank Farms' are regulated as a Treatment Storage and Disposal Facility with associated permits and closure agreements in compliance with regulatory requirements. All interim storage activities must be performed in a manner to assure current and continued future compliance with regulatory requirements.

Planned Upgrades in Support of Controlled - Clean - Stable

Focused tank farm upgrades are planned to improve the reliability of safety-related systems, minimize on-site health and safety hazards, improve the regulatory compliance of tank farm support systems, and put the tank farms into a controlled, stable work environment until disposal is completed. The following upgrades are planned:

Instrumentation such as automatic tank data gathering, management control systems, and closed circuit television monitoring will be upgraded or added to minimize personnel exposure and to provide more accurate data for tank status assessment.

Tank ventilation systems will be upgraded to replace outdated ventilation systems.

Electrical systems will be upgraded to meet capacity needs for both routine monitoring and to support retrieval, as well as to comply with current electrical codes; and

Piping systems will be upgraded to enable transfer of liquid or waste slurries from the decontamination and decommissioning of other selected Hanford Site facilities to the tank waste system.

CHARACTERIZATION OF TANK WASTES

Another essential element of the strategy to achieve the TWRS mission is the characterization of tanks wastes. "Characterization" is understanding the Hanford Tank Waste chemical, physical, and radiological properties to the extent necessary to ensure safe storage, interim operation, and ultimate disposition of the waste. Due to the many processes that have been used at the Hanford Site and the varied waste resulting from them, coupled with ongoing reactions in the waste storage tanks, there is a great deal of uncertainty about the exact waste inventory in many of the tanks. Knowledge of the waste in the tanks is essential to define the extent of existing safety issues, to resolve the safety issues, and to support retrieval, treatment, and disposal system designs.

There are currently five (5) sampling methods used to gather information on tank wastes.

1. Grab sampling of supernatant liquids for laboratory analysis. (Use of a bottle to "grab" liquid at the tank waste surface)
2. Vapor sampling for both on-line and laboratory analysis.
3. Core sampling of solid wastes using core sampling systems designed to drill or push into the waste to retrieve segments that are about 2.5 cm (1-inch) in meter by 50 cm (19 inches) long. These segments are then transported to on-Site laboratories for extrusion and analysis.
4. Auger sampling of the top 40 cm of waste in the tanks.
5. In-situ measurement of the void volumes in the waste and the viscosity of the waste.

To address the challenge of safely characterizing the waste tanks and to bring focus to the program, the TWRS Tank Characterization Project was formed in February 1995. This led to the following accomplishments during the year:

Two (2) new rotary core sampling trucks were delivered and accepted in July 1995. Field testing was completed in September 1995, and operational production commenced in October 1995.

Key improvements were made to the drilling equipment and the drill bits to make them more compatible with the type of waste being drilled and to improve sample recovery. This resulted in sample recoveries increasing from an average of 20% to over 90%. Sampling equipment improvements included:

- developed equipment for sampling different types of waste (dry or wet salt cake, sludge, liquid) which are highly radioactive and/or toxic as well as potentially flammable.
- developed shielding equipment for protecting personnel from potentially high radiation exposure and contamination.
- developed a complete core sampling system including the sampler, sample truck, nitrogen purge supply, exhauster, x-ray imager, and a cask truck for transportation of the waste samples.
- secured radiation hardened video cameras for in-tank color photography.

New x-ray imaging system was added to sampling truck to determine the amount of sample recovery in the field immediately following sample removal from the tank.

The Tank Waste Characterization Basis document was completed for the safety program in June 1995, and upgraded to include the disposal program in August 1995. This document:

- established a prioritization basis for sampling which integrates known safety and disposal programmatic needs.

- defined the key waste tanks to be sampled based on grouping tanks into similar categories and selecting tanks to answer specific safety questions.

Four (4) core sampling crews were trained and certified.

Data quality objectives were issued for the five (5) primary sampling needs: safety program; retrieval, pretreatment, and disposal program; waste compatibility; historical model evaluation; and privatization waste characterization.

Analytical laboratories were upgraded, and the goal throughput of five (5) analytical equivalent units was achieved in October 1995 for the first time.

These changes resulted in a ten-fold increase in the number of samples taken during CY1995 compared to CY1994. This was particularly important for the full-length core samples where 49 core samples were obtained compared to five (5) core samples during CY1994. Sample loads through the analytical laboratory more than doubled. Finally, by the end of CY1995, 116 of the 177 underground storage tanks had been sampled using one (1) of the five (5) sampling methods listed above.

Improvements in characterization capabilities planned for this year include:

1. Deployment of a core sampling system capable of retaining gas in the core samples and then analyzing those samples for the gases that are trapped in the waste.
2. Deployment of a cone penetrometer system for in-situ measurements of rheological properties of the waste and moisture content (using a neutron moisture probe). The cone penetrometer includes a Raman spectroscopy system capable of in-place speciation.
3. Deployment of Surface Moisture Measurement System capable of measuring the moisture content of surface wastes within the tanks up to 6 feet off-center below the 4-inch tank risers into the tank vapor space.
4. Deployment of a Light Duty Utility Arm capable of robotic operations over 10 feet off- center in the vapor space below 12-inch risers into the tanks. This system will provide significant flexibility for operations within the tanks including: inspection, sampling, gripping, and cutting operations.
5. Redesign of some of the core sampling equipment to allow rotary sampling (necessary to retrieve samples from very hard wastes) from tanks that could potentially contain explosive mixtures of gases within the waste.

SUPPORT OF DOE PRIVATIZATION EFFORTS

In September 1995, DOE announced its intent to "privatize" the disposal part of the tank waste remediation program. The idea was to turn clean-up of Hanford's tank waste over to a private company that would do the design work and pay construction costs without Federal appropriations. The company would then be paid for the glass waste logs it produced. The privatization would be done in two (2) phases: 1) design and construction of waste treatment, and immobilization facilities for a small fraction of the waste (6-13%), followed by; 2) design and construction of waste retrieval, treatment, and immobilization facilities for the bulk of the waste. Characteristics of the two (2) phases are summarized in Table I (Page 11). During Phase I, waste retrieval would be performed by the existing Site contractor.

Table I

A draft Request for Proposal (RFP) was issued for comment in November 1995, and a final RFP is expected to be released in March 1995 for the first phase. In August 1996, up to three (3) companies will be selected for more in-depth design work. Each company will design a prototype vitrification plant to immobilize the low-level radioactive wastes. Bidders will also have the option of adding a prototype plant to glassify high-level radioactive waste. In February 1998, DOE will pick the best two (2) of the three (3) bidders proposals to build the low-level waste plants with hot operations to begin by December 2002. It is possible that a third plant to vitrify high-level wastes will be authorized for the same time period.

DOE's goal is for the two (2) prototype plants to process 13,200 (~3%) of waste in the first 2l/2 years and another 24,200 tons (~5-6%) in the second 2l/2 years. As the first phase nears completion, DOE will put out an RFP to build two (2) larger low-level waste vitrification plants, plus a full-scale high-level waste vitrification plant. The second phase bidding process will be open to any company interested, not to just the successful Phase I bidders. Construction of the larger second-phase low-level waste plants is scheduled to begin in 2008. The second-phase high-level waste plant is to begin operating in 2010, and the low-level waste plants are to start in 2011. All of Hanford's liquid radioactive wastes are to be immobilized by 2028.

SUMMARY

To date, 8 tanks have been "characterized"; that is, present requirements for the tank waste information for those tanks have been met. Several tank farms have been designated controlled, clean, and stable. 1995 was a year in which giant steps were taken on the path of real progress in closure of safety issues and ultimate disposal of tank waste.

IN-TANK PRETREATMENT OF HIGH-LEVEL TANK WASTES: THE SIPS SYSTEM*

Morris Reich
James Powell
Robert Barletta
Brookhaven National Laboratory
Department of Advanced Technology
Upton, NY 11973

ABSTRACT

A new approach, termed SIPS (Small In-Tank Processing System), that enables the in-tank processing and separation of high-level tank wastes into high-level waste (HLW) and low- level waste (LLW) streams that are suitable for vitrification, is described. Presently proposed pretreatment systems, such as enhanced sludge washing (ESW) and TRUEX, require that the high-level tank wastes be retrieved and pumped to a large, centralized processing facility, where the various waste components are separated into a relatively small, radioactively concentrated stream (HLW), and a relatively large, predominantly non-radioactive stream (LLW). In SIPS, a small process module, typically on the order of 1 meter in diameter and 4 meters in length, is inserted into a tank. During a period of approximately six months, it processes the solid/liquid materials in the tank, separating them into liquid HLW and liquid LLW output streams that are pumped away in two small diameter (typically 3 cm o.d.) pipes. The SIPS module would be serviced by six small diameter (~3 cm o.d.) pipes - the two output pipes for the HLW and LLW streams

mentioned above, a water input pipe, a nitric acid (~3 M) input pipe, and input/output pipes to hydraulically load/unload ion exchange beads. An illustrative SIPS processing cycle is described. During the first half of the cycle, solid/liquid slurry from the tank is admitted to an internal compartment in the module (Compartment "B"), where the material is water washed. The liquid component flows to another internal compartment (Compartment "D") where cesium is extracted by an inorganic ion exchange bead material (e.g., silico-titanates). The cesium free liquid then flows out as part of the LLW output stream. The solid particle components remaining after water washing are trapped using a magnetic particle seeding/trapping process. After several hours of washing/trapping, the solid/liquid feed from the tank is switched to Compartment "C", while the remaining trapped solids in Compartment "B" are dissolved by nitric acid. The resultant acidified liquid HLW stream is then contacted in a fourth compartment ("E") with a selective extractant (e.g., a chelating polymer with ultra filtration) that removes a portion of the non-radioactive component in HLW streams so that they can be combined with the LLW stream. This reduces the volume of the HLW to be vitrified. Compartments "B" and "C" alternate functions every several hours. When "B" is water washing, "C" is acid dissolving; they then switch functions, and "C" washes while "B" acid dissolves. The ion exchange material in Compartment "D", together with the extracted cesium, is hydraulically unloaded every several days, and a fresh change of material hydraulically loaded. When the ~6 month processing interval is completed, the SIPS module would be moved to a fresh tank. Using an array of only 10 modules, the total inventory of 179 Hanford tanks could be processed in a few years. The construction and operation parameters for the SIPS module, based on Hanford process data, are described.

The SIPS approval appears attractive. It enables a lower cost and more redundant and maintainable processing system. It is very flexible, and can readily adapt to continuing technology improvements and widely disparate feed streams. It can be developed quickly, and is amenable to privatization.

DESCRIPTION OF THE SIPS CONCEPT

SIPS (SIPS In-Tank Pretreatment System), utilizes a small, low cost module that is lowered into a tank to pretreat the waste and separate it into LLW and HLW streams. Virtually all solids are dissolved inside the tank, so that the waste streams leave the tanks as solutions, not slurries.

Figure 1A shows an overall view of the SIPS module inside a waste tank. The module is lowered through a small opening (either preexisting or added) in the tank cover into the tank, and positioned either above or under the liquid surface. Small diameter flexible lines are connected to the intake and discharge ports in the module. Two small diameter lines lead into the tank carrying waste and nitric acid, while two small lines carry out the LLW and dissolved HLW streams. These connect to external transfer lines that lead to final processing facilities.

Fig. 1

Two designs of the SIPS module have been investigated, a "baseline" design, and an "advanced design." The baseline design essentially serves as the head end of the TRUEX process. The supernate and water soluble solids in the tank flow out as the LLW waste stream to an external central facility that extracts 99+% of the Cs (possibly also Tc and complexed Sr). The remaining solids are then dissolved in 3M nitric acid

and flow out as the HLW stream, to be further processed in an external facility.

In the advanced design, the SIPS module removes Cs (Tc and Sr also, if required) from the LLW stream using an inorganic ion exchange material so that the LLW stream requires no additional processing before vitrification. A separate processing zone in the advanced module extracts a portion of the non-radioactive components in the HLW stream, adding them to the LLW stream. No additional processing of the HLW is then necessary.

Figure 2 shows a "black-box" view of the baseline SIPS concept. Four small diameter (~3 cm) liquid flow pipes are attached to the support column that holds the SIPS module. Two of the pipes transport process feed liquids into the SIPS module from external lines outside the tank, i.e., H2O with colloidal ferromagnetic particles, and nitric acid solution (~3 M). The other two pipes transport process liquids away from the SIPS module to external lines outside the tank - i.e., liquid supernate to the cesium extraction and LLW vitrification facility, and nitric acid with dissolved HLW solids to the TRUEX processing and HLW vitrification facility.

Fig. 2

As illustrated in Fig. 3, colloidal ferromagnetic particles suspended in stream 1 are first combined with a slurry of tank solids and liquids (stream 2) in the mixing chamber (Region A). The colloidal ferromagnetic particles absorb on and bind to the solid particles. The slurry mixture then flows into a region where the particles that are not soluble in water are magnetically trapped. Based on the large body of experiments and process experience with magnetic separation, the undissolved particles should be quantitatively removed from the slurry that flow through Region B, leaving only a clear supernate that contains the water soluble materials (including cesium). A portion of this supernate flows back into the tank (Stream 5), with the remainder flowing out of the tank to the LLW processing facility (Stream 4). While the nonsoluble solids (i.e., the HLW solids) trapping process is being carried out in Region B, the previously trapped solids are being dissolved in Region C by nitric acid (Stream 6) fed from outside the tank. The dissolved solution (Stream 7) then flows out from the tank to an external processing facility, and ultimately to a vitrification unit where the concentrated HLW is converted to glass. After a suitable time interval, the flows through Regions B and C are interchanged, so that the trapped HLW solids in Region B are dissolved, and fresh HLW solids are trapped in Region C. The interchange of flows relies only on a simple on-off flow control valve. A total of 11 valves is required. These could be hydraulically or electrically actuated. If desired, all valves could be located outside of the tank for easy accessibility.

Fig. 3

The flow rates are small, and the process equipment volume in the SIPS module and its associated piping are quite reasonable. Table I gives the average values for the process flow rates, based on the Hanford TWRS flow sheet (1) and the stated overall efficiency for simple sludge washing. The integrated total volume of the LLW stream for all Hanford tanks is 251,490 kilogallons. For an inventory of 177 tanks, this corresponds to an average LLW flow volume of 1420 kilogal per tank. Over a 6-month processing interval this would require an H2O feed rate of 5.4 gal per minute into the tank, and an equal LLW removal rate of 5.4 gal/minute out

of the tank. Based on a feed pipe inside diameter of 2.5 cm for these streams, the corresponding flow velocities would be 67 cm/sec (~2 ft/sec). The pressure drop at this flow velocity is very small, on the order of 10-3 atmosphere (0.015 psi) per meter of length. Even smaller pipes could be used, if desired. The TWRS flow sheet shows the total mass of the vitrified HLW waste as 2.28x104 metric tons. Based on the stated loading of 45% by weight of waste oxides in the vitrified HLW output, 1.03x107 kilogram of waste oxides is carried in the 36,040 kilogal of sludge sent to the HLW plant. This corresponds to an average solids loading of 75 grams per liter in the liquid/solid sludge flow stream.
Table I
The flow rates for streams 6 and 7 account for the fact that: a) the mass of solids left after washing by stream 1 will be greater because simple sludge washing - i.e., washing with H2O - is used rather than enhanced sludge washing, which involved the use of 3M NaOH to reduce the volume of HLW solids; and b) there will be additional colloidal ferromagnetic particles added to trap out the solids. In addition, the equivalent solids loading in the solution after dissolution by nitric acid may not equal 75 grams/liter. With regard to point a), Westinghouse states that enhanced sludge washing removes an additional 40% of the solids that remain after simple sludge washing. With regard to point b), 20% additional solids in the form of colloidal ferromagnetic particles are included. With regard to the last point, the equivalent solids (i.e., dissolved) loading in the dissolved solution (stream 7) to be 50 grams per liter, or only 66% of the loading in the TWRS flow sheet. Even with conservative assumptions, the flow rate of dissolved HLW solution from a SIPS module in the waste tank is quite small, and easily handled in a 2.5 cm diameter line. With more concentrated solutions even smaller lines could be used.

MAGNETIC TRAPPING OF SLUDGE PARTICLES

The magnetic trapping process is illustrated in Fig. 4. Water containing colloidal ferromagnetic particles, e.g., iron oxide, is mixed with tank sludge. The colloidal ferromagnetic particles adsorb on the solid particles in the sludge. The combination is attracted to, and held on surfaces where the magnetic field concentrates. This can be provided by contact between ferromagnetic bodies with different geometric shapes (e.g., teeth or cones contacting a plate, particle beds, packed filters, etc.) or by periodically varying the dimensions of the ferromagnetic body (e.e., a helical screw surface). A toroidal magnetic geometry minimizes the magnetizing requirements. Liquid flows radially inwards along the module. Radial flow geometry allows a lower liquid velocity than axial flow, resulting in less hydrodynamic drag on trapped particles. Ferromagnetic particles suspended in the liquid are attracted to zones of higher magnetic field, and stick to surfaces where the magnetic field lines converge. One possible trapping arrangement uses toroidal iron plates that are flat on one side and bumpy on the other. Magnetic flux is greatest where the iron projections contact the bottom of the adjacent plate. Ferromagnetic particles will tend to concentrate at these contact points so as to decrease the magnetic reluctance of the toroidal circuit. Flat-topped cones enable good magnetic contact between adjacent plates, and result in flow passages that are well interconnected with a good open area for flow. Other types of geometries can be considered, including iron fibers or balls between flat plates.
Fig. 4

The ferromagnetic material in the SIPS module must not react (i.e., dissolve or rust) in the water or acid wash or with the trapped solids. Uncoated iron or steel probably is not satisfactory; however, it can be treated with a protective coating. Non-reactive ferromagnetic material, such as nickel, can also be used. Magnetic excitation is necessary to create the magnetic flux in the toroidal circuit. This can be provided by a current winding, or by excitation from high coercive force permanent magnets, such as neodymium-iron. Only about 2 percent of the magnetic circuit has to be neodymium-iron; the remainder is ordinary iron/steel or nickel. If a current winding excitation is used, the current can be de-energized whenever it is desired to flush away any particles that remain after the acid dissolution step. If permanent magnet excitation is used, its excitation can be temporarily nulled out by using a pulsed current winding. The magnetic field in the toroidal trapping region would then go to zero when the pulsed deexcitation winding is turned on.

The excitation power to energize the field in both Regions B and C is low, i.e., only about 13 kilowatts. This is very reasonable. The conductor winding weighs approximately 800 kilograms; this weight could be reduced by a factor of four with an aluminum winding. If permanent magnet excitation is used, the time-average magnetic excitation power would be much less - below a kilowatt - because the deexcitation winding would be on for a very short time.

PROCESS PERFORMANCE OF THE BASELINE SIPS MODULE

Estimates of SIPS performance are based on TWRS experiments (2) and design studies (1). SIPS can operate in a batch wash mode. However, this is not as efficient as the continuous wash mode. In the continuous mode, sludge particles are pre-mixed with water containing colloidal ferromagnetic particles (Region A) and then continuously flow into Region B or C (depending on which phase of the process cycle the module is operating in), where they are magnetically trapped and washed. The soluble solids dissolve, leaving behind the insoluble solids which are dissolved later by HNO_3, during the acid dissolution phase of the cycle. The volume of the trapped insoluble solids builds up with time as the water wash phase proceeds. (In addition, there is always some volume of trapped soluble solids that has not yet dissolved.) After four hours, the total volume of trapped insoluble solids is about 11 gallons. However, approximately 200 gallons of soluble salts have washed away, so that the insoluble fraction remaining after washing is only 5.2%.

A long wash period, e.g., four hours, is adopted. The insoluble solids occupy only about 11% of the flow passage area. Adding the soluble solids that have not yet dissolved, the total fraction of the flow passage area occupied by solids is about 25%, assuming a period of 20 minutes to dissolve soluble solids. With a typical flow passage dimension of ~1 millimeter, this corresponds to an average solids thickness of ~250 microns. This should not significantly change flow hydraulics in the trapping region. The average flow velocity through the passages in the trapping region is very small, about 0.05 centimeters per second. The wash period of four hours should dissolve all soluble solids. There probably would be a wash-only stage at the end during which fresh solids were not introduced. This wash-only stage would be 20-30 minutes out of a 4-hour cycle.

The corresponding 4-hour-long acid dissolution phase for the residual solid appears adequate, based on experiments by Lumetta (2). Undissolved solids would be flushed out into the tank, to reenter later for

additional treatment during the 6-month-long processing campaign. At the end of the campaign, there should be a very small amount of residual undissolved solids left in the waste tank. If 5% of the HLW solids that remained after simple washing (which itself removed 95% of the solids) did not dissolve in the acid dissolution phase, there would be about 500 gallons of undissolved solids in the tank. These could be treated for an additional month or so with special solutions to dissolve most of the remaining material. However, even if no further dissolution occurred, the residual solid volume would still be well below the allowable level of <1% specified in the TPA. It appears likely that special processing will remove virtually all of the 500 gallons of residual solids.

ADVANCED SIPS MODULES

The baseline SIPS module generates LLW and HLW liquid waste streams that go to an external facility for further processing. Cesium is extracted from the LLW stream by ion exchange, while most of the non-radioactive components in the HLW stream are extracted by the TRUEX process.

The advanced SIPS module would eliminate external processing. To achieve this, the advanced SIPS module must remove 1) 99% of the cesium in the LLW stream before it leaves the module, and 2) 75% of the non-radioactive components from the HLW stream before it leaves the module [removal fraction may depend on the element being removed] while retaining 99% of the radioactive species present in the HLW stream. The process technologies for these two functions must be compatible with the relatively small volume of the SIPS module. Moreover, they also must be simple to operate, reliable, and of acceptable cost.

Candidate technologies include both existing processes, as well as promising new processes under development. The 1995 Efficient Separations and Processing Cross Cutting Program (ESP) Annual Technical Exchange Meeting summarizes some of these promising new processes (3).

The cesium removal rate in an advanced SIPS module will be about 0.25 kg per week, assuming a 6-month period to process the tank. Ion-exchange is a proven technology and compatible with a small SIPS module if the IEX material is periodically replaced, i.e., every week or so. It appears simple to hydraulically load and unload IEX beads from the module; alternatively, the spent IEX beads could be periodically dissolved and added to the HLW stream. For simplicity, a non-eluting, inorganic type of IEX material is desirable. Promising new ion-exchange materials have been developed for cesium extraction from tank waste solutions. One of the most attractive are the crystalline silico-titantates (CST). These show very high selectivity for cesium (4) at the conditions expected for the LLW stream: highly alkaline (pH ~15), high sodium concentration (~5 M Na), and low cesium concentration (~2 ppm). Distribution coefficients for cesium extraction of ~2000 mL/g have been measured for CST in simulated alkaline Hanford waste (5). Based on these experiments, the absorptive capacity of CST in an ion exchange column with a 2 ppm cesium feed is estimated as~4x10-3 g cesium per g of absorber. This corresponds to a CST inventory in the SIPS module of ~80 Kg (30% extra above saturation to allow for a breakthrough margin) if the ion-exchange material were to be replaced on a weekly basis, [~35 kg if replaced on a semiweekly basis]. The corresponding volume in the SIPS module is well below 100 liters. The replacement schedule appears acceptable. The volume of the HLW solids to be vitrified increase by ~5% if the spent IEX material is added to the HLW stream without further processing. This minor increase would not significantly impact vitrification cost, nor should it affect repository

cost and availability. If Sr is present in significant concentration in the LLW stream from the SIPS module, an inorganic IEX material could extract it. Distribution coefficients in excess of 10,000 have been demonstrated for Sr removal from alkaline LLW type waste streams using sodium titanate. The amount of IEX material to remove Sr removal would be considerably smaller than for cesium extraction.

There are a number of candidate technologies to remove non-radioactive components from the HLW stream. Solvent extraction processes are probably not satisfactory for an advanced SIPS. A water soluble chelating polymer/ultra-filtration process appears attractive. Retentivity values of 99.9% (much greater than required) of plutonium and americium have been demonstrated under acidic conditions (6). Chelating polymers for retaining cesium and strontium require development. Another candidate is fractional precipitation; here, water would be extracted from the HLW stream using reverse osmosis, resulting in a fractional precipitation of the dissolved solids. Since the non-radioactive components are present at very low concentrations, i.e., a few parts per million, non-radioactive components will preferentially precipitate, which would then be transferred to the LLW stream. However, since co-precipitation will undoubtedly occur, it probably will be necessary to fractionally precipitate several times to adequately decontaminate the separated non-radioactive material.

SUMMARY

The SIPS concept appears attractive for pretreating high level wastes, since it would: 1) process waste in-situ in the tanks, 2) be cheaper and more reliable than a larger centralized facility, 3) be quickly demonstrable at full scale, 4) have less technical risk, 5) avoid having to transfer unstable slurries for long distances, and 6) be simple to decommission and dispose of. Further investigation of the SIPS concept appears desirable, including experimental testing and development of subscale demonstration units.

UNDERSTANDING WASTE PHENOMENOLOGY TO REDUCE THE AMOUNT OF SAMPLING AND ANALYSIS REQUIRED TO RESOLVE HANFORD WASTE TANK SAFETY ISSUES

Joseph E. Meacham
H. Babad
Westinghouse Hanford Company

ABSTRACT

Safety issues associated with Hanford Site waste tanks arose because of inadequate safety analyses and high levels of uncertainty over the

release of radioactivity resulting from condensed phase exothermic chemical reactions (organic solvent fires, organic complexant-nitrate reactions, and ferrocyanide-nitrate reactions). The approach to resolving the Organic Complexant, Organic Solvent, and Ferrocyanide safety issues has changed considerably since 1990. The approach formerly utilized core sampling and extensive analysis of the samples with the expectation the data would provide insight into the hazard. This resulted in high costs and the generation of a large amount of data that was of limited value in resolving the safety issues. The new approach relies on an understanding of the hazard phenomenology to focus sampling and analysis on those analytes that are key to ensuring safe storage of the waste.

INTRODUCTION

Safety issues arose for the 177 (149 single-shell and 28 double-shell) Hanford Site underground storage tanks because of uncertainty over the release of radioactivity resulting from condensed phase exothermic chemical reactions. There are three distinct safety issues that involve condensed phase exothermic chemical reactions: organic solvent fires, organic complexant-nitrate reactions, and ferrocyanide nitrate reactions. A comprehensive safety program was begun in 1990 to examine and resolve these safety issues. Only limited understanding of the hazards existed; consequently, sampling and analysis activities were directed towards sampling the condensed phase and performing complete suites of analyses. The large number of analyses conducted on each waste sample resulted in few tanks being sampled and a large quantity of data that had only limited use in resolving the safety issues.

Much progress has been made on understanding the waste phenomenology and the safety hazards. This understanding has focused sampling effort and narrowed the suite of analyses to those contributing to resolution of the safety issues. The following sections review the background and current understanding of the waste phenomenology, as well as characterization needs based on the current understanding of the safety issues.

ORGANIC SOLVENT SAFETY ISSUE

Background

Various separation processes involving organic solvents have been used at the Hanford Site. These organic solvents were sent to the underground storage tanks, and subsequent waste transfer operations might have distributed organic solvent among several of the 177 high-level waste tanks (1). Given a sufficient ignition source, there are two potential hazards associated with organic solvent, an organic solvent pool fire, and ignition of organic solvent that is entrained in waste solids (a wick fire). A solvent fire would generate and heat headspace gases, pressurizing the tank. This pressurization might be significant enough to collapse the tank dome, releasing radioactive material to the environs.

Hazard Phenomenology

The organic solvent used at Hanford contains semivolatiles compounds (e.g., dodecane, tridecane, and tributyl phosphate); therefore, there is a direct relationship between liquid organic solvent in a tank and the organic solvent vapors found in the headspace. Tanks containing organic solvent can be identified by vapor sampling the tank headspaces. The mass transfer of semi-volatile species in an organic liquid to the headspace vapor is determined by several parameters, including the mass transfer coefficient, gas-liquid contact area, ventilation flow rate, and solvent volatility.

If organic solvent is present, organic solvent vapors should be detectable in a tank headspace, even if the tank is actively ventilated. Most single-shell tanks are only passively ventilated (i.e., the ventilation flow rate is quite small); thus the organic solvent vapors should be present at roughly equilibrium concentrations. Indeed, this was the case for tank 241-C-103, which contains a floating organic solvent pool. Analyses of the liquid organic solvent pool and the vapors in the headspace suggest that semivolatile concentrations are present at close-to-equilibrium concentrations in the tank headspace.

Currently, one tank (241-C-103) is known to contain an organic solvent pool. Additional tanks that might contain an organic solvent pool will be identified through vapor sampling of the tank headspaces. Criteria for organic solvent headspace concentrations have been developed using theoretical analyses and organic solvent sample data from tank 241-C-103. All 149 single-shell tanks will be vapor sampled and screened against the criteria to identify potential organic solvent tanks.

The 28 double-shell tanks do not require headspace sampling for organic solvent. Double-shell tank design will accommodate a substantially larger pressure transient than single-shell tanks. An organic pool or wick fire could not build enough pressure to collapse the double-shell tank dome. Therefore, this safety issue only applies to single-shell tanks.

Organic solvent pool fires are difficult to ignite (2). Sparks, impacts, shocks, and friction sources lack sufficient energy to ignite pool fires, and credible ignition sources have been narrowed to robust and/or sustained energy sources. Experiments with a waste simulant (dodecane) required exposure to a propane torch for 10 - 15 seconds (>1000 Watts) to ignite a 5cm puddle.

Even if a pool fire could be ignited, consequences from such a fire would be very low (within risk acceptance guidelines) if an adequate vent path area exists. A pool fire would heat headspace gases pressurizing the tank. The fire would burn until the oxygen was depleted. The pressurization from a postulated pool fire would increase with the fire spread rate. Calculations indicate that a puddle would have to be larger than 2m2 to create enough pressure to collapse the tank dome. If adequate vent path area was available, the tank dome would not collapse and any radioactive release would be minor. Of the 43 tanks recently vapor sampled, only one has a floating organic solvent pool (241-C-103) and adequate venting is available in this tank (2).

Entrained organic solvent is also difficult to ignite. Hot steel spheres (greater than 270 Joules) and an electronic match (about 138 Joules) failed to ignite entrained organic solvent (dodecane) during ignition experiments. Sparks, impacts, shocks, and friction sources could not ignite entrained organic solvent either.

The consequences from an entrained organic solvent fire are less than an organic pool fire. Open literature and preliminary calculations show that the spread rate for an entrained solvent fire is about an order of magnitude lower then that for a pool fire and would not result in tank over-pressurization. Therefore, the safety issue is bounded by the organic solvent pool fire hazard.

Resolution of the organic solvent safety issue requires two steps a)identification of tanks containing significant quantities of organic solvent (i.e., greater than a 2m2 puddle), and b)ensuring adequate vent path in those tanks that contain significant organic solvent.

Characterization Needs

By understanding hazard phenomenology, the characterization needs can be reduced to vapor sampling of single-shell tanks. Core sampling of the tanks is not required to resolve this safety issue. Only the 149 single-shell tanks need to be vapor sampled for the presence of organic solvent and this will be completed by the end of FY 1998.

ORGANIC COMPLEXANT SAFETY ISSUE

Background

Organic complexants were sent to the high-level waste tanks during the defense mission at the Hanford Site. These compounds and their decomposition products have the potential to react exothermically when combined with an oxidizer. The waste tanks also contain high quantities of sodium nitrate, a strong oxidizer. The organic complexant hazard is represented by two distinct types of reactions, spontaneous chemical runaway (self heating) reactions, and propagating chemical reactions typified by a passing reaction front. These reactions could produce gases that pressurize the tank and cause failure of the tank dome. The aerosols produced would carry radioactive materials to the environs, resulting in unacceptable onsite and offsite doses.

Hazard Phenomenology

Spontaneous chemical runaway reactions are not possible under current storage conditions. This conclusion was reached by evaluating the energy balance for the tanks. For a spontaneous chemical runaway reaction to occur, the chemical heating rate must exceed the tank cooling rate (3). This can be evaluated by comparing the tank cooling response time (i.e., the time required to reach a new equilibrium temperature following an instantaneous change in the heating rate) with the waste storage time. Calculations show that the tank cooling response times range from a few hours to 3.1 years. Some waste has been stored for more than 40 years, and there has been no transfer of waste into the single-shell tanks for about 15 years. Several cooling response times have passed over the last 15 years of storage; consequently, it can be concluded that bulk runaway reactions are not a hazard under current storage conditions. In addition, no credible mechanisms have been identified that would increase tank temperatures and cause a chemical runaway reaction.

Propagating reactions require an ignition source and sufficient fuel and oxidizer. Tube propagation tests with waste surrogates and theoretical analyses have shown that ignition sources greater than 1 Joule (10,000 times more than that required to ignite flammable gas) are required to initiate organic complexant reactions in dry waste. Sparks and static electric shocks lack sufficient energy to initiate organic complexant propagating reactions.

It may be possible to show that no credible initiators exist that cannot be controlled. Laboratory experiments on simulants indicate about 5 weight percent (wt%) free water will prevent initiation of propagating reactions by 100 J ignition sources. Tests on actual waste samples will be conducted to determine a minimum moisture concentration under in-tank waste storage conditions. Confirmation that waste free water concentrations exceed approximately 5 wt%, would reduce the amount of sampling and analysis required to resolve the safety issue.

Safe storage criteria have been established through theoretical analysis and tests on waste surrogates. The minimum fuel concentration required to support a propagating reaction has been determined using a contact-temperature ignition model (4). A necessary (but not sufficient) condition for a propagating reaction is that the fuel concentration be

greater than 1200 J/g (4.5 wt%total organic carbon), on an energy equivalent basis (4).

For fuel concentrations between 1200 and 2100J/g, the waste moisture (free water) content required to prevent a propagating reaction varies linearly from 0 to 20 wt%. Above 20 wt%, the fuel-moisture linear relationship no longer holds because the mixture becomes liquid continuous and a stoichiometric fuel-oxidizer mixture will not support a propagating reaction (4). All of the waste in the double-shell tanks have aqueous supernatants and the waste would be too wet to support a propagating reaction.

Experiments on waste simulants indicate that fuel concentrations in the tanks have been decreased by saltwell pumping and waste aging (i.e., decomposition of the high energy waste into low energy products). Experiments show that the reactive organic complexant salts (e.g., sodium acetate, EDTA, HEDTA) remain soluble in the tank solutions and are removed by saltwell pumping (5). Most of the single-shell tanks have been saltwell pumped (113 out of the 149 total) and the liquid sent to the double-shell tanks. Hence, much of the fuel values in the single-shell tanks might have already been removed.

Experiments also indicate that organic compounds age to less energetic products (e.g., oxalate) (6). Laboratory experiments have shown that these organic salts will not support propagating reactions (4). Therefore, any remaining fuel in the single-shell tanks might not be reactive enough to be a hazard.

It might be possible to show that the fuel concentrations in the single-shell tanks are too low to support propagating reactions. The solubility model indicates that energetic organic species are present principally as solutes in tank liquids. The aging model indicates that organic complexants age over time to less energetic species, providing additional confidence regarding the stability of stored waste. Organic speciation analyses of actual waste will be conducted on selected tanks to confirm that the organic complexants remained soluble, and to confirm that any remaining fuel has aged.

It might be possible to show that tank waste contents meet the safe storage criteria. Information from the solubility and aging models and sample data from selected tanks will be used to assess the potential fuel and moisture concentrations in the tanks. In situ moisture monitoring capability is being developed in an attempt to provide representative measurements of waste moisture concentration in the single-shell tanks.

Characterization Needs

From an understanding of hazard phenomenology, the sampling needs can be focused and the number of analyses performed can be reduced. Only selected single-shell tanks require sampling to resolve the safety issue. Analyses have been reduced to include only measurement of energetics, total organic carbon, moisture, and some organic speciation to confirm organic solubility and organic aging. If tests on actual waste samples indicate that the waste will retain 5 wt% free water, the sampling and analysis needs will be reduced further.

FERROCYANIDE SAFETY ISSUE

Background

During the 1950s, additional tank storage space was required to support the defense mission. To obtain this additional storage volume within a short time period, and to minimize the need for constructing additional storage tanks, Hanford Site scientists developed a process to scavenge

cesium-137 from tank waste liquids. In implementing this process, approximately 140 metric tons of ferrocyanide were added to waste that was later routed to eighteen Hanford Site single-shell tanks. Ferrocyanide, in the presence of oxidizing material such as sodium nitrate, can propagate by heating it to high temperatures or by providing an electrical spark of sufficient energy. Because the scavenging process precipitated ferrocyanide from solutions containing nitrate, an intimate mixture of ferrocyanides and nitrates may have existed in some regions of the eighteen ferrocyanide tanks.

Hazard Phenomenology

Ferrocyanide ages (i.e., decomposes to lower energy products) when exposed to tank waste conditions. Three parameters strongly affect the rate of aging, temperature, exposure to high pH, and radiation dose (7). The current fuel concentration is a function of the starting concentration and the amount of aging that has occurred. Historical data (8) show that all the ferrocyanide tanks have been exposed to enough caustic to promote aging (i.e., had pH values higher than 10). However, ferrocyanide sludge depths in the tanks range from 0.1 to 2.6 meters (9) and there is some question whether the caustic solutions would penetrate more than one meter into ferrocyanide sludge (10). Therefore, ferrocyanide at greater depths might not have been exposed to high pH solutions and might not have aged.

Tanks with high ferrocyanide concentrations and sludge depths, and low temperature and radiation dose histories, have been selected for core sampling to bound aging. If the ferrocyanide has aged in these tanks, then as much or more aging should have occurred in the remaining ferrocyanide tanks.

Nine ferrocyanide tanks have been selected for sampling and analysis to bound ferrocyanide aging. Sampling and analysis have been completed for six of these nine tanks and the data is reviewed in Table I (11). Results indicate that ferrocyanide has aged to concentrations more than a factor of ten lower than the original concentrations. The remaining ferrocyanide concentrations are substantially below the 1200J/g minimum required to support a propagating reaction (4).

Table I

Characterization Needs

Understanding the hazard phenomenology has reduced the number of ferrocyanide tanks that need to be sampled from all eighteen to the nine that bound aging. The analyses required to resolve the safety issue have been narrowed to energetics and ferrocyanide [Na2NiFe(CN)6]. Six of the nine tanks that bound ferrocyanide aging have been sampled and analyzed, and only three tanks remain to be sampled. If aging is confirmed in these final three tanks as expected, then no additional sampling is required to resolve the ferrocyanide safety issue.

ABSTRACT

Four new instruments (a waste void fraction meter, a waste viscometer, a surface- moisture measurement system, and a cone penetrometer) have been developed at the Hanford Site for in-situ characterization of selected physical and chemical properties of high-level waste in underground storage tanks at Hanford. The basis for development of these instruments, the design features, and measurement principles are described along with test results to-date. Planned measurements with the cone penetrometer and surface-moisture measurement system, which have not been deployed in the field, are described.

INTRODUCTION

Extensive efforts are underway to characterize high-level waste stored in 177 underground tanks at the Hanford Site in southeastern Washington

State. In addition to the collection and analysis of samples of vapor, supernate, sludge, and saltcake, several new instruments have been developed for in-situ measurements of waste properties. In some cases, these in-situ measurements may prove to be more representative of waste characteristics than samples that are withdrawn from the tanks. In other cases, the in-situ measurements are less expensive, because full-core samples and their attendant hot cell analysis can cost several hundred thousand dollars each.

Four new instruments have been developed at Hanford for in-situ characterization of selected physical and chemical properties of high-level waste in underground storage tanks at the Hanford Site. These instruments consist of a cone penetrometer, a surface-moisture measurement system, a waste void fraction meter, and a waste viscometer. Measurements performed to date are described for the void fraction meter and waste viscometer. Measurements that are planned later this year with the surface moisture monitor and the cone penetrometer, which have not yet been deployed, are described.

WASTE VOID FRACTION METER

A waste void fraction helps determine the quantity and vertical profile of potentially flammable gases, such as hydrogen, ammonia, and nitrous oxide, that are stored within the thick waste sludges. The design and application of this device was described by Stewart et al. (1995) (1). The quantity of stored gas in the tanks continues to be a high-priority safety issue at the Hanford Site. Efforts that are underway to assess and mitigate this issue have been described by Lentsch et al. (1994, 1995) (2,3).

The principle of the void fraction meter is to insert the device into the waste and capture a sample of waste in a steel chamber. After remote closure and sealing of the chamber, the sample is pressurized to approximately 500 lbf/in2 (gauge) with nitrogen. This compresses any gas voids in the waste sample. The change in volume of the sample is computed from precision measurement of the change in pressure of nitrogen in the supply cylinder. The fraction of the sample originally occupied by gas is then computed. The device is equipped with temperature sensors on the sample chamber, tubing, and supply cabinet for correction of computed volumes.

The void fraction meter is mounted on a 0.76-m-long pivot arm that is attached to a 21.34-m-long, 3-in.-diameter stainless steel pipe weighing approximately 589 kgs. The chamber inlet edges are sharpened to minimize waste disturbance and assure representative collection of the samples. After measurement, the chamber is opened pneumatically to exhaust the sample.

The instrument transducers and electronic processing modules are mounted in an enclosure on the end of the pipe on the outside of the tank. A computer control and data acquisition system is provided.

The entire assembly is lowered by crane into the tank. Measurements are typically performed from the top down, at 0.61-cm intervals, and repeated at 120-degree rotations of the arm. Following removal and decontamination, the device is deployed at a second location on the opposite side of the tank.

Four double-shell, high-level waste tanks have been measured to date (4). The results for three of these tanks are shown in Fig. 1. Significant variation is seen in void fraction, both vertically and laterally. This is not unexpected because the large volume of waste in the tanks is

unmixed. (The tanks are up to 22.86 m in diameter, and the waste is up to 10.67 m deep). The exception is Tank 101-SY, which is periodically mixed with a large mixer pump. Waste in this tank shows less variation.
Fig. 1
The thick, particulate-laden sludge at the bottom of the tanks contains void fractions up to approximately 13 percent, whereas the dense overlying supernate has less than 1 percent void. Average sludge void fractions range from 5 to 7 percent, corresponding to tank gas inventories of 2,000 to 6,000 scf.

WASTE VISCOMETER

A waste viscometer (ball rheometer) was developed to determine the density, yield strength, and viscosity of waste vertical profiles (1). This information is needed for safety analyses of potential flammable gas release accidents. It is also needed to design equipment such as mixer pumps for retrieval of waste from the tanks for waste treatment and disposal. Laboratory analyses of extruded waste cores have not provided accurate measurements of these parameters because of sample disturbance. The waste viscometer consists of a 5.90-kg, 8.89-cm-diameter tungsten ball that is suspended by cable in the waste. The tension in the cable is measured by a precision load cell mounted on a riser penetration above the tank. The cable tension is measured with the ball at rest, during initial movement, and during raising and lowering with the cable spool motor at various controlled velocities. The density, yield strength, and viscosity, respectively, can then be computed from these static loads, starting forces, and dynamic drag forces.
Four tanks have been measured to date with this instrument. The results for one of the tanks are displayed in Fig. 2. The density results show a heavy, convectively mixed, supernatant layer in this tank, with a 250-cm sludge layer. Densities are not accurate in the sludge, which has a yield strength of 50 to 350 Pa in this tank. The apparent viscosity of the supernate in this tank was initially found to be approximately 18 cP, whereas the sludge varies up to 30 million cP. After repeated passes of the ball, the sludge viscosity decreased by an order of magnitude.
Fig. 2

SURFACE MOISTURE MEASUREMENT SYSTEM

An instrument to measure the moisture content of the upper waste layer has been developed and is scheduled to be deployed in a waste tank later this year. The moisture content of the waste is an important safety parameter that strongly determines the combustibility of waste materials that contain appreciable quantities of organic chemicals and nitrates.Key components of the instrument are the deployment mast, Data Acquisition Van (DAV), a neutron probe, and a decontamination spray manifold. The deployment mast consists of a 15.24-m-long stainless steel pipe with a 1.83-m cable-operated drop arm and cable-suspended probe. An upper enclosure supports the mast on the tank top and contains manual winches, cable reels, and electronic components. The DAV supplies power to the probe electronics and processes the neutron information for moisture analysis. The probe consists of an 45.72-cm-long, 8.89-cm-diameter stainless steel certified pressure housing that contains the neutron signal conditioning electronics, three Boron-10-lined thermal neutron proportional detectors, and a Californium-252 fast neutron source. The deployment mast installs in a 10.16-cm tank riser penetration through a spray ring manifold. Spray nozzles, mounted in the manifold, allow high-pressure water to decontaminate the mast and probe upon removal.

A 1.83-m-radius circle, on the surface of the waste, can be measured. The 1.83-m arm allows measurement out from under the riser, where condensation and wash water may have altered the water content of the waste surface.

A video camera is installed in an adjacent tank riser to help position the neutron probe on the waste surface. Measurements will be made at multiple points inside the 1.83-m radius by rotating and repositioning the device.

The moisture concentration is computed from ratios of the count rates from the three neutron detectors, which detect thermal neutrons that are moderated by water in the upper approximate 20.32 cm of waste. Signal processing, of the neutron detector outputs, is used to screen out gamma ray contributions.

This system has been designed to measure down to 3 weight percent water with an accuracy of approximately 1 weight percent. Laboratory testing is underway. Test plans are to validate measurements with this device by correlating the results of surface moisture measurements with measurements of water in vertical waste profiles (by core sampling and laboratory analysis, or by vertical measurements in liquid observation wells that are installed in many of the waste tanks).

Following validation, the surface moisture device will be used for initial safety screening and perhaps to conduct routine future surveillance of tank moisture levels.

CONE PENETROMETER

A specialized cone penetrometer is completing development. This device is used in geological investigation for soil stratigraphy, by pushing a bevelled sensor package into the soil under a heavy load. The instrument being developed for waste tank characterization consists of a custom sensor package with compressive and shear strength load cells, temperature sensors, a pore pressure sensor, a neutron moisture probe, and a Raman spectrometer. The sensor package is shown in Fig. 3.

Hydraulic actuators will place a load of up to 32 metric tons onto the heavy-wall, 4.83-cm-diameter, steel penetrometer push rod. A heavy-wall, 15.24-cm steel guide tube extends through a tank riser down to the waste surface to prevent bucking of the push rod. Testing shows that this device should be capable of pushing the bevelled tip of the sensor package into fairly hard wastes with compressive strengths up to several thousand pounds per square inch. The tip of the sensor contains a magnetrometer to detect the steel tank bottom liner, preventing potential penetration of the tank. An inclinometer is also provided to detect push rod bending prior to buckling.

Fig. 3

A moisture probe using two Boron-10-lined thermal neutron proportional detectors and a Californium-252 fast-neutron source is provided. This probe is inserted into the penetrometer rod by cable after the rod has been inserted. Gamma pulses are screened out by signal processing. Neutron pulse rates are ratioed from the two detectors that are placed end-to-end in the probe at 30.48-cm center-to-center spacing. In this manner, a fairly linear response is obtained between the near-to-far detector ratio and waste water concentration from 5 to 100 percent, with minimal effect from neutron poisons.

The Raman probe directs a beam of near infrared light into the waste through a diamond window, and the reflected light is directed by fibre optics to a tank top spectrometer. This application is highly

developmental. It is hoped that qualitative data will be obtained on the vertical distribution of chemical species such as organics, ferrocyanides, and nitrates that are of concern for tank safety, in conjunction with waste temperature and moisture.

The tip and sleeve load cells on the sensor package will provide information on waste stratigraphy. The tanks are known to contain layers of crust, supernate, sludge, and hard saltcake. This data will be helpful in waste core sampling. It will also be invaluable in determining waste material properties for the design of waste retrieval methods (mixing, lancing, etc.).

This cone penetrometer is scheduled for deployment in the first tank in late 1996.

CONCLUSIONS

A waste void fraction meter and a waste viscometer have been successfully developed and deployed in four waste tanks. The results of these measurements have been useful in assessing the flammable gas safety issue, and in determining physical properties of high-level waste in underground storage tanks at the Hanford Site.

A waste surface moisture monitor and a specialized cone penetrometer have been developed for deployment later in 1996. They will measure waste moisture and physical properties on the surface and at depth. These measurements will be used to assess safety aspects of potential organic-nitrate reactions, to improve core sampling operations, and to design waste retrieval equipment and processes.

These instruments have and will continue to be used as cost-effective tools for tank waste characterization, thereby supplementing the current intensive core sampling and laboratory analysis efforts.

ABSTRACT

Large quantities of organic complexants were used in support of the defense mission at the Hanford Site, and are currently stored as part of 55 million gallons of radioactive waste. The major organic complexants that are believed to have been stored in the tanks are glycolate, citrate hydroxyethylethylenediaminetriacetate (HEDTA), and ethylenediameinetetraacetate (EDTA). Estimated quantities are listed here in kilograms and metric tons:

Glycolic acid, 8.8x105 kg (880 metric tons)
Citric acid, 8.5x105 kg (850 metric tons)
Hydroxyethylethylenediaminetriacetic acid, 8.5x105 kg (830 metric tons)
Ethylenediaminetetraacetic acid, 2.2x105 kg (220 metric tons).

In addition to these complexants, lesser amounts of complexants such as nitrilotriacetic (NTA), di(2-ethylhexyl) phosphoric, and oxalic acids were used, but amounts of these complexants that actually were stored in the tanks are not known.

Despite demonstrated safe storage in terms of chemical stability of the Hanford high level waste for many decades, including decreasing waste temperatures and continuing aging of chemicals to less energetic states, concerns continue relative to assurance of long-term safe storage. Review of potential chemical safety hazards has been of particular recent interest in response to serious incidents within the Nuclear Weapons Complexes in the former Soviet Union (the 1957 Kyshtym and the 1993 Tomsk-7 incidents).

Based upon an evaluation of the extensive new information and understanding that have developed over the last few years, it is concluded that the Hanford waste is stored safely and that concerns related to potential chemical safety hazards are not warranted. Spontaneous bulk runaway reactions of the Kyshtym incident type and other potential condensed-phase propagating reactions can be ruled out by assuring appropriate tank operating controls are in place and by limiting tank intrusive activities. This paper summarizes the technical basis for this position.

CONDENSED-PHASE CHEMICAL REACTIONS

The presence of organic complexants along with oxidizers like NaNO2 and NaNO3 present the potential for condensed-phase chemical reactions, including spontaneous runaway reactions of the Arrhenius type and propagating reactionsa initiated by a local ignition source.

SPONTANEOUS RUNAWAY REACTION

Spontaneous bulk runaway reaction without ignition sources can occur when the chemical heat generation rate produced by an Arrhenius type reaction mechanism exceeds the rate of heat dissipation by conduction in some volume of waste. The requirements for stability are therefore often expressed in terms of two characteristic time constants

Eq. 1

where ta is the characteristic time of adiabatic runaway

Eq. 2

Here T (K) is the temperature, (K/s) is the rate of temperature rise corresponding to temperature T due to chemical heating, Ea is the

activation energy (J/mol), R (8.314 J/mol-K) is the gas constant, H(m) is the height and a(m2/s) is the thermal diffusivity.
The characteristic cooling time tc for an infinite slab geometry is approximatelyb
Eq. 3
While values for tc can be reliably estimated for the waste tanks, values for ta are not known and would be difficult to obtain from waste sampling and analytical measurements.
Fortunately, this concern can be addressed by recognizing that the waste has remained safely stored over a period of time (the 149 single shell tanks have not received wastes since about 1977). That is well in excess of the characteristic cooling times, tc, which range from tens of hours to about 3 years (1). This observation provides proof that Inequality (1) is indeed satisfied, and can be made without a knowledge of ta or the actual chemical composition, water content and waste uniformity, and will not be altered by waste aging or long-term moisture loss. Both shrinkage associated with moisture loss and increasing gaseous porosity both have the effect of decreasing the characteristic cooling times (1).
CONDENSED-PHASE PROPAGATING REACTIONS
In addition to satisfying a certain minimum fuel concentration similar to the lower flammability limit (LFL) for gases, a significant (>10 J) ignition source must be available to assure a propagating reaction. Measured combustion characteristics for several non-degraded organic complexants are summarized in Table I below (2).
Especially noteworthy in Table I is the extremely low burn velocities, implying that if propagating reaction is possible, the chemical energy release rate and corresponding gas evolution rates would be small, limiting the possibility of tank structural tank damage and the release of significant quantities of radioactive material. Furthermore, since the Tig values are much higher than the current waste temperatures, onset of combustion also requires the presence of an adequate ignition source. Potential ignition sources are discussed below including sparks, flames, hot objects and lightning for example, refer to Table I (Sparks) and Table II (Flames). In the discussion to follow it is assumed that combustible conditions exist, i.e., the fuel concentration exceeds its LCL and that moisture concentrations required to suppress combustion are not available unless otherwise specified. The likelihood of satisfying the necessary fuel concentration for a propagating reaction is addressed later.
Table I
Table II
SPARKS
An estimate of the minimum ignition energy (MIE) to initiate combustion can be obtained from
Eq. 4
where r(kg/m3) is the density of the combustible mixture, c (J/kg-K) is the specific heat of the combustible mixture, Tig (K) is the ignition temperature, To (K) is the ambient temperature, and rcrit (m) is the critical radius which is determined from the following heat balance (heat release equals heat loss)
Eq. 5
where Tf (K) is the flame temperature and k (w/m-K) is the thermal conductivity, and results in
Eq. 6

where a(m2/s) is the thermal diffusivity.

First, we will demonstrate that the above ignition theory can be used to predict the MIE of a combustible stoichiometric gas mixture. Considering the following property values for a typical hydrocarbon gas mixture such as methane-air evaluated at Tig = 810 K; r 0.45 kg/m3, c = 1000 K, a = 9 10-5 m2/s, Ub = 0.45 m/s and To = 300 K, we estimate Qmin= 0.21 mJ, which is in excellent agreement with the measured spark energy value of 0.29 mJ (4). The suggested strong sensitivity to the burn velocity (Q ~ Ub-3) is also consistent with experimental observation.

Verification of the strong burn velocity dependence is significant to the application of condensed-phase combustion involving organic complexants such as included in Table I where the burn velocities are noted to be quite low. Application of the above ignition theory using the following property values evaluated at Tig = 520 K; r = 1500 kg/m3, c=1500 J/kg-K, a = 2 10-7 m2/s, Ub = 5 10-4 m/s and To = 320 K, lead to Qmin 3.3 J, i.e., about four orders of magnitude larger than for flammable hydro-carbon mixtures. This energy is well in excess of the maximum spark energies expected from discharge of various types of electrically conducting objects that could be present in the Hanford waste tanks. Typical maximum theoretical spark energies associated with various objects are illustrated in Table II (5).

The above assessment of the MIE value for condensed-phase combustion in case of short duration sparks is considered quite conservative. In contrast to a combustible gaseous mixture, the energy from the spark must be delivered to the condensed phase material. While the power density of the spark is extremely high, the short duration (-second time scale) prevents a sufficient thermal boundary layer build-up required for sustained combustion prior to the dissipation of the spark energy. Considering the previously established ignition theory, the critical ignition thickness for plane geometries is

Eq. 7

The corresponding ignition time, tig, can be obtained by equating the thermal boundary layer thickness

Eq. 8

with the critical ignition front thickness resulting in

Eq. 9

Setting a = 2 10-7 m2/s and Ub = 5 10-4 m/s, the critical ignition time is of the order of 1s. The significance of this value is that potential ignition sources, such as sparks, which have extremely high power densities but are also extremely short-lived (s range), are not capable of initiating condensed-phase propagating reactions in materials of interest. The thermal boundary layer resulting from such ignition sources are much too small to satisfy the requirement for sustained combustion.

FLAMES

In view of the relative ease of igniting a combustible gas mixture, it is of interest to evaluate its potential for subsequently initiating a condensed-phase propagating reaction. The maximum condensed-phase material temperature, Tmax, following a postulated burn can be estimated from Epstein (6).

Eq. 10

where s is the Boltzman constant, e is the emissivity, rg,o (kg/m3) is the initial gas density, Cv,g (J/kg-K) is the gas specific heat, Tg,o (K) is the initial flame temperature, as (m2/s) is the thermal diffusivity of the solid phase, V (m3) is the volume of the burn, A (m2) is the

corresponding surface area of the burn or the surrounding condensed-phase material and ks (w/m-K) is the conductivity of the condensed-phase material. Tabulated values of (Tmax - To) and Tg,o are provided in Table III based on e = 1, Cv,g = 1,000 J/kg-K, V/A = 1, as = 2 10-7 m2/s, Ks = 0.5 w/m-K and rg,o = 1.1 kg/m3.

Table III

Considering that transient burning (if at all credible) would be limited to temperatures of about 1000 K, this type of ignition source would not appear to be a threat to initiating condensed-phase propagating reactions.

The above observation is consistent with the considerable length of time the condensed-phase material must be exposed to a constant burning flame or fire prior to experiencing sustained combustion. For this case, the time to reach the ignition temperature can be estimated from

Eq. 11

where q (w/m2) is the flame heat flux and is usually taken to be of the order of 105 w/m2 (corresponding to the flame temperature of about 1100 K). As such we calculate the time to ignition to be of the order of 10 seconds. It is of interest to note that a burning wooden match develops about 100 W. When subjecting a stoichiometric mixture of Na3Citrate 2H2O and NaNO3 initially at an ambient temperature of 30C to a burning wooden match, a propagating reaction was noticed after about 10 seconds (7).

HOT OBJECTS

The necessary minimum temperature of a hot object to initiate a propagating reaction if brought in direct contact with condensed-phase combustible material can be estimated from the Contact Temperature Ignition (CTI) criterion (2)

Eq. 12

where TH (K) is the temperature of the hot object and s is given by

Eq. 13

where subscript o refers to the combustible condensed-phase material. In the case of a hot steel object, the value of s is about 8, requiring TH to be only about 10% higher than Tig, i.e., about 250C for combustible materials of interest (see Table I). Furthermore, recalling the critical ignition time of the order of 1 second, a minimum steel thickness (considering plane geometry)

Eq. 14

also needs to be satisfied. Setting a = 5 10-6 m2/s, we estimate the value of xmin of the order of 2 mm. It is therefore not surprising that a small hot steel ball (diameter of about 1.6 mm, and TH 1300C and energy content of 10 J) is capable of producing sustained combustion when brought into contact with combustible mixtures, such as those summarized in Table I (7). Such ignition sources, however, can be ruled out by limiting tank intrusive activities.

For completeness, we note that for such ignition sources to be effective requires essentially the absence of free water. Small quantities of water will prevent the contact temperature from reaching the ignition temperature (2).

LIGHTNING

The frequency of lightning striking a Hanford SST is estimated to be about 5 10-4 per year (8). However, as discussed below, ignition of condensed-phase waste materials, including organic solvents, from such a scenario is not considered a credible event. It is important to recognize that the Hanford tanks are buried and the extensive amount of rebar in

the SST concrete domes provide significant overall shielding properties, so that there is a high tendency for lightning produced current fields to be excluded from the interior of the tanks. However, there may be electrically discontinuous paths short that could result in arcing. These paths include arcing between equipment extending through risers, and the risers, arcing at bolted flanges, arcing between the riser or equipment and the rebar in the concrete dome. Lightning will, if the rebar is not well connected and connected to the tank walls in the SSTsc (which it is apparently not) arc to rebar and from rebar to the tank walls. As such, it would be difficult to rule out generation of sparks that would be capable of igniting the presence of a flammable gas mixture in the tank head space. However, considering the limiting durations such flammable gas mixtures could exist in connection with gas release events, these are considered negligible risk scenarios (8).

The above arcing phenomena are much more likely than arcing to the waste surface inside the tanks, as the various tank structures represent much better targets for the lightning current(s). If there is a gap in the conductors carrying a lightning current, the current may arc across the gap. Quoting Uman (9), "The arc energy appears as heated gas, in the tens of thousands of C range, and as heated and melted electrode material, much as in the case of purposeful arc welding. Typical lightning transfers 25 coulombs of charge, and thus an arc due to lightning between metal electrodes could liberate 250 joules of energy at the arc spot, in a volume certainly less than a cubic centimeter, perhaps as small a cubic millimeter." However, further quoting Uman (9). "It is not likely that the total lightning current would flow across one interior gap in a SST or DST because of the many parallel paths available to the lightning current. On the other hand, sparks in the millijoule range are generally thought to be capable of igniting flammable gas." It follows that significant steel melting in connection with such arcing phenomena that subsequently could fall down onto the waste surface would appear very remote. Approximately 250 joules alone would be required to produce a molten steel droplet of about 4 mm diameter, which is less than the capillary size of about 6 mm, i.e., the melted material would quickly refreeze in place.

Furthermore, we have evaluated the likelihood of arcing directly to the waste relative to the above metal arcing dissipation mechanisms for the lightning current energy using the similarity between the arcing caused by a lightning current and purposeful arc welding (9).

To conservatively test the effect or relationship between waste material electrical conductivity and arcing potential, small samples of simulated wastes were placed in a highly electrical conductive environment, i.e., in a small steel crucible (a pipe end cap of about 1.5 inch diameter and 1.5 inch height) clamped to a well-grounded welding table (see Fig. 1). The tungsten electrode was positioned above the waste surface, in direct contact with, as well as below the waste surface. Various types of wastes including organic solvent consisting of dodecane (1a), a stoichiometric mixture of NaCitrate 2H2O-NaNO3 soaked with dodecane (1b), dry stoichiometric mixture of NaCitrate 2H2O-NaNO3 (1c), and stoichiometric NaCitrate 2H2O-NaNO3 mixtures with increasing free water inventories of 5 and 10 wt% H2O (1d and 1e) were placed in the steel crucibles and subjected to arc welding currents of approximately 200 amperes for about one-second intervals.

Fig. 1

No sign of arcing were observed with waste mixtures a, b, and c, including variations in the electrode position relative to the waste material surface. With increasing water inventory, limiting arcing and "crackling" were observed, but in no cases was sustained ignition noticed. While the increasing presence of moisture or water clearly increases the electrical conductivity allowing current to flow, its presence also prevents ignition from occurring by dissipating the arc energy by latent heat of vaporization, keeping the waste temperature well below the ignition temperature. The above observations suggest that if lightning should strike an SST (a very unlikely event), the lightning current and its energy would be largely dissipated before entering the interior of the tank. Multiple paths, including arcing between equipment extending through risers, and the risers, arcing at bolted flanges, arcing between the riser or equipment and the rebar in the concrete dome, arcing from rebar to rebar and from rebar to the tank walls, are much better targets for lightning current energy dissipation than arcing deep into the interior of the tank, such as to the waste surface or below the waste surface. Furthermore, arcing to the waste, if at all likely, would appear to require the presence of moisture to improve its electrical properties, but this moisture would also prevent ignition. A lightning strike is, therefore, not considered a significant risk scenario in terms of presenting an ignition potential for organic solvents or solid wastes.

SUMMARY

Potential chemical safety hazards associated with condensed-phase propagating organic complexant-nitrite/nitrate reactions have been assessed for the Hanford Tank Farm leading to the following observations:

Condensed-phase spontaneous (no ignition source required) bulk runaway reactions are not possible, and

Credible ignition sources, including lightning, that could initiate a condensed-phase propagating reaction can be ruled out by assuring appropriate tank operating controls are in place and by limiting tank intrusive activities.

These observations can be made without requiring a detailed knowledge of the wastes including fuel content, water content, and heterogeneity, and will not be altered by waste aging or long term moisture loss.

ABSTRACT

The underground storage tanks at the Hanford site contain wastes generated from many years of plutonium production and recovery processes, and mixed wastes from radiological degradation processes. The chemical changes of the organic materials used in the extraction processes have a direct bearing on several specific safety issues, including hazards associated with fuel-nitrate combustion accidents. This paper details the second year's findings of a study charged with determining how thermal and radiological processes may change the composition of organic compounds disposed to the tanks. Our approach relies on literature precedent, experiments with simulated waste, and studies of model reactions. Our efforts have focused on the global reaction kinetics of a simulated waste exposed to g radiation.

Our experiments have subjected an "organic tanks" non-radioactive simulant to a range of temperatures and gamma radiation fluxes to determine the effects of radiation on aging of organic tank waste compounds. The simulant contained equi-molar amounts of dodecane, ethylenediaminetetraacetate (EDTA), tributyl phosphate (TBP), dibutyl phosphate (DBP), methyl isobutyl ketone (hexone), stearate, and citrate in an inorganic matrix containing hydroxide, nitrate, nitrite, aluminum hydroxide, and a variety of alkali, alkaline earth, and transition metal cations. We found that gas production is predominantly radiolytically induced. The main gases found are hydrogen, nitrous oxide, and nitrogen. Concurrent with gas generation we observe the disappearance of starting organic compounds and the appearance of condensed-phase products, dodecanones, heptadecane, isobutyrate, succinate, oxalate, formate, and glycolate. The apparent rate of "aging" is TBP>>hexone EDTA>stearate> citratedodecane. In the absence of radiolysis, TBP readily decomposes to DBP and butanol in the basic medium (1-3). However, radiation clearly accelerated consumption of the other compounds.

Our mechanistic studies, combined with literature precedent, suggest that oximes and possibly organic nitro compounds are key intermediates in the radiolytically-induced redox reactions of organic compounds with nitrate/nitrite. Hydrolysis, dehydration and autoxidation of these intermediates lead to ultimate products in which C-C and C-H bonds have been converted to C-O and C=O bonds. The finding of dodecanones in our simulant aging experiments, and homologous series of nitriles, aldehydes and ketones in vapor spaces above tank wastes containing NPH, are consistent with this scheme.

These results indicate that radiation promotes redox reactions between organic compounds (reducing agents) and nitrates/nitrites (oxidizing agents) in the wastes leading progressively to compounds with greater numbers of C-O bonds and fewer C-H and C-C bonds,resulting in an overall lower energy content for the organic inventory. Nitrate and nitrite are reduced to nitrogen compounds of lower oxidation state, primarily N2, N2O and NH3. Thus, to the extent that the tanks have been adequately ventilated and wastes continually dosed by radioactive elements, the total energy content of the tank wastes should have declined. However, aging processes appear to be converting high energy, nonpropagating organic compounds such as NPH, TBP and DBP to lower energy, propagating carboxylate salts. Thus, the level of current risk depends on how rapidly carboxylic salts of moderate energy content degrade to low energy oxalate and formate.

INTRODUCTION

Uranium and plutonium production at the Hanford site produced large quantities of radioactive by-products and contaminated process chemicals that are presently stored in underground tanks awaiting treatment and disposal. Having been made strongly alkaline and then subjected to successive water evaporation campaigns to increase storage capacity, the wastes now exist in the physical forms of salt cakes, metal oxide sludges, and saturated aqueous brine solutions. Those waste storage tanks containing organic process chemicals mixed with nitrate/nitrite salt wastes are thought to be at risk for fuel-nitrate combustion accidents. To assess the hazard and provide information needed to establish safety criteria, test programs must use simulants, at least until actual tank samples and hot cell test methods become available. Historical records can be used to identify the organics originally purchased and potentially present in the wastes, thus allowing experimental determination of the reactivity of mixtures of these materials with nitrates and nitrites as a first estimate of the hazard associated with the wastes. However, only postulated degradation products or analyses of individual tanks can be used to evaluate the current hazard associated with the organic wastes. To obtain more reliable knowledge of the degradation products, experimental studies are needed.

Objective

The purpose of the Waste Aging Task is to elucidate how chemical and radiological processes will have aged or degraded organic compounds stored in the tanks. This information supports efforts to evaluate the hazard as well as develop potential control and mitigation strategies.

Background

Each of the 177 waste tanks on the Hanford Site has a unique and largely unknown composition of organic, inorganic, and radioactive elements. A number of studies have been conducted to assess the inventory of chemicals added to the tanks as a result of chemical processes, such as

uranium recovery, reduction and oxidation (REDOX), plutonium uranium reduction and extraction (PUREX), and waste fractionation and encapsulation, that were performed at the Hanford Site (4-10). Some of these studies were summarized in PNL-8339, Assessment of Concentration Mechanisms for Organic Wastes in Underground Storage Tanks at Hanford (11), which assessed the concentration mechanisms for organic wastes that were believed to have been added to the tanks.

Many of the single-shell waste tanks have been sampled and total organic carbon (TOC) contents measured. However, knowledge of the TOC in a particular storage tank is insufficient to bound the safety risk without knowing the kinds of organic compounds that are in the waste.Because nitrate reaction energies vary widely for organic compounds, some information about the identity and oxidation state of the organic carbon is needed as well. Organic-containing wastes have been stored in Hanford Site underground storage tanks for tens of years. During that time the wastes have been exposed to radiation, temperatures of 20 to 140C (68 to 284F), and a reactive chemical environment having high concentrations of active chemicals, including hydroxide, nitrate, nitrite, aluminate, and transition metal oxides including noble metals, radioactive elements (uranium, plutonium, cesium, strontium, etc.) and many other materials that could act as catalysts and affect aging pathways.

The major organic compounds that were added to the tanks are divided into two classes: extractants/solvents and complexants for di-, tri-, and tetravalent cations. The major organic complexants that are believed to have been stored in the tanks are glycolate, citrate, hydroxyethylethylenediaminetriacetate (HEDTA), and ethylenediaminetetraacetate (EDTA). Allen (4) estimated the approximate quantities, which are listed here in kilograms and metric tons:

Glycolic acid, 8.8x105kg (880 metric tons)
Citric acid, 8.5x105kg (850 metric tons)
Hydroxyethylethylenediaminetriacetic acid, 8.3x105kg (830 metric tons)
Ethylenediaminetetraacetic acid, 2.2x105kg (220 metric tons).

In addition to these complexants, lesser amounts of complexants such as nitrilotriacetic (NTA), di(2-ethylhexyl)phosphoric, and oxalic acids were used, but amounts of these complexants that actually were stored in the tanks are not known.

Process solvents of concern that were used in Hanford Site chemical processes and stored in the tanks are tributyl phosphate (TBP), normal paraffin hydrocarbons (NPHs), and methyl isobutyl ketone. A recent examination by Sederburg and Reddick (12) of the PUREX plant material balances from 1955 to 1991 indicates that the quantities of TBP and NPH that went to tank storage are 7.22x105 and 1.31x106kg (720 and 1,310 metric tons). Other processes also used organic solvents and organic phosphate extractants, but less is known about the quantities that were added to the tanks. Di(2-ethylhexyl)phosphate diluted with hydrocarbon solvent was used in the waste fractionation and encapsulation process. The reflux solvent extraction process used TBP/carbon tetrachloride and dibutyl butyl phosphonate/carbon tetrachloride for extraction solvents. Considerable quantities of methyl isobutyl ketone (hexone) were used in the REDOX process as both extractant and solvent (11). For example, 6.5x104kg (65 metric tons) of hexone were retrieved from one storage tank, treated, and disposed. The evidence suggests that the quantities of organic solvents added to the tanks rival the quantities of complexants. However, the fraction of organic solvents that have escaped the wastes

via evaporation, or, in the case of phosphate esters, have been saponified in the alkaline wastes (1) is not known. Sederburg and Reddick (12) have pointed out that during early PUREX operations, the organic wash waste was combined with high-level wastes that generated enough thermal heat to cause the tank wastes to self-boil.

For complexants such as EDTA, HEDTA, glycolic acid, and citric acid, extensive studies of degradation mechanisms (aging) have been performed by Argonne National Laboratory (ANL) (13-16), Georgia Institute of Technology (Georgia Tech) (17) Pacific Northwest National Laboratory (PNNL) (18) and Westinghouse Hanford Company (WHC) (19,20). The purpose of these studies has been to determine the mechanisms by which organic wastes decompose and generate gases. Much of the work has focused on the role that chelators play in generating H2, N2, and N2O in tanks such as Tank 241-SY-101. The Georgia Tech group has focused primarily on the thermal non-radiolytic pathways that degrade the complexants, mainly HEDTA and glycolate, and produce H2 (21,22). The ANL and PNNL groups have explored direct and indirect radiation-induced pathways, as well as thermally activated pathways.

The simulants used in the above work did not include organic solvents, such as hexone, TBP, and NPH, that were widely used in the processing plants, mainly because the flammable gas-producing tanks of greatest concern did not receive significant quantities of these compounds. Analyses of core samples from Tank 241-SY-101 have shown that a significant portion of the organic carbon is contained in chelators, chelator fragments, and low molecular weight carboxylic acid (i.e., formic, acetic, glycolic, oxalic, succinic, and citric acids). The NPH components amounted to only 2 to 3% of the organic carbon (23). In contrast to Tank 241-SY-101, Tank 241-C-103 contains 15 to 21 kL of organic liquid composed primarily of TBP and NPH floating on the aqueous wastes (24,25). Considering the large quantities and high energy content of the organic solvents disposed to the tanks, how they have aged and become distributed in the tanks is very relevant to the organic tanks safety issue.

As a precursor to the experimental studies described in this report, a literature review was performed to assemble a bibliography (26) of literature relevant to understanding the chemical transformations that have occurred in the tanks (27). The bibliography focused on the hydrolytic, radiolytic, and free radical-mediated chemistry of normal paraffinic hydrocarbons (NPH), TBP, hexone, and other organic constituents. Aging mechanisms of ferri/ferrocyanides and the EDTA-type complexants were not addressed in the bibliography as they have been examined recently by Lilga (28), Meisel (13-16) and Ashby (22). Additional literatures review were done in FY94 (29) to address specific questions concerning aging pathways and products, i.e., alkaline hydrolysis of nitrate and phosphate esters, effects of oxygen and radical initiators on degradation of nitroalkanes, production of organic nitro compounds via reaction of nitrite with organic radicals, and radiation-induced decomposition pathways of phosphate esters.

Approach

Hazards posed by uncontrolled exothermic oxidation of organic compounds by nitrate and nitrite relate directly to the energy content and oxidation kinetics of the various organic compounds present in the waste. Until sampling and analysis of the tank wastes become routine procedures, a viable approach to assessing the current organic content of the tanks

is to simulate the chemical conditions of the tanks and elucidate mechanistic pathways that are key to knowing if the hazards have increased, decreased or remained constant with time. Accordingly, this project is using simulants in its studies of radiation-induced chemical aging effects. The work is proceeding in three sequential steps: 1) simulant selection and preparation, 2) scoping studies, and 3) long term aging studies. To facilitate studies of radiolytic-induced chemical aging, external radiation from a g source rather than use of radioactive chemicals are used. Radiation doses and/or temperatures are selected to produce aging reactions over times ranging from a few days to several months. After being irradiated, the disappearance and appearance of detectable organic products in the simulant and evolved gases are determined.

Although simulant aging studies will provide global pathways for aging, they will not allow confident elucidation of how these reactions proceed on the molecular scale because of the complexity of the simulants. Therefore, in concert with and in support of the simulant aging studies, less complex reaction systems that are more readily probed and understood are being examined. In addition, this part of the aging studies is addressing specific safety/treatment questions. As these questions arise, the literature is consulted for pertinent information, and supplemental experiments are designed and performed as needed.

EXPERIMENTAL SECTION

All of the chemicals used in this study were purchased from Aldrich Chemical Company, Eastman Kodak, or Baker Chemicals. The purity of the chemicals was reagent grade or better, as defined by the American Chemical Society. The chemicals used in this work were not further purified. A high-shear mixer (PoyltronTM PT6000, Brinkman Instruments Inc., Westbury, NY), was used to mix the simulant. The mixer speed was ~6000 rpm. Water used for preparing the simulant was deionized by a Milli-QTM Deionization System (Millipore Corporation, San Francisco, CA).

Simulant Preparation

The simulant used in this portion of the study is designated SY1-SIM-94C. Its composition is listed in Table I. The inorganic components of SY1-SIM-94C are largely based on analytical data for Tank 241-SY-101 waste (30). Sodium nitrate, nitrite, and hydroxide comprise the largest share of the mass of the inorganic and non-radioactive species (30). Also, significant amounts of aluminum are present, presumably, as sodium aluminate, not aluminum oxide, due to high levels of sodium hydroxide. Compared to SY1-SIM-93, five inorganic elements, Ce, Zr, Pd, Rh, and Ru, were added and levels of Cl and F were reduced. The levels of the noble metals Pd, Ru, Rh (as nitrates) were chosen based a report by Reynolds (30). Cerium (III) was added so as to include an element from the lanthanide series. The concentration was set at one third the level of Ca. Zirconium was added and the halides reduced based on information Scheele (31) obtained about the chemical compositions of Sr and Cs removal process waste streams.

The organic components were limited to seven compounds, each added on an equi-molar basis, to facilitate analyses of reactants and products in the condensed phase. Stearate, a long chain carboxylate anion, and dibutyl phosphate were included in the simulant to reflect partial oxidation of NPH and hydrolysis of TBP under plutonium extraction (PUREX) process conditions. Glycolate and HEDTA, present in SY1-SIM-93C, were excluded to

simplify analyses and because their radiolytic breakdown had been elucidated by Meisel (15,16).

The simulant was prepared by first dissolving the total amount of sodium hydroxide in 700 mL of water. Sodium aluminate was added slowly, with stirring. The remainder of the inorganic constituents were weighed out and added successively to the mixture with periodic mixing to homogenize the ingredients. The organic constituents, the first seven compounds in Table I, were weighed into a separate container, and then combined with the inorganic mixture. Next, the remainder of the water was used to wash the organic residue into the mixture. The entire simulant mixture was mixed for an additional 10 min. The resultant light-green solution had the appearance and consistency of a milk shake. The simulant was stored in a tightly capped polyethylene jar at ~4C.

Table I
Irradiation of an Organic Tank Waste Simulant

Until sampling and analysis of the tanks become a routine procedure, hazard assessment must rely on information obtained from studies with simulants. Other studies conducted at Hanford have made extensive use of simulants to mimic the pertinent chemistry of the flammable gas-producing wastes. Their simulants did not include organic solvents, such as hexone, TBP, and NPH, which were widely used in the processing plants. This paper will examine both complexant and organic solvent aging.

The basis of this paper was based on an experimental plan that called for an organic tanks simulant, performance of scoping experiments, and then a series of long-term aging experiments. The simulant composition was determined by consensus of PNNL and WHC investigators involved with tank safety programs and having knowledge of the chemical process streams that were fed to the Organic Tanks. Scoping experiments were performed to optimize procedures and establish the range of conditions over which to collect data. The simulant was dosed with 0.6 MGy at 90C in an O2/Ar atmosphere. In another experiment, the simulant was thermostatted at 90C for the same time (8 d) as the previous experiment, except it was not irradiated. Gas and condensed phase samples were retrieved from the reactor and analyzed. Based on these results, sampling intervals and temperatures were selected for the long-term aging studies. Experimental procedures and results are detailed in our year end report (32).

The schedule of experiments is provided in Table A-I of the Appendix. Most of the simulant irradiation experiments were run at 50, 70, and 90C with samples receiving radiation doses of 0.07 to 1.2 MGy (7 to 120 MRad) at a flux of 2660 to 3100 Gy/h (2.66x105 to 3.10x105 MRad/h). A few experiments were run at a much lower flux. Several duplicate experiments (runs 13-16, 18 and 21) were run to determine reproducibility. Most experiments (nos. 31, 32, and 34) had oxygen gas in the headspace of the reaction vessel at the start of the irradiations. However, three experiments were run without oxygen to learn how oxygen effects radiolytic and thermal reactions of the simulant. And, experiments (nos. 2, B1, B2, B3, and X1) were run in the absence of radiation to determine thermal conversion levels.

Sample irradiation experiments were performed within the g-Irradiation Facility at PNNL. The facility contains 37 stainless steel irradiation tubes positioned in a 2.13-m-diameter by 4.19-m-deep stainless steel tank. Two arrays of 60Co sources with a combined inventory of 1.184x1016 Bq are located near the bottom of the tank. For radiation shielding purposes, the tank is completely filled with water, and a concrete wall,

1.1 m in height, surrounds the top of the tank. The irradiation tubes, which are sealed on the bottom, vary in length from 4.9 to 5.5 m, and in diameter from 4.6 to 5.1 cm. The irradiation fluxes of the tubes range from 2 to 2x104 Gy/h (200 to 2x106 Mrad/h). The uniform flux region varies from 15.2 cm for the tubes closest to the sources to greater than 30.5 cm for the tubes farthest from the sources. All flux measurements of the tubes are traceable to the National Institute of Science and Technology (18).

Vessels of the simulant are manually lowered into the irradiation tubes to the desired flux where they are left in the tubes for a specific length of time to attain the required exposure. No nuclear activation products are associated with the g irradiation, thus the samples and sample vessels can be transported to other facilities for examination after being removed from the tubes.

Other ancillary equipment at the g-Irradiation Facility increases the repeatability of thermal control and sampling procedure. The gas manifold system is used to connect multiple reaction vessels to the initial headspace gas source, pressure monitoring equipment, and a port for headspace vapor removal. A gas sample is removed using an evacuated bulb sampler for analysis by mass spectrometry (MS) at another location. The data logger controls both the automated temperature and pressure measurements of the reaction vessels.

Reactor Vessel

The reactor vessel for this study was made from 1.59 cm inner-diameter 316 stainless steel pipe. One end of the pipe was sealed by welding a plate of 316 steel to the pipe. The other end was welded to a flange, 1.59 cm inner-diameter by 3.49 cm outer-diameter. The reactor cover has two openings. One opening was fitted with a 0.16 cm swagelok fitting (Swagelok Company, Solon, OH) to connect to the gas manifold via small-diameter stainless steel tubing. The other opening was fitted with a 0.32 cm swagelok fitting through which a K-thermocouple was inserted 15.2 cm into the body of the reactor from the top of the flange. The volume of the vessel to the top of the flange was approximately 30 mL.

The reactor vessel was heated to operating temperature by heating tape that had been wrapped around the outside of the vessel. The internal temperature of the reaction vessel was maintained by feedback control to minimize thermal gradient problems (18). Reaction vessel temperatures and pressures were monitored using a data logger.

Filling and Placing the Reactor

The simulant was removed from storage at ~4C, equilibrated with room temperature, and resuspended by mixing with the high-shear mixer. An aliquot of 15 mL was measured out and transferred to the reactor. The reactor was then sealed and transported to the g-Irradiation Facility. The staff at the g-Irradiation Facility performed the irradiation experiments according to a set procedure 32. A mixture of 79.5% argon and 20.5% oxygen was used as the gas phase, instead of air, to facilitate analyses of nitrogen gas. The vapor phase of the reaction was removed at the end of the irradiation time via an evacuated bulb sampler at temperature. The vapor was later analyzed by PNNL staff according to the procedure by Goheen (33). Total moles of gases produced were calculated based on the measured pressure, temperature, and known volume (24 mL) of the gas phase of the reaction vessel plus gas manifold lines. Concentrations (mol%) of individual components in the gas sample were determined using mass spectrometric analyses. The quantities of specific

gases generated were calculated from the total moles of gas generated and the mole fraction data.

No attempt was made to extract product gases that were either dissolved in the simulated waste mixtures or present as gas bubbles. For all product gases except ammonia, this approach should result in negligible errors. Ammonia has significant solubility in the concentrated simulant mixtures (34). Solubilities of gases such as H2, N2, and N2O are known to be quite low in concentrated brines as compared to their solubilities in pure water (35,34). Gas bubbles will contribute to the measured pressure in the test vessel, much as if the bubbles were brought to the slurry surface and eliminated, provided that simulant surface tension does not significantly compress the bubbles.

Condensed Phase Analyses

After the gas sample was removed, the reactor was cooled to below 35C, removed from the manifold, sealed, and transported to another laboratory to retrieve the condensed phase. The lid was removed and the mixture was stirred with a spatula and separated into two samples of ~7.5 mL. One sample was combined with other washings from the reactor to a total volume of ~20 mL and stored at -2C. The other sample was analyzed for the organic constituents by PNNL's Advanced Analytical Methods Development Group.

Continual modifications and improvements to the analyses of the simulant waste samples have been made. Three different analyses are being used to date to obtain quantitative information on the organic starting components. In addition, some of the degradation products from heat and gamma irradiation treatment have been identified.

Gas Chromatography/Mass Spectrometry (GC/MS) is used to quantify dodecane, stearic acid, hexone, and TBP. This procedure requires neutralization of the caustic sample with phosphoric acid followed by extraction of these four organics with dichloromethane (CH2Cl2). Two surrogates, dodecane-d26 and palmitic acid, are added prior to extraction to track the efficiency of the sample preparation procedure. Following extraction, diazomethane is added to methylate stearic acid to enhance its volatility for GC/MS analysis. Analyte recoveries for the CH2Cl2 extraction and sample preparation procedure were determined by spiking known amounts of the organic analytes of interest into the inorganic portion of the simulant recipe. Triplicate experiments gave recoveries of 102% for dodecane, 96% for TBP, and 98% for stearic acid.

Recoveries for dibutyl phosphate with this sample preparation method averaged only 6%. Therefore, this is not a viable method for this analyte. Alternatives for analyzing DBP are being pursued under the Advanced Organic Analysis task. Precision of the GC/MS analysis, determined through replicate sample injections had a standard deviation of less than 2% for all analytes.

Ion-Pair Chromatography (IPC) is the method of choice for the analysis of EDTA. The aqueous layer remaining after extraction of the organics by CH2Cl2 for GC/MS analysis is used for EDTA analysis. An aliquot of the aqueous layer is diluted to a concentration within the dynamic range of the IPC technique. Copper sulfate is added to enhance EDTA detection.

Error estimates for sampling and analysis were performed under the Flammable Gas Safety Organic Analysis Task, but can be applied here as well. The simulant waste samples have similar inorganic matrix recipes. Replicate sample preparations and instrument injections produced standard deviations of 5% for control simulated waste samples and up to 10% for

heated and irradiated simulant waste samples. The increased error in the stressed samples can be explained by possible incomplete separation of degradation products in the stressed samples.

Ion chromatography (IC) with conductivity detection is used for citric acid analysis. This technique was developed under the Flammable Gas Safety Project for detection of low molecular weight organic acids in waste tank matrices. The simulant waste sample is diluted with water. Dichloromethane is added to remove non-polar organics that could interfere with the IC. Recovery studies of citric acid spiked into the simulant inorganic matrix gave a recovery of 97%. Triplicate weighing and sample preparation gave sampling error (standard deviation) of 9%. Multiple injections of the same sample gave a precision of 1%. Therefore, the total error for the IC analysis was determined to be 10%.

RESULTS OF WASTE AGING STUDIES

Gas Phase Analytical Results

Results of headspace gas analyses have been completed. The analytical data are contained in the Appendix (Tables A-II and A-III) of this paper. The quantities of gases found were calculated from reactor head pressures and mass spectral analyses of headspace gases drawn from the reactor. Figure 1 shows a plot of the reactor headspace gas pressures as function of radiation dose and temperature. The pressures in the figure have been corrected for the pressure increases due to raising the reactor temperature from ambient to the actual run temperatures. Control experiments B1, B2 and B3 that were run in the absence of radiation showed little gas increase after correcting for temperature changes. Accordingly, the pressure increases are due to radiolytically-induced gas-producing reactions.

Fig. 1

Induction periods for gas production were observed. For example at 50C, the rate of gas production increases significantly after the simulant has received a dose of about 0.2 MGy (20 Mrad). Gas pressures increase linearly with dose after the induction period indicating that gas production obeys zero-order kinetics, p=kt. Induction periods decreased with increasing temperature.

Hydrogen, nitrogen and nitrous oxide are the major gaseous products produced during g irradiation of the simulant. The yield of individual gases showed behavior similar to that for total gas produced except scatter in the data is greater. Figures 1 and 2 show plots of the production of these gases at 50, 70 and 90C. Yields in Table A-III and Figs. 1 and 2 are in mmol. For reference, the headspace above the simulant initially contained 752 mmol of argon and 192 mmol of oxygen in a volume of 24 mL. Linear fits to the yield data in Figs. 1, 2, and 3 provide zero-order rate constants for production of H_2, N_2 and N_2O gases. Figure 4 plots these rate constants vs. inverse temperature in K.

Fig. 2

Fig. 3

Fig. 4

As shown in Figs. 2 and 4, production of H_2 gas increases markedly when going from 70 to 90C. Scatter in the data is also much greater at 90C. This behavior is attributed to the onset of thermal pathways for generating hydrogen from organic degradation products. Meisel et al. (14-16) found that preirradiation of simulated wastes containing glycolic, EDTA, HEDTA, and citric acids showed enhanced production of H_2 during thermal treatment. Meisel et al. (14-16) suggested that radiolytic

degradation of chelators produced formaldehyde and glyoxylate, which decompose thermally producing H2.
Figure 3 shows that, after an induction period, production of nitrogen-containing gases obeys a zero-order kinetic rate law, m=kt, where m is moles of a gas in the headspace. N2O is produced in greater amounts than N2. The ratios of N2/N2O yields approach ~0.5 at higher does. The ratios decrease with increasing temperatures consistent with a larger Arrhenius activation energy (Fig. 4) for N2O production compared to N2 production. The activation energies are 73 kJ/mol for N2O and 13 kJ/mol for N2. The smallness of these barriers are in accord with the radiolytic mechanism offered by Meisel (16) in which both N2 and N2O gases derive from a common radiolytically-generated intermediate (Eqs. 1-5).
Eq. 1
Eq. 2
Eq. 3
Eq. 4
Eq. 5
According to this mechanism, the combined yields of N2 and N2O are dependent on the production of oximes; whereas, the relative amounts of N2 and N2O depend on how hyponitrous acid (HO-N=N-OH) partitions. Meisel 16) proposed that the oximes originate from combination of radiolytically-generated NO and organic radicals.
Several control experiments were run to examine the role that organic compounds in the simulant might play in promoting the generation of gases. Table II compares results for these runs with results for SY1-SIM-94C runs with and without irradiation. Experiments B4 to B6 were run with the inorganic portion of the simulant which contained only a very small amount of citrate that had been added as zirconium citrate. Its concentration was only 1/70th the molar amount of the total organic constituents in the SIM-SY-94C simulant. Levels of nitrogen containing gases in runs B4 to B6 were four to ten times smaller compared to the SIM-SY-94C runs with irradiation. Hydrogen gas yields were similarly reduced. Runs B1 to B3 with SIM-SY-94C and no radiation produced very little gas. These results clearly show a synergism between radiation and organic compounds in promoting gas production.
Table II
Oxygen gas in the headspace above the simulant was consumed, both in the presence and absence of radiation (compare runs 11 to 13 with B1 to B3 in Table II). Figure 5 plots headspace oxygen levels in mmols as function of dose and temperature. As evidenced by the plot, oxygen levels in the headspace decreased to a non-zero steady-state during irradiation. The rate at which the steady-state was achieved increased markedly with temperature. Furthermore, the steady-state level increased with temperature from 5% at 50C to 30% at 70C, and to 40% at 90C. Fitted rate constants and equilibrium O2 levels are 1.1 MGy-1 (0.011 MRad-1) and 9.8 mmol at 50C, 3.2 MGy-1 (0.032 MRad-1) and 57.9 mmol at 70C, and 18.8 MGy-1 (0.188 MRad-1) and 77.1 mmol at 90C. These equilibrium levels correspond to 5%, 30%, and 40% of the starting amount of O2 in the reactor headspace (~15 ml).
Fig. 5
In the case of a simple reversible reaction, AB, the steady-state level corresponds to the level at which the rates of consumption and rates of production are matched. Runs 31, 32, and 33 (Table II) starting without oxygen gas in the headspace were run to test if steady-state O2 levels

could be reached by starting without O2. Oxygen was produced in these runs, although the rates of production were much slower than the rates of consumption from runs starting with 21% oxygen in the headspace. Perhaps it should not be surprising that the chemical kinetics are much more complex than that for a simple reversible reaction, given the complexity of the simulant and of radiolytic processes in general.

Additional evidence that the oxygen steady-state levels are due to radiolysis was obtained from experiments run in the absence of radiation. The concentration of oxygen decreased well below the steady-state concentration reached during irradiation. The degree of consumption for a given interval of time is dependent upon the temperature of the reaction as can be seen in experiments B1 to B3 in which the only variable was the temperature. Approximately 84% of the initial oxygen was consumed at 90C in 11 days. This length of time is equivalent to the irradiation time for sample to receive a dose of 0.80 MGy (80 MRad) in the g facility.

Small quantities of "other gases" (see Table A-II in Appendix) were detected in the mass spectrometric analyses, but the ions could not be unambiguously assigned. To learn the identities of these gases, headspace gases from run 4 were analyzed using GC/MS according to the procedure by Stromatt (37). The gases were found to be a mixture of butanol and hexone. Butanol was present at 0.2 g/L, and hexone at 4.4 g/L, in the vapor phase. Butene and acetone, the possible products of TBP and hexone decomposition, which have been identified in the vapor of Tank 241-C-103 (24), were evidently below detection limits.

Condensed Phase Analytical Results

Organic analyses for most of the irradiated samples have been performed. Table A-IV contains the analytical data. Only the data for EDTA and citrate lend themselves to kinetic analysis. These data will be analyzed below. Data for the disappearance of hexone, dodecane and stearate are inconsistent and scattered. Data plots for these compounds appear in the FY95 year end task report (32). Control experiments indicate that excellent recoveries of these compounds can be obtained from the unirradiated simulant using the current analysis methods. These compounds are not expected to be soluble in the aqueous phase of the simulant. Therefore, sampling errors caused by sample inhomogeneity may account for the scatter.

Destruction of TBP was near complete at all radiation times. In fact, we observed its to be disappearing even while stored at 4C. The simulant was made up to contain approximately 16 mg/g TBP. Initial analyses found 18.6 mg/g. But, subsequent analyses at 3 weeks, 11 months, and 16 months found respectively 8.9 mg/g, 6.4 mg/g and 4.9 mg/g of TBP in the simulant. The rate of disappearance in the simulant is much faster than would predicted based on literature rates (1) for hydrolysis of TBP in 1 M NaOH. Similarly, results in Table A-IV show it to be disappearing at least 10 times faster than expected when the samples were held in the gamma facility at 50 and 70C even when the samples received no radiation dose. The reason for this surprising result is not known. It may be due to greater interfacial surface area of the emulsified simulant and a catalytic effect of metal oxides, e.g. Zirconia (38,39), or other multivalent cations. Emulsification of the simulant has lead to a significant increase in the effective concentration of TPB and Dodecane solubility and rate of hydrolysis. These two solvents have minimal solubility (10-3 M) in aqueous solutions (1). Work is currently under way to quantify the increased rate of hydrolysis due to cation and mixing.

Recoveries of DBP were only 6% from the unirradiated simulant. Therefore, quantification of DBP in irradiated samples was not attempted. The radiolytic and thermal reactions of DBP are being investigated in a separate study using a less complex simulant and 31P nuclear magnetic resonance detection.

The disappearances of EDTA and citrate in the condensed phase fit the first-order kinetic rate law, A=Aoe-kt. Plots of the data are furnished in Figs. 6 and 7. The radiation doses necessary to reduce the concentration of EDTA in the simulant by one-half were 0.63 MGy (63 Mrad) at 50C, 0.51 MGy (51 MRad) at 70C, and 0.41 MGy (41 Mrad) at 90C. Citrate was less reactive requiring about 5-times more radiation to reduce its concentration by one-half. The greater reactivity of EDTA relative to citrate is consistent with the greater number of C-H bonds in EDTA compared to citrate. Statistically, we would expect an EDTA:citrate reactivity of 3:1. Also, 8 of 12 C-H bonds in EDTA are adjacent to both carboxylate and amine functionalities. This should enhance their reactivity relative to C-H bonds adjacent to carboxyl groups in citrate. Scheme 1 shows a phenomenological model that is consistent with radiolytically-induced consumption of organic substrates in the simulant.

Scheme 1

The scheme assumes that radiolysis intermediates HO, O-, NO3, and H (13,14) attack the organic compounds producing organic free radicals which are subsequently converted to products. According to this scheme, the reactivity of an individual substrate depends on the rates at which it is attacked relative to the rates at which other compounds including inorganic compounds such as NO2- are attacked. Therefore, the rate of disappearance of a substrate depends on its concentration, which leads to the observed pseudo first-order kinetic behavior. Nitrite ion exhibits high reactivity towards e-, H, O-, and NO3: 4x109, 7x108, 3x108, 1x109 M-1s-1, respectively. And, it is present in high concentrations (3.65 M). Therefore, it probably is the major scavenger of attacking intermediates. Figure 8 plots the disappearance rate constants vs. inverse T (C) for EDTA and citrate. Least-squares fits of the standard error-weighted rate constants yielded activation energies of 9.72.5 kj/mol for EDTA and 18.98.7 kj/mol. The smallness of these activation energies is consistent with attack on these compounds by radiolyitically-generated nonselective reactive intermediates such as H, O-, and NO3.

Although data for dodecane, stearate and hexone do not reduce as well as the data for citrate and EDTA, qualitative comparisons of reactivity are possible. For stearate, the 90C data reasonably fit the first-order kinetic model. The fitted rate constant is 0.60.1 MGy-1 (61kRad-1). This value is ~40% of the EDTA rate constant and about twice the citrate rate constant at 90C. Forceda fits to dodecane data yield rate constants that are comparable to citrate. And, similar fits to hexone data yield rate constants that are larger that those for EDTA. Thus qualitatively, the relative reactivities are hexoneEDTA>stearate>citratedodecane.

The first-order rate equation was assumed and the fit was forced through the starting concentration of substrate.

Fig. 6

Fig. 7

Fig. 8

Several solution-phase products have been identified: dodecanones, heptadecane, isobutyrate, succinate, oxalate, formate, and glycolate. Table III lists amounts of glycolate, formate, oxalate and succinate by

IC analyses of the irradiated simulant. We suspect that docecanones are from dodecane, heptadecane is from stearic acid, isobutyrate is from hexone, and oxalate, formate, and glycolate are from EDTA and citrate. Significant quantities of succinate are found in runs B1, 27, 28 that received little or no radiation. Of the organic components in the simulant, TBP was consumed consistently and totally during these runs. Tributylphosphate rapidly hydrolyzes under the reaction conditions producing butanol and DBP. Thus, butanol is a plausible source of succinate.

Table III

Generally, our studies use high radiation fluxes to simulate waste aging over times of 1 to 14 days that are experimentally and programmatically practical. A few experiments have been run and are in progress to assess the effect of flux times that are short compared to the age of tank wastes. In these experiments, similar doses were delivered over times ranging from 90 to 104 days. Only two experiments (29 and 6) run at 90C are directly comparable. The simulant received a dose of ~0.6 MGy (~60 MRad) in each experiment although the flux differed by a factor of 12. Similar levels of EDTA, the kinetically best behaved of the simulant organic compounds, was observed for high vs. low flux: 5.8 vs. 7.5 mg/g. Stearate and hexone showed similar levels in both runs, but citrate was smaller in the low flux run (8.4 vs. 3.4 mg/g) which would be consistent with a thermal contribution (Ashby (15) to its consumption at longer times. The gas data correspond, as well. The combined yields of N2 and N2O are just 24% greater for the low flux run, while H2 runs are 135%. Greater thermal contributions to H2 yields are expected (15,22). These meager results provide tentative evidence that the radiolytic consumption of organics compounds scale linearly with flux. If attack on reactants or generation of a product requires reaction of two radiolytically-generated radicals in a single step (for example, Eq. 1), then quadratic scaling is expected. If additional data confirm that N2 and N2O yields do not scale quadratically then Eq. 1 may not be key in producing of nitrogen-containing gases. The result would be more consistent with the key step being reaction of organic radicals with nitrite. In summary, the results show that thermally- and hydrolytically-stable waste components, EDTA, citrate, hexone, and NPH undergo radiation-induced degradation. Based on the observed gaseous and condensed-phase products and supporting literature information (15,26,22,29), the organic compounds in the tank wastes are degrading by oxidative processes. Degradation rates depend mainly on the strength (flux) of the radiation fields to which tank wastes have been exposed and, to a lesser extent, on tank waste temperatures. If average radiation fluxes and temperatures for various tank wastes can be estimated, then ballpark estimates of the lifetimes (i.e., 1, 10, or 100 years) of organic tank wastes can be made.

CONCLUSION

Many of the organic compounds thought to be in tank wastes have been tested to determine which and what concentrations of the compounds may react with nitrate/nitrite salts in propagating reactions (37). Surprisingly, many of the energetic organic compounds, such as NPH, TBP and DBP, did not sustain propagating reactions because they either volatilized away from the heated initiation zone or decomposed to volatile compounds and gases that escaped before propagation temperatures could be reached. The compounds at most risk for propagating reactions were organic carboxylate salts and complexants. However, oxalate and

formate have too little energy content to propagate at TOC levels found in the tank wastes.

In summary, the total energy content of tank wastes should be declining with time. However, aging processes appear to be converting high energy, nonpropagating organic compounds such as NPH, TBP and DBP to lower energy, propagating carboxylate salts. Thus, the level of risk depends on how rapidly carboxylate salts of moderate energy content degrade to low energy oxalate and formate, and in turn how fast these degrade to CO2/CO32-. Work is in progress that will address this and related subjects.

Under the TWRS program plan, we plan to examine the reactivities of butanol (a possible source of succinate and butyrate), of organic carboxylates and chelator fragments, and of DBP in tank waste simulates, as well as addresses other questions relating to waste aging. To date, much of our work has been with a SY-101-type simulant. Future experiments are planned to examine aging in salt cake simulants and the effects of moisture content on products and rates. We plan to correlate our simulant aging results with currently available and future tank characterization data. We will examine the technical feasibility of making estimates of organic compound lifetimes in the tank wastes in an attempt to predict the degree of waste aging based on historical information (10,9). To support this effort, waste contents and radiation fluxes of individual tanks need to be estimated from Hanford Tank Content Estimates.

Additional study of simulant aging is needed to determine kinetic behavior of intermediate aging products such as chelator fragments and low molecular weight acids. Study is also needed of how radiolytically-induced aging scales with radiation flux. For cases such as Tank 241-SY-101, in which organic analyses of tank waste core samples exist, we plan to learn the actual extent of aging that has occurred. We expect that a coherent picture of aging will emerge from the planned work, which will include integrating the results of Tank Safety Waste Aging Studies at a programmatic level.

ACKNOWLEDGEMENT

Pacific Northwest National Laboratory is operated for the U.S. Department of Energy by Battelle Memorial Institute under contract DE-AC06-76RLO 1830. We thank Dr. H. Babad (Westinghouse Hanford Company) for many helpful discussions.

SUMMARY OF SCIENTIFIC INVESTIGATIONS FOR THE WASTE ISOLATION PILOT PLANT*
W. D. Weart
Sandia National Laboratories
Senior Science Advisor
P. O. Box 5800
Albuquerque, NM 87185-1337
ABSTRACT
The scientific issues concerning disposal of radioactive wastes in salt formations have received 40 years of attention since the National Academy of Sciences (NAS) first addressed this issue in the mid-50s. For the last 21 years, Sandia National Laboratories (SNL) have directed site specific studies for the Waste Isolation Pilot Plant (WIPP). This paper will focus primarily on the WIPP scientific studies now in their concluding stages, the major scientific controversies regarding the site, and some of the surprises encountered during the course of these scientific investigations.
The WIPP project's present understanding of the scientific processes involved continues to support the site as a satisfactory, safe location for the disposal of defense-related transuranic waste and one which will be shown to be in compliance with Environmental Protection Agency (EPA) standards. Compliance will be evaluated by incorporating data from these experiments into Performance Assessment (PA) models developed to describe the physical and chemical processes that could occur at the WIPP during the next 10,000 years under a variety of scenarios.
The resulting compliance document is scheduled to be presented to the EPA in October 1996 and all relevant information from scientific studies will be included in this application and the supporting analyses. Studies supporting this compliance application conclude the major period of scientific investigation for the WIPP. Further studies will be of a "confirmatory" and monitoring nature.
INTRODUCTION
In 1974 the Atomic Energy Commission (AEC) began exploratory investigations for a nuclear waste repository in the salt beds in the southeast corner of New Mexico. Since January 1975 SNL has pursued scientific investigations with the ultimate goal of providing the knowledge base necessary to establish confidence in the ability of the site to safely isolate Defense Transuranic Waste and conform with all applicable waste disposal standards. Some early in-situ tests also evaluated disposal of Defense High Level Waste (DHLW) in salt beds because salt beds in Texas were one of three disposal options. Those

studies were terminated when the Congress focused High Level Waste Repository investigations on the Yucca Mountain tuff in Nevada.

During these investigations SNL has been assisted by the U.S. Geological Survey (USGS) and by private contractors, university researchers, and consultants too numerous to individually recognize. It is important to acknowledge the contributions to the WIPP scientific studies provided by the NAS and by the New Mexico Environmental Evaluation Group (EEG). Both organizations have provided valuable scientific oversight and critical review of the scientific studies since 1978. Many of the studies and approaches to the issues were generated by their thoughtful examination of the technical concerns.

Thanks to the efforts of these organizations and many dedicated SNL WIPP staff, the information developed over the past 21 years allows an informed and confident assessment of WIPP's ability to safely isolate transuranic waste from the biosphere and to comply with EPA repository standards.

The concept of geologic isolation for disposal of radioactive wastes, and in particular, utilization of salt formations, received a primal endorsement from the NAS with the publication of their report in 1957 (1). That recommendation stimulated laboratory and field studies by and for Oak Ridge National Laboratory (ORNL) culminating in the Project Salt Vault experiments (1963 to 1967) in bedded salt at Lyons, Kansas. These tests utilized irradiated nuclear fuel elements, supplemented by electric heaters, to study heat and radiation effects from large-scale experiments in salt. These tests established that salt was an acceptable host rock for radioactive waste disposal but local factors, both technical and potential, resulted in abandonment in 1972 of an AEC proposal to construct a repository at the Lyons, Kansas site.

Subsequently, ORNL and the USGS evaluated existing knowledge regarding salt deposits in the United States and selected the northern portion of the Delaware Basin in New Mexico as having the best prospects of meeting the Site Selection Criteria. By June 1974, two boreholes had explored two corners of the proposed site area when site characterization was suspended in favor of the Retrievable Surface Storage Facility (RSSF) concept. The RSSF was soon abandoned because of objections from intervenor groups and the predecessor to EPA during the environmental hearing process. The concern was that problems created by this generation were being postponed to future generations.

When the Delaware Basin site characterization was resumed in early 1975, the AEC asked SNL to assume responsibility for managing continued site characterization, facility conceptual design,National Environmental Policy Act (NEPA) studies and scientific studies related to waste disposal in salt beds.

The remainder of the paper will summarize the major geotechnical issues and scientific studies that have occurred within the WIPP program over the past 21 years. The discussion will be divided into the major categories of 1) site selection and characterization, 2) facility seals and rock mechanics, 3) fluid flow in the geologic system, and 4) waste room interactions, (including gas generation). This paper will not address the equally interesting history of the political and policy shifts over this period of time even though they often impacted the scientific program.

SITE SELECTION AND CHARACTERIZATION

SNL formally commenced WIPP studies in January 1975 and received funding in March 1975 to begin exploratory drilling activities and NEPA-related field studies. The first task was to "complete" site characterization by exploratory drilling of the remaining two corners of the 11/2x2 mile site inherited from the earlier program. The first of these proposed boreholes, ERDA6, was drilled between June 13,1975 and September 23,1975. This exploratory boring unexpectedly encountered steeply dipping and displaced strata in the Salado and Castile formations and a geopressured brine reservoir in the uppermost fractured Castile anhydrite. This unexpected geologic structure and the inability to predict acceptable repository conditions throughout the site area led to an early disqualification of that site. Site selection investigations then focused on finding a more acceptable site within the Delaware Basin (Fig. 1).
Fig. 1
Intensive evaluation of existing geologic and geophysical information that had been acquired by the potash and petroleum industries was initiated. This examination was allowed by these companies on a "company proprietary" basis. These studies established that the evaporite deformation zone encountered in ERDA6 was primarily confined to a belt about five miles wide paralleling the buried Capitan Reef. Drilling data indicated that away from this zone, toward the interior of the Delaware Basin, the Salado Formation was relatively undeformed. The renewed site selection activities, continuing to focus on the Northern Delaware Basin but using more restrictive site selection criteria generated from the evaluation (and a relaxation of borehole stand-off to one mile allowed by improved knowledge of the hydrology), resulted in the same prime alternative site being independently identified by Sandia and USGS teams in December 1975.
The center of this proposed site, about 5 miles southwest of the first location, was core drilled (ERDA9) by June 1976 and the analyses confirmed the desired bedded salt properties, the anticipated stratigraphy and relatively flat dip. This initial tentative site identification led to a broadly-based geotechnical investigation focused on this region. Between 1975 and 1980, 57 boreholes were drilled and cored to provide basic geologic and hydrologic data, potash resource information, and to aid in interpretation of geophysical surveys. These latter surveys consisted of gravity, aeromagnetics, resistivity, and seismic reflection and refraction surveys. Seismicity evaluations established that the area was basically aseismic and concluded the majority of seismicity in the Central Basic Platform area of west Texas was induced by water-flooding activity. The nearest "active" fault, i.e. exhibiting evidence of motion in the last 100,000 years, was determined to be 65 miles to the west on the western slope of the Guadalupe Mountains. Surface mapping and drilling examined features suspected of being breccia pipes, and determined that breccia pipes occurred only over the Capitan Reef and were not, therefore, to be expected at the WIPP site.
Resource evaluations for potash and oil/gas were conducted based on WIPP drill holes and seismic data coupled with knowledge of oil/gas field development and potash exploration. No other significant resources were identified. With this information the site was located to avoid major known petroleum trends and minimized conflict with potash resources to the extent possible. Complete avoidance of potential conflict with

hydrocarbons and some potash ore was known to be unattainable in this portion of the Delaware Basin.

Studies conducted by the USGS concluded that salt dissolution rates would not breach the WIPP for millions of years. Surface geology, hydrologic studies, and selected drilling and geophysical surveys ruled out point dissolution and the existence of karst geohydrology at the site.

All this geotechnical information was summarized in a site characterization report in 1978 (2). A generalized geologic cross-section is shown in Fig. 2. These characterization studies were conducted prior to the promulgation of EPA standards for nuclear waste repositories. Consequently, the site characterization criteria which governed the studies were based upon the breach scenarios, especially involving natural processes, which were generally regarded by the scientists in the national and international repository programs as being significant to repository integrity and necessary to predict the behavior of a nuclear waste repository in salt. WIPP's self-imposed criterion for the time duration of repository integrity was 250,000 years, approximately 10 half-lives of Pu-239.

Fig. 2

Certain site characterization issues became the focus of much oversight scrutiny during the '70s and early '80s. Chief among these were the salt dissolution aspects of which there were four. Regional dissolution of salt, both at the top of the salt section and within the salt beds themselves was one of the first issues addressed. The former was addressed by geologic studies conducted by the USGS determining both horizontal and vertical rates of dissolutioning over the past million years. This information established that the WIPP would not be threatened by this process for a far longer time than the 250,000 years then used as a criterion. The inter-bed locus for salt dissolution, particularly within the Castile and at the base of the Salado, had been suggested as a cause of some of the local lithologic and structural features in the Castile salt beds and as the cause of Castile salt bed thickness variations. This issue was directly addressed for suspect areas near the WIPP site by borehole drilling and core examination. This evaluation showed no evidence of dissolution features and, together with regional isopach and structural interpretations, led to the present concept of anhydrite foundering in the salt to explain the Castile variations in salt thickness. The third dissolution issue addressed "point source" dissolution as evidenced by features termed "collapse breccia pipes". These breccia pipes were cylindrical collapse structures, about 1000 feet in diameter, caused by dissolution of soluble rock at depth, ultimately resulting in collapse of overlying rock into the solution cavity with the chimney action progressing to the surface. The concern for the repository was that since these features were known to occur north of the site, they might also be developed at the WIPP, providing a permeable waterflow path through the repository horizon and leading to a breach of repository integrity. Studies by the USGS, based on drilling of known breccia pipes and other suspect features, surface mapping and one underground mining intercept, concluded that breccia pipes were not a threat to WIPP because: 1) they occur only over the Capitan Reef--a source of water for dissolution, and 2) the examination of existing breccia pipes revealed they were not a long-term permeable path for water flow.

The fourth dissolution issue dealt with the issue of karst hydrogeology. Karst was known to be well developed to the west of WIPP, in the Nash

Draw topographic depression. This karst expression was postulated by some critics to extend to the WIPP site with the associated consequence of extremely rapid hydrologic transport of any radioactivity release to the Pecos River. Subsequent geologic studies, geophysical surveys and expanded hydrologic testing failed to find any evidence of karst development over the WIPP site or along the indicated hydrologic flow path. Peer reviews of the extensive hydrogeologic database, conducted by the EEG and the NAS WIPP Panel, concluded that karst development was not a threat to the WIPP.

The final stage of the site characterization phase commenced with the Site and Preliminary Design Validation (SPDV) in July 1981. This underground excavation explored the core of the site area and enabled extensive geologic mapping for one mile in the north-south and east-west directions as well as mapping of the exploratory and exhaust air shafts. As a result of this geologic investigation and the accompanying mineralogical analyses, it was concluded that the site met the previously established siting criteria (3). DOE accepted the site and proceeded to full facility construction in July 1983.

FACILITY SEALS AND ROCK MECHANICS

A primary attribute of a salt repository is the ability of the salt to deform or creep over time thereby sealing man-made access and intrusions into the repository and preventing natural processes from causing permeable fractures or faults which could allow entry of water. This creep attribute is utilized in the sealing of repository access shafts and in predicting closure of the waste rooms and resultant encapsulation of the waste placed therein. To allow quantification of this behavior an extensive rock mechanics program has been carried out in the laboratory and in-situ at the WIPP site. Additionally, evaluation of numerous materials, both cementitious and native materials (salt and/or clay), which are candidate seal materials, has been completed.

Prior to gaining access to the WIPP underground, laboratory tests were conducted on rock salt core obtained from surface drilling. The constitutive data thus acquired were used in existing rock mechanics models to predict salt creep in the WIPP. The SNL models SANCHO and JAC were then benchmarked (4) in a program that compared nine different codes from throughout the National and International communities. This exercise revealed that similar results could be obtained from the more sophisticated codes but only if great care was given to assuring the same problem specification. Code operator set-up of the problem could significantly alter the results.

Prior to implementing in-situ tests, an in-situ test plan (5) was prepared which outlined the tests to be conducted in the WIPP underground. The rock mechanics tests in the WIPP ranged in size from single borehole to full simulation of disposal room, configured respectively for TRU and DHLW disposal. Defense High Level Waste experiments in salt were conducted to provide early information about issues that could face a proposed High Level Waste repository in a west Texas salt site.

Measurements were begun in 1983 and the final tests have only recently been terminated. These tests, which span a decade in some instances, relied primarily upon strain and displacement measurements although some tests required extensive thermocouple data. Some stress gauges were emplaced but difficulty in interpreting their results because of the "plastic" nature of the rock limited their utility. At the peak of the

in-situ test program, about 5000 channels of data, most of it for rock mechanics, were being continuously recorded. Figure 3 displays the location of the WIPP in-situ tests.
Fig. 3
The early in-situ observations of salt creep revealed that strain rates and room closure were proceeding at about three times the rate that had been predicted by pre-test modeling. This accuracy was not sufficient for sealing and room-closure prediction requirements. Several laboratory and modeling studies were implemented to establish what modifications were required to our predictive model and to our understanding of the creep process to better predict the observed behavior.
To be certain that errors were not introduced into the two-dimensional model by the geometric abstractions necessary to represent the 3-D world, a large (108-foot diameter) circular test room (Room H) with a cylinder of undisturbed salt 36 feet in diameter at the center was constructed. After acquiring data at ambient temperature for about one year (1985), strip heaters around the pillar were activated to raise the pillar temperature from 50 to 70C, near the center and at the pillar wall respectively. This greatly accelerated the creep rate so that greater strains could be accumulated during the measurement span than would otherwise be possible but assured the strain mechanisms would not be changed. Laboratory tests on salt core containing impurities and from the anhydrite marker beds permitted the model to incorporate a more detailed description of the stratigraphy within and above and below the excavation. Other improvements to the model were incorporated with the realization that transient strain could not be neglected, even long after excavation, because the continuing creep and consequent stress changes, although small at long times after excavation, were enough to cause continued transient creep behavior. The other major change was to the stress generalization, from Von Mises to a Tresca formulation. This change was supported by results from hollow cylinder, salt core tests in the laboratory. Incorporating these modifications to the model and database resulted in agreement between prediction and observation to within 10 to 15 percent--satisfactory for repository modeling purposes.
Full-scale simulation of DHLW, as well as a thermal overtest, were conducted in two test rooms, A and B. Room B and Room D provided data for identical geometry excavations, thermal effects in Room B being the only difference. In a later test a 36-inch diameter borehole 100 feet long, drilled between two-mined drifts, was instrumented to be certain that the creep phenomena observed in the large room tests and that the model adaptations to predict their behavior, were not the result of scale effects. The newly developed model has shown it can predict different scales, geometries, heated and unheated, with equal precision. Prediction of salt creep is now considered to be a resolved issue (6).
Discreet rock mechanics phenomena, such as fracture development and healing, have presented a challenging problem. The healing of salt fractures at stresses typical of the repository has been demonstrated in laboratory experiments. These experimental results support the logic that the disturbed rock zone that forms in salt around excavations will return to nearly in-situ values of density and permeability. This is an essential element in the design of effective long-term seals for the repository. Modeling has developed to the point that stress conditions and locations conducive to fracturing can be predicted as a rough function of time as an excavation deforms. Precise prediction of the time

of failure is still not possible from modeling although deformation rates obtained on failed rooms gives reasonable time estimates for rooms of the same geometry.

Response of the salt beds to internal room gas pressures caused by decomposition of the emplaced waste is still another concern to be addressed by the rock mechanics program. In-situ hydrofracture tests revealed the salt, remote from the excavation, behaves isotropically. The induced fractures don't show a preferred direction on this relatively small scale. Since the salt is layered on a larger scale, with the interbeds of anhydrite containing pre-existing fractures and with clay partings at the base of the anhydrites, these layer features will provide paths of least resistance to propagation of fractures on a large scale. These horizontal bedding features prevent fractures from developing upward through the salt, but they must be considered as potentially more permeable paths when evaluating propagation of fluids horizontally to the site boundary. Detailed calculation of discrete fracture development over large distances is not yet realistic because of natural heterogeneities in the rock. Consequently bounding approaches are taken to model this issue.

Sealing Systems (7)

Sealing systems proposed for the WIPP depend strongly upon the knowledge obtained from the rock mechanics program. The principal seals, those upon which isolation depends, will be in the access shafts into the WIPP and will consist of physically different modules which are designed to be most effective over different time scales (Fig. 4). WIPP in-situ experiments have demonstrated that cementitious seals can be very effective as soon after emplacement as the disturbed rock zone (DRZ) heals. Materials evaluation has permitted development of tailored cements that are relatively compatible with a salt environment and with the non-halite rock of the overlying aquifers. However it is difficult to prove that interface degradation will not occur over the millennia that are required of seals. Thus the WIPP will use materials natural to the WIPP environment, i.e., salt and clay, which will not be chemically foreign to the surroundings and will therefore remain stable for as long as the salt beds survive.

Fig. 4

Utilization of natural materials requires compaction to near in-situ salt densities. Experiments demonstrate that compacting crushed salt to >95% of natural density will achieve the desired permeability. This desired compaction can be initiated by tamping the emplaced material. Tests show that densities of about 90% can be attained by tamping but final compaction will rely on additional compression obtained over time from natural creep of the salt. Densification of crushed salt by applied pressure has been quantified in laboratory testing. Another advantage of tamping to achieve high emplacement density is that it decreases the time interval required to reheal the DRZ since resistive forces to creep closure build more quickly. Shaft seals relying on natural materials can be emplaced in the WIPP which will provide satisfactory seals within 100 to 200 years. During this time span, while natural material seals are becoming effective, sealing will be provided by cementitious seals at other locations higher in the shafts. Conservative properties attainable for the WIPP seals are presented in Repository Seals Program baseline position paper (7).

A third component, clay, either separately or in conjunction with crushed salt has also been evaluated. Clay may be useful to provide low permeability when water may be expected before salt creep has made the salt seals effective. Compacted clay will expand when wetted and intrude into openings and crevices, helping to reduce permeability. Another attribute of clay (but for which the WIPP does not take credit in calculating performance assessment) is its ability to sorb radionuclides should they be present in any fluid moving through a clay seal component. Should it become desirable to enhance sealing of individual waste rooms or panels or to maximize sealing of the water bearing shaft intervals, a special injection technique was developed and demonstrated in the WIPP Marker Bed 139. This development utilized a specially ground microfine cement and fluidizers to allow penetration into microfractures. The demonstration test defined the degree of penetration and the reduction in flow by comparing pre- and post-grouting flow tests.

Fluid Flow in the Geologic System

The hydrology of the WIPP site has been a subject of study since the initial site selection. Ground water flow is a possible dissolution threat as well as the primary transport mechanism for any breach scenario which may be postulated. Consequently it is important that the hydrologic system be known well enough to predict not only its present behavior but the response to future natural variations in climate as well.

Fluid Flow in the Rustler Formation (8)

The earliest studies, in the late 1970s, established that the Culebra Formation, with an average thickness of 7.7m, is the principal aquifer overlying the WIPP site and the aquifer of concern when modeling radionuclide transport. Numerous hydrologic test holes indicated the transmissivity over the WIPP area varied by several orders of magnitude with transmissivity generally decreasing to the east. Further testing which employed larger scale, long-term pumping tests, detected a "channel" of higher transmissivity (1-20 ft2/day), running north-south, on the east side of the site. This feature altered the water flow patterns somewhat but the general flow path from the repository to the site boundary is still generally southward. There has been much speculation about the cause of the general trends of transmissivity over the area and for the origin of the higher transmissivity channel. The most commonly accepted explanation for the general trend is the striking correlation with the extent of apparent salt dissolution from below the Culebra in the Rustler Formation. The more salt missing the greater is the observed transmissivity. The eastern edge of the WIPP site has all the salt still present in the section and the transmissivity is very low . The explanation for the channel is less obvious--there are no apparent structural or stratigraphic features that provide an explanation. Resistivity surveys help to provide additional spatial definition of this feature. Since geologic processes which could extend this feature or cause similar new ones are unlikely over 10,000 years, it is not critical that its origin be understood--only that we can incorporate its effect into our hydrologic model (Fig. 5).

Fig. 5

One of the most useful tools in the hydrologic test program was the implementation of the large-scale, multiwell pump test. This test could be implemented with or without the utilization of conservative tracers to accomplish several objectives. As a purely hydraulic test it has been used to establish effective transmissivity over intervals between pumping

and observation wells that range from tens to thousands of feet. By performing these tests at selected WIPP locations a much better approximation of the transmissivity field has been established. When used as a tracer test it has provided additional information on dispersivity, fracture characteristics and matrix diffusion, all important parameters in modeling transport of radionuclides.

Other observations, such as examination of the Culebra in core and in the air intake shaft, have provided insight into the nature of the porosity and fracturing. The physical variations observed in the Culebra have led to tracer studies where the different Culebra zones are isolated by packers to see which horizons contribute most to the transport and to what extent these horizons are isolated from each other.

Some chemical aspects of the Culebra saline brines south of the site are difficult to explain given the current flow model and the assumptions of steady state and confined aquifer conditions. An early interpretation, utilizing stable isotope and carbon-14 data coupled with geologic interpretations of past climate and recharge, led to an hypothesis that present conditions are not steady state but are recovering from recharge during a prior pluvial period. Current studies, using three-dimensional modeling capability, are examining the confined aquifer premise, allowing some small but perceptible level of vertical recharge to the Culebra. This concept of the hydrologic system can also explain the observed geochemistry. While it is not necessary to understand the origin of the chemical disparity to do transport modeling, a logical explanation lends confidence to our total understanding of the Culebra hydrologic system.

In addition to the field studies, extensive tests have been run to establish retardation parameters for actinides of interest. Many of these tests have been batch tests for Kd determination. Some have looked at the dolomite matrix while others have examined the clay which lines many of the Culebra fractures. A more realistic laboratory evaluation uses long cores taken horizontally in the Culebra by coring from the Air Intake Shaft. These cores, some with intact fractures, were used in flow-through tests using Culebra brine and actual isotopes. These studies provide not only a measure of chemical retardation but the extent of matrix diffusion or physical retardation. Even this best laboratory effort is at a small scale compared to the actual transport one wishes to simulate. Presently the Project does not plan on an imminent implementation of an in-situ field test with sorbing tracers. Such a test could require several years and, if conducted, should be viewed as an experiment to confirm that the conceptual transport model is not violated by observations and to establish beyond doubt that retardation does in fact occur at the field scale.

An extensive hydraulic and non-sorbing tracer test is now underway at the H-19 well complex. This test employs seven (7) wells to investigate such transport issues as dispersivity, fracture spacing and matrix diffusion. Flow in different stratigraphic layers of the Culebra will also be examined. The best interpretation of these results currently indicates that the Culebra aquifer is quite heterogeneous, and different portions of the aquifer are best modeled as either single porosity or double-porosity two-layer flow.

Fluid Flow in the Salado Formation (9)

Salt has always been considered a favorable host rock for a geologic repository because of its propensity to creep and recrystallize under stress load. This characteristic, plus the lack of observed dissolution

within the Salado, led to the assumption that water flow through the Salado would not play a significant role in repository integrity. Because of the potential for gas generation from the wastes, drill stem tests (DSTs) in the Salado were conducted from the ground surface in the late 1970s to establish whether formation permeability would confine the gas. At that time the precise stratigraphic location of the repository had not been established and the DSTs could only evaluate large intervals of the Salado. These tests indicated very low, but non-negligible permeabilities, which were sufficient to dissipate gas before build-up to high pressures. As a result of this finding, gas generation studies were terminated. Access to the underground in 1983 allowed additional observations and tests to address the issue of fluid flow in the Salado units in the immediate stratigraphic interval of the WIPP excavation. A limited number of early in-situ permeability and flow measurements in the salt indicated a disturbed rock zone of increased permeability extending a couple of meters outside the excavation and a "free field" permeability much lower (<10-20M2) than determined from the surface DSTs. Another observation was the seepage of brine to the surface of the excavations. This seepage was observed to vary lithologically, spatially, and to apparently decrease with time. Both observations led to extensive testing--to establish flow parameters of the Salado to explain and model the brine seepage and to implement gas generation experiments to better predict the potential for large volumes of gas. This was now necessary since the indicated low permeability would not allow for adequate escape of the generated gases. The added regulatory requirement (RCRA) to consider the transport of hazardous gases imposed still further incentive to understand both liquid and gas transport in the Salado.

Extensive testing of the Salado has provided considerable permeability data. The "pure" halite intervals exhibit permeabilities at or below the limit of our ability to measure--(10-23 M2). The argillaceous salt exhibits low but measurable permeabilities, one to three orders of magnitude greater than pure salt. Brine seepage has been studied by collecting accumulated brine volumes from many "sealed" boreholes. While the effects of the DRZ on these observations are impossible to rule out, the observations seem consistent with the conclusion that brine seepage occurs from argillaceous halite--not pure salt--and that interbeds and their associated clay seams are also a primary source for and transport of brine.

Despite the study devoted to this area, there is still dispute over the fundamental mechanism controlling long-term brine seepage. One view is that in the undisturbed free field, the little permeability that exists is not interconnected and therefore continued flow into the manmade porosity is not possible and brine seepage will decrease and eventually stop as the brine in the DRZ is depleted. The other view is that, although the permeabilities of the interbeds and argillaceous halite are very small, d'Arcy flow will govern brine seepage from these units, and brine will ultimately fill all porosity until internal room pressure balances the free field pore pressure. Because the operating mechanisms for either process are so slow, and the interference of the DRZ so difficult to segregate, the existing data can be explained by either model within the range of reasonable parameter selection.

A major effort to resolve this issue was to bore a 350-foot drift and seal the entrance with an effective airlock. Pore pressure data outside the walls and brine collection inside the room were obtained. Resistivity

measurements monitored the redistribution of brine in the DRZ around the room. Despite efforts to overcome the shortcomings of earlier, smaller-scale studies, the results of this test are inconclusive for the same reasons as stated above. Consequently, for purposes of performance assessment, the quantity of brine is established by assuming d'Arcy flow limited only by the hydrologic parameters appropriate to the situation.
Another aspect of the fluid flow in the Salado is the transport by fluids outward from the waste rooms driven by gas pressures in the rooms which potentially exceed the pore pressure in the formation. This is complicated by the need to consider the creation of fractures or separations at bedding planes if pressures exceed lithostatic pressure. The orientations of these openings are expected to be horizontal due to the presence of clay partings at the base of anhydrite interbeds and the presence of pre-existing fractures within the anhydrite. Both of these features may provide a minimum stress path for fracture propagation due to the lack of tensile strength across these features.
The geometry of propagation within these horizontal units is more difficult to establish. It is unlikely that a single fracture would propagate to the distance of the site boundary. Efforts of the petroleum industry to create horizontally extensive fractures has shown how unlikely this is. There may, however, be a tendency for a fracture network to develop in a generally preferred direction--perhaps influenced by such factors as regional dip. This may be accommodated in the modeling by assuming a range of "flaring angles" which are more restrictive in geometry than uniform radial propagation. Present expert opinion, however, supports the view that on a large scale, i.e. one to two kilometers, the fracturing and flow are best represented by a two-dimensional radial symmetry. It is not practical to implement an experiment which would be of sufficient scale to effectively examine this issue. The natural heterogeneity of the interbeds make extrapolation of small scale results of dubious value.

WASTE ROOM INTERACTIONS (10,11,12)

The starting point for all the WIPP performance assessment calculations is the waste disposal room and it is essential to have a good understanding of the possible range of physical and chemical conditions that control the source term and behaviors that can occur in the event of human intrusion. The physical process of room closure, fluid flow and chemical interactions are all closely coupled and can significantly affect one another.
The physical condition of the room due to creep closure can be reliably predicted as a function of time if the nature of the room contents (backfill, waste) is known. If the room is backfilled, the room closure will approach its final state of closure before internal gas pressures can build enough to provide much opposition to closure. The studies performed on consolidation of backfills such as salt or clay/salt mixtures show that they will compact to high densities and low permeabilities within 100-200 years. Therefore the nature of the waste form itself, which will vary over time with degradation, is the major uncertainty in determining the physical (and hydrologic) parameters of importance within the waste room. Experiments which assume various physical waste properties have examined the compacted properties such as strength and porosity, and indirectly, permeability. This range of parameter data is used by performance assessment to input such values as

the amount of spalled and entrained waste into flow up a human intrusion borehole (10).

The degree of porosity remaining after compaction by room closure determines the maximum amount of brine that can enter the room and cause metal corrosion and gas generation, and also establishes the amount of liquid available to solubilize the actinides.

The chemistry within a waste room will be a determining factor in the solubility of actinides in brine. Consequently, extensive laboratory tests have been conducted to establish solubility for the possible oxidation states of critical actinides at different values of brine pH. In the last few years, the question of colloid formation and their role in contributing to source term and transport have been examined. Studies indicate most colloids will not be stable in the brines present for the WIPP. Solubility, rather than colloid concentrations, is expected to be the major factor for establishing the waste room source term (11).

The source term predictions will be based on models developed using information from laboratory studies, but both solubility and colloids will be the subject of tests using real transuranic waste. These tests are of liter and drum size scale and are still underway at Los Alamos National Laboratory (LANL). The results will be used to lend confidence to the predicted range of values and, where necessary, will be factored into the model parameters.

The information obtained from the solubility program provides the knowledge base to tailor waste room conditions to lower the solubility of critical actinides. For example, backfill with a cement component would assure basic conditions for which plutonium has been shown to be less soluble.

GAS GENERATION (12)

As previously mentioned, gas generation studies were resumed when permeability studies indicated gas might not escape rapidly enough to prevent build-up of high pressure in the repository. This study received additional impetus when it became apparent that the WIPP would have to comply with the no-migration variance aspect of RCRA. While volatile organic compounds are small in volume, they could be carried towards the unit (site) boundary by the much larger volume of gases derived from waste degradation.

Gases will be generated in the WIPP primarily by anaerobic corrosion of iron and aluminum and by microbial decomposition of organics, principally cellulose. Radiolysis has been determined not to be a major gas generation mechanism relative to the other two. Recent studies confirm the gas production rates and potential established in the late 1970s. Provided sufficient brine is present, there could be enough hydrogen from metal corrosion and CO2, (primarily) from organics to generate enough gas to pressurize the repository, closed by creep, to pressures above lithostatic. Since pressure above lithostatic is not a realistic long-term pressure condition in halite, the repository would increase its volume and reduce its pressure by either expansion of rooms or creation of fractures as discussed in the prior section on rock mechanics. Studies also examined conditions which might lead to a decrease in gas production rates or volumes. Passivation of iron corrosion in the presence of high partial pressures of CO2 was considered for a time to be likely, but continued testing has shown this not to be the case. Experiments continue to show, however, that liquid phase water is necessary for corrosion to proceed--water vapor alone is not conducive to significant anoxic

corrosion rates. If sufficient brine is present for gas generation to proceed at its optimum rate, a few hundred years would be required for pressures to reach levels similar to lithostatic pressure. As gas pressure builds it will decrease, and eventually stop and reverse, the brine inflow into the room. Thus the brine-gas relationship is very interactive and potentially self limiting so that a saturated repository and lithostatic pressures may never be realized. There are factors which complicate this scenario and increase uncertainty such as the presence of a one-degree dip to the beds. This could allow brine to flow in at the bottom gas exits at the top. This is being examined in modeling calculations and will be incorporated in the final performance calculations.

Gas generation studies in the laboratory have been completed. At the Idaho National Engineering Laboratory (INEL), tests of gas generation which employ actual TRU wastes are still ongoing. These tests will serve to provide confidence in the laboratory test results and in the bounding values of gas generation the average stoichiometry model can be used to predict. Some gas generation data will also be produced by the source term tests at LANL although this is not the primary focus of these tests, and the test conditions could result in misleading rate data due to experimental conditions such as agitation.

This summary of scientific studies does not touch upon every experiment and test or upon every issue, but does indicate the major areas of investigation. With the exception of the real waste tests at LANL and INEL, all the currently-planned experimental data are now available.. In some instances it has been impractical to provide total closure to an issue through experimentation. That is where other arguments such as bounding approaches or independent professional judgment are adopted to provide an acceptable, conservative input to performance assessment.

Finally, although this discussion has focused on the experimental tests and geotechnical studies, the area of performance assessment has been a major program development in and of itself (13,14). While performance assessment requires the input from the technical studies, it is the performance assessment result and the associated sensitivity studies that can determine which experimental activities are required to improve confidence in compliance with EPA standards. Equally important, PA can be used to establish when enough testing has been completed in a given area, based upon compliance needs and uncertainty bounds indicated by the analyses.

Several studies have been carried out within the PA arena to allow the EPA probabilistic approach to compliance to be implemented. Codes which run rapidly, but reproduce the results of mechanistic calculations, allow the hundreds of necessary discrete calculations to be performed. Other issues, such as the probability of human intrusion, are critical in implementing the long-term performance modeling and have received considerable study within the PA group. The only practical approach to quantifying input parameters in this arena is through the application of expert judgment since no experiment can be devised to resolve the issues.

SUMMARY

Twenty-one years of geotechnical, chemical and physics studies have provided a comprehensive database to support a confident assessment of the WIPP's long-term performance. Some studies have fully resolved issues--others have established bounds on a range of uncertainty. The limits of our knowledge in these areas have been defined, and these

limits can be used in developing a conservative approach to compliance. The program will continue to assess the results of continuing experiments and other sources of new information to assure the performance assessment inputs and assumptions are consistent with knowledge obtained from longer duration tests.

ABSTRACT
In March 1994, the Department of Energy Carlsbad Area Office (DOE/CAO) implemented a performance-based planning method to assist in programmatic prioritization within the Waste Isolation Pilot Plant (WIPP) project with respect to applicable Environmental Protection Agency (EPA) long-term performance requirements stated in 40 CFR 191.13(a) and 40 CFR 268.6. This method, the Systems Prioritization Method (SPM), was designed by Sandia National Laboratories (SNL) to: 1) identify programmatic options (activities) and their costs and durations; 2) analyze potential combinations of activities in terms of predicted contribution to long-term performance; and 3) analyze cost, duration, and performance tradeoffs. SPM results were the basis for recommendations to DOE/CAO in May 1995 for prioritization within the WIPP project. This paper presents a summary of the SPM implementation, key results, and lessons learned.

THE SPM APPROACH

The goal of SPM was to provide information about how potential activitiestwenty-one scientific investigations, three engineered alternatives, and two waste acceptance criteriawhen viewed singly or in combination, could contribute to a demonstration of compliance with EPA long-term performance requirements for the WIPP disposal system (1-4). For each activity set (a combination of activities), SPM calculated the probability of demonstrating compliance (PDC) if the activity set was implemented, along with the activity set's projected cost and duration. These performance measures (PDC, cost and duration) were contained in a decision matrix that was analyzed to find programmatic options that maximized incremental PDC while minimizing activity set cost and duration. SNL performance assessment models were used to estimate how the disposal system might perform if activities were implemented, and this evaluation was the basis for calculating an activity set's PDC. SPM analyzed roughly 46,700 activity sets. Probabilistic performance calculations for these activity sets resulted in over 1.3 million complementary cumulative distribution functions (CCDFs).

As applied to the WIPP, SPM can be described in terms of eleven key steps (Fig. 1):

1. definition of the performance objective (i.e., long-term performance in 40 CFR 191.13(a) and 40 CFR 268.6);
2. development of a technical baseline for SPM calculations;
3. performance modeling of the baseline;
4. determination of whether the baseline was predicted to succeed or fail in meeting the performance objectives;
5. (if the baseline failed to meet performance objectives), identification of activities that, if implemented, could improve a predicted ability to meet the performance objectives;
6. evaluation of the baseline combined with potential outcomes of activities (i.e., calculation of the probability of demonstrating compliance);
7. creation of a decision matrix containing the PDC, cost, and duration for all activities and subsequent decision analysis to develop final recommendations;

8. DOE/CAO programmatic decisions about which activities to implement, if any;
9. implementation of activities;
10. re-definition of the technical baseline with actual results from the activities, iterating the overall process as necessary until the baseline is predicted to meet performance objectives; and,
11. when the baseline is predicted to comply, final compliance calculations with approved data and models, etc.

Fig. 1

A key to understanding how SPM works is in the relation between the output of the performance assessment models, the regulatory performance requirements, and decision analysis methods used to analyze results (5). It is also important to understand the role of expert judgment in performance assessment calculations.

Performance assessment models are used by the WIPP project to produce performance measures that can be compared to regulatory requirements (4). One such measure is a CCDF, which represents the probability distribution of summed normalized releases from the disposal system to the accessible environment. The WIPP disposal system is predicted to be in compliance with 40 CFR 191.13(a) if no point on the CCDF submitted in the compliance certification application to the EPA exceeds the summed normalized release limits.

While the regulatory release limits are fixed, estimates of predicted performance of the WIPP disposal system is not; they are determined by a state of knowledge that changes over time.Changing the state of knowledge through scientific investigations, implementing engineered alternatives, or modifying waste acceptance criteria can alter the position of the CCDF with respect to the release limits. Our state of knowledge can be expressed, in part, through probability distributions. For example, while the solubility of plutonium in WIPP brines is not known accurately at the present time, a range of solubilities under various chemical conditions and based on many types of existing information can be postulated, thus defining a portion of the WIPP disposal system technical baseline.

Envision the design of scientific experiments to more accurately determine the solubility of plutonium in brine. The experimental design anticipates a range of possible outcomes based on both published information and expert judgment. For simplicity, suppose that the experimental outcomes can be classified into five ranges (really probability distributions), from lowest to highest solubility. Denote the event that the experimental outcomes are in the first range by x1, in the second range by x2, etc. Denote the five possible probability distributions corresponding to the five experimental outcomes by f1, f2, etc. After the experiment is complete, our knowledge of plutonium solubility changes to reflect new information produced by the study. All uncertainty, however, will not be resolved by the experiments. Uncertain repository conditions make it impossible to know with certainty what the solubility will be. Therefore, after the experiments are completed, there is still residual uncertainty about the solubility which can, again, be expressed through a probability distribution that reflects the new evidence and that incorporates new expert judgments.

Now, suppose that we use expert judgment to specify potential experimental outcomes xi and associated probability distributions fi before conducting the experiment and use these distributions in performance assessment models to estimate the corresponding CCDFs: CCDF1,

CCDF2, etc. In addition to providing the xi and fi, we also use expert judgment to specify the relative likelihood or probabilities of the various events (xi), denoted by pi. Suppose that performance calculations predict events x1, x2, x3, and x4 will indicate compliance with long-term performance requirements but that the event x5 will indicate non-compliance. The predicted probability of successfully demonstrating compliance for the five events x1, x2, x3, x4, and x5viewed prior to conducting the experimentis then p1 + p2 + p3 + p4. This process is the fundamental basis for calculating the PDC of an activity set, the key measure of programmatic value in the SPM method. For the WIPP, this technique applies to any activity that can be expressed in terms of effects on WIPP performance assessment components.

Although this discussion has been restricted to compliance with 40 CFR Part 191.13(a), WIPP must also comply with the RCRA regulatory requirements in 40 CFR 268.6. The SPM criterion for success was that the CCDF is at all points less than the release limits and that the RCRA soil concentration limits are not exceeded. The compliance indicator (CI) for each activity set outcome indicates whether the 40 CFR Part 191.13(a) regulatory release limits and the 40 CFR 268.6 soil concentration requirements are met by the activity set. If both requirements are met, the compliance indicator is equal to one; otherwise it is zero.

For example, suppose an activity set composed of activities x1 and x2, each with two possible outcomes, and suppose that performance results show that quantitative performance requirements are satisfied only if activity x1 has outcome OA2 and activity x2 has outcome OB2. The compliance indices for each of the four possible activity set outcomes would then be equal to zero for all but the outcome consisting of both OA2 and OB2, which would have a compliance indicator equal to one. Once the compliance index (CI) values have been determined for each activity set outcome, PDC is calculated by summing the probabilities for all activity set outcomes where CI is 1. The PDC for the activity set consisting of x1 and x2 would then be calculated as follows:

Eq. 1

Thus, because all terms (outcomes) with a compliance indicator not equal to one would drop out of the PDC calculation, the PDC would equal PA2xPB2.

Because of the multiple possible outcomes of SPM activities, activity sets can have anywhere between two and nearly 60,000 possible outcome combinations, each of which corresponds to a CCDF and a compliance indicator. Thus, the PDC for an activity set represents a logically straightforward but very computationally intense set of calculations.

SPM-2 RESULTS

The first iteration of SPM (SPM-1), the prototype of SPM, was completed September 1994. It served to develop the tools needed for the second iteration (SPM-2), which was completed in March 1995 for programmatic decision making. SPM-2 used technical positions derived from WIPP project technical staff, stakeholders, and oversight groups as a starting point for establishing a baseline. Technical teams also defined proposed activities and were elicited on the predicted outcomes of those activities. Trained elicitors external to the WIPP project worked with the technical teams in a formal, structured process to elicit the parameters and models to describe the activity outcomes and the probabilities of those outcomes. Activity cost and duration estimates completed the activity descriptions. DOE/CAO and the Westinghouse Waste

Isolation Division provided information with regard to engineered alternatives, potential changes to waste acceptance criteria, and other programmatic guidance.

Potential outcomes were initially elicited for thirty-seven scientific investigations, eighteen engineered alternatives, and three waste acceptance criteria. These were screened to twenty-six discrete activities for the final SPM-2 analysistwenty-one scientific investigations, three engineered alternatives, and two waste acceptance criteria. SPM-2 used existing WIPP performance assessment computer codes, with modifications required to model the baseline and activity sets, to calculate CCDFs of potential radionuclide releases. SPM-2 evaluated more than 600,000 possible activity sets. Activities that had no performance impact were removed from the decision matrix, reducing the number of activity sets in the decision matrix to roughly 46,700. Because each activity set had multiple outcomes, approximately 1.3 million CCDFs were needed to complete the SPM-2 analysis.

For activities in the decision matrix, SPM-2 showed that the probability of demonstrating compliance generally increased, as expected, with increasing activity set cost and duration. Figure 2 shows the overall structure of the results in terms of the probability of demonstrating compliance versus activity set cost. The large cluster of diamond-shaped points (each one corresponding to an activity set) on the far left includes only scientific activities. Activity sets near the top of Fig. 2 all include one or more engineered alternative. Activity sets with a PDC of zero are not shown in Fig. 2 for reasons of clarity, but are contained in the SPM-2 CD-ROM, an information management tool produced as part of the SPM project (6). Programmatic dependencies were also apparent from general trends in the data and are discussed in the statistical regression portion of this paper.

Fig. 2

The SPM-2 baseline calculation predicted release of radionuclides in violation of 40 CFR 191.13(a) but compliance with respect to 40 CFR 268.6. About 40% of the SPM-2 activity sets also had a probability of demonstrating compliance of zero i.e., with no predicted value in supporting a demonstration of compliance. Of the remaining 60% of the SPM-2 activity sets, one half had a probability of demonstrating compliance equal to one. When conducted alone, no single activitywhether a scientific investigation, an engineered alternative, or a waste acceptance criterionhad a non-zero PDC.

Activity sets with a PDC of 1.0 included the scientific activity for colloids investigation and one of two engineered alternatives: either, (1) backfill and a pH buffer to control actinide solubility (EA1), or (2) an engineered backfill (such as clay) in combination with waste form modification (EA2). (Note that engineered alternatives and waste acceptance criteria were assumed to be optimally effective and were assigned a 100% probability of yielding the predicted performance. Subsequent sensitivity studies investigated the impact of this assumption on the final decision.) Two waste acceptance criteria (WAC) were analyzed by SPM-2. In the WAC-1 activity, steel drums used to store the waste were replaced with noncorrodible materials. WAC-1 added costs to the program and slightly reduced the probability of demonstrating compliance. WAC-2, elimination of all high-molecular weight organic compounds (such as soils) from the waste, had no discernible impact on the probability of demonstrating compliance.

The sensitivity of SPM-2 results to the probability of engineered alternative performance was straightforward to evaluate (see Ref. 3 for details). The DOE/CAO had a preliminary decision to make, either:

1. depend on a program consisting of engineered alternatives and minimal scientific investigations to provide a basis for the final compliance calculations; or
2. reserve engineered alternatives for possible use in providing assurance and depend on the scientific investigation to demonstrate compliance.

In May 1995, DOE/CAO chose the second option. Additional work has been conducted on engineered alternatives since the completion of SPM and the final balance between predicted performance of the geologic system, engineered alternatives, and waste acceptance criteria will be described in the compliance certification application to the EPA (7).

The final programmatic recommendations made to DOE/CAO in May 1995 considered the SPM-2 results along with existing information such as the 1992 WIPP PA Sensitivity Analysis (4) and some sensitivity and uncertainty analyses. The sensitivity and uncertainty analyses did not alter the recommended series of activities. Other issues that were considered in using the SPM-2 results for decision-making were:

1. The technical baseline was for SPM use only. The final project technical baseline that will be used for preparing the WIPP compliance certification application will incorporate information from the activities completed subsequent to the SPM-2 effort.
2. The results were based on calculations using mean values, and were therefore valid for discriminating between activities intended to shift a mean value for a parameter but not for discriminating between activities intended to reduce uncertainty about a mean.

ANALYSIS OF RESULTS

The SPM-2 project generated roughly 46,700 unique activity sets. In order to understand the structure of the probabilities of demonstrating compliance among these activity sets, a statistical regression analysis was conducted. This analysis employed a logit regression methodology. A logit regression assumes that a probability, p, (or other number bounded by zero and one) is related to several independent variables through Eq. 2:

Eq. 2

In Eq. 2, xi are indicator variables (0,1) and bi are regression coefficients to be estimated. Here, p is the probability of demonstrating compliance. Because the left side of the equation is unbounded at p=0 and p=1, the probability of demonstrating compliance values were decreased slightly towards 0.5 as shown in Eq. 3:

Eq. 3

An initial inspection of activity sets in the decision matrix revealed two very strong relations. First, if neither colloid activity (NS 8.1 nor NS 8.2) was included in an activity set, the probability of demonstrating compliance was zero. Second, if either NS 8.1 or NS 8.2 was in an activity set, the probability of demonstrating compliance was one as long as an engineered alternative (EA 1 or EA 2) was also in that activity set, and less than one otherwise. Both of these relations were always true and thus the first relation provided a sufficient condition for creating a probability of demonstrating compliance to equal zero. The second relation provided a condition that was both necessary and sufficient for probability of demonstrating compliance to equal one.

These two relations logically limited the PDC of activity sets without EA 1 or EA 2 to 0<PDC<1.

In the absence of EA 1 and EA 2, what scientific programs should be undertaken to achieve a high probability of demonstrating compliance? This question was important because the predicted performance of EA 1 and EA 2 did not account for the possibility that an EA might prove less effective than assumed. Moreover, there were reasons to believe that the system-wide costs of EA 1 and EA 2 might ultimately be larger than initially estimated. For these reasons and to better understand the cost/benefit tradeoffs for the scientific program, a statistical analysis was limited to those activity sets where: both, (1) NS 8.1 or NS 8.2 was present, and (2) neither EA 1 nor EA 2 was present.

Using the logit model and excluding from the data set those activity sets without either NS 8.1 or NS 8.2 and excluding those having some combination of colloid activity with EA 1 or EA 2, regression coefficients were obtained. Based on regression results, activities are ordered from those with the greatest impact to those with the least impact, creating a series of activities such that as activities are added to the series, the PDC continues to increase but at a decreasing rate (see Fig. 3). If the costs of the activities are similar, it is, in principle, possible to build a concave, monotonically increasing function that maximizes incremental PDC gained while minimizing incremental costs as more activities are added to the series. Two such activity series are shown in Fig. 3 (the two curves on the left-most side of the graph) but they are not fully concave. The far-left curve is unconstrained by duration while the middle curve is constrained by a 19-month duration. The reason that these curves are not fully concave is that there are both thresholds and interactions (synergies) among some activities. The right-most curve in Fig. 3 is a sub-optimal activity series that ultimately reaches nearly the same PDC as the pareto-optimal series but without the same ability to maximize incremental PDC per dollar at every point in the series.

Fig. 3

For both the duration-constrained and unconstrained activity series in Fig. 3, no improvement in the probability of demonstrating compliance was obtained by performing NS 8.1 by itself. (Here NS 8.1 was chosen over NS 8.2 because of equal impact on the probability of demonstrating compliance and lower cost for NS 8.1.) However, for the duration-constrained series, the addition of NS 2 and NS 4 increased the probability of demonstrating compliance to 0.56. Addition of NS 7 further increased the PDC to 0.82. As Fig. 3 shows, the addition of AST 1.2 did not increase the probability of demonstrating compliance. However, AST 1.2 was necessary to gain the PDC improvement provided by the combination of RM 1, SL 4, and DR 2. In fact, without first performing AST 1.2, the addition of RM 1, SL 4, and DR 2 produced a decrement in PDC. The same unexpected behavior occurred when one switched the order of the activities. One therefore concludes, that some interaction is taking place between AST 1.2 and the collection of three activities. Addition of any other activity to the series only brings minuscule improvements. A probability of demonstrating compliance of 0.96 is achieved from the duration-constrained pareto-optimal series.

The two left-most series are both considered pareto-optimal, that is, the series that cannot be bettered simultaneously in both cost and probability of demonstrating compliance. Faced with programmatic options

limited to the scientific programwithout engineered alternatives or waste acceptance modificationsboth the duration-constrained and unconstrained activity series appear to be logical programmatic choices. However, the duration-
constrained series, which eliminated two scientific activities (NS 3 and NS 5), resulted in virtually the same probability of demonstrating compliance as the unconstrained set and with lesser cost. The duration-constrained series was selected for implementation by the DOE/CAO.

DISCUSSION

Lessons Learned

The SPM-2 decision matrix yielded valuable information for identifying: 1) activity sets necessary to achieve a given PDC; 2) activity sets that give the maximum PDC; and 3) activities that have minimal impact on the PDC. Moreover, the use of quantitative analyses balanced with expert judgment was essential in developing insights about decision options in a highly nonlinear system. The SPM project required a significant commitment of human and computational resources but numerous improvements could be made to increase efficiency.

Information needed for the SPM analysis was acquired as expert elicitation from individuals directing the various activities and those proposing new activities. Adequate time for training participants in an expert elicitation process is essential.

Concerns were raised that the SPM baseline was excessively conservative and would not produce a useful basis for evaluation of activities. A management review was held to assure that the baseline was, in fact, appropriately balanced and integrated and that it was acceptable as the basis for performance calculations. Review is recommended of both the baseline and activities prior to performing calculations to assure appropriate consistency and integration of information elicited from many different individuals.

Side efforts (also known as side bar calculations, or side calculations) were also important in being able to keep the probabilistic calculations tractable and in preventing unnecessary conservatism in the baseline. Side efforts refer to confirmatory evaluations required to address certain technical positions embedded in the SPM-2 baseline. These confirmatory evaluations included scenario screening work, literature searches, bounding calculations, and some computer modeling.

There are computational limitations to probabilistic calculations underlying SPM. Suppose, for example, that m activities are to be considered and each activity has k potential outcomes. The number of endpoints to be evaluated is Si=1,m kim!/[(m-i)!i!], which becomes very large, very quickly. Clearly, not all combinations of activities can be evaluated. But this is where judgment and an understanding of disposal system performance can be used to create reasonable sets of activities for evaluation. Other computational schemes, such as sampling certain computational intensive parts of the performance assessment model, should be explored. In addition, multi-attribute utility analysis techniques (5) could be useful for up-front screening and focusing an initial large set of potential activities into a smaller set that require quantitative evaluation.

The usefulness of an SPM-like method depends upon the quality of the elicited information about activity outcomes, their probabilities, and the state of knowledge about system parameters and conceptual models. Retrospective analyses of SPM results can assess the degree to which

actual outcomes were consistent with elicited predictions. Bayesian updating methods could be used if SPM were applied on an iterative basis.

SUMMARY

SPM identified viable combinations of programmatic options (activities) that, if implemented, were predicted to lead to a positive demonstration of compliance with long-term performance requirements. Moreover, analysis of the results also indicated that optimal programmatic pathways existed and that these activity series could provide useful insights into which activities to cut or add if budgets changed. Indeed, the analysis indicated that a positive demonstration of compliance with the long-term performance requirements could be anticipated within the DOE/CAO schedule.

SPM focused on work to achieve compliance with long-term disposal system performance requirements and helped eliminate concerns that activities would merely contribute to scientific knowledge. SPM utilized the existing performance assessment codes to calculate the expected results of various programmatic options. Use of quantitative performance assessment tools for prioritization was essential in gaining insights into the behavior of a highly coupled, nonlinear disposal system. SPM built upon the power of both performance assessment and decision analysis techniques, providing insights for decision making.

The general method could be applied to other complex issues in the environmental and waste management arena that need to clearly focus scientific and engineering activities on specific (and measurable) objectives within cost and schedule constraints. Because SPM combines decision analysis methods with quantitative analyses, it is conceptually applicable to any complex problem for which performance objectives, performance measures, and options to achieve the performance objectives can be defined. Projects that would likely benefit most are those with a complex set of technical issues and decision options that would benefit from planning based on calculated performance, rather than expert prediction alone. Projects with significant stakeholder involvement or with multiple participants might also benefit. Finally, probabilistic techniques used to treat uncertainties in the physical system could also be used to treat uncertainties in the cost or duration of programmatic alternatives (8).

ACKNOWLEDGMENTS

This paper is a summary of work done by many people who are specifically acknowledged in a number of reports now in preparation. The authors gratefully acknowledge their participation and important contributions to this project. We would like to specially acknowledge Walt Beyeler for his significant contributions to many aspects of SPM.

ABSTRACT
As the Cold War and its artifacts came tumbling down, DOE's veil of secrecy began lifting. In the early 1990s, DOE began implementing its new culture of involving the public in its decision making process. Most meetings held by DOE facilities were tied to a regulatory requirement or a specific milestone for which DOE was seeking stakeholder input.

The Public Affairs Office at DOE's Carlsbad Area Office, which manages the Waste Isolation Pilot Plant (WIPP), is undertaking a series of meetings that break out of the traditional meeting format and establish a new model for more meaningful involvement -- by both stakeholders and the DOE. It includes the following:

A stakeholder planning group to help plan the stakeholder forum;

An independent facilitator to serve as the focal point for organizing and managing the meeting;

A policy discussion on broad-ranging issues related to the WIPP; and

Recording the meeting to preserve the ideas generated and shared for use by current decision-makers and future generations.

Key in this new meeting model is a component for feedback to stakeholders to show how their input was or was not used.

This paper documents the evaluation of a meeting format and lessons learned by working with stakeholders in the design of public participation activities.

INTRODUCTION

When the Waste Isolation Pilot Plant (WIPP) was sited near Carlsbad, New Mexico 20 years ago, the U.S. Department of Energy's (DOE) standard procedure for interacting with those affected by any of its activities was somewhere between what the DOE has termed the "Control Paradigm" and the "Public Relations Paradigm." That is, the DOE believed that while it was no longer exempt from public scrutiny, its employees were nonetheless considered the "experts" and the public should trust and accept their decisions.

During that same general timeframe, more stringent environmental laws, such as the National Environmental Policy Act of 1969 (NEPA), the Resource Conservation and Recovery Act of 1976 (RCRA), and the Comprehensive Environmental Response, Compensation and Liability Act of 1980 (CERCLA), imbued the public with a new vision of what they should expect when it comes to protection of the environment and what they can do to protect themselves when it becomes contaminated. These laws required both public and private interests to become more accountable not only to the federal government for their impact on the environment, but to the public as well.

Over time, the result was that parts of the DOE in general and its Environmental Restoration and Waste Management (EM) Program in particular, began to adopt a Public Participation Paradigm. This paradigm shift allows for the views of "stakeholders", or parties interested in DOE decisions to be integrated into the DOE's decision-making process. Stakeholders include interested or affected individuals, organizations, state and local governments, Indian tribes, environmental groups and other federal agencies.

As the DOE's WIPP program progressed, so did its interactions with the public, which slowly changed to reflect this new paradigm. Scientific and philosophical controversies surrounding the project -- which were avoided or even ignored -- are now actively engaged. The DOE's Carlsbad Area Office (CAO), which has responsibility for the WIPP, recognizes that the public determines whether a risk is acceptable or not -- and that the public's concerns and perceptions of risk carry equal validity with risk as determined by scientific theory. In WIPP's case this would include questions such as whether radioactivity or hazardous materials will move beyond the boundaries of the WIPP for 10,000 years.

WIPP INVOLVEMENT STRATEGIES UNDER THE PUBLIC PARTICIPATION PARADIGM

The First Stakeholder Forum

In early 1993, the DOE's EM Program issued guidance on stakeholder involvement. Coincidentally, the DOE began to re-think its program to perform tests with radioactive waste in the WIPP underground. The tests were designed to increase confidence in the WIPP disposal system, including the handling, packaging, transportation and emplacement of waste underground.

Consequently, the DOE held a WIPP program review -- in actuality a stakeholder forum -- in Washington, D.C., with 45 participants and 30 observers from across the country to discuss issues regarding the WIPP Test Phase. Stakeholders were called upon to assist the DOE in assessing the current WIPP program strategy and exploring alternatives in light of budgetary constraints and the passage of the WIPP Land Withdrawal Act (LWA). Another purpose of the meeting was for the DOE to gather perspectives on how it can advance the program in a way that is acceptable to stakeholders.

This meeting was particularly significant because it was one of the first meetings DOE has had with citizens in which input was actually sought and incorporated into actions. For example, when Assistant Secretary Grumbly asked the group about the soundness of DOE's intention of performing tests with radioactive waste in the WIPP underground, he received significant, thoughtful response from stakeholders.

Two participants from the National Academy of Sciences (NAS) recommended that DOE not go forward with planned tests. They and several others suggested the tests with transuranic wastes in the WIPP underground lacked scientific justification and needed to be better designed. They said that the planned experiments would not attempt to confirm the entire WIPP performance assessment computer models, but only a part of them. Instead, they recommended, the DOE should perform short-term tests on key assumptions and hypotheses, and extrapolate long-term performance projections from the short-term tests.

Relatedly, stakeholders expressed concerns about the cost and budget of the project. Assistant Secretary Grumbly asked the group how they would trim the budget, given the opportunity. A member of a technical oversight group said he would focus the testing program on compliance issues and eliminate unnecessary tests.

Outcomes of the First Stakeholder Forum

In keeping with its new public participation guidance, DOE officials considered the concerns and suggestions raised at the meeting and three months later announced a decision to conduct radioactive waste tests in laboratories and re-direct WIPP's focus to showing compliance with the Environmental Protection Agency regulations set forth by legislation. In response to concerns expressed by local leaders, the Secretary also established the CAO in Carlsbad, directing that DOE staff working in Albuquerque on the project move to Carlsbad. These actions validated the DOE's willingness to involve stakeholders in the decisions the Department makes.

The Second Stakeholder Forum

In late September 1994, the CAO held a second stakeholder forum on the WIPP. This meeting included another evolutionary component: it was organized as a series of citizen presentations during which DOE officials listened and responded to questions as appropriate rather than make any formal presentations or defend its position on issues. The meeting immediately preceded a visit from the Secretary of Energy to Carlsbad the

following week. Stakeholder concerns aired at the forum were summarized and included in the Secretary's briefing book for the Carlsbad visit. In addition, stakeholders were invited to select a representative to make a presentation on selected issues during the Secretary's visit.

Stakeholders' major messages, representing divergent points of view, to DOE/CAO officials included the following:

The DOE should provide stakeholders with timely notice of meetings and adequate time for document review. DOE's compressed schedule may affect the quality of stakeholder interactions and relationships.

The disposal decision schedule is too inflexible; "schedule" should not drive good science.

The DOE needs to examine the ethics of permanently disposing of radioactive waste in the WIPP and evaluate potential impacts on future generations.

The DOE must change the way it works with Indian tribes and recognize each is a sovereign nation.

The DOE must further examine issues of waste inventory uncertainty, engineered alternatives, treating the waste before it comes to the WIPP, site characterization, and the WIPP's ability to contain the waste safely for 10,000 years.

The DOE should continue emergency response and hospital personnel training and provide public education programs on transportation risk.

The WIPP needs to open as soon as possible. It is a solution to a national problem, and continued delays are costly.

Despite coming from different perspectives on the WIPP, participants praised the meeting for bringing together divergent views and giving both project opponents and supporters a chance to speak their minds in an open forum.

Outcomes of the Second Stakeholder Forum

In response to these stakeholder issues, the CAO made some key changes. It sought to provide earlier meeting notice and longer document review time wherever possible. It stepped up its outreach program among tribes and pueblos. And it has been deeply involved in waste inventory definition; evaluation of engineered alternatives, including solicitation of stakeholder views on proposed alternatives; consideration of waste treatment options; and long-term performance assessment.

Three issues remained to be resolved: exploration of the ethical issues, the disposal decision schedule, and site characterization. A major goal of the stakeholder forum planned for 1995 had been to explore ethical issues related to permanent disposal of transuranic waste at the WIPP. Regarding the compression of the disposal decision schedule, the CAO is committed to respond positively to the equal or stronger pressures to maintain or accelerate the schedule. Later, in response to congressional pressure, the CAO has accelerated the disposal decision date from January 1998 to October 1997. Finally, site characterization has been completed, and without apparent need to do so, DOE does not plan to revisit that issue.

The oversight in CAO's response, however, was that the overall response was not documented and provided to those who attended the forum.

The Third WIPP Stakeholder Forum

At the conclusion of the second WIPP stakeholder forum, the CAO Manager invited stakeholders to take the lead in setting the agenda for the next stakeholder forum, which would take the WIPP's stakeholder meeting model to its next step. The CAO committed to holding another forum by April or

May 1995 -- but for a variety of reasons, the date was preempted and postponed. In late Spring 1995, the CAO held several meetings on the draft Compliance Certification Application (CCA) and the RCRA Part B application. In early Fall, scoping meetings for the second Supplemental Environmental Impact Statement (SEIS) superseded the forum.

In the interim, a former manager with the New Mexico Environment Department (NMED), a person with significant credibility and contacts within the advocacy community, was sub-contracted to support, among other things, CAO's efforts on the next stakeholder forum.

Part of the CAO's commitment at the September 1994 forum was that stakeholders would be integrally involved in the planning of the meeting, and that it would not be another DOE-planned meeting. Thus, in the Fall of 1995, the CAO's sub-contractor set about organizing a stakeholder planning group to develop plans for the next stakeholder forum, which the CAO hoped to hold before the end of the year.

The most surprising outcome of the initial planning meetings was that the planning group advised against trying to meet before February 1996. At the first planning meeting, stakeholder participants said the time was too short to meet without conflicting with previously planned events, such as tribal elections. In addition, they recommended that the CAO hold forums in smaller communities along the waste transportation routes, in addition to the proposed forum in Albuquerque.

Further, some members refused to participate in the planning meetings until the CAO provided them with the budget for the overall public outreach program and the proposed forum, and documentation of responsiveness to concerns expressed at previous meetings and forums. The overall public affairs budget inside the DOE generally had become an issue in this same time frame, focusing the attention of state advocacy groups on the WIPP as one office within the DOE. The issue accelerated when an Albuquerque paper ran a story about the number and make-up of the WIPP's outreach office, and the request for both the overall and forum budget numbers should not have been a surprise.

More of a surprise was the request for documentation of responsiveness. The CAO has prepared responsiveness matrices for most of the meetings in question. These matrices provided a thorough, organized way to track who was responsible for what, and individual action items were checked off one-by-one. What had not been done as tenaciously, however, was to summarize, at the time when all the action items had been completed, the CAO's response to issues brought up at the forum and to transmit its response systematically to stakeholders. We set about taking that crucial final step.

At a second planning meeting, the group recommended that the CAO not hold the Albuquerque forum in February at all, but rather, concentrate on the recommended smaller meetings and devote available funding to the outreach and involvement program for the second SEIS. They also asked that the CAO invite representatives of diverse points of view to participate in other meetings it has with the public. After further discussion, the group agreed that it would be helpful to the public for any of the concerned entities -- the CAO, the state, or specific interest groups -- to invite representatives of diverse viewpoints to participate in meetings they may hold. This way, stakeholders would not have to attend many meetings to get a balanced picture of the issues. The group also asked the CAO to publish diverse viewpoints.

LESSONS LEARNED

Lessons learned are always somewhat more apparent in hindsight than they are in the making. The lessons below guide our future interactions.

1. Working with stakeholders can have beneficial effects on other programs. Collaboration between the CAO and its stakeholders in advance of the planning of the stakeholder was beneficial to the overall outreach effort. In our pre-forum planning, we quickly identified unresolved issues that we took action to correct.
2. Don't get stuck in a rut. Just because something works well the first and second time does not mean it will work well the third time. We found that although stakeholders praised the forums of 1993 and 1994, it was not necessarily the right thing to do in 1995. Stakeholder interests and concerns should be viewed as an on-going "video," rather than a "snapshot."
3. Be flexible. The CAO wanted to hold another stakeholder forum, but stakeholders stated loudly and clearly that their needs would be satisfied better by smaller meetings in different locations; by meetings at the generator sites; and by a beefed-up hearing process for the SEIS. The CAO's response -- without acrimony -- was, "If you do not need this meeting, we do not want to waste resources organizing it."
4. Be innovative. The CAO's initial response to the "rejection" of a stakeholder forum could have been negative. Rather, it was taken as an opportunity to work with stakeholders to develop a new model for stakeholder interactions, particularly meetings. As of the writing of this paper, CAO intends to continue to work with stakeholders to achieve a model that fits their information needs and CAO's outreach and involvement goals.
5. Tie stakeholder interactions to decisions to be made. The stakeholder forum of 1993 was for the purpose of soliciting feedback on specific decisions the DOE had to make. The 1994 version had no similar "hook," which perhaps caused stakeholders to see it as less fruitful than its predecessor. The CAO did, however, make changes in response to that forum; they simply were not as far-reaching as those of 1993, nor did the CAO provide the clear message of its changes. Stakeholders might have viewed the forum as more successful had they had a clearer idea of its impacts. One lesson here is that action items the DOE agrees to take should be viewed as promises -- as commitments to be kept. The related lesson follows in #6.
6. Make sure responses to concerns are relayed to stakeholders as soon as possible. While the CAO had tracked and responded to stakeholder concerns, it had not completed the circle at the end of the process by preparing a summary of responses and providing them to all who attended the meetings in question. This lack of an "overall" response made the CAO appear to be unresponsive. In these changing times of "more is better," it becomes a refreshing view of a new reality to see stakeholders and the DOE working together to identify the best uses of limited and shrinking funds for the involvement of the public in waste management decisions.

ACTIONS TO BE COMPLETED TO OPEN WIPP

Robert H. Neill
Lokesh Chaturvedi
Environmental Evaluation Group
7007 Wyoming Boulevard N.E., Suite F-2
Albuquerque, NM 87109

ABSTRACT

The Waste Isolation Pilot Plant (WIPP) is intended to be a repository for defense transuranic (TRU) waste in the bedded salt deposits of Southeastern New Mexico. Exploration for the WIPP site began in 1974 but the repository is not open yet. The reason for this delay is that the U.S. Department of Energy (DOE) has not yet completed the documentation to show that the TRU waste can be safely disposed in the repository. From 1974 to 1993, the DOE and its predecessor agencies planned to first emplace varying amounts of TRU waste at the underground repository for "Research and Development" or "Operational Demonstration", etc. Only since 1994 has the DOE focused on completing the scientific evaluation necessary to assess WIPP as a permanent repository. Much work still needs to be completed to prepare a robust document showing compliance of WIPP with the Environmental Protection Agency (EPA) Standards for safe disposal of transuranic waste. This document must then be certified for compliance with the disposal regulations by the EPA. The DOE plans to submit the documentation in the form of an application to the EPA in October 1996. The WIPP Land Withdrawal Act (Public Law 100-579) of 1992 requires the DOE to also demonstrate compliance with other relevant health, safety and environmental regulations. Finally, the WIPP facility must be operationally ready with radiation protection measures in place to start receiving waste for disposal and the DOE waste generators must be ready with appropriately characterized waste to start shipping the waste to WIPP.

INTRODUCTION

The Waste Isolation Pilot Plant (WIPP) has been constructed to be a geologic repository in bedded salt formation in southeastern New Mexico for permanent disposal of defense transuranic (TRU) waste. The repository is located 40 km east of Carlsbad, New Mexico, in the northern part of the Permian age Delaware Basin, at a depth of 655 meter below the surface. The geohydrologic setting of the site and a summary of the geohydrologic issues that affect the WIPP performance assessment are summarized in Chaturvedi (1993)(1). A summary of the unresolved performance assessment issues for the WIPP is provided by Chaturvedi, Lee, Silva and Neill (1995)(2).

The Environmental Evaluation Group (EEG) was established in 1978 as an interdisciplinary group of scientists and engineers to provide an independent technical evaluation of various aspects of the WIPP project to protect the health and safety of the people of New Mexico. The group is funded 100% by the DOE and has offices in Albuquerque and Carlsbad.

WHY IS WIPP NOT OPEN YET?

Site investigations for the WIPP in southeastern New Mexico began in 1974 following abandonment of the Lyons, Kansas site in 1972. The initial site for WIPP was located about 11 km northeast of the present site but was abandoned after a borehole (ERDA-6) indicated unacceptable geologic deformation, and pressurized brine was encountered in that bore hole at a depth of 826 meter. The U.S. Department of Energy (DOE) and its predecessors planned the WIPP to be a "pilot plant" and a "research and

development facility", and expected to justify emplacement of large quantities of waste as much as 200,000 drums of contact-handled transuranic (CH-TRU) waste in 1982 (3) before making the decision to use the facility as a permanent repository. This attempt to temporarily emplace some waste at WIPP continued until 1993 when it became clear that a scientific justification for experimenting with waste in an underground repository did not exist and the cost and engineering problems were too overwhelming to justify such an endeavor. The WIPP is not open for waste in 1996, 22 years after the site investigations began, because the DOE did not focus on demonstrating the suitability of the site and the facility for permanent disposal of TRU waste. Because of the lack of this focus, scientific and analytical work was not targeted towards the goal of making the decision to use the WIPP as a permanent repository until 1993.

PROCESS OF DECISION MAKING FOR A PERMANENT REPOSITORY: THE EPA STANDARDS

The purpose of WIPP is to isolate transuranic radioactive wastes that are hazardous due to the long-lived alpha emitting actinides. The WIPP waste will contain about 9 metric tons of Plutonium-239 with a half-life of 24,000 years. Thus, the decision to permanently dispose waste in such a repository has to be based on projection of the repository's integrity for several tens of thousands of years. A formal process specifically developed to conduct such an analysis is described below.

Beginning in 1979, both DOE and EEG did deterministic calculations of the radiological consequences of the radioactive waste returning to the biosphere. The 1980 DOE WIPP Final Environmental Impact Statement established that the peak discharge activity would occur at 1.3 million years. In 1985, the U.S. Environmental Protection Agency (EPA) promulgated "Environmental Radiation Protection Standards" (40 CFR 191) (4) for the disposal of high level and transuranic waste. Subpart A of these standards specifies maximum allowable radiation doses received by members of the public as a result of management and storage of transuranic waste, i.e. during operations. Subpart B of 40 CFR 191 specifies probabilistic limits of release of radionuclides to the environment for 10,000 years and requires demonstration of projected releases meeting these standards through probabilistic risk analysis called the "performance assessment". The following justification was provided by the EPA for selecting a period of 10,000 years for analyzing the integrity of a repository.

A period of 10,000 years was considered because that appears to be long enough to distinguish geologic repositories with relatively good capabilities to isolate wastes from those with relatively poor capabilities. On the other hand, this period is short enough so that major geologic changes are unlikely and repository performance might be reasonably projected. (Federal Register, Vol. 50, No. 182, pp. 38070-71, September 19, 1985).*

The EPA's disposal standards were legally challenged in 1987 on grounds, among others, that they were less stringent than the Clean Water Act of 1971, without providing any justification for the difference. The First Circuit Court of Boston remanded the Standards to the EPA for revision and repromulgation. The State of New Mexico entered into a formal agreement with the DOE within a few days to continue to evaluate WIPP against the vacated 1985 Standards because the standards were not expected to change significantly. The revised Standards were published 6.5 years later on December 20, 1993 (6). As directed by the WIPP Land

Withdrawal Act (P.L. 102-579, Sec. 8), amendments were made only to those parts of the Standards in which the Court had found fault, leaving the bulk of the Standards unchanged.

The process of assessing compliance with the EPA Standards and the status of the unresolved issues in demonstrating such compliance was described by Chaturvedi, Lee, Silva and Neill (1995) (2). The following section describes a history of this effort and a January, 1996 update on the status of the unresolved issues.

The criteria for compliance (40 CFR 194) with the standards for safe disposal (40 CFR 191) are scheduled to be issued by EPA in February, 1996.

EVOLUTION AND STATUS OF THE WIPP PERFORMANCE ASSESSMENT

The task of assessing the WIPP's compliance with the EPA Standards (4) was first assigned by the DOE to the WIPP Management and Operating Contractor, the Westinghouse Waste Isolation Division, in 1985, and then to the Sandia National Laboratories in 1986. Between 1986 and 1988, the DOE focused on making preparations to start receiving waste in October 1988. One of the 8 panels, consisting of 7 rooms, each 91.5 m x 10 m x 4 m (300 ft x 33 ft x13 ft), enough to store approximately 40,000 CH-TRU drum equivalents in the rooms, was excavated during this period. But the first "Preliminary Comparison with 40 CFR 191, Subpart B for the Waste Isolation Pilot Plant" (7) was not published until December, 1990. Two additional "Preliminary Comparison with 40 CFR 191" (8) and "Preliminary Performance Assessment" (9) were published in December, 1991 and December 1992. The WIPP Land Withdrawal Act of 1992 (P.L. 102-579) allowed the DOE to emplace up to 0.5% of the total planned capacity of the CH-TRU waste at WIPP for a test phase and also required the DOE to submit an application for certification of compliance with 40 CFR 191 Subpart B within 7 years after the first receipt of TRU waste at WIPP.

In less than one year after the promulgation of the WIPP Land Withdrawal Act, however, the DOE abandoned the idea of conducting experiments with actual TRU waste in the WIPP underground. EEG had recommended that this decision be taken and the reasons are described in Chaturvedi and Neill (8).

THE DOE SCHEDULE FOR THE DISPOSAL DECISION

After abandoning the plans to conduct experiments with TRU waste in 1993, the DOE announced an accelerated plan to demonstrate WIPP's compliance with the EPA Standards, 40 CFR 191 Subpart B. A "Systems Prioritization Method" (SPM) plan was instituted in early 1994 to determine the optimal set of "activities" (laboratory and field experiments, numerical simulations, analyses, etc.) that would demonstrate compliance. The SPM was the focus for the DOE compliance activity from March 1994 to May 1995. On June 2, 1995, the DOE announced the decision to conduct some experiments and not conduct others, based on the SPM analysis. The EEG's analysis of the SPM results showed that the particular activity set selected by the DOE was not unique for the assumed probability of demonstrating compliance, the cost, and the duration parameters. There appear to be 690 other activity sets that fulfilled those requirements. The DOE responded by stating that the decision involved a management judgement in addition to the objective analysis. In any case, it appears that the elaborate exercise further detracted the project from conducting activities that would help it demonstrate that the WIPP can be used as a permanent repository.

This is particularly significant because the DOE schedule to submit the compliance application to the EPA has become progressively tighter. According to Revision 2 (October 6, 1995) of the DOE's WIPP Disposal Decision Plan, the Compliance Certification Application will be submitted to the EPA in October 1996. To keep this schedule, the deadline for results of the experiments currently in progress for the "performance assessment" (P.A.) calculations is March 1996, and the P.A. calculations have to be completed by June, 1996. This schedule leaves no time for resolution of the performance assessment issues (see Chaturvedi, Lee, Silva and Neill, 1995) (2), and the certification process of the application may therefore be a difficult one.

OTHER ACTIONS TO BE COMPLETED

In addition to the Compliance (with 40 CFR 191) Certification Application, the WIPP Land Withdrawal Act requires other actions to be completed before TRU waste can be disposed at WIPP. Furthermore, the DOE has to make some decisions (e.g. the design of engineered barriers, shaft and panel seals, etc.) in the process of preparing the application and has to be operationally ready to start emplacing the waste. The following is a brief description of these requirements.

Waste Characterization and Inventory

The Waste Acceptance Criteria (WAC) for the WIPP waste are being changed. The generator sites have to prepare waste for shipment according to these criteria. The inventory of waste meeting the WAC is not yet clear. Because of the lack of waste characterization facilities for remote-handled transuranic (RH-TRU) waste, the RH-TRU waste is not scheduled for shipment until the year 2002 and that projection may be optimistic. Since RH-TRU canisters will be emplaced in the walls of the repository rooms before stacking CH-TRU drums and boxes, initial CH-TRU emplacement will result in lost design space for the RH-TRU.

Performance Assessment

Deficiencies continue to exist in the scenarios for breach that have not yet been analyzed, geohydrologic and waste characteristics data to support the conceptual models selected, quality assurance of data and computer codes, and justification of input parameter values in the absence of experimental data. These deficiencies will have to be resolved to conduct robust performance assessment for an acceptable compliance application.

Operational Readiness

A revised Safety Analysis Report (SAR) is being prepared to document the safety of the operations. Issues remaining to be resolved include: operation of Continuous Air Monitors (CAMs) in a heavy salt dust environment and the degree of reliance on CAMs, operational hazard studies, RH-TRU waste emplacement, and the procedures and practices to ensure radiation protection of the workers and the public.

Section 9 of the WIPP Land Withdrawal Act requires demonstration of compliance with Subpart A of 40 CFR 191 that specifies limits of radiation doses to members of the public during the operational period.

Design and Testing of the Panel and the Shaft Seals

Confirmation of the assumed permeabilities of the seals, used in the performance assessment analyses, has to be demonstrated through tests.

Engineered Barriers

Decisions to incorporate engineered barriers in the WIPP design, as required by the Assurance Requirements of the EPA standards, have yet to

be made. Backfill in the WIPP repository is required by the Consultation and Cooperation Agreement between the DOE and the State of New Mexico.

Plans for Decommissioning and Post-Decommissioning Management of the WIPP Site

These plans are required by the WIPP Land Withdrawal Act (P.L. 102-579, 1992, Sec. 7 (b)(2)).

Acquisition of Federal Oil and Gas Leases

Required by the WIPP Land Withdrawal Act, Sec. 7 (b)(4), unless the EPA Administrator determines that such acquisition is not required.

Comprehensive Recommendations for the Disposal of All TRU Waste

Required by the WIPP Land Withdrawal Act, Sec. 7(b)(5), because the WIPP is intended only for retrievably stored waste and the waste yet to be generated. About 80% of the existing TRU waste is buried in shallow ground at various DOE facilities.

Survey Identifying All TRU Waste Types at All Sites

Required by WIPP Land Withdrawal Act (Sec. 7(b)(6).

Compliance with the RCRA

The TRU waste destined for the WIPP will contain volatile organic compound (VOC) residues absorbed on metal, paper, cloth or other absorbent surfaces. The compounds present in quantities greater than 1 ppm include carbon tetrachloride (CCl_4), methylene chloride (CH_2CCl_2), 1,1,1-trichloroethane and 1,1,2-trichloroethylene (TCE). The WIPP is regulated by Solid Waste Disposal Act as amended by the Resource Conservation and Recovery Act (RCRA, 42 USC 6905 et seq) as a miscellaneous land disposal unit under 40 CFR part 264 Subpart X, and must demonstrate under 40 CFR 268.6 that VOCs will not migrate from the site. Absence of migration is demonstrated by a No-Migration Determination (NMD), to be made by the U.S. Environmental Protection Agency (EPA), and by a permit to be issued by the New Mexico Environment Department pursuant to the New Mexico Hazardous and Solid Waste Act. EPA made a No-Migration Determination for the now defunct test phase of the WIPP. Limits allowed by the EPA in the test phase NMD were based on data from headspace measurements made on about 220 drums (9). The test phase NMD conditions will not apply after closure, and potential emissions from the WIPP must therefore be recalculated.

Compliance with other Environmental Laws and Regulations

Section 9 of the WIPP Land Withdrawal Act also requires compliance with the Clean Air Act; the Safe Drinking Water Act; the Toxic Substances Control Act; the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA); and all other applicable federal laws pertaining to public health and safety or the environment.

SUMMARY

Many actions are yet to be completed by the DOE before a decision can be made to use the WIPP facility as a permanent repository for transuranic waste. Until these actions are completed, neither the Environmental Protection Agency nor oversight agencies can judge whether WIPP is safe for waste disposal.

THE NATIONAL TRU PROGRAM MANAGEMENT OF THE COLD WAR LEGACY

Mark L. Matthews
U.S. Department of Energy
Carlsbad Area Office

Jack B. Tillman
S.M. Stoller Corporation
Southwest Division

ABSTRACT

The United States Department of Energy (DOE) Carlsbad Area Office (CAO) has responsibility for developing and implementing the National Transuranic (TRU) Program (NTP). The mission of the NTP is to integrate the national TRU-waste system in order to ensure that all TRU waste under the purview of the DOE is effectively and systematically managed from its generation to its disposal. The mission encompasses the generation/storage/retrieval, characterization, certification, treatment, packaging/transportation, and disposal of TRU waste. Each element of the TRU system has varying degrees of involvement and guidance from the NTP. In keeping with the DOE goal of integration, the NTP is in the process of merging the individual generator site management efforts into one system. The touchstone of this effort is the preparation of the TRU Waste Management Plan. The benefits resulting from the Plan include savings in costs and efforts, consistency in meeting regulatory requirements, widespread use of developed technologies, and acceleration of site cleanup and permanent disposal schedules. The process for preparing the

Plan requires scrutiny of the entire TRU waste management system by means of utilizing a computer model which, by using differing scenarios, will determine the optimum configuration for TRU waste management activities. Effective integration and execution of this strategy will require centralized guidance from the NTP to the generator sites.

The DOE's goal is to eliminate temporary storage of TRU waste and achieve environmentally sound and permanent disposal at the Waste Isolation Pilot Plant (WIPP) near Carlsbad, New Mexico. In order to accomplish this goal, the National TRU system must prepare waste to support the initial opening of WIPP and provide waste for a consistent and efficient operation at the WIPP facility.

INTRODUCTION

For more than 40 years, the mission of the DOE has involved the production of nuclear weapons and conducting research with nuclear materials. These activities have generated significant quantities of radioactive wastes, which are currently stored at generation sites throughout the DOE complex. Over the past decade, national priorities have shifted, and the mission of the DOE now emphasizes environmental cleanup and safe, permanent disposal of radioactive wastes.

The NTP was established in the newly-created CAO in December 1993 to integrate and coordinate TRU waste management activities throughout the DOE complex. The mission of the NTP is to integrate the national TRU waste system to assure that all TRU waste under the purview of the DOE is effectively and systematically managed from its generation to its disposal.

TRANSURANIC WASTE

To ensure effective waste management and disposal, radioactive wastes are divided into four major categories: spent fuel, high-level radioactive waste, low-level radioactive waste, and TRU waste. The focus of this paper is on TRU and TRU-mixed waste. TRU waste is defined as radioactive material contaminated with greater than 100 nanocuries per gram of transuranic elements (elements which have atomic numbers greater than 92), with half-lives greater than 20 years. TRU waste is further designated as either contact-handled (CH) waste or remote-handled (RH) waste, depending on the dose rate at the surface of the waste container. If the dose rate is 200 millirems per hour or less, the waste is designated as CH-TRU; if the dose rate is in excess of 200 millirems per hour, the waste is designated as RH-TRU. TRU-mixed waste is TRU waste that also contains hazardous constituents (1). For the purposes of this paper, the term "TRU waste" includes both TRU and TRU-mixed waste.

Prior to 1970, there was no classification for TRU-contaminated waste. Waste contaminated with TRU radionuclides was commingled with other wastes and disposed of on-site in shallow landfill configurations. These wastes are referred to as "pre-1970 buried" wastes. In 1970, the U.S. Atomic Energy Commission (AEC) concluded that waste containing long-lived alpha-emitting radionuclides should have greater confinement from the environment. Therefore, all TRU waste generated since the early 1970s has been segregated from other waste types and placed in retrievable storage pending shipment and disposal in a geologic repository. These wastes are referred to as "retrievably stored" wastes. Until 1984 the minimum radionuclide concentration level for defining TRU wastes was greater than 10 nanocuries per gram; however, in 1984 the concentration level was revised to greater than 100 nanocuries per gram (1).

THE WASTE ISOLATION PILOT PLANT

In the 1950s, the U.S. Atomic Energy Commission requested the National Academy of Sciences (NAS) to study the permanent disposal of radioactive wastes. The NAS study concluded that disposal in deep geologic salt beds offered the greatest potential for safely isolating TRU waste from the environment. Consequently, the DOE began developing plans for a deep geologic repository. After evaluating several potential disposal sites throughout the country, the DOE selected a site in southeastern New Mexico which met all selection criteria. The WIPP, located 26 miles east of Carlsbad, New Mexico, is the first DOE facility designed to demonstrate the safe disposal of TRU waste in deep salt beds (1).

The WIPP was authorized by the DOE National Security and Military Applications of Nuclear Energy Act of 1980 (Public Law 96-174) for the express purpose of "providing a research and development facility to demonstrate the safe disposal of radioactive waste resulting from the defense activities and programs of the United States exempted from regulation by the Nuclear Regulatory Commission" (2).

On October 30, 1992, the U.S. Congress passed the Waste Isolation Pilot Plant Land Withdrawal Act (LWA) (Public Law 102-759), which transferred control of the federal land on which the WIPP is located from the U.S. Department of the Interior to the DOE. In addition, the LWA established a set of environmental, safety, and health requirements that must be met before waste can be shipped to WIPP, and required the EPA to establish disposal standards for TRU waste (3).

The WIPP facility, scheduled to begin receiving CH-TRU waste in 1998, has a design capacity of 175,600 cubic meters of CH-TRU waste and 7,080 cubic meters of RH-TRU waste. The WIPP disposal horizon is located at a depth of 655 meters below the ground surface. The waste disposal area will consist of eight panels, each of which will contain seven rooms. Each room will have nominal dimensions of 91 meters long, 10.1 meters wide, and 4 meters high. The storage rooms and panels will be excavated in stages, coordinated with the scheduled arrival of waste (1).

NATIONAL TRU PROGRAM

In order to accomplish its mission of ensuring effective, integrated, cradle-to-grave management of TRU wastes throughout the DOE complex, the NTP is developing a National TRU Waste Management Plan. The Plan will provide long-term guidance for the coordination and integration of TRU waste activities throughout the DOE complex. The Plan will also identify specific TRU waste management initiatives and provide a systematic prioritization of the projects needed to meet the principal NTP waste management objective - the permanent disposal of all TRU waste. The benefits of such a plan include savings in preventing duplication of costs and efforts, consistency in meeting regulatory requirements, expanded utilization of developed technologies, and acceleration of sites' cleanup and permanent disposal schedules.The process for developing a comprehensive National TRU Waste Management Plan is comprised of several major activities. The first involved establishing a National TRU Waste Program Management Objective, which is the cornerstone upon which all of the NTP's goals and initiatives are based. This objective is as follows:

In the interest of ensuring the health and safety of the public as well as protecting the environment, the National TRU Program will pursue the most efficient and effective means, in terms of schedule and budget, for the permanent disposal of all TRU waste (4).

The second major activity is to identify initiatives or special studies and associated milestones for each of the six functional elements of the TRU waste system. These elements are the generation/storage/retrieval, characterization, certification, treatment, packaging/transportation, and disposal of TRU waste. Each of the elements in the TRU waste system are discussed in further detail later in this paper.

Development of the National TRU Waste System Model (NTWSM) is the third major activity in developing the NTP Waste Management Plan. The NTWSM is a computer simulation model designed to evaluate the preparation and flow of TRU waste from generation and storage locations in the DOE complex to final disposal at the WIPP. The NTWSM will integrate the program initiatives, evaluate various TRU waste system configurations, and provide information for decision making and program prioritization. The first product of the NTWSM will be the evaluation, documentation, and acceptance of a baseline system configuration scenario. This baseline scenario will describe the current TRU waste system configuration and capabilities and will be used to compare the effectiveness of all other alternative system configuration scenarios. After the baseline scenario is established, multiple alternative scenarios will be evaluated to determine their effectiveness in terms of cost and schedule improvements relative to the baseline. Once optimal configurations are identified, they will be further developed, evaluated, and documented as part of the Management Plan, which will be used to provide complex-wide programmatic configuration recommendations for future fiscal years. Successful implementation of the plan will result in the maximum amount of TRU waste possible being removed from the generator sites and permanently disposed in a safe, cost-effective, efficient manner.

Stakeholder involvement will be incorporated throughout all stages of the development process, including data collection, scenario development, modeling, and post-modeling evaluations. The acceptance and implementation of the National TRU Waste Management Plan will involve many organizations, including the DOE, regulatory agencies, the National Governors Association, the DOE Federal Facilities Compliance Act (FFCAct), Policy Coordination Group (PCG), and a number of other stakeholders.

Almost all of the TRU waste in the DOE complex generated since 1970, and future TRU waste to be generated, are destined for disposal at the WIPP. Therefore, the WIPP facility is a key component of the NTP disposal strategy.

NATIONAL TRU WASTE SYSTEM

To ensure that generator/storage sites throughout the DOE complex are prepared to ship their TRU waste to WIPP in 1998, the NTP has developed initiatives in each of the six functional elements of the National TRU Waste System. Figure 1 illustrates the TRU Waste System Process in terms of these six elements and identifies significant milestones to be accomplished in developing the National TRU Waste Management Plan. A summary of each functional element, along with a description of current initiatives for each element, is provided in the following sections.

Fig. 1

Generation/Storage/Retrieval

The generation of TRU waste has evolved over time as the DOE mission has changed. In the past, DOE's major role was research, development, and production of nuclear weapons, which produced large quantities of TRU waste. Over the past decade that role has decreased and emphasis has been

placed on decontamination and decommissioning (D&D) of DOE facilities as well as the environmental restoration of the DOE nuclear weapons complex. Both of these activities are expected to add large volumes of newly-generated TRU waste to the current inventory.

CH-TRU waste is currently stored in a variety of facilitiesbermed pads, open storage, air support buildings, expandable engineered sprung structures, and conventional buildings. RH-TRU waste storage facilities consist of a mixture of shielded compartments for the remote handling of highly radioactive wastes (hot cells), covered tanks, and concrete culverts.

Storage capacity at the generator sites for CH-TRU waste is currently being built to ensure RCRA-compliant storage. If the opening of WIPP is significantly delayed beyond its 1998 scheduled opening, additional CH-TRU storage facilities will be needed. With regard to RH-TRU waste, all but two generator sites have adequate storage facilities to accommodate their existing and projected waste. The sites which do not have adequate storage capabilities are the Hanford Reservation (Hanford) and Oak Ridge National Laboratory (ORNL). These two sites have the vast majority of RH-TRU waste. ORNL has plans to construct two new facilities which, if completed as scheduled, will adequately meet its future storage needs. Hanford has the largest demand for RH-TRU waste storage. Assessments have identified an unfinished reactor facility as a possible location for storage and treatment of radioactive wastes, but it would require extensive retrofitting. Another option would be to build a facility specifically designed for RH-TRU waste storage.

According to Revision 1 of the Waste Isolation Pilot Plant Transuranic Waste Baseline Inventory Report (WTWBIR), there are approximately 72,598 cubic meters of CH-TRU waste and 1,165 cubic meters of RH-TRU waste currently in storage at the 10 major facilities (large-quantity sites) and more than 20 smaller facilities (small-quantity sites) located throughout the country. Locations of the major facilities are shown in Fig. 2. In addition, the WTWBIR indicates that approximately 50,553 cubic meters of CH-TRU and 3,650 cubic meters of RH-TRU waste will be generated from D&D and environmental restoration activities through the year 2023 (5). Table I lists volumes of stored and projected TRU waste, by site.

Fig. 2

Table I

The NTP has identified several initiatives within this functional element. One is to develop waste minimization programs at all generator sites. In addition, the NTP is preparing revisions of the WTWBIR, which will describe the WIPP inventory by waste stream and identify important waste parameters of both existing and projected waste volumes at each DOE facility. These data will provide important input to the Performance Assessment and Compliance Certification Application, which is the document demonstrating WIPP's compliance with EPA standards. The NTP will also define documentation and characterization requirements for newly-generated waste in order to preclude the need to re-characterize drums of newly-generated waste prior to disposal at WIPP.

Waste Characterization

Developing a complex-wide waste characterization program is an essential part of the NTP mission. This includes identifying waste characterization requirements and developing the required technology and methods to obtain waste characterization and inventory data that support regulatory compliance and systems planning activities. In order to ship waste to the

WIPP, the generator sites will need to characterize the waste to ensure that the WIPP Waste Acceptance Criteria (WAC) are met. The WIPP WAC document identifies and consolidates existing criteria and requirements which regulate the safe handling and preparation of TRU waste packages for transportation to and long-term emplacement in the WIPP (6). Below is a list of the major documents and regulations which form the basis for the WIPP WAC.

WIPP Land Withdrawal Act (Public Law 102-579)
Resource Conservation and Recovery Act
- Part B (40 CFR 264)
- EPA No Migration Determination (40 CFR 268)

WIPP Safety and Analysis Report
TRUPACT Safety and Analysis Report for Packaging
Compliance Certification (40 CFR 191, 40 CFR 194)

The WIPP WAC provides the specific criteria each waste package must satisfy regarding content, characterization, and documentation. Although some revision to the WAC may be necessary due to the EPA's final WIPP certification and the State of New Mexico's RCRA permit for the WIPP, waste characterization can be performed now. To ensure that the generator/storage sites comply with the WIPP's waste characterization requirements, the Carlsbad Area Office prepared a Transuranic Waste Characterization Quality Assurance Program Plan (QAPP) (7). The QAPP requires site-specific sampling plans, describes sample collection and custody procedures, and establishes the quality assurance objectives for each method used to characterize TRU waste. The QAPP requires that CH-TRU waste streams be characterized using acceptable knowledge, radioassay, radiography, headspace gas analysis, visual examination, and destructive analysis. Each generator site must develop a site-specific Quality Assurance Project Plan (QAPjP) which documents how the site will meet each of the required elements of the QAPP.

An NTP characterization initiative which was recently completed was the development of a Waste Characterization Systems Analysis, which evaluated various configurations of equipment and facilities to determine the optimum configuration for meeting TRU waste storage, transportation, and disposal characterization requirements. In addition, the NTP recently developed the Mobile Waste Characterization Systems Analysis. This analysis was an important element of the Waste Characterization Systems Analysis, but was developed separately. The mobile analysis evaluated various levels of mobile characterization capability, ranging from characterizing waste to meet only transportation requirements, to characterizing waste to meet all disposal requirements. The systems analysis determined operational requirements, defined potential alternatives to enhance current fixed characterization facilities, and identified needed characterization capabilities at TRU waste sites which do not have characterization facilities.

The NTP is currently preparing Revision 5 of the WIPP WAC document, which will reflect several significant developments since the previous WAC was last issued, such as the creation of the Carlsbad Area Office, the elimination of the previously planned Test Phase, and the submittal of several permit and compliance applications. Feasibility studies at Hanford and ORNL for alternate characterization programs and facilities, including privatization, have also been conducted.

Certification

Waste characterization activities and data are subject to certification to meet the acceptance criteria of various regulatory agencies. A key component of certification activities are the various Performance Demonstration Programs (PDPs) which assess and approve the performance of analytical facilities supplying TRU waste characterization services by applying a series of recurring performance tests to specific analytic techniques.

Major certification initiatives of the NTP include the development of PDPs for headspace gas sampling of waste drums, radioassay of waste drums, and chemical analysis of sludges, and all with periodic laboratory re-certifications. Certification initiatives also include conducting site visits, surveillances, and audits at all DOE sites that have TRU waste characterization programs to verify compliance with the WIPP WAC, QAPP, and site QAPjP.

Treatment

Treatment processes are designed to physically, chemically, or radiologically alter waste forms in order to comply with specific waste acceptance standards. The FFCAct required the Secretary of Energy to submit Site Treatment Plans (STPs) for the development of treatment capacity and technologies for treating mixed waste for each facility at which DOE stores or generates these wastes. The DOE submitted Final STPs to the EPA or, where applicable, the state regulating agency; and, by October 1995, Compliance Agreements or Consent Orders had been approved or issued for most sites.

In addition, the Carlsbad Area Office conducted a technology study to fulfill the requirements of Section 19 of the LWA, which stipulates:

> Within three years after the date of this Act, the [DOE] Secretary shall submit to Congress a study reviewing the technologies that are available and that are being developed for the processing or reduction of volumes of radioactive wastes. The study shall include an identification of technologies involving the use of chemical, physical, and thermal (including plasma) processing techniques (3).

In response to this requirement, the Radioactive Waste Processing and Volume Reduction Technology, issued in October 1995, presents background information and summaries of 35 categories of waste processing technologies. Within the 35 categories, 219 processes were reviewed. Of the processes reviewed, the vast majority apply to hazardous waste or to the hazardous component of mixed waste. Few processes presently exist at the commercial level for processing radioactive waste. Many processes that are in the conceptual or pilot stage may apply to radioactive waste; however, their availability for future use is uncertain. Development of these potential applications will depend on research funding, potential cost effectiveness relative to other technologies, and their ability to comply with current and future environmental regulations (8).

The current DOE treatment strategy consists of implementing the treatment necessary to meet the WIPP WAC. However, for waste not designated for disposal at the WIPP, treatment to other standards may be necessary. Initiatives within this element included treatment feasibility studies which examined the benefit and cost effectiveness of treatment processes provided by private companies for TRU and alpha-low-level waste at the Idaho National Engineering Laboratory (INEL) and a treatment/characterization comparison study to determine if the INEL treatment privatization feasibility study results can be extrapolated and applied to other facilities within the TRU waste complex. In addition,

data collected from the Mobile Waste Characterization Systems Analysis and the INEL feasibility study will be combined to determine the efficiency of using mobile characterization units to characterize waste for transportation to a potential privately-owned treatment facility in Idaho or at regional treatment facilities across the DOE complex (9).

Packaging/Transportation

The packaging and transportation element consists of the systems and equipment necessary to safely transport TRU waste between facilities within and across state boundaries. Packaging and transportation capabilities must meet NRC, Department of Transportation (DOT), and other applicable regulations. In addition, transportation systems supporting the WIPP have other requirements such as emergency response and generator site training to assure the health and safety of the public and the environment. A certified Transuranic Package Transporter (TRUPACT-II) and related mobile loading equipment are presently available.

The TRUPACT-II is an NRC-approved Type B packaging for the transportation of CH-TRU waste within the United States. The TRUPACT-II has a maximum payload capacity of 2,835 kilograms, including pallets, slip sheets, and waste packed in either 14 208-liter drums, two 1.9 cubic-meter standard waste boxes, or one ten-drum overpack (1). The DOE currently owns 15 certified TRUPACT-IIs. The current packaging design for RH-TRU waste is the RH-72B Cask. The maximum payload capacity of each RH-72B is 3,629 kilograms. The payload will consist of RH-TRU waste in 114- or 208-liter drums contained in a canister. The canister is a DOT 7A Type A carbon steel single-shell container, with an outer diameter of approximately 66 centimeters and overall length of 3.1 meters. Each canister is capable of transporting three 208-liter waste drums (1). The RH-72B Cask has been designed to meet NRC Type B requirements. An application has been submitted to DOE-Headquarters which will, in turn, forward the application to the NRC for a Certificate of Compliance for the RH-72B cask.

One of the NTP packaging and transportation initiatives is to find ways of expanding the TRUPACT-II Envelope of Performance by conducting tests to allow for an increased fissile gram loading limit and an increased wattage limit, which is related to the isotopic activity and gas generation rates in the TRUPACT-II during transport. The NTP is also finalizing the CH-TRU Package Optimization Study, consisting of a cost/benefit analysis of developing a new CH package for waste configurations which cannot meet TRUPACT-II requirements versus retaining the TRUPACT-II and thereby requiring some sites to repackage the waste to meet current TRUPACT-II limits. Initiatives for RH-TRU waste include completing the final certification process for the RH-72B Cask and investigating alternate packaging configurations.

Disposal

Disposal consists of the permanent, non-retrievable disposition of all DOE TRU waste. The initial disposal priority is to use the WIPP facility for TRU waste generated after 1970, the date retrievable interim storage began. Disposal recommendations for the waste volumes which are not currently designated for disposal at the WIPP are being developed in conjunction with WIPP disposal operation plans. In addition, the DOE has management responsibility for the limited volumes of TRU waste at numerous smaller facilities which can be consolidated to minimize the disproportionate waste management costs prior to disposal.

The DOE CAO is in the process of developing comprehensive disposal recommendations to be submitted to Congress pursuant to LWA requirements. The major activities necessary to support WIPP's opening are identified in the WIPP Disposal Decision Plan (DDP), which provides milestones, deliverables, and coordination points for all WIPP activities. Revision 1 of the DDP, issued October 6, 1995, shows CH disposal operations beginning in April 1998; RH operations are planned to begin in 2002.

A major initiative supporting the disposal system element is to complete the Comprehensive Disposal Recommendation Study required by the LWA. Included in the study is the portion of waste which is not currently designated for disposal at the WIPP, such as any which may exceed the WIPP capacity, pre-1970 buried waste, and non-defense waste. In addition, the NTP recently completed the RH-TRU Waste Disposal Strategy document, which established the management and disposal strategy for RH-TRU waste and satisfied a WIPP DDP milestone. The NTP is also conducting an RH-TRU Disposal Alternatives Study Assessment, which will analyze RH-TRU waste disposal alternatives for the WIPP and will make recommendations for the most cost-, schedule- and safety-effective alternatives.

CONCLUSION

Since the NTP was established in the CAO in late 1993, it has made extensive progress toward accomplishing its goals. However, a significant number of activities remain to be completed. The most important is the completion of the National TRU Waste Management Plan. This Plan will establish what needs to be done at each of the generator sites as well as establish a schedule for completing the tasks. The Plan will identify initiatives and alternatives that will vary input data into the system model. The result will be the best combination of scenarios to achieve the most efficient national system and provide the basis for resource allocation, consistent with DOE commitments (i.e., compliance agreements with states). Given the current and future resource constraints, it is imperative that the diverse TRU waste programs across the DOE system be focused toward a consistent, integrated, and long-term national management program. Once completed, the Management Plan will provide the necessary guidance and prioritization for ensuring an integrated and effective TRU waste management program consistent with the ultimate objective for the safe and efficient management and disposal of all TRU waste.

Technical Coordinator
Waste Isolation Division
ABSTRACT
The Department of Energy (DOE) is preparing for disposal operations at the Waste Isolation Pilot Plant (WIPP) in 1998. WIPP is a deep geological repository designed for the safe and efficient disposal of transuranic (TRU) wastes. The Waste Acceptance Criteria (WAC) for WIPP were initially developed by a DOE steering committee in 1980. Revision 5 reflects the latest negotiations and permit requirements from the Environmental Protection Agency (EPA), the State of New Mexico Environment Department (NMED), and the Nuclear Regulatory Commission (NRC). The regulatory requirements are combined with the requirements derived from the WIPP safety analysis performed for disposal operations and the original criteria established for safe waste handling operations.
The WIPP WAC provides a comprehensive overview of the requirements and basis for developing waste acceptance criteria to meet today's rules and regulations for transportation and disposal of TRU wastes. The authors believe that it is a comprehensive criteria and a guidance manual for generator/storage sites who must characterize and certify TRU waste for disposal at WIPP. It also provides valuable insight to future projects that may develop their own waste acceptance criteria.
The WIPP WAC presents the requirements from the following sources:
1) Resource Conservation and Recovery Act (RCRA) Permit Application
2) Land Disposal No-migration Variance Petition
3) 40 CFR 191 Draft Compliance Certification Application
4) Certificate of Compliance (C of C) from the NRC for a Type B shipping container
5) Federal Land Withdrawal Act for WIPP
6) WIPP Safety Analysis Report
7) WIPP System Design Descriptions (SDDs)
The WIPP WAC combines operations and nuclear safety requirements with transportation and hazardous waste regulatory requirements to provide a comprehensive set of criteria and requirements that ensure the safe disposal of TRU waste.
INTRODUCTION
In 1978 and 1979, the WAC for the Waste Isolation Pilot Plant were initially developed by a U.S. Department of Energy Steering Committee. The WAC Steering Committee generated a May 1980 report, DOE/WIPP-069, titled "Report of the Steering Committee on TRU Waste Acceptance Criteria

for the Waste Isolation Pilot Plant." The purpose of the original WAC was to provide performance requirements to ensure public health and safety as well as the safe handling of TRU waste at WIPP.

A series of revisions consistent with the intent of the original DOE/WIPP-069 were subsequently published to incorporate the results of ongoing project activities and the comments and suggestions from others. Revision 1, September 1981, reflects consultations between the Environmental Evaluation Group (EEG) and the Albuquerque Operations Office WIPP Project. Revision 2, September 1985, reflected continued interactions with the EEG and other TRU program participants. Revision 3, January 1989, incorporated other requirements such as those in the Resource Conservation and Recovery Act (RCRA) and the TRansUranic PACkage Transporter-II (TRUPACT-II) Certificate of Compliance (C of C) from the U.S. Nuclear Regulatory Commission (NRC). Revision 4, December 1991, added specific requirements for the Test Phase. Revision 5 of the WAC reflects the organizational restructuring of the DOE, deletes the Test Phase requirements and updates other requirements instituted since the issuance of Rev. 4.

DOCUMENT LAYOUT

WAC Rev 5 defines current criteria and requirements for characterization, certification and acceptance of TRU and TRU mixed waste at the WIPP. The derivation of the criteria defined in this WAC is shown in Fig. 1.

Fig. 1

As depicted by Fig. 1 the WAC now has its basis or justification in a new set of documents that were not previously published. Because the WAC criteria can now be referenced to WIPP-specific requirements documents the justification section of each criterion was deleted from the current revision.

The criteria and associated requirements needed to ensure safety and compliance are listed in Table I "TRU Waste Acceptance Criteria Summary". The "CRITERIA" column lists the individual criterion addressed in the WAC and the "REQUIREMENTS" columns list the limits or controls applied to each criterion.

Table I

In the WAC document the criteria and requirements for waste certification and acceptance are subdivided into 3 areas, WIPP Operations and Safety Requirements, Transportation Requirements, and Environmental Compliance Requirements. Each subsection lists its own requirements for each criterion. The WIPP Operations and Safety Requirements ensures TRU waste is received and disposed in a manner which protects the public and WIPP personnel. The requirements that limit criteria under this area are derived from the WIPP Safety Analysis Report (SAR) and the WIPP System Design Description (SDD) for waste handling. The Transportation Requirements ensure no release of the payload contents from the packaging, if and when subjected to extreme accident abuse. The requirements under this area are derived from the TRUPACT-II and draft RH 72B Cask Safety Analysis Reports for Packaging (SARPs). Environmental Compliance Requirements ensure that wastes comply with the limits set by the Environmental Protection Agency (EPA), New Mexico Environmental Department (NMED) and Congress. The requirements under this area are promulgated in several documents. These documents are the:

- WIPP RCRA Permit Application
- draft No-Migration Variance Petition
- Waste Isolation Pilot Plant Land Withdrawal Act, Public Law 102-579

It is the generators responsibility to ensure that the waste meets all of the WAC requirements. For ease of understanding and displaying the criteria they were grouped into five categories. The categories are:

Container and Physical Properties
Nuclear Properties
Chemical Properties
Gas Generation, and
Data

The WAC requirements have in the past caused some confusion for generator sites because of the number of requirements required for each criterion and the concept of most limiting condition. In WAC, Rev 5, the requirements have been combined in a summary table which lists the minimum requirements which must be met to demonstrate full compliance with each criterion. To further help the generator/storage site a compliance description section is written for each criterion. The compliance section describes the activities or actions that must be taken to demonstrate full compliance with each criterion. In addition to the organization of the criteria and requirements, the contact-handled (CH) criteria are presented separately from the remote-handled (RH) criteria.

TECHNICAL CONTENTS

WAC, Rev 5 has several technical changes from the Rev 4 version. Some of the more extensive changes are as follows:

The criterion for particulate size and quantity was deleted. This criterion was based on reducing the severity of a dropped drum accident. The latest analysis in the WIPP SAR concluded that accident results are not dependent upon the amount of particulate in the waste form. Neither the TRUPACT-II SARP nor RCRA addressed particulate in the waste, so the criterion was discontinued.

The requirements for liquids was rewritten to clarify the position on free liquids detected in the payload containers. The criteria now clearly states that it is acceptable to have up to 2 liters of liquid total in a 55 gallon drum (~1% of the drum volume). This is not a change from Rev 4, but a clarification of what has always been the intent of the criterion

The ten year life of the bar code labels on drums has been deleted. The requirement for WIPP operations is that it is readable at the time of receipt at WIPP.

The criterion for removable surface contamination on payload containers has been revised to bring it in line with the DOE Rad Con Manual. This is actually a reduction in allowable surface contamination from the Rev 4 requirements. It is not expected that this lower requirement will impose a hard ship on generators because the limits are the same as are currently required by the DOE Rad Con Manual.

The requirements for the payload container (i.e. 55-gallon drum, etc.) has been rewritten to reflect the current configuration of WIPP waste handling operations equipment, the TRUPACT-II and what has been described in the RCRA permit application. There are numerous other payload configurations, but currently, the only containers that can be characterized, shipped in a TRUPACT-II or RH 72B cask and have been described in the permit applications are the DOT Type A 55-gallon drum, TRUPACT-II Standard waste Box (SWB) and the RH canister described in the RH 72B Cask SARP.

The CH TRU drum loading limit for acceptance at the WIPP was reduced from 1000 to 80 Plutonium Equivalent Curies (PE-Ci). The allowable drum

loading activity of 80 PE-Ci resulted from a resent reanalysis of the TRU waste inventory and calculated off-site dose form postulated waste handling accidents. The new drum loading limit of 80 PE-Ci was determined using acceptance criteria for off-site doses to the general public at the WIPP exclusion area boundary rather than at the WIPP Land Withdrawal boundary. Drums exceeding 80 PE-Ci may still be accepted for disposal at the WIPP; however, additional analysis will be required to determine if additional safe guards are necessary to protect the public, workers and environment.

New requirements limiting the levels of drum headspace VOC concentrations was added. The new limits are based on Back-Calculations from the Health-based levels in the draft No-Migration Variance Petition.

New requirements for waste characterization and documenting the characterization techniques was added to the data requirements. This caused a new form called the Waste Stream Profile Form to added to the WAC. The new form will provide WIPP with documentation of actions taken to characterize waste for disposal in the WIPP. This completed form and selected reports from the WIPP waste information system will be part of the records for waste characterization that will be kept at the WIPP.

CERTIFICATION

WAC, Rev 5 furnishes guidance for the preparation of deliverables necessary for implementation of site and waste certification. Site certification and waste certification are imposed on TRU waste generators in lieu of sampling waste at the WIPP. This is because sampling waste at WIPP is neither practical nor economical. Site certification involves generator sites developing written programs that ensure wastes are properly characterized and certified to the requirements required for transportation and disposal of TRU wastes at the WIPP. Site certification is the written acknowledgment by the DOE/Carlsbad Area Office (CAO) that a generator site has the capability to meet the requirements of the TRU Waste Characterization Quality Assurance Program Plan (QAPP) and the WIPP WAC. The CAO ensures these programs are in place and functioning properly by reviewing and approving key generator site documents and performing periodic (annual) audits of the generator sites for evidence that the programs are functioning as described in the site specific documents. Waste certification involves determining and documenting that the waste meets the requirements of the QAPP and the WAC. Waste Certification is the generator sites written assurance that waste containers shipped to and disposed of in the WIPP meet the requirements for transportation and disposal. The WIPP periodically reviews characterization, certification and shipping data maintained by generator sites to verify compliance. Generator/storage sites (sites) must characterize their waste on a waste stream basis to site specific and WIPP approved plans. After characterization of individual payload containers a TRU waste data package is transmitted to the WIPP via the WIPP Waste Information System (WWIS). WIPP personnel review the data package for completeness and acceptability and provide appropriate notification to the Site. When sufficient data from a particular waste stream have been submitted, the site prepares a summary of the waste stream information and reconciliation with the Data Quality Objectives (DQOs) defined in the TRU Waste Characterization Quality Assurance Program Plan (QAPP). This summary is compiled in a Waste Stream Profile Form. The form is completed by the generator/storage site and approved and maintained on file by the WIPP for acceptance information on future waste shipments waste. Waste in

payload containers from approved waste streams are certified for disposal in the WIPP in accordance with the WIPP WAC. When enough payload containers have been assembled to form a shipment they are certified for shipment in the TRUPACT-II for the CH wastes or the RH 72B Cask for RH wastes. The disposal and shipping certification data is transmitted to the WIPP for approval using the WWIS.

SUMMARY

The WIPP WAC is a comprehensive document containing the latest criteria and requirements for TRU mixed waste transportation and disposal. The WAC provides comprehensive operational safety, transportation and RCRA requirements presented in a simple user friendly format. In addition to the waste acceptance criteria and requirements, generator/storage site certification, characterization and data reporting requirements are established.

STORED TRANSURANIC WASTE MANAGEMENT PROGRAM AT THE IDAHO NATIONAL ENGINEERING LABORATORY*

Thomas L. Clements, Jr.
Lockheed Idaho Technologies Company

ABSTRACT

Since 1970, the Idaho National Engineering Laboratory (INEL) has provided interim storage capacity for transuranic (TRU)-contaminated wastes generated by activities supporting U.S.national defense needs. Approximately 60% of the nation's current inventory of TRU-contaminated waste is stored at the INEL, awaiting opening of the Waste Isolation Pilot Plant (WIPP), the designated federal repository for permanent disposal of defense-generated TRU waste. A number of activities are currently underway to enhancing current management capabilities, conducting projects that support local and national TRU management activities, and preparing for production-level waste retrieval, characterization, examination, certification, and shipment of untreated TRU waste to WIPP in April 1998. Implementation of treatment capability is planned in 2003 to achieve disposal of all stored TRU-contaminated

waste by a target date of December 31, 2015, but no later than December 31, 2018.

INTRODUCTION

Transuranic waste is defined (1) as material that has negligible economic value and is contaminated with alpha-emitting radionuclides with an atomic number greater than 92 and a half-life greater than 20 years, and in concentrations greater than 100 nCi/g. Since 1970, the INEL has placed approximately 60% of the nation's contact-handled (CH) TRU-contaminated waste in interim retrievable storage pending establishment of a permanent disposal repository. Approximately 65,000 m3 of TRU-contaminated waste contained in about 129,000 drums and 11,000 boxes and bins are in storage at the INEL Radioactive Waste Management Complex (RWMC). These wastes are stored either in air-supported or pre-engineered metal buildings, or on earthen- or tarpaulin-covered asphalt pads. The total stored TRU mass is 823 kg with 500,000 Ci of activity.

This paper will discuss ongoing activities to: 1) enhance INEL TRU waste management capabilities, 2) conduct technical support projects supporting both local and national needs, 3) implementing full treatment of TRU-contaminated waste at INEL,and 4) identify future strategic direction.

BACKGROUND

Since the early 1980s, the INEL has been on a path to evaluate and improve TRU waste management capabilities. Characterization of various aged waste was performed in 1980-1985 to support development of real-time radiography (RTR) as a nondestructive waste certification technique, address issues related to radiolytic production of hydrogen in waste drums, and support development of the waste certification process (2,3).

The INEL Stored Waste Examination Pilot Plant (SWEPP) was constructed and placed into operation in August 1985. The SWEPP facility provides capability to weigh and nondestructively examine the contents of waste containers for compliance with WIPP Waste Acceptance Criteria (WAC) without container opening, to perform nondestructive assay (NDA) for determining fissile material content and total TRU activity of a waste package, and to perform ultrasonic examination of drums to verify metal wall thickness to meet transportation requirements. The SWEPP facility was placed in operational standby in late 1989 due to delays in opening WIPP and promulgation of final WAC. In 1991, limited operations were initiated to support the WIPP Experimental Test Program and waste characterization activities.

The INEL Drum Venting Facility (DVF) was designed, constructed and placed into operation in May 1987. The purpose of this facility is to remotely puncture a drum and install a carbon composite filter to allow pressure equalization and aspiration of radiolytic-produced hydrogen. Drums destined for WIPP will be vented and the headspace gas sampled. Vented packages are required for transportation if the Transuranic Package Transporter-II (TRUPACT-II) is used as the shipping container.

The INEL TRUPACT-II Loading Facility (TLF) was designed and constructed in October 1988. The facility was brought to operational status in November 1990 to provide shipments of TRU-contaminated waste to Argonne National Laboratory-West (ANL-W) to support preparation of experimental bins for the underground radioactive tests currently at WIPP. Currently, shipments are made for characterizing waste to support WIPP efforts to demonstrate compliance with regulations governing disposal of TRU mixed waste. Use of the TRUPACT-II was implemented in April 1992. Over 35

shipments using the TRUPACT-II have been completed to support characterization efforts.

PROGRESS TOWARDS READINESS FOR DISPOSAL

For the past several years, the INEL has initiated projects to enhance operational capabilities to manage the stored TRU-contaminated waste, to evaluate and upgrade existing waste certification systems to meet new quality assurance objectives for waste characterization, and to conduct technical support activities that meet INEL, U.S. Department of Energy (DOE)-Carlsbad Area Office (CAO) National TRU Program (NTP), and WIPP needs.

Facility Enhancements

In 1989, two Line-Item Construction Projects (LICP), consisting of several subprojects, were initiated to enhance the existing facility infrastructure and increase operational capability to support waste storage, retrieval, and characterization needs. Figure 1 provides an overview of key construction activities.

Fig. 1

Construction has been completed on eight new storage buildings. A Type I Storage Module was constructed over the existing DVF and primarily supports activities performed prior to waste examination at SWEPP. These activities include a warming area for waste containers, drum venting operations, and an aspiration area used to store vented drums for up to eight weeks to aspirate hydrogen. This storage module is a 3790 m2 pre-engineered metal building, 1340 m2 of which is heated to support container warming and aspiration operations.

Seven Type II Storage Modules have been constructed to support waste storage operations. The modules were designed to comply with Resource Conservation and Recovery Act (RCRA) requirements for permitted storage. The modules are approximately 2675 m2 and will contain about 16,000 drums or 2000 waste boxes. The modules are pre-engineered metal buildings with Type K concrete floors and 6-inch berms to meet RCRA containment requirements. The modules are unheated and include a forced-air ventilation system. Two storage modules are currently operational and are receiving waste from air-supported buildings to meet a 1992 Consent Order with the State of Idaho on storage of TRU-contaminated mixed waste. The remaining five modules will be operational by March 1996. The storage modules will be operated in accordance with the RWMC RCRA Part B permit issued by the State of Idaho in November 1995. One storage module will be used only for storage of environmental-remediation-derived waste from activities being performed at the RWMC on pre-1970 buried TRU-contaminated waste.

An Operations Control Building (OCB) was constructed and placed into operation in April 1995. The OCB is a single story pre-engineered metal building approximately 2230 m2. The OCB provides main access control to the RWMC, a changing area for operations personnel, office space for managerial and technical staff, a personnel training area, and conference rooms. The OCB will also serve as the Emergency Control Center for ensuring rapid and efficient response to abnormal operating situations.

Several site improvement projects have been completed to support new facilities. These improvements have included upgrades to the power supply line to meet anticipated power demands, providing fire and potable water to new facilities, a new sewer system and treatment lagoon, and a new communications/alarm system to support the additional facilities.

A Retrieval Enclosure (RE) is currently being constructed over TRU-contaminated wastes stored on asphalt pads under earthen- or tarpaulin-cover. The purpose of the RE is to reduce weather-related degradation of stored waste containers by providing an enclosure over the storage pads to allow year-around retrieval of waste containers and to provide the necessary utilities and systems to retrieve stored waste. The RE, which is weather-tight, has a nominal free span of 366 m by 61 m for one pad, and 146 m by 49 m for the second pad. The total area enclosed is about 29,170 m2. The retrieval work area will be defined by two moveable partitions or shrouds to provide ventilation control and maintain a negative pressure with respect to outside pressure. Ventilation system exhaust air is filtered by a baghouse and High-Efficiency Particulate Air (HEPA) filtration system. The shrouds support selected utilities needed in the retrieval area such as ventilation ducts, lighting, and electrical connections. Heating of the active work space is provided for year-around operation. A dry-pipe fire protection system is used. An oil-free breathing air distribution system is provided to support off-normal retrieval activities, such as retrieval of a breached container. Equipment used to support retrieval operations will include a mobile vacuum system for cleaning off soil overburden on waste containers, forklifts, an excavator called T-Rex with interchangeable end-effectors for removal of soil overburden and retrieving waste containers, and an isolation unit for use when dealing with contaminated containers. Construction of the RE will be completed by July 1996.

A Waste Characterization Facility has been designed to provide an isolated and controlled environment for opening, examining, and sampling the contents of waste containers. These activities will be performed to meet RCRA characterization requirements specified by final WIPP disposal criteria and for storage by the RWMC RCRA Part B permit. Features of the WCF include capabilities for opening drums and boxes in a glovebox environment, coring capability for sampling sludges and other solidified process residues, remote waste sorting, and repackaging capability. Other functions that WCF could perform include repackaging waste that does not meet WIPP WAC into a form that can be shipped to WIPP for disposal, providing characterization of waste forms that will be treated, and providing limited-scale treatment (e.g., solidification, amalgamation) of certain waste forms. Title II design of the WCF was completed April 1994. Initiation of construction has been deferred until decisions concerning privatization of characterization and treatment services are completed.

System Upgrades

Upgrades to several key existing systems are being made to either improve the operational capability, improve efficiencies, or implement new requirements defined in the TRU Waste Characterization Quality Assurance Program Plan (QAPP) (4).

The DVF is currently being modified to alleviate operational constraints imposed to ensure organic emissions do not exceed allowable limits, and to improve efficiencies and reduce costs associated with performing drum headspace gas analysis to determine the concentration of volatile organic compounds (VOCs)to meet WIPP WAC and transportation requirements. A VOC recovery unit consisting of an activated carbon absorption system has been installed to reduce organic emissions. A headspace gas sampling system has been designed and installed to automatically collect a gas sample during remote venting operations. A Fourier transform infrared (FTIR) spectrometer, developed to reduce waste characterization

analytical costs for determining drum headspace VOCs, will provide automated analysis of samples from each drum. A Residual Gas Analyzer has also been installed to determine hydrogen and methane concentrations in the headspace gas sample. The results of these analyses will be used to determine compliance with VOC concentration limits imposed by final WIPP WAC and the presence of flammable gases exceeding allowable facility safety or transportation limits.

Upgrades to the existing SWEPP NDA systems have been ongoing for several years. In 1993, use of high-resolution passive gamma spectroscopy was implemented to support passive-active neutron (PAN) assay measurements. Addition of the gamma spectroscopy system was necessary to determine the relative mass ratios of various isotopes contained in the nuclear source material in the waste. Although the primary contaminant is weapons-grade plutonium, other isotopes such as U-235 and AM-241 have been identified and must be accurately reported to meet waste characterization and transportation criteria. Current efforts are focused on upgrading hardware and software to improve data collection, data analysis, and operation. The PAN system electronics are being replaced with state-of-the-art electronics, such as shift registers. The improved shift register electronics will allow higher count rate data collection needed for wastes containing high (a, n) reactions. Software modifications are being developed to integrate the PAN and gamma spectroscopy systems to provide quantities of isotopes that must be reported, self-diagnostic checks to flag data inconsistencies and reduce manual review of data, and more user-friendly software for technicians operating the system.

Technical Support Projects

Several key technical support projects are being performed to implement new TRU Waste Characterization QAPP requirements to support future production-level waste examination and certification activities and ongoing NTP projects.

The Waste Certification Program is currently undergoing revision to ensure all aspects of the TRU Waste Characterization QAPP have been addressed and incorporated. Logic diagrams or process flow sheets depicting the cradle-to-grave waste management process have been developed, and activities and data that must be performed or collected to meet QAPP and final WIPP WAC have been built into the flow sheets. These flow sheets will form the basis for determining tasks that must be completed to effectively implement all requirements that allow certification and shipment of waste to WIPP.Evaluation of SWEPP NDA system performance and demonstrating compliance with TRU Waste Characterization QAPP requirements are among the most challenging and difficult aspects of future efforts to certify waste for shipment to WIPP. Calibration drums representing several major stored waste streams have been developed, nuclear sources fabricated to meet stringent quality assurance requirements are being procured, and programs are underway to demonstrate NDA system compliance with precision, accuracy, and minimum detectable concentration quality assurance objectives. Total uncertainty, which is the propagated uncertainty of all corrections and factors used by the NDA system during assay, is being performed on a waste form basis. Because of the wide variation in stored TRU-contaminated waste forms and the resulting affect on NDA system response, it is not economically practical to fabricate calibration standards to experimentally assess total uncertainty. Two approaches have been developed to address total uncertainty. One approach uses a neutron transport and temporal response

calculational method based on the Monte Carlo Neutron Photon (MCNP) code. Total uncertainty evaluations have been completed for graphite molds, and are underway for combustible, glass, and sludge waste forms. For solidified process waste forms, such as sludges, a statistical sampling method is being developed. During coring and sampling of sludge waste forms for RCRA analysis, representative samples will also be collected for destructive radiochemical analysis to quantify radioisotopes in the waste. The results from radiochemical analysis and the SWEPP NDA measurements for each of the drums sampled will be used to complete the total measurement uncertainty evaluation.

The Gas Generation Test Program consists of performing controlled tests with actual containers of CH-TRU waste to collect data and quantify the gas generation properties of the waste under simulated transportation thermal conditions. These tests will be performed due to concerns that hydrogen and methane concentrations in shipping containers destined for permanent storage could exceed their flammability limits. Waste to be tested will be placed in one of five heated enclosures which simulate temperature increases due to decay heating, warmed to 57C - 63C, and held until steady state is attained. An offgas collection system is attached to the carbon composite vent filter installed in the waste drum so that total gas flow may be measured, and samples can be directed to a process mass spectrometer for analysis. The mass spectrometer measures the concentrations of hydrogen and methane in the offgas at frequent intervals during the test. Figure 2 is an internal view of the gas generation test assemblies. The Gas Generation Test assembly is in the final stages of performance testing now, and will be operational in February 1996. The Gas Generation Test Program will also support the Matrix Depletion Program by measuring the concentrations of hydrogen and methane to verify that the rate of gas generation decreases as gas producing matrices (e.g.,combustibles, organic sludges) are depleted.

NTP Support Projects

Since 1990, the INEL has been actively involved with DOE-CAO efforts to demonstrate WIPP compliance with disposal standards and supporting NTP Office objectives. Key technical support projects have included: 1) development of the TRU Waste Characterization QAPP and Performance Demonstration Programs (PDPs) supporting characterization of TRU and TRU-mixed wastes, 2) characterization of stored TRU-contaminated waste to support WIPP data needs for regulatory compliance documents, 3) development of advanced waste characterization methods to reduce waste generator/storage site costs, 4) development of a method to determine internal waste package VOC concentrations without intrusive sampling, 5) developing a system-wide computer simulation model to support national strategic planning efforts, and (6) developing a program to reduce the impact of current transportation wattage restrictions on transportation by analyzing and modeling depletion of gas-producing waste matrices.

Data quality objectives have been developed to provide a uniform and complete suite of requirements that must be met prior to disposing of TRU waste at WIPP. The objectives, which are compiled in the TRU Waste Characterization QAPP, support ongoing efforts at WIPP to demonstrate compliance with regulations governing transportation and disposal of TRU waste. The QAPP has been reviewed by the external DOE agencies that have regulatory authority over WIPP. The intent of the QAPP is to provide generator/storage sites with a single document that identifies characterization requirements that will provide data of known quality to

meet various regulatory compliance needs. Additionally, specific guidance for sampling and analysis methods to be used during TRU waste characterization processes was developed and documented in a guidance manual (5). Several PDPs have been developed to provide an independent method for evaluating and ensuring a waste generator/storage site method for characterizing TRU waste meets quality assurance objectives established in the QAPP. To date, three PDP programs have been developed for DOE-CAO: 1) analysis of VOCs and gases (6), 2) nondestructive assay (7), and 3) RCRA constituent analysis of solidified wastes (8). Waste generator/storage site implementation of these requirements is a key step in achieving authorization to dispose of TRU waste at WIPP.

Fig. 2

Since 1991, the INEL has been actively retrieving and characterizing accessible stored TRU waste forms to supply information primarily supporting development of the No-Migration Petition for WIPP. Characterization activities, at a minimum, include headspace gas sampling, weighing, RTR, and radioassay. Intrusive sampling, completed to meet visual examination, inner bag sampling or collection of sludge samples for RCRA analysis,is performed at the ANL-W Waste Characterization Area (WCA). The WCA provides capability to open and examine waste drums and collect samples in a glovebox environment. Wastes are transported to ANL-W using the TRUPACT-II shipping container. Analysis of sludge samples for RCRA constituents is being performed by Oak Ridge National Laboratory. Quality Assurance Project Plans have been prepared to implement the requirements of the TRU Waste Characterization QAPP. By January 1996, 595 drums have been characterized and the results reported to DOE-CAO.

FTIR spectroscopy was evaluated as an alternative approach to analyzing headspace gas from TRU waste containers. Current practices involve collection of the gas sample in a SUMMATM canister followed by analysis of the gas at the INEL Environmental Chemistry Laboratory using gas chromatography/mass spectrometry. Use of the FTIR method offered a simple, rapid analysis that could be performed at the location the sample was collected. Significant cost savings could be realized over the conventional sampling approach. A two-phase study (9) was completed over about three years to evaluate FTIR capability to simultaneously quantitate the 29 VOCs required by the QAPP and then evaluate application of the FTIR on actual TRU waste drum headspace gas samples. Results of this effort have been successful, with FTIR meeting the TRU waste characterization requirements of 30% accuracy and 25% precision. As previously noted, this system is being installed on the Drum Venting system to support venting, sampling, and analysis needs.

A test program (10) has been completed to demonstrate that VOC concentrations in the void space of each layer of confinement in vented waste drums can be estimated using the measured drum headspace gas and a model incorporating theoretical diffusion and permeation transport principles. The conditional No-Migration Determination for WIPP requires that gas sampling of all layers of confinement within a container for flammable and nonflammable volatile hazardous constituents be performed unless DOE demonstrates this sampling is not necessary. A VOC transport model was developed and experiments completed to measure VOC concentrations in laboratory-scale simulated waste drums and actual waste drums. Both transient and steady-state modeling were completed. Results of this test program provided information that has demonstrated that

headspace gas sampling of inner layers of confinement is not necessary to characterize VOC concentrations in the void volumes of drums and to safely manage waste at WIPP. This provides a significant reduction in costs by not opening and sampling inner bags of waste. A position paper has been prepared and submitted to DOE for regulatory compliance discussions.

A National TRU Waste Model was developed by INEL to support NTP planning efforts. The model, developed using commercially available personal computer software, is a decision-making tool for evaluating the preparation and flow of CH-TRU waste from eight major storage sites to WIPP. The model is designed to predict the course and results of hypothetical actions, understand observed or projected events, identify inefficiencies and problem areas, evaluate alternative management approaches, improve understanding of variables that influence waste flow to WIPP, and support development of an integrated complex-wide plan for achieving disposal of TRU waste. This simulation model forms the core of a larger system being developed by INEL, Sandia National Laboratory, and the NTP to address other management aspects such as budgeting and remote-handled waste. Results of these efforts will be assimilated into a complex-wide National TRU Waste Program Management Plan by September 1996.

The Matrix Depletion Program (11) is a cooperative effort between the INEL, Los Alamos National Laboratory (LANL), and Rocky Flats Environmental Technology Site (RFETS) for DOE-CAO. The objective of this program is to investigate the phenomenon of matrix depletion as it affects the generation of radiolytic-produced gases over time, and to develop age-dependent gas generation values. The expected outcome of this program is the development of data that will support an application to the Nuclear Regulatory Commission for lower effective gas generation values and corresponding higher thermal wattage limits for wastes shipped in the TRUPACT-II. This will increase the amount of untreated waste that can be shipped to WIPP without repackaging or treatment. Radioactive tests containing various waste matrices are expected to begin at LANL in February 1996 to provide quantitative gas generation data and development of bounding effective gas generation rates. Predictive modeling will be completed for actual TRU waste drums, followed by sampling of this waste by INEL and RFETS, for determination of actual hydrogen content to verify experimentally-derived time-dependent gas generation rates are bounding. This program is expected to be completed in February 1998.

Procurement of Treatment Services

In 1992, efforts were initiated to evaluate the feasibility of procuring treatment services needed for TRU-contaminated waste from the private sector as an alternative to design, construction, and operation of a DOE-funded LICP. Results of these studies have indicated that significant cost savings could be achieved for DOE, and completion of waste disposal could be accomplished eight years earlier. The INEL has issued a Request for Proposal (RFP) for treatment services. It is expected that award of the contract will be completed in September 1996. Treatment of all TRU-contaminated waste will commence by March 2003. Until that time, untreated waste will be shipped to WIPP for disposal.

FUTURE STRATEGIC DIRECTION

In October 1995, a settlement agreement was reached between DOE, the State of Idaho, and the Department of the Navy concerning future receipt of spent nuclear fuel at the INEL. This agreement will result in

significant impacts to the future management program for INEL stored TRU waste. Although the stored TRU waste program was moving in a direction consistent with the general terms of the agreement, the establishment of specific dates and volumes of waste to be removed from the State of Idaho will result in acceleration of planned activities. Key agreement conditions affecting management of stored TRU waste include: 1) the first shipment of TRU waste out of the State to WIPP or another designated facility must be accomplished by April 30, 1999; 2) by December 31, 2002, 3100 m3 of waste (15,000 drum equivalents) must be shipped out of the State; 3) after January 1, 2003, a running three-year average of 2000 m3/yr must be shipped out of the State; 4) a mixed waste treatment facility contract must be established by June 1, 1997, construction completed by December 31, 2002, and operational by March 31, 2003; and 5) shipment of TRU out of the State must be completed by a target date of December 31, 2015, but not later than December 31, 2018. Failure to comply with these conditions could affect the receipt of DOE spent fuel at the INEL.

As originally planned, production-level waste examination and certification operations will be initiated in the summer of 1997 to begin building a backlog of certified waste for shipment to WIPP in April 1998. Receipt of final WIPP WAC is assumed by December 1996. Alternatives for achieving shipment of 15,000 drums by December 31, 2002, are currently being evaluated.

SUMMARY

Historically, the INEL has proactively and successfully enhanced management capabilities for stored TRU waste. These capabilities include facility, operational, and technical development and support activities. Initiation of shipment of INEL stored TRU waste to WIPP will begin once WIPP is opened and authorization to ship is received.

ABSTRACT

The Department of Energy (DOE), Office of Environmental Management (EM), Office of Information Management (EM-14), established the EM World Wide Web Server (EMweb) to provide up-to-date information to DOE Headquarters, Operations Offices, stakeholders, contractors, and the public. Information on the server is kept current through a configuration management plan maintenance schedule that includes a weekly upload of new information.

EMweb supports EM's mission by making data available on demand to users throughout the world. The categories of information currently on EMweb include Public Information Resources, Regulatory Information, Waste Management, Environmental Restoration, Science and Technology, Facility Transition, Site Operations, Crosscutting Programs, and Other Servers. The server also provides features to view on-line usage statistics for all applications; capability to review draft documents before public release of information; a response mechanism through electronic mail for users to contact staff that manage the server or are responsible for information posted on the server; and search engines that let users search the EMweb server or servers throughout the Internet. Licensed access to Secretary of Energy Notices, the Code of Federal Regulations, the Federal Register, DOE Orders, state environmental regulations, and the Commerce Business Daily is also provided for staff members located at DOE Headquarters.

INTRODUCTION

The Department of Energy (DOE), Office of Environmental Management (EM) World Wide Web Server (EMweb) was established to provide up-to-date

information to DOE Headquarters, Operations Offices, stakeholders, contractors, and the public. The server is located in Washington, D.C., and is accessible over the Internet throughout the world. Parts of the server are available to all users, and other parts are secured through passwords or specific Internet protocol (IP) addresses. This paper will describe EMweb features and discuss some of the more widely used documents on the server. The uniform resource locator for EMweb is "http://www.em.doe.gov."

Information on EMweb is organized by subject categories and programmatic management authority. Because EMweb menu structures are updated whenever the information posted by DOE and its stakeholders is changed, the current configuration of the server may not match that shown below. The main menu is currently subdivided into

- Public Information Resources,
- Regulatory Information,
- Waste Management,
- Environmental Restoration,
- Science and Technology,
- Facility Transition
- Site Operations,
- Crosscutting Programs, and
- Other Servers.

The server also provides several features to ensure that users find the information they need and can communicate with the providers of the information. Server features include

- on-line usage statistics for all applications;
- a "limited access" review area for use by information providers before public release of information;
- a "feedback" mechanism that can be used to send electronic mail to those that manage the server and are responsible for information posted on the server;
- search engines that let users search the EMweb server or servers throughout the Internet;
- a "restricted area" that can be used to post information only of interest to internal DOE Headquarters staff;
- licensed access to Secretary of Energy Notices, the Code of Federal Regulations (CFR), the Federal Register, DOE Orders, State Environmental Regulations, and the Commerce Business Daily;
- a "What's New" feature that identifies documents or features recently added to the server; and
- a "Features" highlight that denotes new items added to the server.

EMweb has been registered with all major search engine and Internet directory providers so that users throughout the world can locate the information they need on the EMweb server. In addition, EMweb is managed to ensure that information added to the server meets the needs of DOE, its programs, and stakeholders. All information on the server has been processed through a rigorous configuration control procedure that ensures information accuracy and consistency. All information posted must conform to the DOE Office of Environmental Management World Wide Web Server (EMweb) Hypertext Markup Language Style Guide (DOE/HWP-164). After information is converted to the hypertext markup language (HTML) format, the information is reviewed and approved by the federal employee who is responsible for the information.

Every World Wide Web server provides access to on-line text and graphics. EMweb goes a step further to help ensure that users get the information they need. EMweb provides services to download large documents, debate issues with other EMweb users, and access data in legacy database management systems.

INFORMATION PUBLISHED ON EMweb

EMweb Public Information Resources

The EMweb Public Information Resources directory contains information of general interest to EM and its stakeholders. Two documents are currently featured. Committed to Results: DOE's Environmental Management Program, An Introduction, which is also known as the "EM Primer," describes the EM organization, its goals, and objectives. It provides a colorful picture story of EM and its programs. A second document, Closing the Circle on the Splitting of the Atom, characterizes the environmental legacy of nuclear weapons production in the United States and describes what DOE is doing to address the resulting environmental problems.

The EM newsletters EM Progress, EMformation, and Full Circle, DOE's Quarterly Solid Waste Reduction and Affirmative Procurement Bulletin are also featured in this section. Efforts are being made to ensure that publication on EMweb corresponds with hardcopy distribution to more effectively communicate the newsletters' contents to DOE and its stakeholders.

Other information in the Public Information Resources section of EMweb includes

- EM Fact Sheets;
- Environmental Management 1994;
- Environmental Management 1995;
- Anuario Hispano 1995 Hispanic Yearbook;
- Estimating the Cold War Mortgage: The 1995 Baseline Environmental Management Report (Executive Summary only);
- Resource Conservation and Recovery Act (RCRA) Corrective Action & Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) Remedial Action Reference Guide;
- Speeches;
- Integrated Risk Management Home Page;
- Information and Announcements;
- Press Releases;
- Public Participation Information;
- Conference and Meeting Information; and
- Job Listings.

EMweb Regulatory Information

The Regulatory Information portion of the server contains information for

- The Advisory Committee on External Regulation of DOE Nuclear Safety
- Regulatory News and Meeting Notices
- National Environmental Policy Act Implementation

EMweb Waste Management Information

The Waste Management portion of the server features the Integrated Data Base (IDB) Report, the Federal Facility Compliance Act (FFCAct) Bulletin Board, and the Waste Management Programmatic Environmental Impact Statement (PEIS) Bulletin Board.

The IDB reports for calendar years 1992 and 1993 are currently on the server. The 1994 edition is currently being prepared for publication. The IDB reports offer historic data on inventories and characteristics of both commercial and DOE spent fuel and commercial and U.S. government-

owned radioactive wastes. The report is published annually by DOE's Office of Civilian Radioactive Waste Management and Office of Environmental Management.

The FFCAct Bulletin Board contains information concerning

Federal Facility Compliance Act Approved Site Treatment Plans;
Overview of the Draft Site Treatment Plans;
Overview of the Proposed Site Treatment Plans;
Downloadable Documents and Files;
FFCAct Federal Register Notices;
FFCAct Issue Alerts and Fact Sheets;
Federal Facility Compliance Act of 1992;
Site FFCAct Points of Contact Listing;
DOE Mixed Waste Inventory by State;
Progress Report to Congress - 1994;
Progress Report to Congress - 1993;
Implementation Plan for the Programmatic Environmental Impact Statement for the DOE Environmental Restoration and Waste Management Program; and
National Summary Report of Draft Site Treatment Plans.

The Waste Management Programmatic Environmental Impact Statement (PEIS) Bulletin Board contains information concerning

Waste Management Programmatic Environmental Impact Statement (PEIS) DOE Update: September 1995;
Waste Management PEIS Site-Specific Fact Sheets;
National Results of the Waste Management PEIS;
An Overview of the Waste Management PEIS;
The Waste Management PEIS and Public Comment Opportunities;
Implementation Plan for the Programmatic Environmental Impact Statement for DOE EM; and
A description of the "Relationship Between the Environmental Management Programmatic Environmental Impact Statement and the Federal Facility Compliance Act."

EMweb Environmental Restoration Information

The Environmental Restoration portion of the server features the DOE Environmental Management Benchmarking Clearinghouse, the Generic Technical Management Plan, and the Environmental Restoration Strategic Plan.

The Benchmarking Clearinghouse section contains

Benchmarking Abstracts and Reports,
Current DOE Comparative Performance Data,
Benchmarking Data Sources,
Points of Contact for Additional Benchmarking Information,
Frequently Asked Questions About Benchmarking in Environmental Management Projects, and
Remedial Action Program Information Center.

The Environmental Restoration Strategic Plan was developed to guide decision-making in the planning and execution of DOE's National Environmental Restoration Program. The plan is designed to implement the Environmental Management Strategic Plan and to reflect the roles, responsibilities, and authorities of Headquarters and field organizations as defined by the Assistant Secretary for Environmental Management.

EMweb Science and Technology Information

The Science and Technology portion of the server features the complete text and graphics for the June 1995 Technology Summary Reports (Rainbow

Books) that are published by DOE EM's Office of Technology Development. The following Rainbow Book Reports are provided:

- Robotics Technology Crosscutting Program;
- Characterization, Monitoring, and Sensor Technology Crosscutting Program;
- The Landfill Stabilization Focus Area Technology Summary;
- Contaminant Plumes Containment and Remediation;
- Efficient Separations and Processing Crosscutting Program;
- Facility Deactivation, Decommissioning, and Material Disposition Focus Area; and Tank Focus Area Technology Summary.

Also included in the Science and Technology section are the Technology Information Exchange (TIE) Bulletin Board, the U.S. DOE Office of Environmental Management Oak Ridge Operations Technology Needs Database, and the U.S. DOE Scrap Metal Inventory Report.

EMweb Crosscutting Programs Information

The Crosscutting Programs section of EMweb is the fastest growing section, partly because the Internet has become an excellent mechanism for disseminating up-to-date information quickly and effectively across the DOE complex. Home Pages on the Crosscutting Programs section include

- Progress-Tracking System Information Home Page,
- Training and Education Home Page,
- Transportation Program Home Page,
- Facility Representative Bulletin Board,
- Pollution Prevention Home Page,
- National Decommissioning Program Home Page, and
- National Recycle Program Home Page.

ACCESS TO SPECIAL SERVICES

Because of the demand for on-line access to government-generated laws, regulations, and guidance documents; DOE EM has made arrangements with a publishing company for access to

- The Commerce Business Daily,
- The Code of Federal Regulations,
- The Federal Register,
- DOE Orders,
- Secretary of Energy Notices, and
- State Environmental Regulations.

Access to these services is controlled by Internet Protocol (IP) address. Currently, anyone within the Class B IP address scheme for DOE Headquarters can access these services. EM is attempting to acquire free access to these services. DOE is also negotiating with the service provider to widen the agreement to cover Operations Offices and contractors if free access cannot be provided. At the time of this printing, a contract has not been awarded.

SUMMARY

EMweb has been established as a resource that provides up-to-date information to DOE Headquarters, Operations Offices, stakeholders, contractors, and the public. The server is updated weekly, so new items are continuously available to users.

ABSTRACT

This paper summarizes the strategy and supporting activities for developing proposed alternatives for remediation of the Subsurface Disposal Area (SDA) at the Radioactive Waste Management Complex (RWMC). These activities are being described to illustrate one approach to tackling a complex, comprehensive clean-up decision using an interim action as a vehicle for focusing the technology evaluations. Prior to the start of this feasibility study the interim action was initiated to clean-up part of the SDA, Pit 9. The Pit 9 clean-up comprises remote retrieval under containment, physical separation processes, soil treatment, and stabilization via thermal treatment. The cost of the Pit 9 interim action is estimated to be approximately $260 million. While this is clearly a significant investment it represents only a small portion of the potential cost of remediating the SDA if ex situ treatment is needed. The feasibility study will include detailed evaluations using Pit 9 processes as representative processes for an alternative of retrieval and ex situ treatment, along with other alternatives that will make up the remainder of the evaluations.

BACKGROUND

The SDA is a large (38.85-ha) landfill located at the Idaho National Engineering Laboratory (INEL) that contains buried radioactive waste generated at the INEL and shipped in from other waste generators starting in 1952. The SDA is still being used for current low level radioactive waste disposal. A Federal Facility Agreement and Consent Order (FFA/CO) for the INEL was signed by the U.S. Department of Energy, U.S. Environmental Protection Agency, and State of Idaho Department of Health and Welfare to address past releases of radioactive and hazardous substances, including the migration of contaminants to the Snake River Plain Aquifer which underlies the INEL (1). This aquifer was designated as a sole source aquifer by the EPA in 1991. The agreement effectively moved the investigation and cleanup of specified releases at the INEL from a RCRA to a CERCLA process. Remediation of the SDA is included under this agreement, and development of a proposed remedial alternative for the SDA will be conducted under a CERCLA Comprehensive Remedial Investigation/Feasibility Study.

Much of the waste disposed in the SDA was TRU-contaminated waste generated at the Rocky Flats Plant and shipped to the INEL for burial from 1954 to 1970. Waste was buried in pits, trenches, and soil vaults, and historical records from the SDA indicate that prior to 1970 TRU-contaminated waste was mixed with non-TRU waste during burial (2). After 1970 the Atomic Energy Commission (AEC) issued a policy regarding segregation and storage of waste contaminated with TRU radionuclides

which led to the decision to cease all burial of TRU-contaminated waste at the SDA in that year. The general categories of waste buried at the SDA include construction and demolition materials, laboratory equipment and materials, process equipment and materials, nuclear reactor components such as fuel scraps and radioactive sources, maintenance equipment and scrap metals, decontamination materials, and miscellaneous waste. Miscellaneous waste includes such things as process sludges, animal carcasses, contaminated jet engine components, contaminated vehicles, batteries, etc.. Preliminary investigations evaluating human health risk drivers at the SDA (3) have identified contaminants of potential concern (COPCs), including 43 radiological contaminants and 44 non-radiological contaminants that will be evaluated under a Remedial Investigation/Feasibility Study. Plutonium and Americium are included in the list of COPCs. Additionally, the waste inventory at the SDA includes a large list of other hazardous constituents that do not pose a risk to human health or the environment in their current state. These must be evaluated for potential problems, such as potential worker exposure and interference with process equipment performance, under a scenario where there is intrusion to the buried waste as part of a remedial alternative. The breadth of the list of contaminants, variety of contaminated media, and potential for staggering clean-up costs make for a daunting task to remediate the SDA. In 1991 an Interim Action was initiated to clean up part of the SDA, Pit 9, using a private sector, turnkey approach to meet key Department of Energy (DOE) objectives. Several objectives for the Pit 9 Interim Action are directly applicable to the SDA remediation. The Pit 9 Interim Action is designed to be a near-term remediation of plutonium, americium, and other identified risk drivers in Pit 9 at a minimum cost to DOE, as well as a demonstration of private industry's capabilities for remediating TRU-contaminated mixed waste sites using innovative technologies (4). The remediation of Pit 9 includes excavation and segregation of buried waste with greater than 10 nCi/g TRU elements for input to the treatment process train. Treatment includes chemical extraction, physical separation, and/or stabilization to remove radionuclides and hazardous constituents. The remedial design for the Pit 9 remediation is scheduled to be complete April, 1996, followed by a Limited Production Test (LPT) which will provide early data on equipment performance and operational readiness prior to remediating the remainder of Pit 9. LPT data will be available for evaluation under the Feasibility Study (FS) for remediating the remainder of the SDA.

KEY OBJECTIVES AND INTEGRATION OF THE FS

A strategy for the FS was developed prior to detailed scoping between stakeholders. The strategy included documentation of key assumptions used for the FS (5). This assumptions document has been and will continue to be revised until completion of the FS. It provides some boundaries to the scope of work, and a starting point for stakeholder consensus-building. The strategy also included the development of some high level questions that needed to be answered as part of the FS. Using the Pit 9 Interim Action to answer some of these questions is a critical piece of the strategy. Key objectives for the FS include:

Identify and group contaminated media from the operable unit so that a reasonable number of response actions can be developed.

Gather early information on technology costs/complexities to identify areas of greatest uncertainty, and rough order of magnitude costs for

technologies that can be used for screening decisions and integration with risk assessment activities.

Identify areas where costs are most significant so that this information could be factored into the remedial decisions.

Develop a list of remedial alternatives that will be used to evaluate and compare grouped technologies in accordance with CERCLA criteria.

Some high level questions that need to be answered in this FS include:

1. Is it likely that a landfill cap will be protective for the period of time necessary to prevent groundwater risk from the SDA? To answer this question functional and operational requirements for a cap over the SDA need to be considered, particularly the required design life for a cap. Based on preliminary risk calculations, for example, some contaminants of potential concern pose risks to groundwater for thousands of years6.
2. Is it feasible to consider in situ or ex situ treatment of the entire SDA considering potential costs and complexities that arise from treatment of such a large volume of heterogeneous waste?
3. Do we have necessary data, primarily from waste inventory and shipping records, to define partial treatment scenarios that will reduce the volume of waste that would need treatment?
4. In the case of an alternative to retrieve and treat waste, will the treatment technologies work on heterogeneous waste such as will be found in the SDA?
5. Are treatability studies necessary to provide part of the technical basis for confirming the feasibility of a technology/alternative or are existing data adequate?
6. Can opportunities for technology development be identified in time to provide a window for bringing in new technologies that could be used to reduce complexity and/or cost of remediation?

The feasibility study will include the following conceptual response actions:

No Action

Occupational Period to prevent or limit access to contaminated areas

Containment In Situ Treatment

Retrieval, Ex Situ Treatment, Storage, and Disposal

Retrieval, Storage, and Disposal

The containment response action will include evaluation of composite capping technologies. It will likely use water balance caps similar to those developed at the Hanford Site as representative technologies. Generally these designs are being considered for applications with 500 - 1000 year design lives.

EARLY RISK ASSESSMENT INDICATORS

In preparation for conducting the remedial investigation a Preliminary Scoping Risk Assessment (PSRA) was completed in 1994 (6). The primary objective for this task was to provide early information regarding contaminants, exposure pathways, and other factors in determining potential adverse human health effects from the SDA. This activity provided some conclusions on key sensitivities for risk assessment of the SDA, and will be used to prioritize modeling and data-gathering efforts in preparation for the next major task of the remedial investigation, the baseline risk assessment, scheduled to begin spring of 1996.

The PSRA provided a list of contaminants that posed potential risk for all pathways under evaluation. The groundwater contamination pathway is considered the most influential in coming to a remedial decision for the SDA. Using conservative assumptions resulted in three inorganic

contaminants potentially presenting the highest risk to groundwater from the SDA: C-14, I-129, and Tc-99. Later evaluations of SDA inventories support a significantly lowered inventory for I-129, which will result in a lower risk to groundwater. The main transuranic contaminants in the SDA, Pu and Am, were retained as contaminants of potential concern but based on current assumptions these contaminants pose less of a risk to groundwater than the C-14, Tc-99, and I-129. There has been and continues to be public concern about the transuranic waste buried in the SDA and this concern will also be factored into the feasibility study. Hazardous organics also pose a potential groundwater risk based on early models of the SDA, and recent groundwater samples from monitoring wells indicate there may be an increasing trend in carbon tetrachloride concentrations. The baseline risk assessment will be used as the final tool for determining contaminants of concern, but until these results are known, PSRA results are useful indicators for what kind of remediation alternatives are likely.

According to the results of the PSRA, several parameters were very sensitive in influencing risk assessment results. Release rate was considered the most important of these parameters. Release rate generally models how contaminants move and at what rate they move from the disposed waste. It includes parameters that are derived from three main release mechanisms for SDA waste, namely, surface to water partitioning of sorbed constituents between solids and water, corrosion of metal waste with corresponding release of constituents, and equilibrium solubility limit applied for dissolution of liquids and solids in oxide, hydroxide, nitrate, particulate form, etc. Source inventory was another sensitive parameter and is dependent on our current ability to accurately estimate how much of a given contaminant was placed in the SDA. Inconsistencies and incompleteness in inventory and shipping records create uncertainty in many contaminant inventory estimates. Discussions with Rocky Flats Plant employees and others have been conducted to obtain better waste inventory information from process knowledge, but there have been no direct measurements to calibrate current inventory estimates with field data. Additional information that could be gained regarding release rates, source term inventory and other sensitive parameters would be of highest priority in completing the remedial investigation/feasibility study since input to these terms will greatly influence the results of the risk assessment, and therefore influence the complexity and cost of any necessary remedial action.

PIT 9 INTERIM ACTION

The Pit 9 interim action has the potential of answering many questions regarding how effective specific retrieval and treatment processes are for remediation of heterogeneous, buried waste. It also provides opportunities for learning how the contaminants in Pit 9 have changed and migrated over a period of about 25 years. The remedial action will include a containment building that can be repositioned along the length of the pit as excavation proceeds. Remote operation of the waste retrieval process will occur within this containment after the clean overburden is removed from Pit 9. The retrieved waste and/or soil will be assayed to determine whether it needs treatment or not. Waste and soil requiring treatment will be packaged and transported to either the thermal treatment or the soil treatment process. Treatment residuals from the soil treatment process will be fed to the thermal treatment process. Treatment residuals from the thermal treatment process will be packaged

and stored in preparation for ultimate disposal as transuranic waste at the Waste Isolation Pilot Plant (WIPP).

The Pit 9 clean-up specification calls for collection and analysis of approximately 114 soil samples during the remediation phase. These samples will be analyzed for VOCs, semivolatile organics, transuranics, Pu-241, Co-60, Sr-90, C-14, I-129, Cs-137, Tc-99, H-3, Ni-59, Ni-63, Hg, Pb, Be, Zn, As, Cr, cyanide, and nitrates. Whatever portion of this information that is available during the FS for the SDA will be used to understand what kind of contaminants the Pit 9 treatment processes are actually seeing in the feed, and what contaminants are present in different areas of the pit.

One area of significant uncertainty in conducting the FS for the SDA is evaluating the viability of technologies for treating waste considered infinitely heterogeneous. Performance of any treatment process is highly dependent on the waste feed, and evaluating technology performance using data on actual waste is the optimum situation. The Pit 9 interim action provides exactly this for the FS. While Pit 9 is not representative of all pits and trenches in the SDA, it does provide a relatively broad envelope of waste feed that will rigorously test technology performance. A list of other waste found in the SDA and not in Pit 9 is being compiled for the FS to determine if additional testing is warranted or if assumptions can be made on technology performance with these wastes, with acceptable uncertainty to the stakeholders. The vast majority of radionuclides known to be disposed in Pit 9 are transuranics, therefore, it is assumed that very little Tc-99 or C-14 will be processed during the interim action. Since these contaminants posed the highest risk to groundwater in the PSRA special consideration will be used to verify Pit 9 technologies are feasible for these waste forms.

Another area of uncertainty when evaluating technologies for waste treatment is estimating the cost of remediation, including operations and maintenance. Particularly for the case of plutonium operations, on-stream time and maintenance costs are extremely important parameters in gauging the success and cost of the treatment train. The Pit 9 interim action will demonstrate the cost of operations and maintenance during the limited production test and during the one year full-scale clean-up of the pit. This kind of cost information is far more accurate than estimates based on historical treatment of waste that may not be at all like that found in the SDA.

The safety of the operations will also be demonstrated during the Pit 9 interim action. A CERCLA feasibility study must include an assessment of the risk of implementing each remedial alternative. Retrieval and treatment of buried waste from the SDA does include some risk, including potential exposure of workers to hazards of the operation. The Pit 9 operations will provide data on the severity of these hazards, and the ability of the equipment and operational designs to accommodate all hazards that arise. This information is invaluable in convincing stakeholders of the viability of a remedial alternative.

CURRENT AND FUTURE ACTIVITIES

Technical activities for the FS are still in the early, data-gathering stage. Screening decisions will begin in 1996 as the results of the baseline risk assessment are compiled. Detailed evaluations of remedial alternatives will be finalized after the Pit 9 LPT results have been incorporated, tentatively as early as January, 1997.

Prior to screening, several parallel activities have been initiated. In preparation for the Pit 9 LPT, engineers responsible for the FS are reviewing Pit 9 design documents and test plans to identify the data most useful for the FS anticipated from Pit 9, as well as data that would be valuable but are not currently defined within the LPT. The list of valuable data not currently in the scope of the LPT will be evaluated to determine if additional testing should be done with Pit 9 processes to generate these data, or whether the stakeholders are willing to accept the uncertainty and forego additional testing.

Another activity that has been initiated is to answer the question previously raised on partial retrieval/treatment scenarios. While it is straightforward to identify pits and trenches that could not contain specific contaminants using available inventory records, there is much greater uncertainty regarding which pits and trenches contain which contaminants. The uncertainty rises again in estimating concentrations of contaminants for a given pit or trench. A preliminary look at which pits and trenches could not contain specific contaminants showed only a small percentage of the SDA that did not contain some of the contaminants that may pose a future groundwater risk (based on PSRA results). Less than 40% by area of the SDA does not contain Pu or Am, for example, according to inventory records. About the same percentage (though not necessarily the same pits or trenches) can be shown to not contain Tc-99 and C-14. VOCs were disposed in over 30% of the SDA by area according to records. It has been estimated that retrieval and treatment of the entire volume of contaminated media at the SDA will cost over $1.5 billion (7), excluding the cost of interim storage and final disposal of treatment residuals. One can easily infer from this that even small reductions in volume of waste that must be treated would reduce the cost of remediation by millions of dollars. One strategy for reducing the volume of waste that might require treatment is to go back to the inventory and shipping records to find information that could eliminate more pits and/or trenches from the list of known pits containing contaminants of concern. Information that could eliminate portions of a pit or trench would also be useful, but this is less likely to have been documented in historical records. Another avenue for addressing this uncertainty is to evaluate options for locating specific contaminants by measurement at the SDA. If these measurements could only be done by intrusion into the waste the cost of obtaining these data could be prohibitive and safety issues would need to be addressed beforehand. If, however, some contaminants could be located via non-intrusive measurements through the overburden then a window of opportunity exists for attempting these measurements before the FS is completed.

We are just beginning to ask and attempt to answer the hardest questions of this feasibility study. While the focus of this paper has been on the importance of the Pit 9 interim action, it should be noted that a significant portion of the FS will be devoted to other alternatives in addition to ex situ treatment. Containment issues, in particular, will require careful evaluation against the problem at hand, and making maximum use of existing data on capping technologies is a key step in accomplishing the technical objectives of this program.

Having access to a large interim action to support this FS will be a great asset to this work. Unfortunately, other feasibility studies have been completed with the benefit of an interim action and were not entirely successful. The usefulness of this work will be bounded by our

ability to distinguish what aspects of the interim action can be extrapolated to the waste that may need remediation in pits and trenches outside of Pit 9, and what judgment we apply to evaluating the treatment processes for contaminants, and a scale of operations not tested in the interim action.

COST-EFFECTIVE APPROACHES TO SUCCESSFUL REMEDIATION OF UNEXPLODED ORDNANCE (UXO) AT THE IDAHO NATIONAL ENGINEERING LABORATORY (INEL)

Terrell J. Smith
Hanceford Clayton
Lockheed Idaho Technologies Company
Idaho National Engineering Laboratory
U. S. Department of Energy

ABSTRACT

Unexploded ordnance (UXO) and explosively contaminated soils were remediated at the Idaho National Engineering Laboratory (INEL). A Geographical Information System (GIS) was used to map areas of contamination and a Global Positioning System (GPS) was used to identify the location of ordnance explosive waste (OEW). Using these systems has improved the accuracy of the data collected. A central demolition site was used instead of the traditional method of detonating unexploded ordnance in place. Field screening of explosive contaminated soils was performed instead of using a more expensive laboratory analysis. In addition, an Air Force remote excavator was used to remediate potentially sensitized ordnance disposal pits in a cooperative technical demonstration arrangement with the Department of Defense (DoD) and the Department of Energy (DOE). The use of these methods and technologies has resulted in an enhanced remediation process and significant cost savings.

The next phase of ordnance work at the INEL will involve using a computer-based site statistical sampling model for UXO estimation entitled SiteStats. This model will eliminate the need for labor-intensive field searches to estimate ordnance concentrations.

INTRODUCTION

Before the inception of the Idaho National Engineering Laboratory (INEL), military activities such as aerial bombing practice, naval artillery testing, explosive storage bunker testing, and ordnance disposal took place on a large portion of what is now the INEL. As a result of these past activities associated with the former Naval Proving Ground (NPG), numerous unexploded ordnance (UXO) devices have been discovered by INEL personnel. In addition to UXO and ordnance explosive waste (OEW), explosive agents such as TNT and RDX, released during partial detonation during NPG tests, have contaminated soils at the INEL. This paper will describe how: a) UXO has been remediated effectively and in a cost-effective manner, b) technologies have been used to enhance cleanup, and c) to save money sampling explosive contaminated soils.

Over the past 3 years, UXO and explosively contaminated soils have been removed from the INEL. Lessons have been learned on appropriate approaches to take to effectively and in a cost-effective manner remediate OEW. While the cost of remediating ordnance from former military installations continues to rise, efforts are being made at the INEL to reduce these costs using innovative technologies.

Beginning in 1993, work began to remediate ordnance and explosive contaminated soils at six INEL locations. This work was completed the same year. The specific mission of this action was to locate, identify, detonate, and dispose of UXO and associated shrapnel and to characterize, remove, and incinerate soils contaminated with explosive residues.

The first phase of the ordnance removal was to set up search lanes in each area to sweep for ordnance. Five-foot lanes were established by placing metal posts and running string to each point. A visual search was made first for UXO/OEW and debris on the surface. Each potential ordnance item was flagged by explosive ordnance disposal (EOD) technicians. This search was followed by a magnetometer search to check for subsurface anomalies to a 2-foot depth. On the second search, any additional items were marked. Each flagged anomaly was investigated to determine if UXO existed. Located UXO was collected and if determined to be safe, was transported to a central blast area for destruction.

Following the clearance of an area, a quality survey of the lanes cleared was performed. If any ordnance items were discovered during the quality check, the EOD team would reclear the lanes while in the area. This ensured that a thorough clearance was performed and saved project costs.

Historical U.S. Department of Defense (DoD) EOD publications were used to positively identify ordnance in the field. Some of these publications include: Bombs for Aircraft (TM 9-1980, 1944); General Ammunition Technical Manual (TM 9-1900, 1942); and U.S. Explosive Ordnance (NAVSEA OP 1664, 1947). Since ordnance deposited by the military during World War (WW)-II is outdated, the newer DoD publications usually do not identify the older ordnance. These historical publications assisted with identifying ordnance type, filler, and fusing. This reduces the expense of blowing up inert and nonhazardous ordnance in place. Another benefit of using these publications, eliminates the necessity of sending pictures, drawings, dimensions, and other features of the ordnance to the

EOD Technical Center for identification. Processing this information through the EOD Technical Center would slow field work and cause additional project expense.

Cost savings have been realized by transporting ordnance to a central disposal area. This eliminated the need to clear areas around ordnance that would be normally blown up in the field. Clearing areas around ordnance to prevent fire danger is time-consuming and labor-intensive. Also, if each item discovered in the field is blown-in-place, considerably more explosives will be used and each detonation introduces risk. Decreasing the number of explosive detonations decreases risk associated with each disposal. Additional time and money would also be spent filling in craters and reseeding areas if ordnance was blown-in-place.

During the EOD search efforts to locate UXO, locations of soil contaminated with explosive compounds were marked. Locations with pieces of explosive compounds or stained soil present were flagged by EOD teams for sampling and the level of soil contamination was identified using field screening methods. A field laboratory was set up to conduct the sample analysis. The Jenkins Method (1) was used to perform the onsite field screening for explosive contaminated soil. This approach proved to be much less expensive than traditional laboratorysample analysis. The field screening cost per sample was $25, where the EPA 3380 Method for analysis averages $600 per sample. An estimated $297,000 was saved by using the field screening method. Ten percent of the samples were sent to an offsite laboratory for the full EPA 3380 Method analysis for verification purposes. The verification samples indicated the field screening sampling to be accurate. (2) Future samples of explosive contaminated soils will use the field screening methods. The INEL has worked with the U. S. Army Corps of Engineers (Corps) in testing and improving the Jenkins field screening methods (1,3) originally developed by the Corps.

After the soils were characterized for concentrations of explosive materials, the decision was made to remediate 186 cubic yards of soil. The soil was excavated, containerized, shipped offsite, and incinerated. The cost to incinerate the soils was $1,000 per cubic yard. (4) The current preferred method for remediation of explosive contaminated soils has changed to bioremediation. Bioremediation of explosive contaminated soils has been estimated at between 200-$400 per cubic yard. (3) The INEL is exploring ways to begin bioremediation of explosive contaminated soils. This new approach will realize substantial cost savings compared to past incineration of explosive soils.

A second ordnance removal action began in 1994 and was completed in 1995. This activity included the removal of ordnance from 90 acres from the Twin Buttes Bombing Range and 40 acres and six disposal pits at the Naval Ordnance Disposal Area (NODA).

Collecting information to identify the location, type, and disposition of ordnance is an important part of ordnance removal projects. In the past, ordnance information was manually collected and location information estimated. During the ordnance removal action in 1995, use of a Geographical Information System (GIS) to map areas of ordnance concentrations and a Global Positioning System (GPS) to identify locations of OEW has aided and enhanced the remediation process. Using these systems has improved the accuracy and quality of the information collected. Cost savings have been realized by eliminating the need to

manually input field data. The field data collected can now be electronically transmitted to the GIS. The information collected will assist in future assessments of UXO at the INEL and provide a baseline for projecting further cleanup needs.

During cleanup of the NODA area, a potentially sensitive ordnance disposal pit was identified. To mitigate the potential hazards of this area, it was determined that a remote operation was necessary in this area. Costs to bring in a remote excavator were estimated at $200,000. An Air Force remote excavator (Track Catapiller 325) from Tyndall Air Force Base was selected, which was part of a previously scheduled joint demonstration project between the U.S. Air Force and the U.S. Department of Energy (DOE). The excavation of the potentially sensitive pit was included as part of the technology demonstration project. As a result of these unique activities, sites at the INEL were successfully remediated of UXO/OEW. Continued remediation will be performed in a cooperative arrangement with the DOE, DoD, and the Corps, who all work toward cost reductions for ordnance removal.

The next phase of ordnance work at the INEL will be to assess the overall levels of bothordnance contamination and the volume of explosive contaminated soils. As part of this assessment, a computer-based site statistical sampling model for UXO estimation will be used. The software entitled SiteStats, a methodology developed by the Corps, will be used at the INEL. This tool will reduce the number of labor-intensive field searches for estimating ordnance concentrations. SiteStats will allow a minimal number of ordnance investigations, which will result in cost savings.

Innovative and efficient ordnance removal techniques will save taxpayers' money. By using new technologies, the cleanup of ordnance can be enhanced. Such techniques as field sampling for explosive contaminated soils versus traditionally more expensive laboratory analysis, electronic collection of field information, cooperative demonstration projects, and bioremediation of explosive soils will greatly improve and make ordnance removal projects much more cost-effective. The INEL has developed an integrated ordnance remediation approach the can be applied at other DOE/DoD sites.

It is important to promote cost-effective methods especially during these times of Government downsizing and reduced budgets. There remains a number of former defense sites that will require ordnance removal and soil remediation. Sharing information among those organizations responsible for ordnance removal will result in substantial cost savings.

"TOOLS" INTRODUCTION TO THE INEL ER PROGRAM MANAGEMENT TOOLS

Leonard L. Hutterman
Rulon R. Nielsen
INEL

ABSTRACT

The INEL ER Program discovered early in the program that it needed two things: 1) an agreement with the State of Idaho and the EPA that supported working together to deal with the CERCLA problems at the INEL, and 2) tools to manage the program in a time of change. These tools needed to meet the needs of the program and the intent of the DOE Orders. This paper presents these tools in a condensed format developed to do many communicating tasks. Three of the most used applications of these tools are:

Training aid for new members of the staff

Communication tool for all of the organizations performing overview activities of the program

Background for new management joining the program.

These papers were developed in a standard format and were called the two-page papers. This title was derived from the requirement that all of the information provided must fit on the front and back of a single sheet of 8 1/2 11 sheet of paper. As you read these two-page papers you will discover that each paper provides 1) Background, 2) How the Process Works, 3) Who Could Use This Process, 4) Why Should the Process Be Used, and 5) INEL ER Program Contacts. This format has been very successful. The next step is to place these papers on the INEL internet home page so that everyone has access to this information. In developing this tool system we had strong support from many in the program but the brunt of the work fell on the point of contacts listed in the papers. If you have questions on the subject matter of any of the tools please contact one of the program contacts. If you are interested in the two-page paper process to outline tools please contact L. Hutterman at (208) 526-3647.

THE INEL EXPEDITED CERCLA PROCESS

Background

The Idaho National Engineering Laboratory (INEL) has developed, and successfully implemented, guidance for a structured process to address known and potential environmental restoration sites. Numerous environmental restoration sites are present at the INEL. Many of these are low-probability hazard sites, which are those with suspected or unknown quantities of contamination. Typically, these sites are characterized by an uncertainty about the existence, quantity, type, or location of hazardous substances.

The Federal Facility Agreement and Consent Order (FFA/CO) Action Plan defines these sites as Track 1 and 2 sites. A Track 1 site investigation involves compiling existing information combined with conducting a very conservative qualitative risk assessment. Track 2 investigations are similar, but they allow for limited data collection. Based on the very conservative assumptions applied by the Track 1 and Track 2 processes, remedial action project managers can make timely decisions concerning these sites with a relatively high degree of certainty.

Track 1 and 2 sites at the INEL are a result of disposal operations and waste generation from activities such as nuclear reactor testing and development, nuclear fuel processing, abandoned underground storage tanks, and solid waste landfills spanning over 45 years. Many of the processes and associated facilities that created these sites were

abandoned long ago or evolved over years, making it difficult to obtain accurate documentation and make accurate assessments. Site information is often nonexistent, limited, or takes months to compile. Personnel familiar with the past operations of these sites are either unavailable or unable to give factual information.

In an effort to better incorporate these sites into the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) process, Track 1 and 2 sites were deliberately separated from the standard Remedial Investigation/Feasibility Study (RI/FS) process; a subpathway to the RI/FS process was developed (see figure). The sites may still require additional data collection, but to a lesser extent. CERCLA provides a rigorous decision process for determining the need to perform remedial actions on hazardous waste sites. Remediation decisions are based on the concept of acceptable risk. Using the RI/FS process on the low-probability hazard sites would divert funding from areas where remedial actions are required because of known unacceptable risks. The documents, Track 1 Sites: Guidance for Assessing Low Probability Hazard Sites at the INEL and Track 2 Sites: Guidance for Assessing Low Probability Hazard Sites at the INEL, were developed as guidance for evaluating these low-probability hazard sites and developing documented, defensible decisions concerning whether the sites require a more quantitative risk assessment to determine the need for remedial action. However, the decision making responsibility of the remedial project managers is not diminished.

Another process negotiated and implemented at the INEL involves acceleration of the typical 40-month RI/FS schedule in cases where the contaminant types and concentrations were well known and exhibited unacceptable risks from the outset. During the scoping phase of the RI/FS process, it was determined that sufficient information was available to conduct a baseline risk assessment; therefore, the RI/FS work plan tasks could be eliminated. Additionally, using the team approach, the participating agencies significantly shortened document development and review cycles.

How The Process Works

Rigorous quantitative risk analysis as outlined by CERCLA is not appropriate for Track 1 sites. Funding for feasibility studies and interim remediation is more fittingly directed to known hazard locations. The Track 1 guidance was developed to provide defensible qualitative evaluation of low-probability hazard sites and to record compliance with environmental regulations. The Track 1 guidance was designed to direct project managers through a qualitative risk assessment and provide a compliance template for Track 1 sites. The guidance provides detailed instructions for performing the essential components of risk assessment, from hazard identification through a final recommendation. A conservative screening technique is used that accounts for both human health risks and environmental impacts, with humans as sensitive indicators for the environment. This technique, in conjunction with the organized collection of historical data and all other available information, is used to develop a qualitative risk assessment. The result is a compact document that contains a template, references, and information used in the decision process and presents defensible recommendations for the Track 1 sites under consideration.

The Track 2 classification was developed specifically for the INEL to use in streamlining the implementation of CERCLA. Track 2 low-probability hazard sites are not described in the National Contingency Plan or in

existing regulatory guidance. The goal of the Track 2 process is to evaluate such sites using existing qualitative and quantitative data to minimize the collection of new environmental data. The Track 2 guidance presents a structured format consisting of a series of questions and tables and qualitative risk assessment to provide the information necessary to make decisions concerning the remedial action to take at a site. The process is iterative and addresses a site from multiple perspectives (e.g., historical, empirical, process knowledge) in an effort to generate a reproducible and defensible method. This approach follows the data quality objective process and establishes a well organized, logical approach to use in consolidating and assessing existing data and establishing decision criteria. If necessary, the process allows for the design of a sampling and analysis strategy to obtain new environmental data of appropriate quality to support decisions. Finally, the guidance expedites consensus between regulatory parties by emphasizing a team approach to Track 2 investigations.
RI/FS schedule acceleration has almost always occurred within the scoping process for the site under investigation. Presentation of sufficient existing data for a well defined site has allowed INEL environmental restoration project managers to negotiate the elimination of RI/FS work plans. This can eliminate several months from the overall schedule. The team approach has also been developed with respect to document development and review. Shortened review cycles, and, in some instances, concurrent reviews, have been negotiated to further accelerate the schedule. These shortened schedules are developed and documented in the scope of work for the specific site undergoing the remedial investigation.

Who Could Use This Process?

The INEL's expedited CERCLA process is flexible enough that it could be used at any Federal or commercial facility with either low probability hazard sites or sites posing high risks. The expedited CERCLA process can focus the scoping phase of any CERCLA investigation.

Why Should The Process Be Used?

- Reduces cost and schedule of CERCLA investigations
- Provides a method for collecting and organizing information for decision making process
- Develops a team approach between agencies (encourages open communication)
- Affords an iterative/flexible process and addresses sites from multiple viewpoints
- Requires a rigorous approach following the Data Quality Objective and Observational Approach process
- Provides a well organized, logical approach for consolidating and assessing existing data
- Establishes decision criteria and acceptable uncertainty levels in a timely manner
- Allows for design of a sampling and analysis strategy that collects limited data of sufficient quality to support a remedial decision
- Saves valuable resources and refocuses these resources on the higher risk sites that require more in-depth study.

INEL ER Program Information

Additional papers that have been developed explaining the INEL ER Program and procedures are available on the Internet. The address for the papers is http://www.INEL.gov/environmental/tools/index.html. This address has

been developed as a clearing house for new ideas. Authors not from the INEL with innovative ideas are able to submit 2 page papers for inclusion in the briefing papers collection. Submission parameters are:

- The entire paper may not exceed 2 pages
- The topics are; Title, Scope, How it works, Who could use it, Why should it be used, and a contact name, phone number, address, and fax number.
- Type - use 10 point Gothic
- Submit papers in "HTML"

ENVIRONMENTAL MANAGEMENT AT BELGOPROCESS: THE CENTRALIZED WASTE TREATMENT FACILITY IN BELGIUM

Rik Vanbrabant
Jean-Paule Deworm
Jef Claes
Belgoprocess
Gravenstraat 73
B-2480 Dessel
Belgium

ABSTRACT

The services that Belgoprocess is offering in the field of radioactive waste treatment and storage, decommissioning of nuclear installations, or the sanitation of contaminated sites generate potential risks to the workers, the public and the environment. The company strategy is to keep the risks of harmful effects for people and the environment to an absolute minimum. Therefore Belgoprocess is working along a company wide environmental management program (EMP). This EMP consists of a set of combined measures (organizational, administrative, managerial and technological) to minimize the overall environmental impact according to the ALARA-principles and the application of BATNEEC.

The paper is focused on the detailed analysis of the key elements of the EMP:

internal measures

- combined safety, quality and environmental management program
- organizational structure with decentralized responsibilities and participation of all workers
- the use of stretched management goals
- internal communication and employee involvement
- technological measures, including the use of BATNEEC
- monitoring programs

external measures

- communication with the public
- communication with the clients
- information towards authorities
- environmental reporting.

COMPANY PROFILE

Belgoprocess is a private company, located in Dessel, Belgium, which was established in 1984. It is a subsidiary of the Belgian National Agency for Radioactive Waste and Irradiated Fuel (NIRAS/ONDRAF).

Nuclear energy accounts for more than half of the electricity produced in Belgium. Radioactivity plays a major role in health care and in industrial and scientific applications. As the last link, Belgoprocess has an essential role to play. The company ensures that radioactive waste is processed and stored in such a way that the safety of people and the environment is guaranteed at all times.

It is also extremely important that nuclear installations which are no longer used can be decontaminated and dismantled effectively. Belgoprocess is experienced in this field. On our site in Dessel, the Eurochemic installations are located. This reprocessing plant was closed down in the '70s. Belgoprocess was made responsible for dismantling the installations safely and responsibly.

ENVIRONMENTAL MANAGEMENT PROGRAM

The services Belgoprocess is offering in the field of radioactive waste treatment and storage, decommissioning of nuclear installations, or the sanitation of contaminated sites generate potential risks to the workers, the public and the environment. The company strategy is to keep the risks of harmful effects for people and the environment to an absolute minimum. Therefore Belgoprocess gradually implements a company wide environmental management program (EMP). This EMP consists of a set of combined measures (organizational, administrative, managerial and technological) to minimize the overall environmental impact according to the ALARA-principles and the application of BATNEEC. To stress the importance for an environmental care taking program Belgoprocess has signed the "Responsible Care Act", which has been set up by the Federation of Chemical Industries in Belgium, and which summarizes the management principles toward safety and environmental care taking programs. The text of this act is given in annex 1.

Environmental management is a complex issue. It is an integrated part of the company wide management policy and program which is governed by several external and internal forces. For industrial oriented companies Michael Porter developed a model to better understand and manage company strategies. The company strategy and underlying activities are well balanced taking into account the complex external field of forces, especially for the nuclear industry.

Fig. 1

Political decisions have a major influence on the development of the nuclear industry as a whole. Belgoprocess is acting at the tail end of the nuclear chain. Waste management and decommissioning of nuclear installations are the company domains of excellence. Even in a shrinking nuclear market, excellent services for waste management and decommissioning will be needed, and will play a fundamental role for the overall acceptance of nuclear industry. It is in this frame that Belgoprocess has set up its mission statement which illustrates the essential role of environmental management for the company. Also the influence of the other external forces, namely the economical factors, the social factors and technological factors are well positioned.

Table I

INTERNAL MEASURES

Safety, Quality and Environmental Management Program

Environmental management is not a separate and independent management program. It is part of the company wide management program, where quality and safety management, as well as production management, human resources management, financial management, etc. play an equal role. Company management is a holistic approach and all parts of it are interconnected and influenced by one another. Quality assurance, safety management and environmental protection form the well known triangle of managerial interrelationships.

Fig. 2

Belgoprocess has implemented an overall QA/QC management system. The process of treatment and conditioning of LLW is QA certified to ISO 9001 standards. The process of decommissioning of nuclear installations is prepared to be certified by the end of March 1996. Other processes will be gradually aligned to be certified as well in 1996.

The basic rules of QA can be summarized as follows:

- write how work has to be done
- do the work as written
- prove that work is done as written.

The implementation of a QA system leads therefore to the documentation of all work procedures. Prior to finalize these procedures, it is necessary to analyze and optimize them by incorporating safety analyses and environmental impact evaluation. The QA system driven approach will therefore optimize the company processes.

Safety management, quality assurance and environmental management implemented in this way, enforce one another and leads to an efficient organization. This is the reason Belgoprocess will review the actual QA-procedures in future and integrate measures for environmental impact limitation.

Organizational Structure

Environmental consciousness is a matter of every employee, whatever his role is within the company. Every employee has to consider himself or herself as responsible for reaching the goals the company has set for environmental impact limitation. It is by the combined action of all individual work done that services to clients are offered, and that the safety, quality and environmental impact goals are reached.

Environmental management is therefore not the sole responsibility of the manager. Its the managers duty to set up, implement and control the work being done according to the EMP. Its the employees duty to work according to the rules of the system. Every employee has to know the company goals, the management systems, and its responsibility. According to Belgian law it is not the company but single employees who can be prosecuted according to criminal law for infraction of environmental rules and regulations.

Belgoprocess is structured according to their two main processes: radioactive waste management and decommissioning. Supporting services are formed for administrative work, technical services, safety support and quality assurance. The manager of the safety support service has been appointed as environmental coordinator. He reports directly to the manager. In this way split-up responsibilities are overcome and it is clear that the company stresses the importance of implementing a safety culture in association with an environmental care program. The environmental coordinator is the initiator and controller of the environmental responsible care programs. Their execution is a matter of every employee. A working group is established within the company which

act as a think tank for environmental affairs. The environmental coordinator ensures that all legal aspects applicable for the company are well known, that the company is working according to the rules, and that the results of the responsible care programs are communicated to the authorities.

Internal Communication and Employee Involvement

Effective execution of the EMP supposes an open internal communication network and culture.

The manager has to set clear and stretched goals. This information has to be communicated to all employees. By continually repeating communication about environmental company goals and policies, employees know it is important for the company because the manager puts a lot of effort and time in communicating the message. Data concerning the environmental impact levels, analysis results etc. have to be known by the employees immediately after measurement. In this way employees can evaluate the results of their efforts towards reaching the company goals. This leads to real involvement and foster employees at all levels an individual sense of responsibility for the environment and the need to be alert to potential sources of pollution associated with the operations.

Effective internal communication has a positive impact on external communication as well. Employees are in close contact with the surrounding community and are thus very effective ambassadors.

Technological Measures

Environmental impact limitation is established by applying available technology. The use of suitable or best available technology out of a broad spectrum of available technology is stressed by applying the principles of ALARA and BATNEEC. These principles stipulate that aspects as costs are part of the justification process for the selection and application of technology. Reduction of environmental impact has to be expressed in terms of reduction of costs. The costs of the use of alternative technologies or the application of alternative working procedures for obtaining a lower environmental impact has to be of equal level, without it the alternative practice cannot be justified. ALARA-principle is mainly used for radiological impact optimization, whereas BATNEEC-principle is applied for other industrial sectors or contaminants.

Monitoring Programs

Measuring the performance and efficiency of the applied technology and working procedures is essential in good environmental care taking practices. Knowing the relevant parameters characterizing processes and practices permits the optimization (justified limitation) of residual environmental releases. Exploitation licenses contain release limits for aqueous and gaseous effluents. It is the company strategy not only to operate the technical installations at all times within the imposed release limits, but to excessively reduce the residual releases as long as economically justifiable. The laboratory infrastructure of Belgoprocess and the use of on-line measuring equipment permits the control of technical installations and processes.

EXTERNAL MEASURES

Communication with the Public

As part of management policy special attention is given towards communication with the public. The management principle is to provide the public with the information necessary to enable them to understand the potential environmental effects of the companies' operations and to be

prepared to respond positively to expressions of public concern. The headway made with the cleansing plan for the site and the investment in new equipment and working procedures are the instruments which we are using to establish a new relationship of trust and understanding between Belgoprocess and society. The nature and frequency of communication is adapted to factors such as the nature of the work activities, their impact on local amenities, the level of risk and the level of public interest in information.

The Isotopolis information center was inaugurated in 1993. Isotopolis is a forum from which information on radioactivity and radioactive waste products can be distributed to a wide-ranging public. From the beginning a large number of visitors have witnessed the efforts Belgoprocess is taking as part of the EMP to reduce the residual releases to an absolute minimum.

Communication with the Clients

The same open communication policy is practiced towards our clients. Belgoprocess is achieving transparency and operates as an open book. By strengthening the environmental care taking practices clients have trust in the good functioning of Belgoprocess and the quality services the company is guaranteeing to their clients.

Information Towards the Authorities

On a regular basis the measured residual releases into the environment are transferred to the controlling authorities. Every six months the management of the company informs the authorities about the internal functioning of the company, the planning of future programs, the measures Belgoprocess is taken to guarantee the fulfillment of the imposed limits, etc. On a local basis a contact group with the municipalities is institutionalized and on a regular basis they are informed about the company strategies, programs and results. This intense and open communication process convince national and local authorities that the services Belgoprocess is offering are acceptable on broad basis.

Environmental Reporting

Yearly an environmental impact report is published. The most important results are summarized as follows.

To determine the impact of the activities on the public and the environment, the liquid and gaseous releases and the direct radiation are measured. For these source-terms the federal and regional authorities have fixed limit values. Its Belgoprocess' duty as nuclear responsible operator to assure that releases always are lower than the imposed limits. Belgoprocess is further reducing the releases to minimize its impact as long reasonably achievable. Based on the measured radioactivity the dose-impact is calculated according to a model. For the release of treated wastewater in the river MolseNete the annual dose is calculated being lower than 0,6 mSv for the mean inhabitant. For the gaseous releases the model is based on the impact of the most critical person. The dose-impact for gaseous releases is lower than 0,6 mSv as well. The dose-impact for the mean inhabitant is even lower. The measurements are performed as part of an environmental control program for the surroundings of Belgoprocess. This program is imposed by the competent authorities. The results are independently controlled.

Liquid Releases

In 1994 Belgoprocess released 63615 m3 treated wastewater into the river Molse Nete. This is 15% of the limit value. The measured radioactivity of the released wastewater was 5500 GBq. Activity consists off 99.75% 3H

which can not be captured by the applied treatment processes and equipment. For the other radioisotopes present in the released wastewater, the technical purification limits are reached. The released wastewater contained a weighed radioactivity of 27 GBq which is 1.36% of the limit value. The predominant radioisotope 3H generates only 20% of the weighed activity. b-isotopes which are present for only 0.249% account for 79% of the weighed activity. a-isotopes are present for 0.0006% and account for 1% of the weighed activity. Also for the release of pure chemical substances the actual amounts were only a few % of the limit values. In total only 44 tons of chemical load was released, or 4% of the limit value. The three most important groups of substances were suspended materials and oxygen-binding substances, heavy metals, and eutrophying substances such as N and P. The dose-impact for the inhabitant along the Molse Nete was lower than 0,6 mSv. The release of the wastewater had no negative effect on the biological quality of the river water. The biological quality is expressed in term of the bio-index (a 1 to 10 scale: bad .. excellent). The index upstream the point of release was only 3, but increased up to 6 due to the modernization of the community wastewater treatment station. The index downstream the point of release was 5 to 6.

Gaseous Releases

The release through several chimneys consists off mainly ventilation air. This air is released after effective filtration. All installations keeping or treating radioactive substances are kept in underpressure through a ventilation system. In this way uncontrolled releases into the environment are prohibited.

Also process gases are released. The most important ones are gaseous releases from the evaporation process of high level liquid wastes, from the incineration of solid and liquid radioactive waste, and from the bitumization plant of radioactive sludges. Through the chimney of the combustion furnace, 720 MBq or only 1% of the limit value, was released. For all other chimneys the releases were even lower than 0.1% of the limit values. Through usage of heavy fuel with lower S-content, the release of SOx was further reduced.

Direct Radiation

The storage of radioactive waste on site is a potential burden of direct radiation. Waste is stored and treated in adequately shielded buildings. At the periphery of the premises of Belgoprocess the radiation levels are measured, controlling the affectivity of shielding used. Around site 1 of Belgoprocess radiation levels of 60 to 80 nSv/h are measured, which are natural background levels. Around site 2 radiation levels up to 600 nSv/h are measured. They are due to the presence of radiation sources with limited shielding. New storage buildings have been built and waste packages will transferred in near future.

The following figures illustrate the key data of the environmental report 1994.

FEDERATION OF CHEMICAL INDUSTRIES IN BELGIUM

COMPANY ENVIRONMENTAL AND SAFETY POLICY

- RESPONSIBLE CARE PRINCIPLES -

Belgoprocess, who signed the Responsible Care Act, applies the following principles:

1) To implement an integrated company policy on safety and environment and to apply the guidelines and codes of good practice to assure this policy.
2) To make sure that this policy and its objectives are well known to all employees and that this policy is applied.
3) To take actions to continuously improve the results of the company on safety, health and environmental protection.
4) To gather the necessary data to be able to evaluate the impact of processes, products and activities on the environment, and the health and safety of the public, in order to control possible effects.
5) To make health, safety and environmental considerations a priority in our planning for all new products and processes.
6) To report promptly to officials, employees, customers and the public, information of company-related health or environmental hazards. To oblige the employees to follow up adequate protective and safety measures and to oblige subcontractors to do the same.
7) To inform the public, directly or through the authorities, to allow the public to form its opinion on environmental, health and safety effects of the company activities. To recognize and to respond to the concerns of the public.
8) To counsel customers on safe use, transportation and disposal of our products.
9) To operate our plans and facilities in an manner that protects the environment and the health and safety of our employees and the public, and to assist the competent authorities to arrange corresponding external measures.
10) To extend knowledge by conducting or supporting research on the health, safety, and environmental effects of our products, processes and waste materials.
11) To participate with the government in creating responsible laws, regulations and standards to safeguard the community, workplace and environment.
12) To promote the principles and practices of responsible care by sharing, where possible, experiences with other companies and offering assistance to others.

ABSTRACT

A remedial investigation/feasibility study was undertaken at Oak Ridge National Laboratory (ORNL). Bechtel National, Inc. and partners CH2M Hill, Ogden Environmental and Energy Services, and PEER Consultants have been contracted to Lockheed Martin Energy Systems, performing this work for ORNL's Environmental Restoration (ER) Program. An on-site Close Support Laboratory (CSL) established at the ER Field Operations Facility has evolved into a laboratory where quality analytical screening results can be provided rapidly (e.g., within 24 hours of sampling). Management of the CSL has been transitioned to T N and Associates this fiscal year. CSL capabilities include three basic areas: radiochemistry, chromatography, and wet chemistry. Besides environmental samples, the CSL routinely screens health and safety and waste management samples. The cost savings of the CSL are both direct and indirect. Direct cost savings are estimated based on comparable off-site quick-turnaround analytical costs. Indirect cost savings are estimated based on: reduction of costs and liability associated with shipping for off-site analyses, preparation for sampling, assistance to Health & Safety staff, use of CSL results to focus further sampling efforts, and sampling crew downtime. Lessons learned are discussed.

INTRODUCTION

A remedial investigation/feasibility study (RI/FS) began at Oak Ridge National Laboratory (ORNL) in 1987 for ORNL's Environmental Restoration (ER) Program. Bechtel National, Inc. and partners CH2M Hill, Ogden Environmental and Energy Services, and PEER Consultants are the RI/FS subcontract team. In 1989 the project established the Close Support Laboratory (CSL) to provide rapid radiological (a/b/g) and volatile organics screens on samples to determine DOT classifications before shipment to the off-site CLP laboratory. The advent of the Observational Approach and SAFER led the RI/FS team to shift the main use of the CSL from preshipment screening to screening to help in technical decisions (e.g., delineating the extent of contamination). Basic wet chemistry techniques were added to assist in rapid and cost-effective sample characterization. CSL scope has recently changed further to support other groups performing environmental restoration activities for the Oak Ridge Reservation. The CSL is now managed and staffed by T N and Associates, an 8(a) small business subcontractor. Also, the CSL now has an interface to the Reservation-wide Analytical Services Organization (ASO), to provide integrated analytical service to its customers.

TECHNICAL SUPPORT

The CSL provides the quality, quick-turnaround data needed to support results-based field decision making. Analytical results can be provided to the data user overnight or within 24 hours as required by the customer (currently, a thirty day turnaround time is standard if there is no quick turnaround request). Under Bechtel's contract, CSL staff assisted RI/FS project geologists with planning, interpretation, and application of sampling and analysis plans and associated support documents. The staff have supported ER field efforts with analytical planning, cost estimating, and data interpretation for the past two years.CSL staff interact with various ER project staff to provide pre- and post-field-support activities. These including preparation of sampling kits, sample

screening for DOT transportation/packaging and radioactivity checks, analytical planning and coordination with either on- (ASO) or off-site confirmatory-level laboratories, receiving excess sample returned from these labs, and archiving or disposing of sample remnants (thus closing the chain-of-custody).

Immobile laboratory trailers at the ORNL ER Field Operations Facility (FOF) house the CSL. This location is convenient for sampling teams to pick up sample kits or to deliver samples since the FOF is the starting and stopping point for most ER field activities. We routinely screen environmental, health and safety, low-level decontamination and decommissioning and waste management samples. Our sample screening results are used by ASO and off-site labs to guard against instrument contamination and detector saturation.

ANALYTICAL TECHNIQUES

The analytical scope of the CSL covers basic radiological and volatile organics screening, and basic wet chemistry. Analyses can be performed rapidly, and results from complementary techniques are reviewed to provide a more complete technical understanding. Method detection limits are comparable to off-site confirmatory labs.

Primary radiological contaminants of concern are 90Sr, 137Cs, and 3H. Radiochemical analyses include gamma spectroscopy, tritium and carbon-14 screens using liquid scintillation analysis, and gross alpha and beta counting. Cerenkov counting and crown-ether-based separation are the two rapid methods used for determination of radiostrontium in water samples. Minimum detectable activity values for radiological samples may be adjusted by changing sample sizes and count times to meet the customer's needs.

Gamma spectroscopy is performed via an intrinsic germanium detector with a computer-based multichannel analyzer. Due to the lack of an autosampler and the long count times often required, the gamma detector system is a bottleneck in sample throughput. A second detector will soon be on-line to increase the CSL's capacity.

Liquid scintillation is used to perform 3H and screening 14C analyses. Samples are not distilled; instead, soil samples are DI water extracted (1:1 w/v) and instrumentation software corrects for quenching effects in all samples. Carbon-14 can be excluded based on negative screening results but cannot be confirmed based on positive results (other weak or quenched b particles may cause 'false' positives).

Gross a and b are measured using proportional counters. Low-activity samples are analyzed on a low-background gas-flow proportional counter. Higher-activity samples are analyzed on scalers because higher-activity samples might contaminate the low-background counter, and the ZnS solid scintillator probe is immune to the b->a cross-talk observed in the a signal from the gas-flow proportional counter.The CSL analyzes 90Sr in water samples using one of two methods. Strontium may be separated from unfiltered or filtered samples using SrSpec columns (EiChrom), then immediately counted for 90Sr as gross b before substantial 90Y ingrowth. Alternatively, after a two-week 90Y ingrowth, 90Sr Cerenkov counting may be performed on filtered samples using the liquid scintillation counter (and no scintillation cocktail). Strontium-90 Cerenkov counting also requires gamma spectroscopy to provide 137Cs/60Co correction to the Cerenkov-determined 90Sr activity.

The primary volatile organic contaminants of concern are fuel-based aromatics and solvent-based chlorinated hydrocarbons. Volatile organics

screens are performed by gas chromatography (GC) using photoionization (10.2 eV) and Hall electrolytic conductivity detectors and a CSL-specific method based on EPA methods 601 and 602. A sixteen-port purge-and-trap autosampler introduces samples onto the GC column.

Basic wet chemistry for environmental waters includes alkalinity, dissolved and suspended solids, ion chromatography (IC), and, (for various matrices) pH and resistivity. IC is used to analyze both cations and anions following a CSL-specific method based on EPA 300. Together, IC and alkalinity provide an ionic profile of water samples, and their sum can be compared to the total dissolved solids measurement as a performance check.

QUALITY ASSURANCE

The mission of the CSL is to provide rapid screening (EPA level II) for the ORNL ER program. The lab delivers these results, using lab-specific methods, without time-consuming deliverable requirements. Controlled CSL procedures and the laboratory quality assurance plan document quality requirements for each analysis and general laboratory practices. QA staff from ORNL Oak Ridge Reservation, DOE Oak Ridge, and, formerly, Bechtel, routinely audit the lab's procedural conformance and good lab management practices. The CSL has used independent performance evaluation (PE) samples to fine tune method accuracy. The PE samples were obtained from commercial sources. Recently, the lab has begun to take part in government-sponsored radiological (DOE MAPEP and EPA EMSL-LV) and chemical water pollutant (EPA EMSL-Cinci) PE studies. Participation in these studies confirms the CSL's accuracy and interlaboratory comparability.

COST EFFECTIVENESS/SAVINGS

The CSL is saving dollars both directly and indirectly. Direct cost savings are based on comparable off-site quick-turnaround analytical costs; premium charges for rapid response from off-site laboratories make the CSL especially cost-effective. The RI/FS team has documented CSL savings estimated to be greater than $1 million for fiscal years 1993 and 1994.

Indirect savings are difficult to quantify. They are based on reduction of costs and liability associated with shipping samples off-site for analysis, preparing for sampling and sample shipping, assisting Health and Safety (H&S) staff, and sampling crew downtime. CSL data provides analytical information for proper DOT classification of radioactive environmental samples. Sample container procurement, sample kit preparation, and sample chain of custody are all centralized through the CSL for most samples analyzed by the CSL. CSL staff also generally prepares and packages samples for shipment to off-site or ASO labs for further analysis. H&S staff uses the CSL to analyze monitoring samples to minimize personnel risk, and field sampling crews can be more productive because of the rapid turnaround of data from H&S and sampling based on results of previous sampling. The RI/FS team made extensive use of CSL data in the Remedial Investigation for Waste Area Group 5 at ORNL and other site characterization projects.

LESSONS LEARNED

Several lessons learned at the CSL may apply to similar screening laboratories.

- Participate in the initial scoping or DQO Process activities to identify data uses and opportunities to use CSL data.

Determine a general prioritization scheme for samples and analyses before competing deadlines or customers demand one. This planning should include holding time, data end-use, and lab staffing considerations. Lab customers should be aware of and agree with this scheme.

Establish appropriate sample selection guidelines to identify possible further analyses (e.g.,perform g spectroscopy only when b activity is greater than x) within the screening lab or at an off-site confirmation lab. Setting up a formalized analytical decision tree will save money by reducing unnecessary analyses and documentation requirements.

Invest in an expandable data handling system and integrate data handling into the appropriate project data management plan. Data quality can be undermined by a poor or 'make-do' handling system.

Stagger staffing hours. Varied schedules reduce overtime, improve morale, and serve both the first-of-the-day customers (generally technical staff) and end-of-the-day customers (generally field sampling staff).

FUTURE DIRECTIONS

The mission of the CSL continues under T N and Associates. With the recent appointment of an ASO technical interface, Energy Systems is taking a more active role in CSL activities. This interface is likely to strengthen as DOE analytical strategies become more coherent. Improvements in data handling will ensure seamless electronic data delivery to CSL customers and the Oak Ridge Environmental Information System. As quick-turnaround screening data are more broadly accepted, the analytical capability and sample capacity of the CSL will likely expand.

SUMMARY

The ORNL RI/FS team established the CSL to provide rapid radiological (a/b/g) and volatile organics screens for ER. Basic wet chemistry techniques were added to assist in rapid and cost-effective sample characterization. Today T N and Associates continue that mission. The CSL provides its customers with technical and analytical support, and lessons learned have potential application for similar sites or labs. ER is expanding the CSL's scope to support more environmental restoration/waste management activities at ORNL.

LOW-RESOLUTION SIM MODE GC/MS ANALYSES REQUIRING HIGH-RESOLUTION GC/MS TECHNIQUES FOR QUALITATIVE COMPOUND IDENTIFICATION

Lynelyn Fitzgerald
Douglas J. Scott
Richard A. Kulp
Parsons Engineering Science, Inc.

ABSTRACT

The United States Air Force (USAF) is conducting a site investigation at Air Force Plant (AFP) PJKS near Waterton, Colorado. The compound n-nitrosodimethylamine (NDMA) was identified as a contaminant using gas chromatography/mass spectrometry (GC/MS) selected-ion monitoring (SIM) analysis of soil and groundwater samples. As part of the investigation, several background wells were sampled to determine environmental levels of specific target compounds in groundwater. NDMA is not naturally occurring, but was detected in one of the background wells. Upon reanalysis of the sample by another methodology, it was discovered that an organic acid was a direct interferent of NDMA in the SIM method. The interfering organic acid was also found to be present in some of the

project environmental samples with detected NDMA results. As a result, all positive detections determined by the SIM method were considered suspect. A new method of analysis was needed that maintained the analytical comparability with previous data collected (e.g., low detection limit). It was decided that high-resolution GC/MS would be used to confirm any detections produced by the SIM method. If a result was confirmed by the high-resolution method, then the NDMA result from the SIM analysis would be reported as usable.

INTRODUCTION

A supplemental remedial investigation/feasibility study (SRI/FS) was performed at AFP PJKS, near Waterton, Colorado as part of the Air Force's Installation Restoration Program (IRP) to assess past hazardous waste disposal and spill sites and develop remedial action strategies for cleanup. AFP PJKS activities included rocket fuels development, purification, and testing activities in support of the Titan missile. Hydrazine fuels (hydrazine, unsymmetrical dimethyl hydrazine, and monomethylhydrazine) were used in the testing and development activities. A degradation product of these hydrazines, NDMA, was detected in the soil and groundwater. The approved detection limit of US Environmental Protection Agency (EPA) method SW8270 (EPA,1987) for this compound (10 parts per billion) was considered inadequate in comparison to human health and ecological risk levels for soil and water samples. As a result an alternative method was needed. A modification of the EPA GC/MS method SW8270, for semivolatile organics, capillary column technique, was developed. This method, which involved the use of SIM GC/MS, was reviewed and/or approved by multiple regulatory and federal agencies during work plan development for the investigation. After several years of data analysis using this method, it was discovered that an organic acid present in the samples shares the primary ion with NDMA and acts as an interferent, which leaves much of the data unvalidatable (unconfirmed target compound identification) and therefore of limited use. It was determined that the modified method produced false positives for some sample results for NDMA analyses. A description of the method and resolution of the interference problem are discussed in the following paragraphs.

SELECTION OF ANALYTICAL METHOD

When determining the method for analysis of NDMA at AFP PJKS, detection limit requirements were of utmost importance. The concentrations of concern, as related to ecological and human health risk assessment (12.5 g/kg for soil samples and 0.000362 g/l for water samples), were compared to the detection limits for three analytical methods. Two of these methods, SW8070 and SW8270, are standard SW846 analyses. The third is a modification of SW8270 using the SIM mode of acquisition. Method SW8070 is a GC method that requires second-column confirmation and has estimated method detection limits (MDLs) of 0.15 g/l for water and 1.5 g/kg for soils. This analysis was rejected because second-column confirmation of NDMA detections increases the cost of analysis, and the detection limits were not as low as those provided by other methods under consideration. The detection limit for NDMA analysis by SW8270 also was insufficiently low to meet risk assessment quality objectives. An alternate method with a lower detection limit was required. It was determined that a modification of method SW8270 would produce the lowest detection limits. An explanation of why the SIM mode is a more sensitive modification of the method is given below.

There are two commonly used methods to acquire data from an analysis by GC/MS operating in electron impact (EI) mode. Scan mode, the most commonly used method, acquires information continuously from a signal originating from an electron multiplier over a wide range of ions. These ions have a specified mass, measured in atomic mass units (AMU), which is used to help identify the compound of interest. A scan of the range of ions (usually 35 to 500 AMU) occurs a minimum of one scan per second. SIM GC/MS functions in an identical manner with one exception. The designated scan range for SIM GC/MS is much narrower and is specific to the mass of the primary ion for the compound of interest. Therefore, when acquiring data in the SIM mode, a greater amount of data is collected for a specific ion mass. As a result of greater amount of acquired data over the same amount of time, greater instrument sensitivity is obtained in the SIM mode as opposed to the scan mode, resulting in a lower limits of detection for the target compound. Because the SIM mode produced lower detection limits that were more in keeping with the risk-based concentrations of concern, the SIM mode modification of the SW8270 method was selected as the investigative protocol.

ANALYSIS OF NDMA USING SIM GC/MS AND PROBLEMS WITH INTERFERENCE

Analysis of NDMA using SIM GC/MS involves the following procedure. A measured volume or weight of sample is extracted with methylene chloride at pH 11, and then extracted again at pH 2. The solvent extract is dried with sodium sulfate and concentrated to a final eluate volume of 1 ml. Surrogate spiking compounds are added during the extraction phase, and internal standards are added prior to sample analysis and after extraction. After chromatographic separation, qualitative identification is performed using peak retention time and the relative abundance of the primary NDMA ion, at 74 AMU. Quantitative analysis is performed using the internal standard technique relating the response of the internal standard to the response of the NDMA primary ion (74)(Southwest Laboratory of Oklahoma, 1992).

As part of the field effort for the AFP PJKS site investigation, several groundwater monitoring wells were chosen outside of suspected contaminated areas to measure the background levels of specific target compounds, including NDMA. NDMA was detected at a level of 39 g/l in one of the background wells. NDMA is not naturally occurring and should not have been detected in this well. The sample analysis was confirmed for NDMA when reanalyzed by method SW8270 SIM mode using the two secondary ions (42 and 43) in addition to the primary ion (74). The laboratory was asked to reanalyze the sample in the scan mode, where it was discovered that an unknown compound (an organic acid) coeluted with NDMA. The unknown compound contains, as part of it's spectrum, the same ion abundances of 74, 42, and 43 AMU that were used in the SIM mode to identify NDMA. It also produced a response at 73, 57, 56, and 45 AMU. Therefore the unknown organic acid (believed to be propanoic acid) produced a spectral signature in the SIM mode identical to that of NDMA, and was responsible for the false positive NDMA detection in the background well. Because of the shared ions and the similar retention time of both compounds, the positive detections which had been achieved so far in the investigation immediately became suspect. It could not be determined by the data available which compound had produced the positive results in the SIM mode. The samples that produced no detections were determined to be valid results, because neither NDMA or the unknown organic acid was present to produce a positive detection.

ANALYSIS OF NDMA USING THE SIM MODE GC/MS WITH CONFIRMATION BY HIGH-RESOLUTION GC/MS

The immediate problem was to find a reliable method for analysis of NDMA which would allow a low enough detection limit to be comparable to the concentrations of concern and also allow confirmation of the detection of NDMA. It was also important to maintain the comparability of the data so that the results of the samples that produced no positive detections could be used. It was determined that comparability could be maintained if the SIM mode GC/MS method was used with a confirmation method for positive detections. The confirmation method would distinguish between NDMA and the organic acid.

It was decided to confirm the positive detections with high-resolution MS in the SIM mode. The original SIM mode method measured the response of 74+/- 0.5 AMU. The high-resolution method measured the exact molecular ion at 74.048 AMU specific to NDMA only. When NDMA was detected in the low-resolution SIM mode analysis, a confirmation analysis using the high resolution technique was used. If NDMA was confirmed by the high-resolution analysis, then the original NDMA result from low-resolution SIM mode analysis was reported. If the confirmation method proved that the detected compound was the unknown organic acid, then NDMA would be reported was not detected.

CONCLUSIONS

GC/MS analysis techniques are commonly thought of as confirmational qualitative methods not requiring alternate analyses with dissimilar columns or detectors, as is typical when using GC methods without a MS detector. When utilizing SIM mode GC/MS methods, this may not always be an accurate assumption, as proven by the results for NDMA at AFP PJKS. The use of SIM methods requires knowledge of the project site operational and analytical history. If analytical history is unavailable, site screening of soil and water by full-scan GC/MS methods should be performed prior to the use of SIM methods in order to identify possible sample interferences. Without sample interferences, SIM mode analysis provides a qualitative and quantitative result in the primary sample analysis. Confirming results using high-resolution SIM techniques is an alternative to site screening with full-scan, low-resolution methods. Unique project considerations must be evaluated to determine the most cost-effective approach to this qualitative method-selection issue.

ABSTRACT

A full-scale field demonstration of an innovative subsurface stabilization technique was performed on simulated transuranic waste pits at the Idaho National Engineering Laboratory. The demonstration involved jet grouting simulated buried transuranic waste pits with an acrylic polymer. The jet grouting created a monolith out of the buried waste pits. The monolith can either be considered for in situ disposal of the buried waste with improved confinement or can actually enhance the contamination control of the transuranic material during a hot-spot retrieval effort by agglomerating the contaminants into courser less aerosolizable materials. The demonstration involved pit construction, two-component jet grouting for the polymer pit, destructive examinations of the polymer pit, and evaluation of the contamination-control aspects of using the polymer material to bind the contaminants.

INTRODUCTION

This project was sponsored by the Department of Energy Office of Technology Development Landfill Focus Area. It investigated two potential applications for jet grouting: 1) creating monoliths out of the soil/waste matrix for in situ disposal of buried waste, and 2) creating monoliths for interim storage of buried waste for eventual retrieval, treatment, and processing. Both of these scenarios are being considered by the Idaho National Engineering Laboratory (INEL) Environmental Restoration Program as part of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) process. Results of this investigation can be used to establish the Record of Decision for the 2 million cu ft of buried mixed transuranic waste commingled with 6-8 million cu ft of soil in shallow land burial at the INEL.

To accomplish these tasks, two simulated waste pits were jet grouted with two different formulations of an acrylic polymer grout provided by 3M Company, Inc. The grout is an acrylic chemical grout based on an acrylic comonomer blend. Jet grouted into one waste pit was a version of the polymer that produced a hard durable monolith out of the waste. This version of the polymer simultaneously stabilized the waste against subsidence and provided complete waste encapsulation. This monolith could be considered for disposal in situ of the buried waste. For the other pit, a slightly different formulation of the same basic polymer was jet grouted, which resulted in the same monolithic structure. However, the mixture of soil-polymer that resulted was eraser-like in texture and easily retrievable with enhanced contamination-control and dust-control attributes.

The experiment involved pit construction, grouting, retrieval of the soft eraser-like monolith with air sampling, and coring and destructive examination of the hard monolith.

PROCEDURE

Two identical pits (4.5 9 6 ft) were constructed with the same composition as the transuranic pits and trenches found in the INEL Subsurface Disposal Area. The pits contained 15 to 55-gal drums of simulated waste material including cloth, paper, metal, wood, asphalt, concrete, glass, and sludge. Loading of the simulated waste in the drums was typical of those from the Rocky Flats Plant, with a range of up to 50% voids for the metal-containing drums and 10% voids for the sludge

drums. A rare-earth tracer (dysprosium oxide) was placed in each container to simulate the plutonium/americium oxide present in the actual buried waste.

Past studies have shown that the rare-earth oxides move like plutonium under the INEL soil conditions. (1) The two pits were typically backfilled with INEL soil identical to the practice in the actual waste pits. The grouting phase involved jet grouting with the CASA GRANDE C6S drilling/jet-grouting system using a dual concentric annulus drill stem and two positive displacement pumps with balanced flows. This allowed mixing of the two parts of the polymer grout in the ground through a single nozzle at the bottom of the drill stem.

One component of the grout was injected at 6,000 psi using the CASA GRANDE JET5 pump, and the other component was injected at 1,000 psi using the Schwing pump. A typical grouting operation was to deliberately drive the 4-9/16 in. drill stem through the waste. When fully inserted, the procedure was to withdraw the drill stem while jet grouting. The test variables were withdrawal rate, drill stem rotation, pump pressure, and withdrawal step size. Based on field trials, the step size was set at 3 cm, with 2 revolutions per step, and 3 s on each step. This resulted in placing nominally 65 gal of combined polymer material into each of the holes. Also based on field trials, the holes where placed at 2-ft spacing on a closed-pack triangular pitch.

The retrieval phase of the soft eraser-like monolith involved placing a weather structure over the pits and using air samplers during retrieval to evaluate the contamination control by measuring collected dust and tracer. Retrieval was accomplished with a backhoe with thumb attachment. The hard monolith was evaluated by coring in two locations and by destructive examination (isolation and uncovering of the monolith). Laboratory durability studies were also performed involving the hard monolith for compressive strength, effect on compressive strength due to base attack, water immersion testing, and permeation of liquid phase volatile organics.

RESULTS

The demonstration involved jet grouting, retrieval (soft polymer pit), and destructive examination (hard polymer pit). The main objective was to prove the concept for this technology.

Grouting

Grouting was performed in 1 working day for both the soft polymer pit and the hard polymer pit. A total of 33 combined holes were grouted into the two pits (18 holes in the hard polymer pit and 15 holes in the soft polymer pit) as shown in Fig. 1. Grout returns (a mixture of soil and uncured polymer mix that flows up the drill stem during grouting) were considerably higher than returns previously experienced when jet grouting lower viscosity Portland cement/water mixtures. During a Fiscal Year 1995 demonstration called Innovative Grout/Retrieval, (2) jet grouting with Portland cement produced about 2gal of returns per 10-ft hole, and these returns were easily contained in a spoils collection hole around the drill stem.

Fig. 1

For the Fiscal Year 1995 polymer demonstration, 5 to 7 gal of returns were observed in each hole, and a special collection pit and canal system were employed to manage this secondary waste material. Figure 2 shows the jet-grouting operation, with the spoils collection pit and canal system to divert the spoils into the collection pit. Cure time in laboratory

mixtures of polymer and INEL soil was about 70 minutes. Therefore, the jet-grouting operation had to be sensitive to timing to avoid premature curing in the injection equipment. Premature curing of the polymer material was not observed during grouting, and the jet-grouting apparatus performed even better (less breakdown time) than with Portland cement, primarily because of the lower viscosity material. Since the jet-grouting operation used a dual concentric annulus drill stem, any mixing of the two components occurred outside the injection apparatus.

Fig. 2

Retrieval (Soft Polymer Pit)

Once grouted, a weather structure was placed over the pits and 10 high-volume (25 cfm) air samplers were oriented around the pits. With no operations inside the weather structure, dust and tracer concentration data were obtained (8.42E-7 g/L-air; less than 30 ppm dysprosium on the filter). Next, approximately 3 ft of overburden was removed while taking air-sampling data to establish a baseline digging scenario for comparison with digging in the soft polymer pit. Comparison of the dust concentration for digging of soil with no polymer verses excavating the pit with polymer gives an assessment of the degree of dust and therefore contamination spread data.

For the overburden removal case, the dust concentration was 1.21E-5 g/L-air and the dysprosium concentration averaged 20 ppm. A dust concentration of 1E-5 g/L-air is comparable to digging in a soil condition during the excavations discussed in the innovative grout/retrieval demonstration report.2 During digging of the soft polymer pit, the measured dust concentration was considerably lower than the baseline digging case. For the polymer pit, the dust concentration averaged 1.11E-6 g/L-air compared with 1.21 E-5 g/L-air for overburden removal. The dysprosium concentration averaged 3,397 ppm, or a two-order-of-magnitude increase in the concentration during overburden removal. Reduction in dust concentration for digging in the polymer pit compared with digging in just soil was 91%. To put this into a radiological perspective, if the source term were 450 nCi/g (estimated as an average concentration at the INEL buried

At the INEL, bubble-suited entry above about 10 nCi/g would require special waivers. The two-order-of-magnitude increase in dysprosium concentration for digging the polymer pit compared with either background or overburden removal is attributed to the presence of an ungrouted drum punctured during retrieval. The drum was a metal container interred on the edge of the pit. During backfilling, the drum moved outside the surveyed pit boundaries and was missed in the jet-grouting operation. In an actual pit retrieval, this event would not be a problem, because the area of grouting surrounding a hot spot or actual pit would extend up to 10 ft beyond the area excavated, which would avoid the ungrouted drum scenario. It is unlikely that with a 2-ft grid spacing, a drum in any orientation would go ungrouted.

Examination of the debris retrieved from the soft polymer pit showed that the polymer did cure and was easily retrievable. The pit came apart with standard backhoe digging as if the soil/waste matrix was merely wet clay. Examination of the debris showed that unlike the Portland cement pit described in past studies, (1) the individual waste forms were coated in a cured polymer material. Especially impressive was the paper material that had the appearance of having been first soaked with the polymer and then cured. The Portland cement would not have penetrated the paper.

Figure 3 shows a drum containing paper impregnated with the cured polymer.

Fig. 3

Examination (Hard Polymer Pit)

The hard polymer pit was first cored with 2-in. coring equipment and then isolated and finally destructively examined. Results of the two cores obtained show that the monolith was free of voids and that the polymer material did indeed cure while buried. For the destructive examination, the weather shield was removed and the monolith was isolated (9 4.5 6 ft). The structure maintained the monolithic shape. The southeast corner was accidently removed as one piece about 3 ft long by 4 ft wide during the isolation. The monolith was lifted from the pit as one unit with a 7-yard front-end loader but broke along the lines of the waste containers into three distinct pieces when placed on the ground. Based on visual observations, this hard polymer may have resulted in a considerable reduction in the spread of dust and contaminants during retrieval mainly because the waste can be removed in larger pieces.

Durability Tests

Representative samples were subjected to a set of scoping performance and durability tests to determine the adequacy of the polymer for in situ treatment of INEL buried waste. Testing included measuring hydraulic conductivity, resistance to immersion in water, resistance to immersion in a saturated aqueous solution of trichloroethylene (TCE), resistance to immersion in alkali, and resistance to wet-dry cycling. These resistance tests were designed to evaluate the effect of the test on compressive strength, which is an indicator of durability.

Hydraulic Conductivity

Hydraulic conductivities were measured using a flexible wall permeameter following American Society for Testing and Materials (ASTM) D-5084. The hydraulic conductivities of duplicate samples were found to be below the detection limit of the permeameter. Ignoring leakage and evaporation and using only the inflow volume results in a maximum hydraulic conductivity of 1.210-14 m/sec (1.2 10-12 cm/sec) for the brass blank and an average of 2.8 10-14 m/sec (2.8 10-12 cm/sec) for the polymer-soil grout specimens. This indicates a low leaching material with hydraulic properties superior to Portland cement soil grout.

Permeation of Volatile Organics

Original plans called for determining the effect of aqueous solutions of TCE on the hydraulic conductivity of the polymer-soil grout. It was postulated that the TCE might swell clay particles in the soil and further reduce permeability. Because of the low permeability of the specimens, it was impossible to perform this task.

Baseline Compressive Strength

Ten replicate samples of the soil grout were tested for unconfined compressive strength (ASTM C-39) to determine baseline strength. Average compressive strength was 20.7 0.9 MPa (3,000 130 psi).

Water Immersion

It is expected that stabilized buried waste may be exposed to aqueous environments from percolate water. The Nuclear Regulatory Commission (NRC) takes the position that all radioactive waste forms must be able to withstand at least a rudimentary water immersion test. Exposure of barrier materials to aqueous solutions can result in swelling, cracking, or dissolution. Also, soils (i.e., expansive clays) used as aggregate may interact with the water through swelling or dissolution of mineral

components. Aggregate interactions can cause internal stresses with resultant cracking and degradation of the waste form.

Following the testing procedure recommended by the NRC, five replicate samples of the acrylic/INEL soil grout were immersed in deionized water for 90 days. The samples were inspected visually for cracking and swelling periodically during the course of the test. The samples were weighed, measured, and destructively tested for compressive strength (ASTM C-39) at the end of the test period. No visual, dimensional, or structural changes were observed. The average compressive strength was 19.6 0.3 MPa (2,840 40 psi), which shows a very small change from the baseline compressive strength of 20.7 MPa.

Wet-Dry Cycling

The INEL is located in a semiarid region. The soil moisture content is low, ranging between 3 and 15%, but occasional precipitation percolates the ground. The waste form will be under saturated conditions during these times. Wet-dry cycling has a severe impact on construction materials such as hydraulic cement. Five replicate samples of the soil grout were subjected to wet-dry cycling adhering to ASTM D-4843. No dimensional changes were observed. The average compressive strength was 22.9 1.3 MPa (3,320 184 psi) compared with the baseline of 20.7MPa.

Base Attack

At the INEL buried waste site, waste forms will be expected to see alkali conditions. These conditions can arise from the pH of the soil (~8.4) due to the carbonate content, or the buried waste itself can be alkali (e.g., sodium hydroxide used to neutralize nitric acid from reprocessing). Five samples were immersed in an aqueous, sodium hydroxide solution at pH 12.5 for 90 days. The average compressive strength was 16.2 0.6 MPa (2,340 90 psi) for a change in compressive strength compared with the baseline of 20%.

Volatile Organic Attack

Five replicate samples of the acrylic polymer-soil grout were immersed in water saturated with TCE at room temperature for 90 days. TCE was chosen as the candidate medium for volatile organic compound solvent testing because it appears to be one of the predominate contaminants found throughout the DOE complex and it is expected in the INEL buried waste site. The average compressive strength was 19.6 0.3 MPa (2,850 40 psi), which compares favorably with the baseline of 20.7 MPa.

CONCLUSIONS

Based on the results, it was concluded that the two-component acrylic polymer grout can be jet grouted with the dual concentric annulus drill stem and jet-grouting equipment. The resulting monolith is a durable, stabilized matrix suitable for either long-term disposal of buried transuranic waste or interim storage and eventual retrieval. Indications from durability testing show that the polymer/waste/soil matrix is stable for a variety of conditions and is chemically compatible with the environment at the present time. If conditions do not drastically change, the monolith of soil/waste/polymer should remain stable.

During retrieval operations, for the soft polymer pit there is a 91% reduction in dust spread but a two-order-of-magnitude increase in the tracer concentration in the air compared with digging in soil only, suggesting that plutonium might have spread for this retrieval scenario. On a qualitative basis, however, it appears that the hard monolith material may prove to be a superior material compared with the soft polymer for the interim storage/retrieval idea, in that the monolith is

more cohesive. Nevertheless, further testing of that concept for top-down digging would be required to answer that question. In general, the concept of jet grouting a two-component acrylic polymer mixture was demonstrated, and there is a positive proof of concept both for leaving the waste for final encapsulation and for interim storage and eventual retrieval.

ABSTRACT

An interest in using bryophyta as bioindicators has recently emerged considering their great capacity for accumulating pollutants, more specifically metallic ions from their environment. For example, Phacelia sericea has been used to detect the presence of gold in British Colombia (6). However, few studies on aquatic mosses have been undertaken, until now, in Quebec. The aim of this project is to assess the metallic ion content of natural bryophyta from different regions of Quebec. To realize this objective, -calcium, magnesium, copper, cadmium, manganese, iron, nickel, cobalt, and chromium- were analyzed in a number a species. The bioaccumulated load seems to differ depending on the type of metal analyzed, the species, and the part of the plant studied. The structure of most bryophyta is quite simple; no roots, a very simple vascular system and a single thickness cells in their leaves. These plant cells possess many negatively charged sites where the positive metal ions can attach, hence the rapid accumulation that is observed initially which appears to be centered on an ionic exchange (adsorption) process. Our results show that mosses coming from the Cach River near Quebec City are highly contaminated with cobalt. As for copper, this element is present in high concentrations at St-Alexis-des-Monts, Loretteville and around Quebec City. Fontinalis dalecarlica Schimp. ex B.S.G. and Platyhypnidium riparioides (Hedw) Dix. tended to accumulate more than the other species; thus indicating a species dependant selectivity. In comparing two mosses from Loretteville, P. riparioides contained 300 times more copper than Brachytecium rivulare. Except for calcium and magnesium, our results of the metal concentrations found in the stems and leaves correspond with those mentioned in the literature (9,4,8).

INTRODUCTION

Our aquatic environment is becoming more and more stressed by the various pollutants generated by modern industries. One of the main problems associated with the analysis of heavy metals is their very low concentration in the natural waters. In such cases it is often necessary to use bioindicators which concentrate the metals in order to monitor their evolution over time and space (1). To date a variety of bioindicators have been used and depending on the chemical substances, the efficiency will vary according to the type and complexity of the biocaptor chosen (2). Since 1970, the bryophyta are being studied for biomonitoring and assessment of water pollution. Up to now, most of the research is oriented toward the selectivity of the best indicators. Many scientists have been studying the physiological processes in plants for a better understanding of the metal ion interactions. Mosses are very simple plants that have no root structure. Their vascular system is not complex and suggests an easy accumulation process. The metal ionic exchanges reported are principally centered on the stems and leaves. According to some studies undertaken in Quebec, it seemed important to understand the metal accumulation and elimination mechanisms of these bioindicators. In order to use this kind of biomonitor in an assessment program, it is important to know how this organism lives and the capacity it has for concentrating heavy metals. Moreover, it is interesting to compare the metal accumulation by different plants as well as by their different parts which reflects the condition of the plants' natural environment. The capability to accumulate specific toxic substances is generally determined by the species. However, the selective sampling of mosses is not easy because many species often cohabitate on the same substrate. In addition, their identification is not simple since there are only a few specialists in Quebec who can do the identification.
The objectives of this study are 1) to find and to study an efficient and a resistant biomonitor for metal monitoring in aquatic environments 2) to verify the efficiency of the different parts of the plant for accumulating metals in the natural environment and 3) to characterize different regions of Quebec according to the metals thus bioaccumulated.

MATERIAL AND METHODS

Sampling site

The mosses were collected in the summer of 1993 from various rivers of the province. Five sites were found favorable for the sampling of the mosses: La Rserve Mastigouche near St-Alexis-des-Monts, La Rserve des Laurentides near Quebec city, Val-Jalbert near Roberval , Windsor and Loretteville. Many mosses live totally submerged and are attached to the bottom rocks by their rhizoides (a type of small hook on the end of a semi-root) while others are semi aquatic.

Table I

Here, only B.rivulare are considered to be a semi aquatic bryophyta. This moss lives in or outside of the aquatic environment.
Once the mosses were found, they were collected by cutting the top two thirds of the plant rather than tearing them from their anchorage so as to preserve the survival of this species. A serie of successive washings helped remove the unwanted debris (invertebrates, sand, stones, etc.). Then the samples were placed on ice and transported to the laboratory for the acclimatization period. It is well known that mosses harvested during the summer season will have less difficulty adapting to laboratory temperatures (18-20C) than those collected in the fall (3).

The physico-chemical parameters (temperature, conductivity, dissolved oxygen, pH, and oxydo-reduction potential) were measured with a Hydro-Lab Surveyor II (SVR 2 model).

The conservation of the muscinal biomass necessary for the experimental stage was done in rectangular basins made of fiber glass (1 x 2.5 meters). The water temperature was controlled by a glycol filled serpentine which cooled the water in an adjacent container. This temperature adjusted water was circulated by the continuous pumping action of pressurized air in the return pipe. A Fluorescent "Grow Lite" furnished sufficient light to maintain the aquatic mosses in good health (7) .

Chemical Analysis

Each sample was subdivided in five replicates. Each subsample was oven-dried at 110C for 12 hours. The mass of each subsample was approximately 0.3 grams dry weight. After weighing, the samples were digested in concentrated nitric acid (HNO3) for 7-8 hours until the elimination of the brown fumes; the reaction was driven to completion with 30% hydrogen peroxide (H2O2) (2). When the reaction was finished, the reaction tubes were cooled and maintained at 4C. The digestions were diluted to exactly 50 mL each with distilled water. They were then manually stirred to assure a completely homogeneous solution. Before proceeding to the spectroscopic analyses, it was very important to allow the solutions time to attain room temperature, otherwise a physical interference was evident in the subsequent analysis. The digested mosses were analyzed by atomic absorption spectrophotometry (Varian model AA1275) with air/acetylene flame. Certified standards for water (Standard Reference Material 1643 C) and mosses (Certified Reference Material BCR No 61) were used in the quality control scheme. The digested mosses were analyzed for their Ca, Mg, Cu, Cd, Mn, Fe, Ni, Co and Cr content.

RESULTS

Fig. 1

In Fig. 1, the cobalt concentration in F. dalecarlica (stem) is 138 gg-1 when coming from Quebec area (Cach River) while that at St-Alexis des Monts is only 74 gg-1. For the other metals, the concentration varying from 0 to 20 gg-1. No significant concentration was found for chromium.

Fig. 2

Examining the histogram of the abundant metals, the copper concentrations was elevated in seven of the cases. The highest concentrations was found in F. dalecarlica and P. riparioides . For the latter species, the value is around 24 000 g-1 while the other cases varied from 7 400 to 15 000 gg-1 (Fig. 2). The magnesium and calcium in the five sites varied according to the species and the site, but all concentrations are below 3500 gg-1.

Table II

The cobalt concentration for all the mosses was the highest for F. dalecarlica from the Cach River near Quebec City (81 gg-1) and from St-Alexis-des-Monts (58 gg-1) while the copper concentration was the highest in P. riparioides at St-Alexis (23 589 gg-1) and Loretteville (24 331 gg-1). For other species studied, the copper values presented a irregular dispersion pattern from 44 to 12 261 gg-1 (Table II).

Table III

Generally, the concentration of the metals in the stem or in the leaves attained a higher value than that found in the whole plant depending on the type of metal. For example, F. dalecarlica from St-Alexis-des-Monts

had the highest values in the leaves for calcium (3 248 gg-1), copper (17 205 gg-1) and magnesium (23.75 gg-1) while it appears that the stem had the highest values for the cadmium (3.62 gg-1), cobalt (74.61gg-1), iron (23.36 gg-1), manganese (19.29 gg-1) and nickel (6.80 gg-1) concentrations. A similar pattern was founded for F. dalecarlica from the Cach River near Quebec City.

DISCUSSION

The aquatic mosses are good bioaccumulators of metals and as such can indicate their regional distributions. The results obtained from this study illustrates the capacity of mosses to accumulate well copper ions. In addition, the comparison of the accumulation results shows that Fontinalis is a better accumulator of cobalt than the other aquatic species. Mosses coming from the Cach River near Quebec City are contaminated by cobalt. Oddly, the Cach River is located in a provincial park (Le Parc des Laurentides, Qubec, Canada); one must presume a natural mineral source of cobalt exists upstream.

The bioaccumulation capacity of the different parts of the plant is an important factor if they are to become official bioindicators. For example, the metal ions are more concentrated in the stems rather than in the leaves except for calcium and magnesium. Our results are consistent with other reported studies except for calcium and magnesium (8). It will be important to consider the part of the plant in order to apply this method in different countries. Except for calcium and magnesium, Brachythecium is only slightly contaminated by environmental metals ions. This species is not as useful for monitoring the aquatic environment. We presume this low accumulation potential is due to its semi aquatic nature. The "aquatic" mosses appear to be better accumulators of metals than the "semi aquatic" ones. This result is due to the ionic exchange process between the organism and the water.

Aquatic mosses can store a considerable amount of metallic pollution. Generally, they accumulate a large amount of pollutants on their cell walls, whereas only a small portion of these non-essential metal ions are being absorbed into their cytoplasm. One exception appears to be the chromium ions which are effectively excluded from the inside of bryophyta.

ABSTRACT

This paper describes the design, development and implementation of control systems for a Self Guided Transfer Vehicle (SGTV) and a Remote Excavator (REMEX) used for cooperative buried waste integrated demonstrations with a remotely controlled gantry system. Demonstrations were carried out at the Idaho National Engineering Laboratory (INEL) cold test pit site in August 1995. The INEL test site provided simulated Low Level Transuranic Wastes (LLTW) and facilities for demonstrating remote operations from workstations in a cooperative manner for command and control of the remotely operated systems. These systems were developed in support of the integrated approach to retrieval and were part of a contract with INEL to further develop the technologies from the equipment developed, integrated and demonstrated in 1994.

The retrieval of Transuranic waste from landfill type pits/trenches using remotely controlled systems is being considered as part of the Department of Energy (DOE) plans to remediate sites such as INEL's Radioactive Waste Management Complex (RWMC). Over 65,000m3 of TRU wastes are stored in the RWMC in the form of barrels, boxes, large objects and organics.

The purpose of these demonstrations has been to expand on the successful FY94 demonstrations using the REMEX with an Innovative End Effector (IEE) to remotely excavate simulated LLTW and to perform cooperative exchanges with an Integrated Transfer Module (ITM) to the SGTV for remote conveyance of retrieved waste. To accomplish this the Telerobotic Transfer Vehicle (TTV) control system was converted into a self guided vehicle by incorporating a navigation control system combined with GPS and compass. In addition a path planner and high level controller were added at the remote work station to implement self guidance from the operator station.

INTRODUCTION

To upgrade the TTV (2) to an SGTV (Fig. 1) required significant technology enhancements to the TTV control system by the addition of more

processor boards, a fully integrated dead reckoning sensor suite, new collision avoidance sensor suite, GPS interface, compass, new software and a task/path planner control system in a remote workstation.
Fig. 1
For the REMEX (Fig. 5) a change in the innovative end effector size and reconfiguration front shovel to back hoe required retuning of the control system.
The purpose of the integrated demonstrations at the INEL through August and September, 1995, was to verify performance of the SGTV self guidance control system in representative cooperative retrieval demonstrations with the REMEX and as appropriate with a Gantry crane system.

PROJECT DESCRIPTION AND OBJECTIVES

The design, development, integration, testing and evaluation of the control system for the SGTV was funded by the DOE's Office of Technology (OTD) through the Buried Waste Integrated Demonstration program managed by the INEL. The program was contracted by the INEL through RAHCO International to Spar Aerospace in conjunction with RSI Research Ltd. The control system for the REMEX was developed jointly by Spar and RSI in conjunction with the University of British Columbia from 1992 through 1993. Enhancements to the control system to meet the needs of this program were undertaken by Spar Aerospace with funding by the OTD for end effector modifications and the addition of extra cameras.
The objectives of this program were to demonstrate self guided control of the SGTV, the development of a mission planner with user friendly Graphical User Interface (GUI) to permit creation of SGTV paths, initialization and alignment with GPS derivatives and to create a field of safe operational zones for high level control of the SGTV. These objectives were to be demonstrated in conjunction with the REMEX in representative cooperative retrieval of simulated LLTW. The FY94 demonstration program had successfully demonstrated the concept of remote excavation and dust free dumping between the REMEX and TTV.

SELF-GUIDED TRANSFER VEHICLE SYSTEM

Control System Development

The SGTV control system (Fig. 2) was developed from the TTV controller which was designed with the "Hooks" and "Scars" for upgrade to self guidance in place. The SGTV system thereby retains the telerobotic TTV (manual) control mode as the first failure level recovery of the vehicle.
Fig. 2
The control system for the TTV was developed by Spar Aerospace and RSI Research Ltd in the first instance at a higher level to derive the most cost effective solution that met schedule and technical requirements for a self guided vehicle that was ultimately to operate within a containment building.
The earliest concepts by RAHCO International for remote conveyancing evolved very rapidly from a static loader container transfer station and straddle type crawler to a skid mounted container towed behind the excavator. Robotic transfer was assumed to be achieved by having the SPAR/RSI team adapt a front end loader with a self guidance control system for the purposes of the demonstrations.
The SPAR/RSI team proposed a reconfiguration to a dedicated vehicle using an available track set and building these from the skid concept together with an available diesel power unit for propulsion. Transmission and actuation of the TTV functions were developed from standard hydraulic system components typically used in mobile machinery. Hence the basic

vehicle represented low risk established technology to which it was required to add a telerobotic control system.

Functionally it was required that the system be designed to provide the following performance criteria: Control and maneuverability of vehicle within +/- 1 ft of the desired track path; ability of the vehicle to turn on its own centre and within a 20 ft wide roadway; variable speed control from zero to a maximum of 300 ft/min; capable of detecting obstacles in the path of the vehicle and providing a warning indication to the operator as well as slow down or stop the vehicle; operation and status of the Transfer Container lid; sensors status and displays at the operator's workstation.

Proposed Vision Tracking System

To implement self guided control the original TTV control system had been designed to accommodate growth to self guidance using a vision tracking system. The proposed vision tracking offered a completely external wrap around controller with no changes to the original TTV control system. This therefore would provide a completely separate system that was independent of the vehicle and required no inputs, calibrations, initializations, resets or loss/interference from EMI and/or satellite constellations. Vision tracking determines position, rate, collision detection and visual oversite of vehicle at all times. Later it was determined that the demonstrations would be conducted outside with many obstacles and that use of Differential GPS (Global Positioning System) was preferred.

Self-Guided Control System

Self-guided control is divided into two stages: Mission Planning (MP) and Vehicle Control and Command Generation (VCCG). MP is an off-line operation which allows the operation to plan a path. A path (Fig. 3) consists a start point, pause points, flyby points and an end point. Each point is assigned with two circles, which are either used for smooth acceleration or deceleration. The speed limit for each segment of the path can also be defined. VCCG is executed in real time to control the vehicle to follow a planned path based on the feedback of the sensed position and heading of the vehicle provided by GPS and dead reckoning. VCCG generates linear rate command to move the vehicle towards a target position and angular rate command to correct both the off-track error and heading error. VCCG also has a simulation capability which allows the operator to simulate the vehicle tracking prior to an actual run. To allow the operator interacting with the tracking operation, a Graphic User Interface (GUI) was implemented. Through the GUI, the operator can pause, resume, reverse or stop the vehicle at any time.

Fig. 3

In the new SGTV control system, the telerobotic mode and Direct Track mode are still retained from TTV developed in FY94. Both control modes use a two-axis joystick to generate vehicle commands. The difference is that the Direct Track mode is an open loop control with the sensory feedback for the track servos disconnected. Also retained is the lid/latch open and close control which can only be used when the vehicle is stationary.

The control system architecture is shown in Fig. 2. The sensory units consist of a Trimble 4000SSI differential GPS, a Precision Navigation TCM2 electronic compass, a Systron Donner Rate Gyro, dual track encoders and 18 acoustic range sensors (9 at each end of the vehicle). These sensors were connected to the onboard computer system. The onboard

computer system comprises of five RSI Research Ltd. microcontroller units. Each microcontroller is dedicated to the following functions: Network between microcontrollers, servo controllers of the vehicle, camera control, obstacle detection and avoidance, and navigation algorithms such as dead reckoning. Two color cameras, with weather-proof enclosures and pan and tilt units, are mounted separately at each end of the vehicle. A control pendant is available for local operation.

The remote control room has one workstation for Self-guided operation and one for Teleoperation. The Self-guided workstation consists of Pentium Personal Computer system. Whereas the Teleoperation workstation consists of a microcontroller based computer, a control panel and a telemetry radio. The control panel consists of a two-axis joystick, switches for mode selection, camera control, lid open/close and latch/unlatch, emergency stop, keypad and LCD display. A color monitor displays the vehicle's camera's view.

A spread spectrum radio modem provides the telemetry communication between the onboard computer and control station computer. A redundant, dedicated radio controls the emergency stop of the vehicle.

A dead reckoning system is implemented to solve the 1.5 seconds latency in the GPS feedback. Sensor data from rate gyro, compass and track shaft encoders are used to estimate the incremental position. A final best estimate of the vehicle position is calculated by combining weighted GPS data and dead reckoning estimate. Dead reckoning also estimates the vehicle heading using the above data.

An Obstacle Avoidance System (OAS) was implemented in a dedicated microcontroller. OAS has nine acoustic range sensors mounted on each end of the vehicle. The sensors can detect objects within about 35 feet. The obstacle ranges are divided into three zones: detection zone, collision zone and E-stop zone. In the detection zone, the operator is alerted but no action is taken. In the collision zone, the vehicle speed is reduced gradually as it approaches the obstacle. In E-stop zone, the vehicle is stopped automatically.

System health monitor was also implemented with sensors installed on the vehicle to keep the operator advised of the control status and to monitor important system health parameters. System health monitoring includes: engine oil pressure, engine temperature, engine speed, battery level, hydraulic oil temperature, onboard electronics temperature, base latch status, container lid status, GPS status, electronic compass status, data network status and telemetry status.

Test Results

Factory acceptance testing of SGTV was held at the Idaho Falls National Engineering Laboratory (INEL) in September 1995. Three paths, from simple to complex, were used for testing the performance of the Self-guided mode. Each of the path was repeated ten times to determine the repeatability as well as the off-track errors. The vehicle was on average able to track the planned paths within +/- 1 foot error in steady state. The final docking always achieved a position error of less than 1 foot and the heading was locked on the target orientation. The errors might increase when the control system encountered GPS error, telemetry error, compass error or network error. Once the errors were cleared, the vehicle would return the planned path gradually. There were several causes for errors encountered in operation: vibration of the vehicle, electromagnetic interference from other systems operating in close

proximity and GPS loss/float. The maximum commanded rate achieved under self-guided mode was 150 feet/min.

Normally, the telerobotic mode could be operated at higher speeds, up to 300 feet/min, than the self-guide mode, mainly because the telerobotic loop has shorter time delay. As expected, it had much higher off-track errors, which could exceed 5 feet easily, and required cognitive attention by the operator to generate rate commands to navigate and monitor the tracking.

Due to the high sensitivity and resolution of key sensors set up and calibration was found to be one of the most difficult tasks. For example the compass was sensitive to local magnetics, vehicle and vibration during operation. Due to metallic body of the vehicle, the compass's bias varied with the heading and therefore required non-linear calibration. When the vehicle was moving, the heading was determined by the weighted compass output, GPS output and dead reckoning estimate from gyro and rate sensors. The OAS was able to detect obstacle within the specified zones. The vehicle would slow down or stop according to the obstacle range. With a sharp corner of an object facing the vehicle, OAS was not able to stop the vehicle before hitting the object because acoustic signals were reflected away by the sharp corner.

The SGTV GUI and an example of the test runs are shown in Fig. 4.

Fig. 4

REMOTE EXCAVATOR SYSTEM

The control system (Fig. 4) of the REMEX was designed for installation on a conventional excavator and in this instance the Hitachi EX200LC (Fig. 5) was selected as this had already been developed by Spar Aerospace and RSI. The control system implementation described is generic and therefore applicable to all existing excavators as these use similar systems.

The existing manual controls for the Hitachi comprise a right hand side joystick for boom and bucket and a left hand side joystick for the arm and swing. Travel is derived from right and left pedal controls. These manual controls provide outputs to pilot valves that provide signals to control valves operating the hydraulic motors and cylinders.

The modifications to the excavator were designed to demonstrate remote, or in the cab, coordinated motion control of the bucket, stick , boom and swing functions. The travel function was not included with these but was provided separately with manual remote controls.

Remote coordinate motion control of the bucket is implemented using the following items:

4-Degree of Freedom (DOF) handcontroller; control console and VME CPU (VM30 running 68EC030 Mp); ruggedized Vehicle mounted VME CPU (as above); Bucket, Stick, Boom & Swing sensors; vehicle cabling systems and telemetry cable for remote operations.

Inputs from the handcontroller are processed in the workstation CPU according to mode selected and then fed to the vehicle CPU to perform the inverse kinematics for coordinate control of the bucket. Joint sensors data are monitored and fed to the vehicle CPU to derive joint angle and rate for closed loop control of each joint. Joint and engine sensors data are also fed back to the remote workstation for status and health monitoring. These functions are described in more detail as follows:

REMEX Operator's Workstation

The remote workstation console provides system power up, enable and safety controls. Track control levers are provided for travel under remote control. System status is provided by LED's for remote power and

enable, engine oil pressure, alternator and temperature. A mode switch is provided to select the following modes: Off-hydraulics disabled; coord-vehicle operates in coordinate motion; joint-vehicle operates in joint control; manual-vehicle operated joints open loop; remote-C, J&M modes operated remotely via telemetry cable.

The handcontroller provides operator inputs for control of the excavator in any of the modes and can be located remotely at the workstation or in the cab so that the operator always uses the same control input at either location.

Fig. 5

Handcontroller inputs are processed by the workstation CPU to derive command outputs to the vehicle CPU via the telemetry cable in a similar manner to a master/slave manipulator. The design is rugged and had been field proven for control of machinery in the forestry industry.

Modes of Control

Coordinated Motion Control

In coordinated motion control the operator uses the 4DOF handcontroller to control all of the functions of the excavator. The handcontroller provides an intuitive correspondence between the motion of the handcontroller and the bucket at the designated point of resolution (POR).

Joint Control

In joint motion control the deflections of each degree of freedom of the handcontroller are reproduced by each of the joints of the excavator. The rates of each joint are scaled in direct proportion to the deflection of each DOF of the handcontroller. In this mode of control the joint velocities are independent of load and kinematic configuration as hydraulic pressure is modulated in each actuator.

Manual Control

In manual control, as in joint control, the deflections of the joystick correspond to motion of the corresponding joints. However in this instance the deflections are fed directly without feedback from the joint sensors.

The system provides diagnostics features via a port into the vehicle CPU. The range of diagnostic functions offered are as follows:

1) Calibrate joint sensors
2) Calibrate handcontroller
3) Edit faults
4) Test Outputs (digital & binary)
5) Display mode
6) Download
7) Test Response

REMEX Modifications for Innovative End Effector (IEE)

To fit the IEE to the REMEX in either a front shovel or back hoe configuration with a Balderson thumb required an additional actuator, modified four bar linkages, joint sensor ,hydraulic valves and circuitry. To provide thumb control a special unloading circuit was conceived with a simple switch operation. This provided the operator with control of the thumb and the ability to grapple an object between the thumb and bucket and to retain this without the operator maintaining control of the thumb switch.

To operate the ITM lock and unlock functions another single control switch was provided at the operator's workstation together with LED's to indicate status. These arrangements were typical of an R&D configuration

but were nevertheless found to function quite satisfactorily to demonstrate the proof of concept and operator functionality. For fully remotized operations a basic video system was installed on the REMEX to provide overview of excavation , general positioning and interoperation with the SGTV and Gantry.

CONCLUSION

A SGTV control system and modified REMEX was developed and tested in an very aggressive schedule of four months. The system was fully functional and tested successfully at INEL. The precision specification in self-guided control was to track a path within +/- 1 foot and the test data showed that the tracking accuracy varied from an average of 0.58 for 0.972 ft. The Obstacle Avoidance System was able, except when facing a sharp corner, to reduce or halt the vehicle motion prior to reaching an obstacle. Both the Mission Planner and Vehicle Command and Control Generator exceeded the specifications. The coordinated operations of the SGTV, REMEX and Cooperative Telerobotic Retrieval Gantry Crane was demonstrated in performing retrieval and conveyance of simulated buried waste. The equipment used for this demonstration was design to investigate concepts for remote conveyance of buried waste. Prototype hardware were used to facilitate an inexpensive, short schedule and proof-of-concept demonstration. Based on the successful test results, it will not be difficult to upgrade the hardware to operate in a transuranic buried waste retrieval environment.

RETRIEVAL SYSTEM FOR THE INEL PIT 9 REMEDIATION

Charles Yemington
SONSUB Inc.

Blake Burt
Lockheed Martin

ABSTRACT

The world's largest remotely operated mobile work system is being built to excavate landfills. This 1,500 ton, self propelled machine is 260 feet long, 100 feet wide, and 60 feet high, and can span landfills up to 120 foot wide. It is designed to separate waste from the soil, package them separately for transport to processing, and backfill the pit while maintaining double containment and negative internal pressure. An inert atmosphere can be maintained inside the system if needed to prevent ignition of pyroforic materials.

The first application of this system is to be excavation of Pit 9, a 379 foot long by 120 foot wide waste burial site at the United States Department of Energy's Radioactive Waste Management Complex at the Idaho National Engineering Laboratory. Pit 9 was used as a waste disposal site between November 1967 and June 1969 and is being remediated in accordance with a Record of Decision signed by the United States Department of Energy, the United States Environmental Protection Agency, and state of Idaho Department of Health and Welfare.

The mobile work system is operated entirely by remote control. Seven remotely operated tool systems operate within the enclosure. Two use neutron radiation detection instruments to look into the dig face for radiation sources strong enough to require special handling. Two soil retrieval tools use brushes to dig out the soil and expose the waste. Two grapple tools gather and size reduce the waste and box it for transport to a processing area. The seventh tool system is designed to do routine maintenance on the other tools, resolve contingency situations, take samples, and excavate items which require special handling.

The telerobotic tools are monitored by software which prevents the tools from colliding and allows digging only in areas which have passed survey by the criticality control survey instruments. A thousand foot fiber optic umbilical connects the mobile work system to consoles located in a control room well away from the excavation area. Advanced telemetry systems relay commands from the consoles and provide the operators with video and feedback from an extensive array of instruments which monitor the status and activities of the equipment.

The remotely operated work systems separate the excavated soil and waste, package them separately in steel boxes, check the boxes to ensure that radiation levels are safe for downstream handing, and load the boxes on special trucks. Specially designed, remotely operated equipment keeps the outside of each box clean as the boxes are filled, closed, and air-locked into trucks for transport to a processing area.

HISTORY OF THE TECHNOLOGY

The technology upon which this system is based has evolved from mobile remotely operated equipment used for sophisticated work tasks in unstructured environments in the offshore oil fields.

In the early days of the offshore oil industry, designers placed as much equipment as possible atop steel platforms which rested on the sea floor and rose higher than storm waves. Divers did the construction and maintenance work on the platforms and pipelines, and on other equipment could not be placed above the surface. By the mid 1970's these platforms were being installed in water too deep for divers to reach the sea floor. This forced development of Remotely Operated Vehicles, or ROV's, capable of sophisticated work tasks in the unstructured environment of construction sites deep in the ocean.

By the mid 1980's, 100 horsepower ROV's with multiple onboard computers, highly dexterous manipulators, 1,000 pound "draw bar" pull at any vector, and an extensive suite of tool sleds and manipulator tools could perform almost any task that a 20 man saturation diving team could handle.

By the early 1990's these vehicle systems were routinely doing nondestructive testing of welds and were capable of repairing pipelines and replacing four inch valves in well head control units. The capability of these remote work systems made it practical to construct and maintain oil production equipment installed directly on the sea floor, thereby avoiding the need for giant steel platforms which can cost hundreds of

millions of dollars. In 1995 the reliability of these remotely operated work systems allowed extended sea floor work missions of a month or more without recovery to the surface for maintenance or repair.

The Kerr Hollow Quarry site on the Department of Energy's Oak Ridge reservation saw the first application of this remote work systems technology to remediation of a radioactive waste site. Remotely operated work systems were used exclusively to retrieve over 50 tons of mixed radioactive, toxic, and energetic waste and process it for long term storage as low level radioactive waste. The work was done entirely by remotely operated work vehicles, and no personnel entered the contaminated zone or the processing area at any time.

This remote systems technology is now being applied to excavation of Pit 9, a landfill site at the United States Department of Energy's Radioactive Waste Management Complex at the Idaho National Engineering Laboratory.

PIT 9 SITE

Pit 9 is a 379 foot long by 120 foot wide landfill used as a waste disposal site between November 1967 and June 1969. It is being remediated in accordance with a Record of Decision signed by the United States Department of Energy, the United States Environmental Protection Agency, and state of Idaho Department of Health and Welfare.

Approximately 110,000 cubic feet of waste generated at Department of Energy's Rocky Flats Plant and 40,000 cubic feet of waste generated at Department of Energy's Idaho National Engineering Laboratory was placed in Pit 9. A nominally 8 foot thick waste zone is situated on top of three and a half feet of soil and covered by six feet of overburden soil. The pit is to be excavated down to the underlying basaltic rock formation which is nominally 17 to 20 feet below grade.

EXCAVATION SYSTEM

An artist's concept of the remotely operated excavation system is shown in Fig. 1. This self propelled machine is 260 feet long, 100 feet wide, and 60 feet high, and weighs over 1,500 tons. It is designed to span and excavate landfills up to 120 foot wide. It moves along the length of the land fill, excavates the waste and the interstitial soil in separate waste streams, packages them for transport to processing, and backfills the pit. The system is designed to maintain double containment of all exposed contaminants under environmental extremes including 84 mile per hour winds, seismic events, and temperatures down to -40 degrees Fahrenheit. Negative internal pressure helps prevent the escape of airborne contaminants. Extensive measures are included to help prevent ignition of the waste mass in the event that pyroforic materials are exposed during excavation.

Fig. 1

All excavation tools are deployed by bridge cranes. Several design considerations led to this configuration. Since it is supported from overhead, the retrieval equipment can not collapse into any voids in the waste mass. The hoists on the bridge cranes can be readily controlled to ensure that the tools do not dig beyond the depth which has been surveyed and released for excavation. All power and control umbilicals run overhead and are therefore not exposed to damage or entanglement in the waste. Perhaps most important, the bridge crane deployment approach ensures that the retrieval tools can be removed from the excavation area, isolated, and washed down prior to any manual intervention for maintenance or repair.

REMOTELY OPERATED TOOLS

The mobile excavation system is operated entirely by remote control. Seven remotely operated tool systems work inside the enclosure. Two of the seven tools deploy passive neutron detection instruments to examine localized volumes of the dig face before it is disturbed. Special excavation and handling procedures are implemented if these instruments detect a radiation source which approaches the established limits for which criticality control measures are required.

Two remotely operated soil removal tools use rotary brushes to remove interstitial soil and expose the waste. Figure 2 shows one of the soil brush tools during factory acceptance tests. The X, Y, Z position of this 150 horsepower precision excavation machine is controlled by a bridge crane. This deployment method provides precise, reliable control of the location and depth of each cut. Six independently mounted rotating brush heads sweep an eight foot wide path, digging down only a few inches on each pass.

Fig. 2

The brush heads remove interstitial soil without disturbing large waste items such as drums or gas cylinders. Figure 3 shows drums which were buried in a test site and then exposed by the soil brush tool. The six brush segments move up and down independently to remove soil from between waste forms such as these drums. Video observation of the freshly exposed surface can then identify waste items which may require special handling. Shielding materials which may have blocked the view of the neutron sensing instruments can also be identified when exposed in this manner.

Fig. 3

The brush heads sweep soil and loose material onto elevating conveyors which dump onto a vibrating screen where fines are separated from debris. These two waste streams are accumulated in separate compartments on the tool. When approximately a ton of fines and debris have been accumulated the bridge crane positions the tool to dump the fines onto the cross pit conveyor and dump the debris into a waste transfer box.

The brush heads are made from materials similar to commercially available street sweeper brushes. Tests were conducted to determine the most effective range of bristle stiffness, size, spacing, and configuration for use with various soil conditions. Alternating wire and elastomeric bristles were found to be effective in both damp and dusty soils. This same bristle configuration has proven to effectively cut hard, dry, highly consolidated soil and exposes buried waste containers without significantly degrading them.

A cross pit conveyor transports soil from the soil brush tools to a hopper which meters out 64 cubic foot batches of the soil into soil transport boxes. The soil box lids are then closed by a remotely operated double lid transfer system.

After waste items have been exposed by the soil brushes, those items which do not require special handling are retrieved by one of the two grapple tools and placed in 4' by 4' by 8' steel waste transport boxes. Items too large to fit in a box can be cut down by a remotely operated shear. When a waste box is filled it moves to the end of the enclosure on a mine car trolley system and is removed from the contaminated area by a remotely operated double lid transfer system which keeps the outside of each box from becoming contaminated. Remotely operated sensors check radiation levels to ensure that each box meets the requirements for downstream handing.

Soil and waste boxes are individually air locked from the retrieval system into specially designed truck bodies so that double containment is maintained at all times. A fleet of four trucks transports the 10,000 pound boxes of soil and waste to the process building for assay and treatment.

The seventh tool system is designed to do routine maintenance on the other tools, resolve contingency situations, take samples, and excavate items which require special handling. This tool can also be used to wash down the enclosure after excavation is finished.

All seven telerobotic tools are monitored by computer software which prevents the tools from colliding and allows them to dig only in areas where the survey instruments have shown that there are no criticality concerns. A thousand foot long fiber optic umbilical connects the mobile work system to consoles safely located in a control room well away from the excavation area.

SAFETY AND ALARA CONSIDERATIONS

The system is designed to complete the excavation exclusively by remote operation, with no need for personnel to cross the pit boundary once excavation of waste commences. The tools are designed to deal with any waste items which may credibly be encountered. Electrical utility equipment, air filtration systems, and other service equipment are located in exterior rooms which are not exposed to the retrieval area.

One of the seven bridge crane tools, called the Robug, is designed to perform most of the routine maintenance and repair tasks required for the other bridge crane systems. This tool and two others are equipped with fire suppression systems as an additional safety feature.

Occasionally a bridge crane system will require more extensive maintenance than can be accomplished by the Robug. To accommodate this need, any of the bridge cranes can be moved to a maintenance area which is beyond the pit boundaries but still in containment. If a bridge crane should fail to move under its own power it can be moved by one of the other bridge cranes. The maintenance area can be isolated from the retrieval area and washed down before personnel enter.

This approach ensures that personnel are never exposed directly to the waste, and need never be exposed to a retrieval tool until after it has been washed to remove gross contamination. Radiation dose is thereby kept as low as is reasonably achievable, and the level of personnel exposure to toxic or energetic materials is likewise minimized.

ABSTRACT

This paper describes the development of a surface acoustic wave/ (SAW) technology for the rapid characterization of waste site radiation emissions. Developed under an EM-50 Department of Energy contract, the system was designed to rapidly assess contamination in field conditions.

The new technology allows capture, identification and analysis of Volatile Organic Compounds (VOCs), Non-VOCs, Dioxins, PCBs, and Energetics. This is done within water and soil matrices, within real time, on-site with parts per billion accuracy. The system has been modification capability to detect mixed waste containment, in radioactive environments. The ability to detect to picogram or ppb levels of compounds using fast chromatograph columns has been demonstrated for a wide range of materials. The application of SAW/GC technology will lead to the manufacturing of low cost, field portable products for waste site characterization and monitoring.

The design theory and development of the technology will be presented as well as the test results from the Savannah River Facility field demonstration. The SAW sensor has demonstrated high specificity and sensitivity for trace analysis screening at DOE remediation sites. Also, the results demonstrate significant cost savings when compared to reference laboratory analysis. The related deployment strategies for the various mixed waste sites and product maintainability issues will also be noted.

INTRODUCTION

This paper describes research on a fast GC vapor analysis system which uses a new type of Surface Acoustic Wave detector technology for characterizing organic contamination in soil and groundwater. The technology was originally developed through a Small Business Innovative Research (SBIR) Contract awarded by the United States Department of Transportation for the rapid field detection of contraband drugs of abuse. A proof of concept prototype was built and demonstrated for this project. Follow-on awards resulted in a portable fast gas chromatograph that detects contraband drugs of abuse. The system was again modified to detect compounds of pollution related to environmental site characterization and monitoring. The effort in developing this capability was sponsored by the United States Department of Energy (DOE).

PROJECT OBJECTIVES

The DOE research objectives were to demonstrate detectability and specificity of a Surface Acoustic Wave Gas Chromatograph (SAW/GC) for a representative number of Volatile Organic Compounds (VOC) materials. Once the VOC compounds were identified, data gathering and field demonstrations of the new analyzer were executed at a DOE site. Field testing of the SAW/GC was performed at the DOE Savannah River Facility, Augusta, Georgia. Matrix testing was performed with water, soil and gas samples. The performance of the SAW/GC analyzer was validated by comparing results taken with an on-site HP chromatograph. Through these tests, the system, based upon surface acoustic wave/ gas chromatography, demonstrated the ability to identify and quantify the presence of VOCs.

DESCRIPTION OF THE TECHNOLOGY

The SAW/GC instrument is comprised of a head assembly that contains the capillary column and the SAW detector and the support chassis, containing the helium carrier gas, laptop computer and the related micro-processors. There are two modes of operation: Sample and Inject. The system utilizes a two position, 6 port GC valve to switch between sampling and injection modes. In the sample position, environmental air containing the suspect compounds, is passed through an inlet preconcentrator or water trap and then through a sample loop trap. The function of the loop trap is to concentrate VOC materials when in the sample position. During the sample mode, helium carrier gas flows down a capillary column and impinges onto

the surface of a temperature controlled SAW resonator crystal shown in Fig. 1.

Fig. 1

Switching the valve to the inject position causes helium carrier gas to flow backward through the loop trap and onto the column. After the valve is switched into the inject position the loop trap is rapidly heated to 200C causing the trapped VOC materials to be released into the GC column. The temperature of the GC column is linearly raised to approximately 125C over a 5-10 second time and this causes the VOC materials to travel down the column and exit at a time characteristic of the VOC material.

The SAW resonator is a unique type of GC detector that, incorporated with the theory of gas chromatography, allows for the analysis of suspect compounds to new ranges of specificity and concentration. VOC materials as they exit the GC column are trapped on the surface of the resonator and cause a change in the characteristic frequency of the crystal. The adsorption efficiency of each VOC material is a function of the crystal temperature and by operating the crystal at different temperatures the crystal can be made specific to materials based upon that materials vapor pressure. Also, since the crystal acts as a micro-balance it integrates the total amount of material present. To obtain a conventional chromatogram plot of retention time, the derivative of frequency versus time is calculated. This is in contrast to a conventional GC detector which detects the flux and where peak integral calculations are required to obtain the amount of each material present.

RESULTS AND ACCOMPLISHMENTS

To demonstrate the technology a portable laboratory scale instrument was constructed and tested with the representative VOC materials listed in Table I. Each material was tested with a calibrated vapor source either purchased as calibrated bottled gas or created by injection into a known volume (tedlar bag). Calibration results based upon a 10 second sample are listed in Table II. In general the sensitivity of the instrument for all materials was 1 ppm or better. For materials with lower vapor pressure, such as Toluene and tetrachloroethylene, sensitivity extends well into the ppb range. To achieve ppt sensitivity it is only necessary to extend sample time. However, the advantage of a short sample times is near real time operation.

Table I

Table II

FIELD TEST RESULTS

The prototype instrument was shipped to the DOE Savannah River Facility, Aiken, SC, where it was used to obtain real time measurements of well head gases. Place in a small van, the system was transported to numerous well heads for sample analysis. The instrument was designed for battery power, however, it was discovered that it could operate for long periods of time by drawing power from the transport vehicle. Power was supplied utilizing a 110 volt DC-AC invertor connected to the automobile battery. Samples were taken under 3 modes: 1) the instrument was stationary and engineers brought tedlar bags to a central point for well-head analysis; 2) the system was mounted in the van and driven to various well head locations for sample analyte analysis using tedlar bags; 3) the system was driven next to a well head and with the detectable head unit, connected to a sampling port for direct injection of sample analytes. To verify the accuracy of the instrument, calibrated tedlar bag samples were used to calibrate the SAW/GC. A typical output screen for one such

bag containing approximately 100 ppm TCE and PCE is shown in Fig. 2. The user interface shows two chromatograms, one is the derivative of SAW frequency and the other is SAW frequency vs. time. The duration of the chromatogram is 10 seconds and retention times for TCE and PCE is 3.54 and 5.54 respectively. The operator can display quantitative information as ppm/ppb, in mass units of picograms or nanograms, or alternately in SAW units of frequency.

Fig. 2

Many different measurements were taken and compared with an on-site HP GC as shown in Fig. 3. The results of this relative comparison indicate that the SAW/GC and the HP GC agree within approximately 20%. Much of the variation is attributed to variations in sampling and preconcentration within each instrument.

Fig. 3

APPLICATION , BENEFITS AND ISSUES

Those involved in environmental characterization and monitoring are demanding innovative technologies that are significantly lower in cost while providing rapid methodologies for the collection and analysis of soil, water, and air samples in the field. The SAW/GC instrument, if properly integrated into the sampling/analytical plan, represents a significant savings in cost and time. The instrument can be effective if the 2 major criteria are met affirmatively: 1) Is there a need for measurement or monitoring decision making data "in situ"? and 2) Is there a critical need to make decisions in the field in real time, e.g. 8 hours or less.

On-site Monitoring (OM) is useful for the following situations:

- Define emergency response actions
- Assess impacts to potable water
- Monitor purge water
- Screen ground water during exploratory drilling
- Screen monitor wells
- Define the extent of soil contamination
- Determine migration pathways
- Estimate the amount of contaminated soils
- Obtain ground water samples without monitoring wells
- Determine sources of contamination

Rapid on-site screening and analysis has been identified as a potential solution to four major issues:

Operator Safety- Is the exposure level too high for site personnel? A significant problem exists regarding the safety of personnel involved in characterization and remediation. Several solutions exist using amino-assay kits, however, specificity and real time analysis is limited. The SAW/GC analyzer represents a solution for identifying suspect compound specificity and concentration in near real time (10 seconds).

Real-Time Analysis- How can we identify contaminated areas by reducing the total number of samples taken for analysis? Past site characterization techniques follow a pattern of sending samples at regular intervals to a reference laboratory for validation of suspected areas of contamination in both specificity and concentration.. Fixed laboratory costs range from $600 to 700 per sample and average 6 days from sample submittal to reporting of anlyte results. Mobile field laboratories range from $250 to $300 per sample and can process between 30 to 40 samples a day. A portable SAW/GC instrument can be utilized effectively by defining the three to four (instead of 40) compounds in

the suspect anlyte you are searching for at the site. This planning will allow for site screening for mixed waste by identifying commonly related compounds.

Screening- Where will we most likely find contamination? Reducing the turn-around time associated with analyzing compounds will save money. Field personnel can make decisions in hours instead of waiting days for the return and analysis of data. The use of a portable SAW/GC allows an operator to rapidly screen for suspect compounds and in turn make cost effective decisions.. Compounds found in rapid screening are confirmed by a reference lab for compliance risk assessment. This reduces the cost of site assessment and remediaton.

Primary Remediation Site - Can we characterize the primary location to remediate by identifying the "hot spots" of contamination? Historically, field portable instruments were limited because they lacked specificity and sensitivity. The advantages of the SAW/GC are portability, accuracy, and speed. The new SAW sensor demonstrated sufficient specificity and sensitivity to be used as a fast trace analyzer or screening tool at DOE remediation sites. Using the SAW/GC analyzer as a field screening tool, cost savings over current techniques, which require expensive laboratory testing, are estimated to be more than $50,000 per month. The cost of the SAW/GC screening instrument will be recovered within less than two months of operation.

SAW/GC technology provides both advantages and disadvantages to current analytical methods. A brief comparison is as follows:

Advantages

- Easy to learn the Instrument
- Easy to Use
- Inexpensive, and portable
- Capable of correlation with laboratory analysis
- Verifiable and reproducible
- Capable of calibration to contamination matrix

Disadvantages

- On Site Personnel must be mechanically competent
- Field personnel must have the authority to make decisions
- Cost effective if a large number of samples are collected
- Contaminant must be known prior to site activities
- Heterogeneous conditions may lead to inconsistent data sets
- Field screening methods may not be applicable to all site conditions

FUTURE PLANS

There are many related applications for SAW/GC technology. While at Savannah River the instrument was also used to measure catalytic converter performance, DNAPL probe experiments, and to characterize VOC break through in carbon scrubbers. Future plans are to use the instrument in field conditions to measure performance against existing methods. Based upon the current results the goals are to begin development of SAW/GC screening instruments for use at DOE remediation sites. The commercialization effort is being carried out by Electronic Sensor Technology, Inc., a limited partnership company managed by Amerasia Technology and tasked with the development of SAW/GC instruments. The commercialization effort is being aided by a partnership between Amerasia Technology, Inc., and the U. S. Department Of Energy Morgantown Energy Technology Center. This new program will involve continued Field testing at DOE sites, EPA certification and verification, and the development of new SAW/GC instruments to detect and quantify Dioxins,

Furans, and PCBs at DOE sites. The new units are smaller in size and contain improvements noted from the Savannah River Field work. These units will be available for field demonstrations and data gathering in the First Quarter of 1996. Designated the Model 4100, it has been designed for environmental needs. A photograph of the Model 4100 is shown in Fig. 4.

ABSTRACT

A successful proof of concept demonstration has been conducted of operational methods and tooling for the in situ construction of underground horizontal barriers for the control and containment of groundwater and contamination. The method involves jet grouting with specially adapted tools guided between twin, parallel directional wells for the placement of a grout "slurry floor" beneath a waste site. This paper describes progress by principal subcontractor Brown and Root Environmental on the Fernald Environmental Restoration Management Corporation (FERMCO) In Situ Land Containment Project sponsored by the U.S. Department of Energy (DOE) Office of Science and Technology (OST) through DOE's Fernald Environmental Management Project (FEMP). Two types of special horizontal grouting tools that operate on different principles have been designed and tested through significant field trials. Experiences with the tools and results of field tests are presented.

INTRODUCTION

Brown and Root Environmental has undertaken a project, under contract to FERMCO and DOE, to develop advanced technology for the construction of underground, horizontal, "slurry floor" barriers for application to

environmental restoration of contaminated soil. Horizontal barrier construction capability is desired within the remediation industry and by DOE to enable containment of environmental contamination where inadequate natural barriers exist to mitigate the spread of the contaminants.

The objective of the work is to develop reliable methods of constructing extensive, competent horizontal barriers underneath waste sites without excavating or penetrating the waste during the process. The principal technical objectives of the work include in situ constructability, the ability to form a barrier of sufficient width and length to be of practical value, and the ability to operate in the various types of soil encountered on a significant number of waste sites.

This project stems from an approach developed by Halliburton Services, a sister company of Brown and Root Environmental which provides commercial environmental services. The approach involves an adaptation of a construction method known as jet grouting. The new method is a process for depositing grout(or any pumpable fluid) underground in the horizontal plane using special jetting tools. In late 1992 a proof of concept demonstration was conducted which resulted in the successful construction of a prototype horizontal barrier of limited width. Although successful in placing a horizontal barrier, the demonstration revealed several technical hurdles relating to grouting tool design and operation that need to be overcome to enable practical (economical) application of the method. The following sections describe the progress toward overcoming the hurdles.

HOW THE PROCESS WORKS

To apply the process, parallel, directionally drilled pipes (guide tubes) are installed under the waste site, as indicated in Fig. 1. A special horizontal jet grouting tool is attached one end of two of adjacent pipes so that the tool spans between the pair. The other end of the pair of pipes is attached to a controlled pulling device. High pressure grout is supplied through one of the pipes to the special tool that has jet orifices through which the grout exits with high kinetic energy. The grout jets fluidize the soil into a slurry, and the tool is then advanced along the trajectory between the pair of pipes by withdrawing the pipes using the pulling device. As the tool moves through the soil it continues to fluidize soil in front of it and leaves behind a panel of amended soil. The panel or section of barrier formed by a single pass of the jetting tool is the unit "building block" for construction of a large horizontal barrier formed by joining several panels side-by-side. Figure 2 shows a single panel constructed during the proof of concept field demonstration.

Fig. 1

Fig. 2

The spacing of the drill pipes, and the degree to which they must be parallel depends on the design of the grouting tool. For example, rigid tools (described below) require placement of the drill pipes within close tolerances, say + six inches of design centerline, while the flexible tools have a high tolerance (+ several feet) for being non parallel.

Forming competent (waterproof) joints between adjacent panels is essential for successful construction of large barriers. The technique devised by Brown and Root for assuring that the next panel formed mates up with the previous panel is to have the jetting tool draw in the next drill pipe along one edge of the panel as it is being formed. This drawn-in pipe is used as one of the pair needed to place the next adjoining

panel of the barrier. The grout planned for use in construction of horizontal barriers is cement-bentonite mixtures of the type commonly used in the construction of vertical slurry walls, although any pumpable grout can be used in the process. Note that the grout must be able to withstand high pressure, shear and impact.

EVOLUTION OF HORIZONTAL JET GROUTING TOOLS

Four different concepts have been investigated for the design of the special tool required for in situ construction of horizontal barriers. The approach planned for use of each design was the same; that is, the tool spans a pair of drill pipes and is advanced by pulling the pipes. The four initial concepts were as follows:

1. A rigid member (rigid bar tool) with a line of jets facing the direction of advancement of the tool. This tool might resemble a comb, with the teeth of the comb representing the jets. This design was intended to achieve a simple, no moving parts approach but with jets all along the advancing face of the tool.
2. A rigid tool (Rotary Tool) that rotates and operates in a manner similar to a rototiller with blades, as well as jets that cut through the soil. This design was intended to provide mechanical assist to the jets, form a thicker panel, and allow the rotating jets to compensate for others that may become plugged.
3. A shuttle tool with a rigid frame and a mechanism with forward facing jets on the leading edge of the tool that shuttles back and forth across the face of the tool. This design was intended to minimize the number of jets required for formation of a single horizontal panel, since the higher the number of jets, the more energy is required to conduct the operation.
4. A flexible tool (FlexTool) that operates in a manner resembling that of a cable saw. This design was intended to minimize the need for precisely parallel drill pipes, as well as to minimize the number of jets.

The four candidate tool designs were subjected to a series of field trials with the objective of selecting the tool(s) with the highest prospect for successful application. Previous reports (1,2) detail testing and results that eliminated the rigid bar tool (made barriers of variable and insufficient thickness, and failed due to jet plugging), and the shuttle tool which failed from mechanical complications related to subsurface reciprocating parts. The tools selected for further adaptation were the RotaryTool and the FlexTool, pictured respectively in Fig. 3 and Fig. 4 in their latest stage of evolution.

Fig. 3

Fig. 4

The Rotary Tool is powered from the surface by a shaft passing down through one of the drill pipes to transmit torque to a universal gear which rotates the tool. The Rotary Tool is constructed of a 10-ft (width of horizontal tool) section of 6-in pipe with blades affixed to mechanically cut a minimum barrier thickness of 12 inches. Each end is equipped with outboard cutting blades and jets intended to cut into neighboring barrier panels to facilitate seaming.

The FlexTool shown in Fig. 4 was constructed of 100 feet of sealed bearing chain resembling the track on heavy earthmoving equipment. This equipment was found to have sufficient strength to withstand the tensile forces placed on it by the pullers, yet have sufficient flexibility to operate during barrier formation between drill pipes at reasonable and

approximately parallel spacing. The "treads" of the FlexTool consist of 6" x 12" bearing plates intended to slide horizontally along the subsurface cutting face. Jet substructures (subs) are located at three positions along the tool: one at the center, and at each end of the tool. The center sub has an 8" x 18" port through it to allow passage of small rocks. There are twelve jets in each of the subs.

This report focuses on the advances and results of field tests with the FlexTool, as testing of the Rotary Tool is less advanced, and is intended to be the subject of future detailed reports.

FLEXTOOL TEST RESULTS

Field trials of the FlexTool were conducted in October 1995 at a testing facility in Duncan, Oklahoma operated by Halliburton Services, a provider of high pressure pumping services. The soil at the site is dense, red Oklahoma clay with occasional strata of hardpan, and is considered to provide stringent test conditions since the clay is very dense, with standard penetrometer test results exceeding 100 blow counts in some locations of the site. The purpose of the testing was to check out operating characteristics and mechanical features of the tool, and to practice the type of operations to be performed with the tool and support equipment during construction of horizontal barriers.

Two parallel, 2 3/8-in drill pipes for advancing the FlexTool were installed on 30-ft centers 6 feet below grade. The pipes were installed by cut and cover: trenching, laying the pipe in the trench, and then backfilling and compacting. The pipes formed a gentle arc to the surface at each end, and the horizontal portion of each pipe was 100 feet in length. The cut and cover pipe placement method was used, instead of installation by drilling, simply as an economy measure to avoid the cost of directional drilling. The cut and cover method is considered to result in a more severe test condition, since friction on the pipes and resistance to advancement is expected to be greater in the compacted backfill than for drilled-in pipes installed using lubricating drilling fluids.

The jetting fluid used in the field trial was water at a pressure of 4,000 psi. With the FlexTool at the surface, jetting was started and the tool pulled into the soil and advanced along the path between the drill pipes. The drill pipes were pulled with a D-6 class bulldozer attached to each pipe. The method of operation was to advance one bulldozer approximately 20 feet, stop it, and then advance the other one a similar distance. This operation was conducted for 60 minutes, advancing the FlexTool a distance of 117 feet and forming 3,510 square feet of subsurface "barrier". The operation progressed smoothly with no interruptions, despite encountering a buried trash disposal pocket containing debris including plastic construction barrier fence and hose. Some fluid breakthrough to the soil surface occurred at the location above the debris, otherwise the surface between the buried drill pipes subsided uniformly by about 1 foot as the tool passed beneath. The subsidence resulted from the use of water as jetting fluid. The water cut through the soil in front of the tool, forming a fluid soil/water slurry which washed out behind the tool through the pathway the tool had traversed. When grout is used as the jetting fluid, the increased density and viscosity of the resulting slurry is expected to minimize washout and reduce subsidence.

CONCLUSIONS

The work produced several advances in the technology of barrier construction and provided the following conclusions relating to equipment and method of operation.

A viable method exists for in situ construction of horizontal, sub surface soil barriers using the FlexTool. Barriers of at least 30 feet width are constructable with present technology.

The FlexTool is operable for barrier formation in clay and other cohesive soil without cobble and large rock.

State-of-the-art precision in placement of directional drilled pipe is adequate for construction of horizontal barriers using the FlexTool.

Horizontal barrier can be formed at a rate of 3,500 sq.ft. per operating hour at an approximate cost of $50 per square foot.

ABSTRACT

Perfluorocarbon tracer technology is being tested at the Hanford Geotechnical test facility as a means of verifying subsurface barrier integrity. To support the experimental design of this project modeling of the transport of the tracer from its injection point to monitoring wells placed outside the barrier has been conducted. The conceptual model considered diffusion and advection due to barometric pumping as the transport processes. Simulations were performed for intact barriers as well as barriers with small (1 - 10 cm) imperfections in the barrier. The role of advection in determining the distribution of a contaminant in the subsurface was also studied.

INTRODUCTION

Subsurface barriers are a promising remediation option. Some uses of subsurface barriers include surrounding and/or containing buried waste, as secondary confinement of underground storage tanks, to direct or contain subsurface contaminant plumes and to restrict remediation methods, such as vacuum extraction, to a limited area. The performance of these barriers will be most effective if the barrier is continuous around the wastes. If a breach forms, that is, the barrier is noncontinuous around the wastes, performance will be degraded. It is recognized that current methods to verify the barriers integrity do not exist (1). Perfluorocarbon tracer (PFT) technology is being tested at the Hanford Geotechnical test facility as a means for verifying subsurface barrier integrity.

The physical system under study is displayed in Fig. 1. The approximate dimensions of the system are 25 feet deep and 40 feet in diameter. The barrier walls slope at an angle of 45 degrees. Eight monitoring wells are

uniformly spaced parallel to the barrier wall at a distance of approximately one meter from the wall. The final subsurface barrier will consist of a close-coupled system of a polymer inner layer and a soil/neat cement outer layer. To better understand the performance of the entire system, testing will be conducted in two phases. In the first phase, only the soil/neat cement barrier will be in place. PFT's will be injected into the soil inside the barrier. Detection wells placed approximately one meter outside the barrier will be used to follow the time evolution PFT concentration. In the second phase, the polymer grout layer will be emplaced and the testing repeated.

Fig. 1

To support the PFT testing procedure, modeling of the subsurface movement of the PFT gas has been conducted for the soil/neat cement barrier. The modeling will be used to estimate the rate at which the tracer will travel through the barrier and reach the monitoring wells, the effects of small holes (1 - 10 cm) on concentration at the well, and the effects of the waste tank on movement of the gas. This information will be used to assist in the determination of injection rates for PFT's into the subsurface system, the frequency and duration of sampling, and the time to flush the system prior to testing the close-coupled system.

After the tests are completed, the data will be analyzed and the modeling will be repeated. In this stage, modeling will be used to attempt to determine the size and location of breaches (if any), and estimate the range of possible values for transport parameters (i.e., diffusion coefficients of the PFT's in the barrier and soil).

This paper will discuss the modeling work performed to support the experimental design of the subsurface barrier verification testing program. Currently, the data collected from the in-situ experiment is being analyzed and modeling to match the data will be attempted and reported later.

CONCEPTUAL MODEL

The problem involves transport of an injected tracer through an engineered barrier (soil/neat cement) to a monitoring well. To model this requires knowledge of the rate of tracer injection, location of injection, geometry of the system, location of the monitoring well, and transport properties of the PFT through the soil and soil/neat cement barrier.

The inverted pyramidal structure is displayed in Fig. 1. The subsurface barrier consists of a cone of injected soil/neat cement with a subtended angle of 90 degrees, approximately 1250 cm in diameter and 630 cm in height. The upper, open end, of the cone is covered with approximately 60 cm of soil. The design basis for the effective thickness of the barrier is 100 cm (this is the thickness of the barrier in the plane that is parallel to the barrier). Monitoring wells are placed at a distance of approximately 100 cm from the outside edge of the barrier and parallel to the barrier. To simulate this geometry, a two-dimensional slice through the center of the cone was taken. Cylindrical geometry was used to represent the subsurface system. The tank in Fig. 1 was represented as a no flow boundary. The original plans were to inject the PFT tracers inside the pyramid at the centerline near the bottom. Therefore, symmetry was assumed along the centerline of the inverted pyramid.

To determine the effects of a small breach in the barrier, simulations with a completely intact barrier will be performed as a baseline. Then the effects of having small imperfections (caused by imperfect grouting)

will be studied. In this analysis, the imperfections are represented as a hole through the entire wall. The range of hole sizes that were modeled was between one and ten cm.

The dominant transport process for air in soil systems is believed to be diffusion (2). Advection resulting from barometric pressure changes can facilitate the release of the tracers to the atmosphere and is also considered. Site specific data on appropriate transport parameters are not available. Therefore, literature values have been used. For simplicity and because of the lack of site-specific data, it is assumed that there are two distinct materials in the subsurface system, the soil and the soil/neat cement barrier.

For the base case, the diffusion coefficient of the PFT in the soil has been selected as 10-2 cm2/s. This value is similar to that for radon gas in dry soils (3). The diffusion coefficient through the soil/neat cement was selected as 10-4 cm2/s. This is on the low end of the range of diffusion coefficients for radon gas through residential concretes (4). The low value was selected in an attempt to provide a lower estimate of release to the monitoring wells and to insure that sampling would be able to detect the PFT's.

Advection in the subsurface system as a result of barometric pressure changes was modeled assuming a sinusoidal change in velocity within the soil which corresponded to changes in the barometric pressure. The amplitude of the velocity was 3.4 10-4 cm/s. This corresponds to the velocity expected for a pressure variation of 1/30 of an atmosphere and permeability consistent with the range of values found for sandy soils (5). The period was five days, 2.5 days of which the system exhaled air from the contaminated region and 2.5 days of which essentially tracer free air from the atmosphere entered the subsurface. It was assumed that the response to the pressure variations was instantaneous within the entire modeled domain. Ancillary calculations were performed to support this as a reasonable first approximation for the parameter values selected in this simulation. The permeability of the soil/neat cement is expected to be a few orders of magnitude lower than in the soil. Therefore, it was assumed that the advection velocity in the barrier was zero.

COMPUTATIONAL MODEL

The subsurface barrier system is modeled in cylindrical geometry using a two-dimensional finite-element transport code, BLT (6). This problem has two size scales. The first scale is that of the system itself. The height from the bottom of the subsurface barrier to the ground surface is 6.6 m. The radius of the barrier was also approximately 6.6 m and a total distance of 12.8 m was simulated in the direction parallel to the ground surface. The second scale is that of the size of the potential breach which is on the order of a few centimeters. It would require nearly one million computational points to model the entire system on the scale of one centimeter. This was not computationally feasible. To account for the two scale sizes, variable mesh spacing was used. A fine mesh (order of one centimeter) was used in the region of the hypothetical breach. The mesh was increased in size as the distance away from the hypothetical breach increased. The slanting soil/neat cement barrier was modeled through definition of the finite elements used to represent the barrier to also slant at a 45-degree angle. These two details caused a complicated mesh with three thousand computational points to be used. The finite element grid is displayed in Fig. 2.

Fig. 2
Initially, the system is tracer free and, therefore, the initial condition is zero concentration at all locations. The boundary condition assumed zero flux at the centerline due to the assumed symmetry. Zero concentration boundary conditions were used at the top boundary, bottom boundary, and right-hand boundary defined in Fig. 2. The right-hand boundary is located at a large enough distance such that essentially no tracer reaches the boundary of the simulation period of 0.1 years. The top boundary was selected to have zero concentration to represent PFT concentrations in the atmosphere which are assumed to be zero.
The source was treated as a point source being injected at the centerline at an elevation of 97 cm above the bottom of the facility. This is 40 cm above the top of the soil/neat cement layer in Fig. 2. Two injection scenarios were modeled: a 3.7 day pulse injection and continuous injection over the entire simulation period of 37 days. The air injection rate was assumed to be 30 cm3/min at a unit tracer concentration. This problem exhibits a linear response to the injection concentration. This information was used to normalize all of the simulation results to the injection concentration.
PFT tracers are non-reactive in soil systems and can be detected at levels of one part in 1015. Typically, injection concentrations are on the order of one part per million. Therefore, the detection limit will be approximately 10-9 of the incoming concentration. One objective of the modeling work was to define the time at which the PFT's will first be detected at the monitoring wells and the time evolution of concentration at the monitoring wells. For the purposes of defining the experimental protocol, the minimum detection limit was multiplied by a factor of 100 for the design objective. This provides a design goal for the normalized concentration in the monitoring wells of 10-7
The advective-dispersive transport equation for a non-zero velocity in the z-direction only is used to solve for the movement of the tracer from the injection location throughout the modeled domain. The equation is:
Eq. (1)
where:

C(x,z,t) is the tracer concentration
D is the diffusion/dispersion coefficient (cm2/s)
V(t) is the volumetric flow rate per unit area of the gas in the subsurface system,
Q is the volumetric air content of the porous medium, and
Q(x, z, t) is the rate of contaminant injection into the system.

The diffusion/dispersion coefficient consists of two terms, one term represents molecular diffusion while the other represents dispersion due to advective flow in a porous medium. Mathematically it is expressed as:
Eq. (2)
where:

Dm is the molecular diffusion coefficient, (cm2/s),
Dt is the transverse dispersion coefficient (cm),
Dl is the longitudinal dispersion coefficient (cm),
Vx is the x component of the velocity, (zero in this study),
Vz is the z component of the velocity,
|V| is the magnitude of the velocity, and
dij is the Kronecker delta = 1 if I=j and 0 otherwise.

For the problem under study, molecular diffusion is expected to dominate over the dispersion terms.

In the above expression, the air phase Darcy velocity is expressed as a function of time. It is assumed that the Darcy velocity responds instantly to barometric pressure changes at all locations in the modeled domain. As stated before, the velocity through the wall is assumed to be zero. Elsewhere, it is assumed to flow only in the direction perpendicular to the ground surface. With these assumptions, the flow occurs only in the z-direction in the soil and is:

Eq. (3)

where:

V0 is the amplitude of the velocity,
w is the frequency of the pressure oscillation, and
t is time.

MODEL RESULTS

The computer code BLT (6) was modified to simulate the time-dependent velocity as expressed in the preceding equation. The modified BLT code was then used to solve the above equations for the contaminant plume due to injection of the tracer. A wide range of cases was considered to assist in gaining an understanding of the system behavior. The objective of these simulations was to estimate the time evolution of tracer concentration at the monitoring well.

The time evolution of the contaminant plume was followed for 0.1 years (36.5 days) using the base case parameters in Table I. In the base case it is assumed that the subsurface barrier wall is intact and no substantial breach occurs. The results of this simulation 14.6 days after the start of the experiment are presented in Fig. 3. The contour plot color key is presented in Fig. 4. All projected concentrations are normalized to an injection concentration of unity.

Table I

Fig. 3

Fig. 4

In Fig. 3, it is seen that for the base case parameters, the soil/neat cement wall provides an effective barrier to migration of the PFT's. Concentrations at the well 14.6 days since the beginning of tracer injection are more than eight orders of magnitude (which is the design objective of the experiments and the lowest value represented on the contour plots) less than the injection concentration. Inspection of the output files indicates that the projected baseline concentrations are nine orders of magnitude less than the injection concentration at this time.

To determine the effect of the barrier diffusion coefficient on release, the base case was modified by increasing the barrier diffusion coefficient by a factor of 10 to 10-3 cm2/s. This value is toward the high end of measured radon diffusion coefficients through residential concretes (4). In this case, predicted concentrations at the monitoring well at 14.6 days reached a maximum normalized concentration of 7 10-6 and averaged more than 10-6. This exceeds the design basis concentration by an order of magnitude.

To determine the effect of a small breach in the barrier a 5-cm hole was simulated as having the same properties as the soil, diffusion coefficient of 10-2 cm2/s. This hypothetical hole in the barrier was located at an elevation of 1.8 m from the bottom of the modeled domain, 0.8 m higher than the source. The total distance from the source to the edge of the hypothetical hole in the barrier is 1.8 m. The results of this analysis at 14.6 days after the start of the injection, Fig. 5,

indicate that the breach has a pronounced effect on the contaminant plume. Streaming through this 5-cm breach is clearly evident. The peak normalized concentration at the well is 4 10-6. Average concentrations along the lower section of the well are above 10 -6 a three order of magnitude increase over the projected concentration for the intact wall. In fact, the projected concentrations at the monitoring well for the 5-cm hole simulation was of the same order of magnitude as the case with the barrier diffusion coefficient increased an order of magnitude over the base case value.

Fig. 5

In all three cases, the contaminant plume within the region bounded by the subsurface barrier is almost identical. Average concentrations in this region are approximately 10-3, four orders of magnitude larger than at the monitoring well location for the case with a barrier breach. This indicates that only a small fraction of the tracer reaches the monitoring wells under the conditions simulated.

The hole size was varied from 1 - 10 cm and the results were similar. Even a 1 cm. hole would permit the concentration of PFT tracer that reaches monitoring well to exceed the base case (an intact barrier) value by 2 - 3 orders of magnitude.

The role of advection was studied by comparing the case with the 5-cm hole in the barrier to an identical simulation except that the amplitude of the advection velocity was set to zero. In this case, diffusion is the only transport mechanism. Predicted concentrations at the monitoring well increased by as much as an order of magnitude in the absence of advection. Advection tended to smear the plume and shift the plume slightly toward the surface on average. Therefore, it did increase the release of the tracer through the ground surface to the atmosphere. Following the time evolution of the plume, it was observed that the plume did shift up and down with the changes of advection velocity. Although, the velocity variations were cyclic, when the flow was directed out of the subsurface, it moved tracers from a region of higher concentration upwards to regions of lower concentrations. When the flow was into the system, it moved tracers in regions of lower concentrations deeper into the subsurface toward regions of higher concentrations. The net effect was a slight shift in the plume toward the surface as compared to the simulations that did not model advection. The net upward shift is due to the fact that the source is injected at the bottom of the domain. It may not be true for a source located in the middle of the modeled domain.

COMPARISON OF EXPERIMENTAL RESULTS WITH MODEL PREDICTIONS

PFT tracers were continually injected for three days into the area contained by the soil/neat cement barrier, Fig. 1, just beneath the empty tank at the center of the region bounded by the cone. Seven monitoring wells were located parallel and approximately 1 meter outside of the barrier. The wells were approximately 1 meter from the barrier. Measurements for PFT tracers were taken from each well for 18 days after the start of injection. PFT concentrations within the region bounded by the barrier were measured for the three-day injection period

The data showed a net drift toward one side of the barrier. The interior monitoring well designated as N, for North, had measured concentrations approximately one order of magnitude greater than the interior well designated S, for south. This indicates that advection is occurring. The cause of this net drift is not known, however, it has been postulated

that it is due to the injection velocity (12 - 15 cm3/min). This and other possible explanations are under investigation.

The drop in concentration between the inner and outer monitoring wells (i.e., across the barrier) was approximately four orders of magnitude. There was no evidence of a substantial breach in any region as the drop in concentration across the barrier was consistent at all monitoring wells.

To estimate diffusion coefficients in the soil and the barrier, prospective model evaluations were performed. The computational model is similar to the one described to examine the influence of a breach in the barrier, Fig. 2, with the exception that the dimensions were changed to match the as-built dimensions exactly and the source location was changed to reflect the experimental conditions.

The base case diffusion coefficient values, Dsoil = 10-2 cm2/s and Dwall = 10-4 cm2/s, provided concentration estimates that were far lower than the measured value. This was expected because the base case values were chosen with the intent of under predicting the amount that would reach the wells to insure that detection would be possible.

A range of different values of the diffusion coefficients was simulated. The results have been compared to the measured average value of the seven monitoring wells and are displayed in Fig. 6. From these evaluations, the soil diffusion coefficient for the PFT has been determined to lie between 1 - 5 10-2 cm2/s under the test conditions. The diffusion coefficient for the soil/neat cement barrier has been determined to lie between 1 - 5 10-3 cm2/s. The best fit was obtained using a soil diffusion coefficient of 2 10-2 cm2/s and a barrier diffusion coefficient of 2 10-3 cm2/s. Further evaluations to improve the best fit will be taken.

Fig. 6

In Fig. 6 the effects of barometric pumping can be seen from the two simulations with Dsoil = 10-2; Dwall = 10-3 cm2/s. In one case, barometric pumping was not simulated. In the other case, barometric pumping was simulated and the fluctuation in concentration at the well is clearly in evidence. The fluctuations had only a minor impact on the concentration and were not in evidence in the experimental data. Therefore, barometric pumping was not simulated in other evaluations.

CONCLUSIONS

Modeling of transport of PFT tracers in a subsurface system consisting of soil and a soil/neat cement barrier has been conducted. The results support the feasibility of detecting tracers outside of the barrier on the time frame of a few weeks. For the base case, a two order of magnitude difference in the PFT diffusion coefficient in the soil and barrier, small holes (on the order of cm) should be easily detectable. As the difference in diffusion coefficients of the soil and barrier decreases, the ability to detect small holes also decreases.

Site-specific data on transport parameters were not available. Therefore, the model evaluations were compared to the experimental data and used to estimate the diffusion coefficient for the PFT through the soil and barrier. The best fit to the data indicates that the soil diffusion coefficient is approximately 2 10-2 cm2/s and the barrier diffusion coefficient of 2 10-3 cm2/s. It was determined that barometric pumping did not contribute significantly to transport in this experiment.

ABSTRACT

The Idaho National Engineering Laboratory (INEL) has been involved in nuclear reactor research and development for over 40 years. One of the first major projects involved the development of the nuclear powered aircraft engine. This project used mercury as a shielding medium and over several years a significant amount of mercury was spilled along the railroad tracks where the test engines were transported and stored. In addition, experiments with volume reduction of waste through a calcine process resulted in mercury contaminated calcine waste. Mercury was used as a catalyst in this process.

These wastes have been identified in a Removal Action Work Plan to be retorted and thereby separating the mercury from the various contaminated media. Lockheed Idaho Technologies Company awarded the Mercury Retort contract to ETAS Corporation and assigned Parsons Engineering Science, Inc. to manage the Removal Action field activities.

The mercury retort process is a mobile unit which consists of several trailer-mounted units, requiring electricity, propane, and a water supply. The conclusions presented in this paper will describe the performance of the retort unit for the various waste streams and show how the mobile unit is an effective means to retort waste and generate minimal secondary waste.

SITE BACKGROUND

The Idaho National Engineering Laboratory (INEL), formerly the National Reactor Testing Station (NRTS), encompasses 2,305 km2 (890 mi2), and is located approximately 32 km (20 mi) west of Idaho Falls, Idaho (Fig. 1). In 1949, the United States Atomic Energy Commission, now the Department of Energy (DOE), established the NRTS as a site for building and testing a variety of nuclear facilities. Since 1952, the INEL has also functioned as the storage facility of transuranic radionuclides and low-level radioactive waste. At present, the INEL supports engineering and

operations efforts of DOE and other Federal agencies in areas of nuclear safety research, reactor development, reactor operations and training, nuclear defense materials production, waste management technology development, and energy technology and conservation programs. The DOE Idaho Field Office (DOE-ID), having responsibility for the INEL, designates authority to operate the INEL to government contractors. The primary contractor for DOE-ID at the INEL is Lockheed Idaho Technologies Company (LITCO), which provides managing and operating services to the majority of INEL facilities. The remedial design/remedial action contractor for LITCO at the INEL is Parsons Engineering Science, Inc., which provides complete remedial design and remedial action (RD/RA) services.

Fig. 1

ORIGIN OF MERCURY CONTAMINATED MATERIAL

Calcine Material

In the late 1950's and early 1960's, research teams at the INEL conducted developmental work on the recovery of uranium from spent nuclear fuels and the subsequent treatment of the resulting wastes. Solutions from which the uranium had been extracted were calcined to reduce their volume and make them easier to handle and dispose. In various pilot studies, carried out at the Central Facilities Area (CFA) Chemical Engineering Laboratory at the INEL site, simulated aluminum clad fuels were treated, with mercury added as a catalyst in the calcining process. The calcined material and elemental mercury was disposed in a depression near the test facility and eventually covered with gravel. Through different mechanisms, the calcine waste was partially exposed to the elements. Subsequent investigations determined that the calcined material exhibited low-level radioactivity (from radioactive tracers, Cesium-137, Strontium-90, Ruthenium-106, and unidentified Uranium isotopes used during the calcine experiments) and mercury concentrations above 260 mg/kg. The waste calcine and surrounding contaminated soil were retrieved and containerized for future treatment. In a fluidized-bed calciner, the calcined material was formed at temperatures between 400 and 500 degrees Celsius. Held at this temperature only long enough to drive off the water coming in with the feed, the material left a large percentage of the feed mercury in the calcine when the calcine cooled. Though the calcine is porous, the mercury had insufficient time to vaporize and migrate out of the calcined material. A significant portion of this mercury is still present in the calcine in the form of mercury oxide.

The selected remedial action will meet final concentration limits of less than 0.2 mg/L mercury as determined by the Toxicity Characteristic Leaching Procedure, Environmental Protection Agency (EPA) analysis Method 1311, and less than 80 mg/kg total mercury as determined by EPA Method 7470/7471 (SW846).

Test Area North Material

In addition to the calcine waste, a second waste stream will be treated. This waste stream consists of mercury contaminated soil and railroad ballast contaminated by a large spill of elemental mercury at the INEL's Test Area North (TAN) in 1958. This mercury contaminated material was excavated and containerized in 1994. Sample results indicated that the material exhibited low level radioactivity (Cesium-137 and Strontium-90) and mercury concentrations above 450 mg/kg. The radioactive isotopes , Cesium-137 and Strontium-90, are the result of radioactive storage in the immediate vicinity.

The selected remedial activity will meet final concentration limits of less than 0.2 mg/L mercury as determined by the Toxicity Characteristic Leaching Procedure, Environmental Protection Agency (EPA) analysis Method 1311, and less than 4 mg/kg total mercury as determined by EPA Method 7470/7471 (SW846).

MERCURY RETORT SYSTEM

ETAS Corporation is not only the operator of the mercury retort system, but ETAS developed, designed, and fabricated the mercury retort system as well.

System Components

The mercury retort process entails a mobile unit which consists of trailer-mounted sub-systems with multiple components or units in each subsystem (Fig. 2). The four subsystems are:

- Feed System
- Retort Main System
- Vapor Recovery System
- Material Discharge System

Fig. 2

Feed System

Vacuum Unit

A vacuum unit was initially used to transfer material from the drums and boxes into the retort main system. The vacuum unit, an off-the-shelf manufactured system, is equipped with integral dust controls, including a multi-stage cyclone and a HEPA filter. A slide gate between the vacuum unit and the retort provided the necessary seal between the units.

The vacuum system was designed to minimize blowing dust during transfer of dry material from the waste containers. As treatment progressed, monitoring showed that almost all the material was at least damp and much was very wet, producing severe caking in the vacuum unit. Subsequently, an auger feed was tried, and finally a conveyor belt system installed. After the material was shoveled from waste containers into a hopper at ground level, a fully enclosed conveyor belt dumped the material onto a slide gate. The slide gate opened periodically to feed the material into the retort. The conveyor enclosure minimizes blowing material. The slide gate seals the feed end of the retort and provides for circulation of gases through the retort and into the vapor recover system.

Retort System

The Retort Main System consists of the following components/units:

- The Retort Chamber
- Burners and Mechanical Controls
- Gas Supply Piping Components
- Burner Control Cabinet
- Power and Motor Control Cabinet

Retort Chamber

The Retort Chamber is a heated assembly, which consists of a rotating process tube mounted axially inside a refractory lined shell. The rotating drum is lined with curved vanes, which both propel material forward and mix the material as the drum rotates. This not only conveys the material, but assures that the material is heated quickly and evenly. The unit rotates from 4 to 25 rpm, which allows a material transfer rate of 0.54 to 4.51 m3 (0.7 to 5.9 yd3) per hour. Constructed entirely of 304 steel, the rotating drum sits in the refractory lined outer tube chamber, which houses the burners. The curved shape of this chamber directs the burner flames around the tube for efficient heating.

Burners & Mechanical Controls

The burners essentially fire horizontally under the process tube for minimal flame impingement on the tube. The radiant heat of the flame and the convective heat of the hot combustion products heat the tube, which transfers heat to the product traveling through the tube.

Although the burners can be individually started and stopped, the burner firing rates are controlled by three process tube zone temperature controllers, with each controller driving three burners. ETAS has included several automatic features to provide remote and dual temperature controller set points, and will provide "cutback" logic in case stack temperatures become too high.

Rated for 1.0 MBTU/H firing propane, each burner consists of an integral fan housing directly coupled to the fan motor, gas burner and blast tube, gas pilot/igniter assembly, flame detector port, and viewport. The burners utilize modulating motors to control firing rates and fuel/air ratios. The system is equipped with temperature controllers for each of the three process tube zones; each controller will provide a control signal to regulate the modulating motors on all three burners for that zone.

Gas Supply Piping Components

Propane to the main fuel and pilot on each burner is turned on and off by the burner safety shutoff valves, with the fuel rates being controlled by the regulators and the main fuel modulating control valve. All safety shutoff valves are of the automatic type. The automatic shutoff valves provide for automatic shutdown of the fuel feed during certain conditions, and further provide for a single button shutdown during any emergency situations.

Burner Control Cabinet

The burner control cabinet is an air purged, free standing cabinet containing all burner system controls, indicators, and alarms.

The entire system is designed for maximum burner operating flexibility and maximum user friendliness. The system utilizes individual flame programmers for each burner, each with its own status indicator visible through a window on the cabinet door. ETAS included one enhanced display module designed to automatically switch to display the operating burner, providing enhanced sequence and alarm information for that particular burner. In addition, the system includes extensive alarm logic and indications for virtually all operating conditions, as well as main system purge controls and indicators.

Power and Motor Control Cabinet

This cabinet is an air purged, free standing cabinet, containing circuit breakers and motor starters for all nine unit motors, all nine burner motors, and control power circuit breakers for the burner control cabinet. Main 480 volt 60 cycle 3 phase (480/60/3) power and all nine unit motors can be controlled by the respective start/stop push buttons, and are indicated by the respective lights mounted on the cabinet door. The primary side of these transformers are protected by two-pole circuit breakers. The main logic section and each of the nine burner sections are protected by individual single-pole circuit breakers.

Vapor Recovery System

The vapor recovery system (VRS), having its own control cabinet, is a stand-alone system designed specifically for the removal of mercury. The entire Vapor Recovery process is performed under a vacuum created by a blower, which pulls the vapor stream through the VRS and pushes the final

vapor stream out through the carbon canisters. This vacuum assures that no pressure can build in the vapor recovery system. Pressure buildups have been shown to cause leaks in retort operations without vacuum assisted vapor recovery systems.

The VRS consists of three main removal sections, followed by carbon canisters. These sections are the Spray Scrubber, the Sieve Tray Scrubber, and the Vapor Separator.

Spray Scrubber

Material first passes through the spray scrubber, a direct contact heat exchanger which condenses the bulk of the vapors. This scrubber is powered by process water, which in turn is cooled by an indirect heat exchanger linked to a cooling tower.

Sieve Tray Scrubber

The Sieve Tray Scrubber condenses any remaining condensable vapors which escape condensation in the Spray Scrubber. The Sieve Tray Scrubber is also a direct contact heat exchanger, linked to the same cooling tower and indirect heat exchanger as the Spray Scrubber. Condensed vapors from both scrubbers are collected in a common surge tank, where baffles at the bottom of the tank capture mercury and particulate matter from the process water stream.

Vapor Separator

The vapor separator, the last piece in the system, provides a mist eliminator and a low vapor velocity zone to collect mist and return it to the surge tank.

Product Cooler System

An airlock provides a vapor seal between the retort and the material discharge system.

Airlock

The airlock is a rotary eight-vane unit, which provides a high-quality seal against air leaks. As the airlock rotates (at approximately 40 RPM), material passes via the rotating vanes from one end of the airlock to the other. The unit has a 1.5 HP motor and uses sizable gear reducers to achieve the 40 RPM working speed.

Product Loading System

The material discharge system cools the treated material while moving the material from the retort into storage boxes. The cooling and transfer is accomplished by three totally enclosed screw augers, two of which have coolant passing through jackets. This system shares a cooling tower and refrigeration with the Vapor Recovery System.

SYSTEM PERFORMANCE

Production Rates

The retort system has proven effective at meeting the treatment standards. Production rates have not reached the maximum potential of the system's capacity due to site specific issues. Feed material high moisture content in conjunction with freezing temperatures, size gradation of the railroad ballast relative to the material handling system design, and foreign objects, such as railroad spikes and construction debris, have all been contributing factors to the production rates contained in the feed material.

Treatment Results

Based on more than 20 samples taken and analyzed for total mercury and/or TCLP, the retort system is demonstrably effective in removing mercury from various waste streams, as summarized in Table I.

Table I

CONCLUSIONS

Material Handling Considerations

Subcontractors must evaluate the feed stock and determine the appropriate material handling equipment needed to handle the feed material and all expected worst case conditions. A proactive design that addresses the above concerns may require a greater initial capital cost, but consistently proves less expensive in the long run when compared to the costs of frequent mini-design changes occurring as situations arise.

Cold Weather Operations

Manual labor operations and work activities in unprotected areas in the winter may result in hypothermia or exhaustion caused by working in heavy clothing and respirators. Equipment, particularly wetted systems, must be protected from freezing, especially during non-operating periods. Employee well-being is directly proportional to production and every effort must be made to account for the expected climate during the project execution.

DOE Contracting

Subcontracts let at DOE facilities in the future will rely more heavily on fixed price lump sums or unit rates for fixed quantity contracts. These contracts will require subcontractors to incur more initial financial risk: the bulk of their payment will be received only after their services have been both completed and certified as meeting all performance specifications.

This requires bidders to ask for more clarification so that they are fully aware of the site conditions, as change orders and overruns are being tolerated less and being funded even less.

If conditions are accepted by the subcontractor, then it is assumed by the contractor that the subcontractor is comfortable with the site conditions and has bid the project accordingly.

ABSTRACT

The National Air and Radiation Environmental Laboratory (NAREL) received eight whole soil samples from four individual sites collectively referred to as the Tonawanda FUSRAP Site. The four sites are Ashland I, Ashland II, Linde, and Seaway. The primary radioactive contaminants in the soils are uranium-235, uranium-238, radium-226, thorium-230, and their decay products. Two samples were received from each site, one sample collected to represent the maximum levels of radioactivity (Bias) and one to represent the average levels (Systematic). The samples were designated as

Ash I Bias, Ash I Systematic, Ash II Bias, Ash II Systematic, Linde Bias, Linde Systematic, Seaway Bias, and Seaway Systematic.

The primary objectives of this initial characterization of the samples were to: 1) determine if particle-size separation techniques could be effective in reducing the volume of contaminated soil, 2) identify any radiominerals present, 3) determine the presence and magnitude of contamination associated with particles of high density and ferromagnetism, and 4) determine if chemical scout extraction tests are effective in reducing the volume of contaminated soil in these samples. Particle-size separation by wet sieving and hydroclassification was performed after the samples were subjected to particle liberation by vigorous washing. Fractions were analyzed for radionuclides, and select fractions were subjected to petrographic analysis after density separation at 2.89 g/cc. Magnetic separations, using a hand-held magnet, were also performed on the heavy-mineral fractions to separate the ferromagnetic particles. The heavy-mineral nonmagnetic and magnetic fractions were analyzed for select radionuclides. Scout chemical extractions were performed with hot nitric acid on the samples that were judged to be amenable to contaminant reduction by the technology: four Systematic Tonawanda samples, the +50 and -50-mesh portions of the Linde Bias sample, and the +50-mesh fractions of the Linde Systematic sample. Analysis of data from the eight Tonawanda samples examined in this study demonstrates that particle-size separation alone will not provide a successful remediation solution for any of the sites. Although significant concentrations of the radionuclides were identified in the heavy-mineral fractions of materials from the eight samples, there were insufficient quantities to affect the overall radionuclide concentrations by their removal. Ferromagnetic materials separated from the heavy-mineral fractions also contained elevated concentrations of radionuclides; but these were, likewise, insufficient in quantity to affect the remediation potential by their removal. The results of the 3M nitric acid extraction indicate that the Linde +50-mesh material, particularly the Bias soil, shows promise for meeting cleanup criteria with additional chemical extraction.

INTRODUCTION

The National Air and Radiation Environmental Laboratory (NAREL) received eight whole soil samples from four individual sites collectively referred to as the Tonawanda FUSRAP Site. The four sites are Ashland I, Ashland II, Linde, and Seaway. Two samples were received from each site, one sample collected to represent the maximum levels of radioactivity (Bias) and the other to represent the average levels (Systematic). The samples were designated as Ash I Bias, Ash I Systematic, etc.The primary objectives of this initial characterization of the samples were to: 1) determine if particle-size separation techniques could be effective in reducing the volume of contaminated soil, 2) identify any radiominerals present, 3) determine the presence and magnitude of contamination associated with particles of high density and ferromagnetism, and 4) determine if chemical scout extraction tests are effective in reducing the volume of contaminated soil in these samples.

The radionuclide cleanup criteria for the Tonawanda FUSRAP site soils (in pCi/g) are: radium-226, 5-15; thorium-230, 5-15; thorium-232, 5-15; uranium-238, 28.4, and total uranium, 60.

EXPERIMENTAL

Gamma Spectrometry

Whole soil samples, particle-size fractions, and wash waters were analyzed for gamma-emitting radionuclides using high-purity germanium detectors (1). The wash water samples were counted for 1000 min, and the soil samples were counted for 100 or 1000 min, depending on the levels of radioactivity. With the relatively large uranium concentrations in the samples, erroneous Ra-226 values were obtained from the gamma spectrometry analysis program. Values cited for Ra-226 are based, therefore, on the Pb-214 values reported by the program and are more indicative of the actual Ra-226 concentrations.

Alpha Spectrometry

Analyses for uranium and thorium radionuclides were performed by alpha spectrometry (2). Uranium was extracted, coprecipitated with lanthanum fluoride carrier, and analyzed by alpha spectrometry. Thorium was separated by ion-exchange chromatography, coprecipitated with lanthanum fluoride carrier, and analyzed by alpha spectrometry.

Sample Preparation

The eight whole soil samples were received at the NAREL and initially screened for gross beta/gamma activity using a Geiger-Mueller portable survey instrument. After initial screening, each sample was thoroughly mixed and split into 400-mL aliquots using a riffler. The aliquots were weighed, dried at 60C for 48 hr, and reweighed. Four aliquots from each whole soil were analyzed by gamma spectrometry. The whole soil samples taken from Ashland I and Linde (Ash I Bias, Ash I Systematic, Linde Bias, and Linde Systematic) were also analyzed for uranium and thorium by alpha spectrometry, after they were ashed at 565C for 72 hr.

Vigorous Wash

The vigorous washing process liberates small particles from large particles without generating excessive fines. After sample preparation, each aliquot from every soil was vigorously washed in water for 30 minute in a Nalgene container at a rotational velocity of 350 rpm with a liquid-to-solid ratio of 4 mL/1g (3).

Wet Sieving

After vigorous washing, an aliquot of each soil sample was fractionated by wet sieving with American Standard Testing of Materials (ASTM) standard sieves (4). The aliquots were separated into particle-size fractions at 4 mesh (4.75mm), 8 mesh (2.38mm), 16mesh (1.19mm), 30 mesh (0.590mm), 50 mesh (0.297mm), 100 mesh (0.149mm), 200mesh (0.074mm), and 400 mesh (0.037mm). The fractions were dried at 60C for 48 hr, weighed, and analyzed for radionuclide content by gamma spectrometry. Analysis by alpha spectrometry was performed on only fractions from two of the four sites, Ashland I and Linde.

Process Water

Water from the vigorous wash and separation procedures for each sample was collected and a Percol 788N flocculant was added to settle suspended material. The water was then filtered through a 0.025-mm pore filter paper to separate suspended solids from the wash water. The material retained on the filter was analyzed by gammaspectrometry and, if called for, by alpha spectrometry and reported as the -400 activity. An aliquot of filtered wash water from each of the eight whole soil samples was analyzed by gamma spectrometry.

Petrographic Study

Petrographic examination was performed on the eight radioactive soil samples to determine the minerals or materials comprising the radioactive particles as well as the physical properties and composition of the host

materials. The petrographic tests were conducted according to the EPA protocol procedure for radioactive soils (5).

Soil-size fractions from vigorous washing and wet sieving were examined for mineral identification and physical properties by an optical petrographic microscope and a binocular microscope. In order to provide an assessment of the heavy-mineral fractions that frequently contain a major portion of the radioactive materials, density separations using the sink-float method with sodium polytungstate were performed on the -50/+100, -100/+200, and -200/+400-mesh fractions to remove heavy minerals (specific gravity greater than 2.89) and to facilitate mineral identification and preparation of photomicrographs. The gravel material on the 4-mesh sieve and materials on the 8, 16, and 30-mesh-size sieves was examined under the binocular microscope. A minimum of 100 particles were counted; all particles were counted if 100 were not present. Particle-size material from each fraction was divided into rock, mineral, slag, and other-mineral categories to illustrate the make-up of the soil sample. The materials on the 50, 100, 200, and 400-mesh sieves were examined under both the binocular and optical petrographic microscope. The material examined under the petrographic microscope was immersed in an index oil of 1.544 refractive index. Photomicrographs of significant features were made in both transmitted and reflected light.

Magnetic separations, using a hand-held magnet, were also performed on the heavy-mineral fractions to separate the ferromagnetic particles. The heavy-mineral nonmagnetic and magnetic fractions were analyzed by alpha spectrometry.

Scout Chemical Extractions

Scout chemical extractions using hot nitric acid (HNO3) were performed on Systematic whole soil samples collected at each of the four sites. In addition, nitric acid extractions were conducted on the combined +50-mesh fraction and -50-mesh fraction of Linde Bias samples and +50-mesh fraction of the Linde Systematic samples.

The nitric acid extractions were performed on aliquots (approximately 50 mL) from each Systematic soil prepared by proportionally recombining each of the wet-sieved fractions from the particle-size study described above. The resultant recombined fractions represented the whole soil. The aliquots used for extraction of the Linde +50 and -50-mesh fractions were similarly prepared from the previously sieved material.

For the chemical extraction, a spherical reaction kettle was closed with a 4-neck cover and fitted with a reflux condenser, centigrade thermometer, stirrer with paddle, and thermocouple assembly. The stirrer was rotated by a high-torque electric motor. Stirring speed was monitored every five minutes by an optical tachometer. The thermocouple assembly consisted of a iron-constantan thermocouple sealed in a glass tube to protect it from acid corrosion and packed with glass wool to aid the transfer of heat from the glass tubing to a thermocouple. Heat was provided by a mantle whose temperature was monitored and controlled by a Glas-Col Digitrol connected to the thermocouple and the variable autotransformer. Visual monitoring of temperature was also performed by observation of the centigrade thermometer.

Each aliquot was extracted with 3M nitric acid (5 mL/g of soil) heated to 90C while stirring at a nominal 350rpm. The sample was introduced to the reaction flask with a spatula over a five-minute period to assure complete contact between the reagent and the sample. The sample was extracted for 60 min, then filtered through a Buchner funnel, and rinsed

using hot 3M HNO3 followed by hot water. The resulting filtrate was again filtered over a membrane filter using a Millipore filtration apparatus to collect any fine particulates. The whole soil, extracted soil, membrane filter, and filtrate were analyzed for radium by gamma spectroscopy and for uranium and thorium by alpha spectrometry.

RESULTS AND DISCUSSION

Particle-Size Distributions

The particle-size distributions for Ash I, Ash II, and Seaway are similar with at least 49 percent -400-mesh material, as illustrated in Fig. 1. The Ash I Systematic soil contains notably more gravel and coarse sand-sized material than the Ash I Bias and both Ash II and Seaway soils. The Ash I, Ash II, and Seaway soils all contain from 50 to 60 percent -400-mesh (silt and clay) material. The Linde Bias and Systematic soils are similar in their distributions with 41 and 37 percent -400-mesh material, respectively. These soils are notably different from the other soils in that they contain 45 percent +50-mesh material.

Fig. 1

Radionuclide Distributions

The primary radionuclides above background levels identified in the Tonawanda samples are members of the U-238 and U-235 decay series. Radionuclides associated with the Th-232 series are present at quantities within the range of natural background. The nuclides of primary concern are U-234, -235, and -238; Th-234 and -230; and Ra-226. Gamma spectrometry data were collected for all whole soils and soil fractions, and those from alpha spectrometry (U and Th) were collected for the AshI and Linde samples. Uranium and thorium analyses were not performed on the Ash II or Seaway soils.

The concentrations of the primary radionuclides of the U-238 decay series in the eight whole samples are shown in Fig. 2. With the possible exceptions of the Linde samples, the uranium series radionuclides do not appear to be in equilibrium. (While the radium-226 values are about one-half those of the Th-230 and U-234/238, the great inaccuracy in the Ra-226 values, discussed earlier, does not preclude secular equilibrium.) With the exception of the Ash II Systematic soil samples, the Th-230 concentration of the remaining sample is higher, by up to 18 times that of the U-234/238 values. The Ra-226 concentrations are approximately one-half those of U-234/238 in the Linde samples, approximately equal in the Seaway samples, and lower, by up to a factor of 13, in the Ash I and Ash II samples.

Fig. 2

The relative relationships between uranium-series radionuclide concentrations in the whole soil remain stable for the separated fractions in the Ash I soils. The concentrations of the radionuclides are relatively constant throughout the particle sizes. There is a general inverse relationship between particle size and radionuclide concentrations for all the radionuclides in the Linde samples. However, the Th-230 is more highly concentrated in the smaller size fractions than are Ra-226 or the uranium nuclides.

Ash I Samples

The radionuclide with the highest concentrations in the Ash I samples is Th-230. The average concentrations of Th-230 are 2,100pCi/g and 1,526pCi/g in the whole soils of AshI Bias and Ash I Systematic, respectively. The values in the sieved fractions range from 394 to 2,585pCi/g (coarse to fine) for Ash I Bias and from 168 to 3,723pCi/g for

Ash I Systematic. Th-234, U-234, and U-238 are present in approximately equal concentrations throughout all size fractions in both samples. The values range from approximately 20 to 300pCi/g (coarse to fine) for Ash I Bias and from approximately 20 to 200pCi/g in Ash I Systematic. The Ra-226 concentrations are 71pCi/g in the Ash I Bias and 65 in the Ash I Systematic whole soils. Concentrations in the size fractions range from 17 to 125 and from 9 to 68 (coarse to fine) in the size fractions of the Bias and Systematic samples, respectively. Because of the magnitude of the radionuclide concentrations throughout the size fractions, for both Ash I samples, particle-size separation alone will not achieve the remediation levels required to meet site cleanup criteria.

Ash II Samples

Only gamma spectrometry analyses were performed on the Ash II sample fractions, thus no data are available for Th-230 as a function of particle size. However, a Th-230 concentration of 1,545 pCi/g in one aliquot of the Bias whole soil sample and its particle-size distribution suggests that it is similar to Ash I Bias. The Th-230 concentration in the Ash II Systematic whole soil is 520 pCi/g.

The Th-234 values may be used to estimate the U-238 concentrations since these two nuclides should be in equilibrium. The average ratio of Th-234 to U-238, as determined on the samples for which alpha spectrometry was performed (Ash I Bias, Ash I Systematic, Linde Bias, and Linde Systematic) is 0.88; therefore, the uranium concentration can be estimated from the Th-234 values derived from gamma analysis. There is no valid way to estimate the Th-230 concentrations in each particle size. The Ra-226 concentrations in the whole soil samples are 51pCi/g for Ash II Bias and 38pCi/g in the Systematic sample. Based on the Th-234 gamma values, the U-234 and U-238 concentrations are approximately 120 and 70pCi/g in the AshII Bias and Systematic samples, respectively. The Ra-226 concentrations in the size fractions range from 10 to 96pCi/g (coarse to fine) in the Bias sample and from 7 to 61pCi/g in the Systematic sample; the Th-234 ranges from 31 to 248 pCi/g in the Bias sample and from 15 to 125 in the Systematic sample.

Since only the +4-mesh particle-size fractions, representing less than six percent of the Bias and Systematic samples, contain Ra-226 concentrations at or below 15pCi/g; particle-size separation alone will not serve as a volume reduction technique to achieve site cleanup criteria.

Linde Samples

The Linde Bias whole soil sample contains concentrations of U-234 and U-238 of approximately 300pCi/g, Ra-226 of 120pCi/g, and Th-230 of 245pCi/g (Fig. 2). The +50 material, which represents 45 percent of the sample, has concentrations of U-234 and U-238, Ra-226, and Th-230 of 105, 20, and 31pCi/g, respectively. The uranium is virtually evenly distributed in the fractions with particle sizes greater than 100mesh, with U-234 and U-238 above 200 pCi/g in each size fraction.

The Ra-226 and Th-230 concentrations are greater than 15pCi/g, and the uranium is above 60pCi/g in all size fractions with significant volumes. Therefore, particle-size separation techniques alone will not achieve results consistent with cleanup criteria. However, with the concentrations of +50-mesh fraction only slightly higher than the clean-up criteria, the results suggest a potential for volume reduction by attrition scrubbing of the +50 material in a solution that will extract the uranium. Attrition has the potential to reduce the radium and thorium

concentrations by removing contaminated surface material from the coarse fractions. If the uranium can be removed so that it is primarily concentrated in the -50 material, volume reduction of up to 50 percent may be possible.

The Linde Systematic whole soil sample contains concentrations of U-234 and U-238 of approximately 150pCi/g, Ra-226 of 81pCi/g, and Th-230 of 140pCi/g. The +100-mesh material, which represents 50 percent of the sample, has concentrations of U-234 and U-238, Ra-226, and Th-230 of 102 and 103, 26, and 37pCi/g, respectively. The uranium and Ra-226 are approximately evenly distributed within fractions having particle sizes greater than 200mesh. Results from the Linde Systematic samples suggest that attrition scrubbing might reduce the radioactivity in the +100-mesh material, and chemical extraction might reduce the uranium.

Seaway Samples

The Ra-226 and Th-234 concentrations in the Seaway Bias whole soil sample are 74 and 17pCi/g, respectively. The U-238 and U-234 are expected to be below 60pCi/g, based on the Th-234 values as determined by gamma spectrometry. Only the +4 mesh particle-size fraction has a Ra-226 concentration of 15pCi/g or less (8 percent of the material). No thorium alpha spectrometry was performed on the particle-size fractions. However, based on the fact that the whole soil sample contained 724 pCi/g of Th-230 like other samples in this study, no size fraction is expected to be at or below 15 pCi/g.

The Ra-226 and Th-234 concentrations in the Seaway Systematic whole soil sample are 33 and 13pCi/g, respectively. The U-238 and U-234 are expected to be below 60pCi/g, based on the Th-234 values determined by gamma spectrometry. The +50-mesh material has a Ra-226 concentration of 14pCi/g. However, the +50-mesh material represents less than 17 percent of the total soil.

In summary, analysis of data from the eight Tonawanda samples examined in this study demonstrates that particle-size separation alone will not provide a successful remediation solution for any of the sites. Particle-size separation alone is not capable of achieving significant volume reduction because a number of factors including: the relatively high concentrations of radionuclides; their uniform distribution, in most cases, throughout the range of particle sizes; and the high quantity of fines in most of the tested soils. Attrition studies on the +50 or +100-mesh material in combination with chemical extraction might, however, remediate up to 50 percent of the Linde soils.

Petrographic Study

The bulk composition of the soil samples from the Ashland sites is generally similar to the host constituents but differs from the host materials of the Linde and Seaway sites. The radioactive constituents are but minor constituents of the host material. However, because of the variance in the host constituents, the Ashland, Seaway, and Linde sample results are described separately in the following paragraphs.

Ashland Soil Samples

The Ashland Bias and Systematic soil samples contain mostly natural rock and mineral particles, significant amounts of slag materials, and minor amounts of other man-made materials and plant debris: 1) limestone, dolomiteite, and dolomite minerals constitute 40 to 60 percent of the gravel-sized (+4.76 mm) materials and three to 45 percent of sand-sized materials; this material is natural rock aggregate native to the area and essentially free of radioactivity above background levels; 2) calcareous

siltstone and minor claystone comprise from 20 to 33 percent of the gravel-size and approximately 50 percent of the sand-size material; these particles are essentially free of radioactivity above background levels; 3) quartz occurs in the sand-size fractions with greater abundance with decreasing grain size; in the finer sand fractions, the quartz generally averages about 20 percent; minor occurrences of feldspar are included in this category; this is natural material free of radioactivity above background levels; 4) man-made slag materials comprise from three to 40 percent of the gravel-sized particles with greatest abundance in the Ash II Bias and least abundance in the Ash I Systematic samples; the slag particles in sand-size material generally occur in lesser amounts; the solid crystalline slag has its highest concentration in the Bias samples; this material is anthropogenic material that has been identified in previous studies as containing radioactivity above background levels; 6) the black, glassy slag averages six percent of Ashland II Bias sample but generally less than two percent in the other Ashland samples; this material has also been related with radioactivity counts above background levels (6).

The heavy minerals separated by sink-float from the fine sand and coarse silt-size fractions comprise between two and nine percent of the fractions separated on the Ashland samples. To facilitate identification, the heavy minerals were further separated into a magnetic and nonmagnetic fraction. The magnetic fraction comprised 10 to 30 percent of the heavy-mineral fraction.

The magnetic fraction consists of black angular magnetite, red oxidized magnetite particles, and round metal balls. The distribution of metal balls in the three size fractions for the Ashland samples is listed in Table I:

Table I

The metal balls vary in color and luster suggesting variable properties and composition. Some resemble ion-exchange beads that collect uranium, and this specific material may possibly have radioactivity above background levels.

The nonmagnetic, heavy-mineral fraction comprises 70 to 90 percent of the heavy-mineral fraction. The opaque minerals comprise approximately one-third of the nonmagnetic heavy-mineral suite and, in order of decreasing abundance, include red hematite, ilmenite/leucoxene, metal balls, and black, angular uraninite. The latter is radioactive but is very minor in occurrence; it should be further examined by specific tests for opaque minerals for verification.

The transparent, nonmagnetic, heavy-mineral fraction is comprised of predominantly hornblende and garnet, minor epidote, zircon, hypersthene, and monazite, and trace amounts of rutile, chlorite, apatite, staurolite, sillimanite, and tourmaline. In addition, the Ash I Bias and Systematic samples contain appreciable melitite-rich slag particles.

The radioactive minerals present in the transparent fraction are zircon and monazite, which occur most abundantly in the Ash II Bias and Systematic samples. Zircon in the Bias samples ranges from trace amounts to five percent and in the systematic fractions from three to eight percent. Monazite in these samples ranges, respectively, from trace to two percent and from zero to one percent. In zircon, radioactive thorium or uranium is capable of as much as four percent substitution of the zirconium in the minerals structure. In monazite, the chief ore mineral

of thorium, thorium oxide, ranges between three and 10 percent, while uranium is generally present in lower percentage distribution (7).

The alpha spectrometry results of heavy-mineral, nonmagnetic material from the Ashland sample indicate that, in general, the activity is concentrated in the heavy-mineral magnetic fractions. However, the heavy-mineral magnetic fractions represent a small percentage of the whole soil; thus, the total radioactivity is minimal. By removing the heavy-mineral or heavy-mineral magnetic material, the specific activity in the whole soil either remains unchanged or increases slightly. This is true for both the U-238 and Th-230.

The organic materials in the Ashland soil samples occur in all size fractions in generally trace amounts. These materials, in order of abundance, include woody plant fragments, seed spores, snail shell, and diatoms. Other materials in the Ashland samples range from trace amounts to as much as four percent. They are comprised of cement, ceramic materials, glass beads, amorphous putty, and miscellaneous concrete aggregate particles.

Seaway Samples

In the Seaway Bias and Systematic soil samples, the most abundant materials are limestone and dolomite followed by sandstone and siltstone. The latter differ from the material found in the Ashland soil samples. Three slag varieties are generally similar to those observed in the Ashland samples. The quartz is also generally similar, but the heavy minerals are more abundant than the average Ashland sample: 1) limestone and dolomite average 19 and 17 percent of the Bias and Systematic sample, respectively; this is natural rock aggregate similar in physical properties to the Ashland samples; this rock is free of radioactivity above background levels; clastic sandstone and siltstone comprise respectively 21 and 12 percent of the Bias and Systematic samples, respectively; this material is generally free of radioactivity above background levels; 2) quartz grains average 32 and 40 percent of the Seaway Bias and Systematic soil samples, respectively; this fraction is free of radioactivity above background levels; 3) anthropogenic slag materials average 26 percent of the Seaway Bias and 20 percent of Seaway Systematic soil samples; the categories of slag are similar to the Ashland soil samples but occur in different proportions; it is essentially free of radioactivity above background and constitutes, respectively, 11 and five percent of the Seaway Bias and Systematic samples; the dense crystalline slag and glassy slag have radioactivity levels above background(6); the dense crystalline slag comprises 20 and 10 percent of the gravel-size particles of Seaway Bias and Systematic fractions, respectively, and lesser amounts in order of decreasing grain size.

The heavy minerals comprise eight, nine, and 11 percent of the -50/+100, -100/+200, and -200/+400 mesh-size fraction of the Seaway Bias, respectively, and nine, seven, and eight percent of the corresponding Seaway Systematic soil samples, respectively. The magnetic fraction of the heavy-mineral fraction ranges from 16 to 36 percent of the heavy minerals.

The magnetic fraction is comprised of black magnetite, reddish, oxidized magnetite particles and round metal balls. The distribution of metal balls in the three size fractions for the Seaway Bias and Systematic sample locations is similar to Ash II Systematic Samples described above.

The nonmagnetic fraction averages about three-fourths of the heavy-mineral fraction or about seven percent of the fine-sieve fractions. The mineral species are generally similar in abundance to the Ashland samples except for the radioactive minerals, which are several times more abundant. The relatively high zircon and monazite composition is, respectively, 18 and two percent of the Seaway Bias -100/+200-mesh fraction and 11 and two percent of the same size of Seaway Systematic sample. Of all the Tonawanda locations, the Seaway samples have the highest concentration of zircon and monazite, and this is reflected in the concentrations of Th-232 observed.

Alpha spectrometry results reveal that the activity is concentrated in the heavy-mineral magnetic fractions. However, as with the Ashland soils, the heavy-mineral magnetic fractions represent a small percentage of the whole soil; thus, the total concentration represented is minimal. By removing the heavy-mineral or heavy-mineral magnetic material,the specific activity for both the U-238 and Th-230 in the whole soil either remains unchanged or increases slightly.

The organic materials comprise from trace amounts to two percent of the Seaway samples; materials are plant fibers, and minor spores and snail shells. Brick, concrete, and cement constitute the bulk of other materials, which comprise from trace amounts to five percent of some sieve fractions.

Linde Samples

In the Linde Bias and Systematic soil samples, the predominant host material is a carbonate rock that is unique to these samples. These samples are also void of some of the siltstone/claystone or sandstone/siltstone found as abundant host material in the other Tonawanda samples: 1) white to light-gray carbonate rock comprises approximately 40 percent of the Linde soil samples; this rock resembles lime rock from Florida but not material native to the Tonawanda area, such as the limestone and dolomite sedimentary rock; it is probably carbonate rock produced or modified by an industrial process; 2) dark-gray to light-gray cherty limestone and dolomite particles comprise 21 percent of the Linde Bias and six percent of the Linde soil analyzed on the sieved material; in general, this is sedimentary rock native to the area and similar to that reported from the other Tonawanda soil samples; this material is essentially free of radioactivity above background; 3) dark-gray dense chert particles comprise from 10 to 14 percent of the gravel-sized material and not more than two percent of the finer-sieve fractions; the chert is derived from the limestone and dolomite rock and is free of radioactivity above background levels; 4) quartz on the average comprises 20 to 30 percent of the material retained on the sieve fractions of the Linde soil samples.; this fraction also contains very subordinate amounts of feldspar; it is free of radioactivity above background levels; 5) slag material consists of three to four percent cinder slag of similar composition as that from the other Tonawanda soil samples; this material is known to contain some radioactivity above background levels (6).

The heavy minerals (greater than 2.89 specific gravity) comprise 33, 23, and five percent, respectively, of the -50/+100, -100/+200, -200/+400-mesh size Linde Bias fractions and 31, 33, and five percent, respectively, of the Linde Systematic soil sample. The magnetic fraction of these samples ranges from 12 to 22 percent.

The magnetic, heavy-mineral fraction is comprised of similar materials as the other Tonawanda soil samples. The distribution of the metal balls in the three size fractions is similar to the Ash I Systematic sample except that the Linde samples contain a higher percentage of metal balls in the -100/+200 fraction than does the Ash I Systematic sample.

The nonmagnetic fraction comprises about 85 percent of the heavy-mineral fraction and contains appreciable dense, angular, slag particles. Some of the slag particles contain amorphous coatings. The other heavy minerals are generally in similar proportion as the Ashland soil samples.

Alpha spectrometry results indicate that, in general, the activity is concentrated in the heavy-mineral magnetic fraction, except for the Linde Systematic -50/+100 fraction. In this fraction the Th-230 activity, 17 pCi/g, is concentrated in the heavy-mineral nonmagnetic fraction. The specific activity reduction resulting from removal of the heavy minerals is from 60.5to 22.6 pCi/g in the total fraction. Like the Ashland and Seaway soils, the heavy-mineral and heavy-mineral magnetic fractions from the remaining Linde fractions represent a small percentage of the whole soil. Thus the total concentration represented is minimal.

Organic materials comprise trace amounts of woody plant material. The other materials, comprising up to five percent of gravel-sized fractions but generally less than two percent of finer fractions, consists of concrete, concrete aggregate (some with cement adhering to the particle surface) and red brick fragments. This material is free of radioactivity above background levels.

In summary, significant concentrations of the radionuclides were identified in the heavy-mineral fractions separated by sink-float methodology at 2.89 g/cc in samples from each of the eight locations. However, there were insufficient quantities to affect the overall radionuclide concentrations by their removal. Ferromagnetic materials separated from the heavy-mineral fractions also contained elevated concentrations of radionuclides; but they were, likewise, insufficient in quantity to affect the remediation potential by their removal.

The presence of slag materials identified by SEM (6) to contain uranium compounds warrants further study into the potential of froth floatation as a possible removal technology.

Chemical Extraction

The extraction results are summarized in Tables II and III. In these tables, the results are tabulated for the four critical radionuclides for the Tonawanda Site: Ra-226, U-234 and U-238, and Th-230.

Table II

Table III

Significant amounts of the soils were solubilized during the extractions. The solubilized amounts varied from 44% for the Linde Bias +50 mesh to 17% for the Linde Systematic sample. The reasons for this degree of solubilization require further study.

The "fractional activity recovered" column of Tables II and III provides a materials balance indicator by comparing the total radioactivity in the head sample (whole soil) to that contained in the end products (recovered soil, membrane filter, and filtrate). The values given are the ratio of the total radioactivity of the extraction products to the radioactivity of the head sample for the individual radionuclides. The values range from 0.6 to 1.6 and indicate that, within experimental error, no significant material was unaccounted for in the final measured products.

The Ra-226 removal percentages for the whole Systematic soils range from 79 percent (Ash I) to 86 percent (Seaway). The concentration in the extracted Seaway sample was reduced from 25 to 3.4 pCi/g. The uranium (U-234 and U-238) removal percentages for the systematic whole soils range from 32 percent (Seaway) to 73 percent (Linde). The low values for the U-234 removals on the Ash II and Seaway soils are considered to be an artifact of the inordinately high values in the recovered product, as compared to the U-238, reported for these samples. The combined uranium concentration for the Seaway sample is 25 pCi/g (U-234 + U-238). The Th-230 removal percentages for the systematic whole soils range from 65% (Ash I) to 84% (Seaway). The lowest Th-230 concentration for a recovered soil is 42.2 pCi/g for the Linde soil.

The hot nitric acid extractions on the Linde Bias +50-mesh material produced a product with Ra-226 and Th-230 less than 15 pCi/g (7.4 and 8.5, respectively) and combined U-234 and U-238 of 63 pCi/g. Additional extractions may have further reduced the radionuclide concentrations. Comparable results were achieved for the Linde Systematic +50-mesh material with the exception of Ra-226. The lack of radium removal in this sample is difficult to understand and may be the result of a laboratory error in counting the sample. Of note is the excellent removal percentages achieved for all radionuclides in the extraction on the Linde Bias -50-mesh fraction. It begs speculation on the results of a second extraction and on how the other seven soils would react to an extraction performed on only their -50-mesh fractions.

In summary, the hot 3M nitric acid extractions performed on the four Systematic soils did not remove sufficient quantities of the radionuclides from any sample to produce products that would meet the cleanup criteria for all radionuclides. However, there was no optimization of the extraction conditions, and sequential extractions were not performed. The removal percentages for all the radionuclides in all the samples, on the other hand are significant; for the Ash I and II soil samples, the Th-230 was not removed below a level that makes chemical extraction a promising process for meeting the cleanup criteria. The nitric acid extraction of the Linde and Seaway soils produced extracted products with radionuclide concentrations sufficiently proximate to site cleanup levels to warrant continuation of the scout chemical extraction studies as originally proposed.

The results of the 3M nitric acid extraction indicate that the Linde +50-mesh material, particularly the Bias soil, shows great promise for meeting cleanup criteria with additional chemical extraction. This process should be linked to the attrition study previously recommended to achieve the optimum removal.

Because of the exceptional results achieved on the chemical extraction of the -50-mesh material for the Linde Bias sample, a comparable experiment should be conducted on the Linde Systematic -50-mesh fractions.

ADVANCES IN SOIL DECONTAMINATION METHODS FOR ROCKY FLATS SOILS

Robert L. Kochen
James D. Navratil
Rust Federal Services, Inc.
1597 Cole Blvd., Suite 350
Golden, CO 80401-3414

ABSTRACT

Improved separation methods are needed to remove contaminants selectively and efficiently from soils at the Rocky Flats Environmental Technology Site (RFETS). The methods must meet appropriate state and federal regulations for residual contaminant concentrations, and to minimize waste generation, the radioactive contaminants need to be incorporated in as small a waste volume as possible. To meet these needs, advances have been made for decontaminating soils at the RFETS.

Based on recent decontamination studies with Rocky Flats (RF) soils, the americium and plutonium in the >0.5-millimeter soil fraction (>90 wt.%) can be lowered to <5 picocuries per gram of soil via wet sieving/size separation and rotary scrubbing/soil dispersion. The benefit of utilizing established wet screening technology is high volume soil decontamination. The contaminated fine fraction (clays) can be treated to further reduce the volume of contaminated soil.

INTRODUCTION

Soil decontamination studies have been conducted at Rocky Flats in the past (1-8). These studies evaluated wet and dry sieving, attrition scrubbing, rotary scrubbing, ultrasonic scrubbing, vibratory grinding, calcination, vitrification, flotation, acid leaching, hydraulic classification and mineral jigging. Various dispersants, surfactants, complexing agents and adsorbents were incorporated into these evaluations. The most promising technologies tested were wet sieving, attrition scrubbing, vibratory grinding, hydraulic classifying, acid leaching and the use of dispersants. Previous results showed that wet screening was effective in removing plutonium and americium from the larger soil particles, thereby concentrating the activity in the fine clay and silt fraction (6-8). Vibratory grinding was more effective at physically decontaminating RF soil than rotary scrubbing, and sodium hydroxide solution at pH 12.5 was found to be the best washing solution to lower actinide concentrations in RF soils (3). Recent work with wet sieving, scrubbing and a gravimetric separator (mineral jig) showed that sieving removed >98% of the activity in the <50 to 4.0-mm soil fraction, representing >50 wt.% of the soil, and attrition scrubbing was better

than wet sieving and rotary scrubbing in removing activity from the <4.0 to 0.42-mm fraction; the mineral jig was effective in removing actinide-containing clays from the <0.42-mm fraction (4).

As a part of the process to screen and select remedial options at the RFETS, a treatability study was recently performed to evaluate a series of soil decontamination techniques. The study assessed the technological capability of high-potential physical and chemical separation processes to decontaminate the soil media of its Pu and Am constituents. The results of this study are described below.

EXPERIMENTAL

Testing was conducted using soils collected from a location on the east side of the 903 Pad (9). Each wet sieve test was performed with a Tyler Model RX-24 sieve shaker and U.S. Standard sieves (20-cm diameter). A sieve lid (with spray head) and bottom pan (with drain tube) was used in conjunction with the sieves (see Fig. 1). In addition, a Masterflex peristaltic pump as well as a supply reservoir and receiving vessel (4-liter containers) was part of the wet sieving system. Several wet sieve tests were conducted in duplicate, each using 500 grams of soil with 2.5 liters of wash solution, to evaluate various types of wash solutions. The soil was wet sieved into five fractions (<50.0- to 12.5-mm, <12.5- to 4.0-mm, <4.0- to 0.5-mm, <0.5- to 0.063-mm, and <0.063-mm). Each of the soil fractions separated was dried at ambient temperature and weighed. Samples of the soil fractions were collected and sent to a certified laboratory for complete soil digestion and analysis of Pu-239, Pu-240 and Am-241 by specific alpha and gamma counting.

Fig. 1

The spent wash solutions from the wet sieve operations were filtered through coarse (Whatman No. 41 or 20-25 m) and fine (Whatman No. 42 or 2.5 m) paper. A portion of these wash solutions was syringe filtered through a 0.2 m membrane, and these samples were sent to the laboratory for specific Pu-239, Pu-240 and Am-241 analysis.

A subsequent wet sieve test was performed in duplicate using 500 grams of soil (from the recombined fractions of the sieving processes which identified the most effective wash solution) with an additional 2.5 liters of the fresh wash solution. The second sieving operation separated the soil into five particle size fractions (<50.0- to 12.5-mm, <12.5- to 4.0-mm, <4.0- to 0.5-mm, <0.5- to 0.063-mm, and <0.063-mm). Each of these fractions was dried and weighed. Samples of the soil fractions and wash solutions were collected and treated as described above prior to analysis. Two rotary scrub tests were performed. Two samples of 500 grams of soil were initially wet sieved into five fractions (<50.0- to 12.5-mm, <12.5- to 4.0-mm, <4.0- to 0.5-mm, <0.5- to 0.063-mm and <0.063-mm) using 2.5 liters of 0.1 M sodium hexametaphosphate (HMP) wash solution. Next, the separated soil fractions were recombined (except the <0.063 mm fraction) and placed into an 8-liter wide-mouth polyethylene bottle with 2.5-liters of fresh wash solution. The soil slurry in the bottle was then rotated on a rotary jar mill at 80 rpm: one batch for 8 hours and the other for 18 hours. Each of the rotary scrubbed soil slurries was then wet sieved into five fractions (<50.0- to 12.5-mm, <12.5- to 4.0-mm, <4.0- to 0.5-mm, <0.5- to 0.063-mm, and <0.063-mm) with 2.5 liters of fresh wash solution. The soil fractions and wash solutions generated were filtered and sampled as described above.

One attrition scrub test was performed with soil (<4.0- to 0.5-mm) which was previously wet sieved and rotary scrubbed. The soil was attrition

scrubbed with 0.1 M HMP wash solution at a soil to solution mass ratio of 1:5 for 10 minutes at 1,000 rpm using a laboratory attrition scrubber. This scrubbing device consisted of two three-bladed, stainless steel opposed-pitch propellers (7-cm diameter) mounted in tandem (4-cm apart) with one propeller at the end of a stainless steel drive shaft. The propeller assembly (lowered into a 1-liter stainless steel beaker containing the soil slurry) performed the scrubbing action. The attrition scrubbed soil was then wet sieved into three fractions (<4.0- to 0.5-mm, <0.5- to 0.063-mm, and <0.063-mm) with fresh wash solution. Each of these fractions was dried, weighed and sampled for analysis. The wash solutions generated during the experiment were filtered and sampled as described above.

A chemical leaching test was performed using the <4.0-mm soil fractions from the attrition scrub experiment and the <0.5-mm soil fractions from the rotary scrub experiments. The chemical extractant solution was 0.1 M sodium citrate with 0.1 M sodium dithionite. The soil and leaching solutions (a soil to solution mass ratio of 1:10) were placed into an 8-liter wide-mouth polyethylene bottle and rotated on a rotary jar mill at 290 rpm for 18 hours. The soil slurries were then wet sieved into three fractions (<4.0- to 0.5-mm, <0.5- to 0.063-mm, and <0.063mm) with 5 liters of water. The resultant soil and water were treated as described above.

RESULTS AND DISCUSSION

Different wash solutions tried made little difference in the weight percent of soil reporting to each of the size fractions (9). As expected, there was no significant soil dissolution or dispersion between the wash solutions. However, greater dispersion of the smaller particles from the larger particles could have been attributed to the characteristics of some of the reagents. Essentially 33-34 wt.% of the soil reported to the <50 to 12.5-mm fraction; 9-11% to the <12.5 to 4.0-mm fraction; 24-25% to the <4.0 to 0.5-mm fraction; 23-27% to the <0.5 to 0.063-mm fraction; and 5-8% to the 0.063-mm fraction. These data (all are averages of duplicate runs) are in good agreement with previous studies of RF soils (6).

Generally the actinide concentrations remaining in all the fractions above 4.0-mm were within the same range (1-3 pCi/g Am and 2-11 pCi/g Pu) except water washed soil (9); thus hot water works about as well as wash solutions containing phosphate and/or hydroxide ions. However, for the next smaller size soil fraction (<4 to 0.5-mm), a 0.1 M solution of HMP at pH 11 and hot water gave the lowest actinide results. The actinide concentration only varied between 1 and 4 pCi/g. The <0.5 to 0.06-mm fraction contained high concentrations of Am and Pu with the lowest amount after HMP washing. The HMP solution also decontaminated the <0.063-mm fraction and transferred some of the contamination to the liquid phase. All of these results as well as the data below are an average of duplicate runs.

An additional wet sieving operation with fresh HMP wash solution was performed during the second soil decontamination test to gauge if improvement in the effectiveness of the separation resulted from the supplemental washing and mechanical sieving action contact time. Data from this double wet sieving treatment process were used for comparison with the rotary and attrition scrubbing soil treatment processes, as they involved a secondary wet sieving procedure. Additionally, the second wet sieving operation separated the recombined fractions from the initial wet sieving operation into fractions of even finer particle size

discrimination. Measurements of the physically separated soil fractions were repeated to determine the mass of soil distributing into each of these fractions as well as the partitioning of the Pu and Am contaminants into each mass fraction. The results are shown in Figs. 2 and 3, and are described in detail elsewhere (9). The double wet sieving showed slightly improved decontamination compared to a single wet sieving operation.

Fig. 2

Fig 3

After an initial wet sieving wash with HMP, the >0.063-mm soil fractions were recombined and rotary-scrubbed for 8 and 18 hours with fresh HMP wash solution. The purpose of recombining the soil fractions was to provide enhanced scrubbing action of the fine soil particles by the coarse soil particles. The 18 hour time interval was selected to encourage maximum dispersion of the clay particles in the soil. Each soil slurry was wet sieved after rotary scrubbing using fresh HMP wash solution. Soil fractions were then analyzed for Pu and Am content, and the results are shown in Figs. 2 and 3. The rotary scrub promoted further decontamination of the larger fractions compared to wet screening, and the eight hour period provided approximately the same result as 18 hours, showing that 8 hours or less is a sufficient rotational time.

Recombined soil fractions between 0.5-mm and 4.0-mm, previously wet sieved and rotary scrubbed,were attrition scrubbed with fresh HMP wash solution for 10 minutes at 1,000 rpm. This soil slurry was then wet sieved using fresh wash solution, and the soil fractions and solutions analyzed for Pu and Am content. The results are shown in Figs. 2 and 3; although additional activity was removed from the <0.5 to 0.063-mm fraction with attrition scrubbing, the small decrease in decontamination would probably not warrant the use of attrition scrubbing in a large-scale process.

A solution of sodium dithionite with sodium citrate was tested with rotary scrubbing because of its ability to desorb Pu and Am from the fine soil fractions by leaching the transuranics into the aqueous phase. This solution was chosen because of favorable results from another experimental investigation (10). The <4.0-mm soil fractions from the attrition scrubbing experiments and the <0.5-mm soil fractions from the rotary scrubbing experiments were utilized in this evaluation, which provided the best conditions for decontamination of soils >0.063-mm. The dithionite-citrate mixture leached more actinide from the clay-silt fraction than HMP (see Figs. 2 and 3).

CONCLUSIONS

Different types of wash solutions made little difference in the quantity of soil reporting to each of the size fractions: 34, 10, 24, 25, and 6 wt.% reported to the <50 - 12.5, <12.5 - 4.0, <4.0 - 0.5, <0.5 - 0.063 and <0.063-mm fractions, respectively. Actinide concentrations remaining in all the fractions above 4.0-mm (except room temperature water washing) were within the same range (1-3 pCi/g Am and 2-11 pCi/g Pu). Thus, heated (near boiling) water works about as well to decontaminate the >4.0-mm soil size fractions as wash solutions containing phosphate and/or hydroxide ions. However, for the smaller size fractions, a 0.1 M solution of sodium hexametaphosphate at pH 6.5 gave the lowest actinide results as well as yielding the highest results for the wash solution, showing that actinide was transferred from the soil to the solution phase.

The most favorable decontamination conditions found in this study were a preliminary wet sieving with a sodium citrate/sodium dithionite solution

followed by a five hour rotary scrub and a second wet screening using citrate/dithionite wash solution; these conditions decontaminated about 87 wt.% of the soil to <2.4 pCi/g Pu activity and outperformed a double HMP wet sieving and a single wet sieving followed by either attrition or rotary scrubbing and a second wet sieving using HMP. To simplify wash solution recycle operations and reduce waste generation, hot water rotary scrubbing followed by wet screening with hot water may be sufficient to decontaminate the >0.5-mm soil particles; further decontamination of a smaller soil fraction may require chemical processing with HMP or citrate/dithionite.

ABSTRACT
The transfer, modification, and application of well formulated and tested quality assurance (QA) procedures from one project to another deserves consideration. The use of a proven QA program design could result in cost savings and the collection of data with a greater degree of confidence. To test this thesis, a QA program, originally developed for large nationwide Environmental Protection Agency (EPA) programs, was adapted and implemented in a site characterization study at the Department of Energy (DOE) Nevada Test Site to ensure that laboratory data satisfied pre-determined measurement quality objectives (MQOs). The QA procedures were adapted from EPA programs such as the National Acid Precipitation Assessment Program and the Environmental Monitoring and Assessment Program, and to a lesser degree, from programs operating under the requirements of the Comprehensive Environmental Recovery, Compensation and Liability Act (CERCLA) and the Resource Conservation and Recovery Act (RCRA). The QA design adopted the batch or lot concept, in which samples are organized into groups of samples for laboratory analysis. Approximately 10 percent of the total samples were measurement quality samples (non-blinds, blinds, and double-blinds), which were included in each batch to evaluate and control measurement uncertainty. Detectability was assessed using instrument detection limits and precision data for low-concentration samples. Precision was assessed using data from reference samples under a two-tiered system based on concentration ranges. Accuracy was investigated in terms of bias with respect to reference values. The results showed that QA concepts developed for previous nationwide EPA programs were successfully adapted for the site-specific DOE project.
INTRODUCTION
Protocols from well formulated and tested quality assurance (QA) and quality control (QC) programs are potentially applicable to what may appear, initially, as programmatically unrelated projects. This is not an endorsement of the unwavering application of one QA/QC program to different projects without an evaluation regarding applicability. However, the evaluation and transfer of a functional and efficient QA/QC program for its application to other projects certainly has merit. The use of a proven QA program results in obvious benefits, such as the reduction in time needed to develop a new design, and less obvious benefits, such as those resulting from the collection of data with a greater degree of confidence.
During the 1980s, the U.S. Environmental Protection Agency (EPA) brought together scientists and managers with expertise to integrate QA and QC into nationwide programs such as the National Acid Precipitation Assessment Program (NAPAP) and the Environmental Monitoring and Assessment Program (EMAP) for assessing the status and health of our nation's ecological resources (1,2). One consequence of their efforts was the development of protocols for environmental sampling and analysis of soil (3).
The subject of this paper is the transfer of the protocols developed for these nationwide EPA programs as well as programs operating under the

requirements of the Comprehensive Environmental Recovery, Compensation, and Liability Act (CERCLA) and amendments under the Superfund Amendments and Reauthorization Act (SARA), and the Resource Conservation and Recovery Act (RCRA), to a U.S. Department of Energy (DOE) site-specific project. Specifically, this paper focuses on a laboratory QA program implemented for a soil characterization study conducted at the DOE Area 5 Radioactive Waste Management Site (4) on the Nevada Test Site (NTS).

LABORATORY QUALITY ASSURANCE PROGRAM

The laboratory QA program for this soil characterization study was designed to increase the likelihood that the data satisfied or exceeded the data quality objectives (DQOs). DQOs, which are statements of the levels of uncertainty that data users are willing to accept in the data, are quantitative and qualitative goals established by the data users prior to the initiation of an investigation (5).

The sample measurement system employed by this soil characterization study consisted of sample collection, preparation, and analysis phases. Measurement uncertainty is a small part of the allowable overall data uncertainty (including uncertainty from possible spatial or data aggregation sources) defined by the data users because the quality of data can be quantified in relation to the DQOs, thereby allowing the data user to evaluate the hypotheses with a known level of confidence. Uncertainty that exceeds the DQOs renders the data less reliable in the judgement of the data users. The DQOs encompass all components of uncertainty resulting from sample measurement, operational activities, and population-based uncertainties (e.g., spatial variability). Measurement quality objectives (MQOs) are specific goals that clearly describe in a quantitative manner the data quality that is sought for each measurement phase being monitored.

The QA program for this soil characterization study included the following components: batch sample design, measurement quality samples, and data quality attributes. These aspects of the QA program are described below.

Batch Sample Design

The design of the QA program incorporated the concept of batch sample analysis, which is an adaptation of lot analysis familiar to manufacturing QA/QC programs. For this DOE soil characterization study, soil samples were combined by the QA staff into batches containing approximately 40 samples each. The batch sample design was based on the following assumptions and considerations:

- The primary sources of measurement uncertainty to be identified, controlled, and assessed are produced during the sample preparation and analysis phases;
- Each of the primary sources of measurement uncertainty can be considered a combination of several smaller component sources of uncertainty (e.g., sample analysis can include within-laboratory, within-batch, and among-batch uncertainties);
- Measurement uncertainty at any given phase (e.g., analytical within-batch precision) can be confidently evaluated using data from a minimum of 20 measurement quality samples of a given type (6). Because a large number of soil batches were expected to be analyzed, a sufficient number of samples would be present to make reliable among-batch statistical estimates;
- The quantitative within-batch MQOs can be attained if each batch satisfies predetermined acceptance criteria; and

Approximately 10 percent of the overall soil analysis effort is applied to the analysis of soil measurement quality samples for independent assessment purposes. Based on previous studies of this nature (7,8,9), this level of QA sample analysis is a reasonable proportion to achieve QA optimization. Also, batches of approximately 40 samples are sufficient for an effective soil QA program based on organizational, operational, and cost considerations.

Measurement Quality Samples

The specific QA acceptance criteria provided a balance between time and cost constraints and the data quality necessary to achieve the study objectives. To assess the quantitatively defined MQOs, a series of measurement quality samples was analyzed with the routine samples in a manner that was statistically relevant and that allowed conclusions to be drawn concerning measurement quality.

Measurement quality samples used in this study, although originally developed for the EPA's NAPAP and EMAP programs, were similar, or in some cases, equivalent to the samples used in EPA's CERCLA Contract Laboratory Program and in RCRA projects (Table I). This similarity occurs even though the QA/QC program for this study was primarily modeled after earlier EPA programs developed for tracking non-point acidic deposition and detecting long-term environmental change rather than CERCLA and RCRA projects that emphasized point-source contaminants. Sample terminology was changed slightly in order to adequately identify the different types of samples being used and the phases in which these samples entered the sample measurement stream. For instance, the analytical laboratory calibration check (ALCC) sample was introduced during the Analytical Laboratory phase of the measurement system and was used as a Calibration Check sample. The use of this terminology allows the data user to uniquely identify the status and utility of a sample in the measurement quality assessment scheme; it also accommodates the insertion of other types of samples into an ongoing QA/QC program (e.g., as necessary to assess field sampling error or overall measurement uncertainty, or to calculate a measurement system detection limit).

Table I

Measurement quality samples were of three types: non-blind, blind, and double-blind. By definition, a non-blind sample has both a concentration and a location within the batch that are known to the analyst. A blind sample has a concentration that is unknown to the analyst. A double-blind sample cannot be distinguished from a routine sample and has a concentration that is unknown to the analyst (10). For this soil characterization study, each measurement quality sample had a specific purpose in data evaluation and was used in a distinct manner to assess variability or adherence to the sample preparation and analysis protocols (Table II).

Table II

Two distinct groups of measurement quality samples, contractual compliance samples and laboratory QC samples, were randomly inserted into each batch to evaluate and contractually control the various laboratory components of measurement uncertainty. The contractual compliance samples, which were double-blind soil samples, allowed an independent assessment of measurement quality by the QA staff. The laboratory QC samples, which were non-blind and blind (both soil and liquid matrices), enabled the laboratory to control its measurement error (random and

systematic) in anticipation of satisfying contractual quality requirements. The QA staff also had access to all laboratory QC data.

Contractual Compliance Samples. Two varieties of contractual compliance samples were used in this study:

Analytical Laboratory Measurement Reference (ALMR) Sample - The ALMR sample is a median-concentration soil reference sample that was randomly assigned by the QA staff in duplicate or triplicate within each batch sent to an analytical laboratory. The ALMR sample material was collected in bulk at the NTS during routine sampling, and its matrix was representative of the routine samples analyzed in this study. The bulk sample was air-dried, disaggregated, sieved, homogenized, and subsampled by the QA staff. Aliquots of the subsamples underwent replicate analysis at a referee laboratory, and the resulting data were used to establish confidence intervals and tentative acceptance criteria for precision and accuracy. Known quantities of rock fragments were added to batched sets of ALMR samples to help ensure their suitability for independent double-blind evaluation of data quality by the QA staff. The ALMR sample data was used by the QA staff to estimate analytical within- and among-batch imprecision, bias and its sources (e.g., contamination or method error), and laboratory trends (e.g., interlaboratory and intralaboratory differences among batches). With the exception of the added rock fragments and its usage for precision assessments, the ALMR sample is roughly equivalent to the regional blind performance evaluation (PE) sample used commonly in CERCLA and RCRA.

Preparation Laboratory Homogenization Duplicate (PLHD) Sample - The PLHD sample was homogenized and split-subsampled at the sample preparation laboratory. One replicate remained at the laboratory as the first sample in the batch, and the other replicate was returned directly to the QA staff who reconstituted the sample with a known quantity of rock fragments and placed it randomly as a double-blind measurement quality sample in the next batch assembled. Confounded PLHD sample error (i.e., due to statistical confounding encompassing the sample preparation and analysis phases) can be distinguished by comparing variability of the different PLHD-and-routine sample pairs with the variability observed in the corresponding ALMR sample pairs. The PLHD was primarily used to estimate the sample preparation (homogenization and subsampling) error component of measurement uncertainty. In addition, the PLHD-and-routine sample pairs spanned multiple batches, which allowed the QA staff to use PLHD data to make assessments of among-batch precision at the analytical laboratory. With the exception of its double-blind character in this study, the PLHD sample is comparable to the internal laboratory duplicate (split) sample used occasionally in CERCLA and RCRA.

Laboratory QC Samples. Six types of laboratory QC samples were used in this soil characterization study:

Analytical Laboratory Control Reference (ALCR) Sample -- The ALCR sample is a soil reference sample of known concentration that the QA staff provides directly to the analytical laboratories along with corresponding reference values. The ALCR is used as an internal QC sample to control laboratory bias and to minimize the among-batch component of measurement uncertainty. The ALCR sample is roughly equivalent to a sample of certified reference material used commonly in CERCLA and RCRA.

Analytical Laboratory Control Duplicate (ALCD) Sample-- A duplicate subsample of the 12th soil sample in each batch was selected as the ALCD sample at the analytical laboratory. It is used as an internal check by

the QA and laboratory staff to ensure that predefined within-batch precision MQOs are being satisfied. The ALCD sample is equivalent to an internal laboratory duplicate (split) sample used occasionally in CERCLA and RCRA.

Analytical Laboratory Calibration Check (ALCC) Sample-- The ALCC sample is a liquid (or occasionally a solid) sample containing the analyte of interest at a concentration in the mid-calibration range. It is used to verify the calibration curve or mid-range of an instrument reading. The ALCC sample is equivalent to a calibration verification sample used commonly in CERCLA or a quality control check sample (QCCS) used in RCRA.

Analytical Laboratory Detection Check (ALDC) Sample-- The ALDC sample is a low-concentration liquid (or occasionally a solid) sample that contains the analyte of interest at a concentration specified by the QA staff. Typically, the concentration is two to three times above the established instrument detection limit. The primary uses of the ALDC sample are for the estimation of laboratory detection limits and as a check for significant baseline drift. The ALDC sample is roughly equivalent to a low-level calibration verification sample used occasionally in CERCLA or a low-level QCCS used in RCRA.

Analytical Laboratory Calibration Blank (ALCB) Sample-- The ALCB is a test for baseline drift. The ALCB sample is defined as a zero mg/L standard and contains only the matrix of the calibration standards (i.e., equivalent to the first standard in the set of standards). The ALCB sample is equivalent to a calibration blank sample used commonly in CERCLA and RCRA.

Analytical Laboratory Reagent Blank (ALRB) Sample-- The ALRB sample is a liquid (or occasionally a solid) sample composed of all the reagents in the same quantities used in actual sample analysis and which undergoes the same digestion and extraction procedures as an actual test sample. The ALRB reflects any analyte contamination from the sample matrix and apparatus used in the analytical procedure. The ALRB sample is roughly equivalent to a reagent blank or method blank sample used commonly in CERCLA and RCRA.

Data Quality Attributes

The attributes of data quality are qualitative and quantitative characteristics which provide an overall assessment of quality for the various measurement phases of the data collection activity. For the purposes of this report, measurement quality was defined in terms of the following four quality attributes:

Detectability is the determination of the low-range critical value of a soil characteristic that a method-specific procedure can reliably discern;

Precision is the level of agreement among multiple measurements of the same soil characteristic;

Accuracy is the level of agreement between an observed value and the true or accepted value of a soil characteristic; and

Completeness is the quantity of soil samples and soil sample data that are successfully collected with respect to the amount intended in the experimental design.

Detectability. The primary consideration in the evaluation of detectability is whether a measured sample value can be considered to vary significantly from the measured value of a sample blank. Detectability guidelines commonly are based on the number of standard deviations (SDs) the analytical signal varies from the mean value of

blank responses. In lieu of soil blank samples (which cannot be synthesized), laboratory stock solutions and low-concentration replicate soil samples were used to estimate the variability expected of blank samples.

The required instrument detection limit (RIDL) for each analytical parameter was defined prior to beginning sample analysis. The RIDL was based on the average variability expected among a series of five low-concentration ALDC samples analyzed in each batch of samples, and was calculated as three times the mean SD of numerous initial runs of ALDC samples. The actual instrument detection limit (AIDL) was calculated using real-time ALDC sample data and was used to assess contractual RIDL compliance by the analytical laboratories. Each AIDL served as an estimate of the lowest concentration of an analyte that a laboratory could reliably detect. Each parameter for each batch was required to have AIDL values less than or equal to its respective RIDL. If an AIDL exceeded its respective RIDL, the batch was reanalyzed for the parameter of interest. Incidentally, the RIDL is comparable to the contract-required detection limit (CRDL) used in CERCLA.

Precision and the Two-Tiered Analysis. Precision is the level of agreement among multiple measurements of the same soil characteristic or parameter. Laboratory imprecision was assessed for both within-batch and among-batch variability using data from the ALMR samples. The MQOs were established for within-batch imprecision estimates using data for the ALMRs from an external laboratory. The within-batch variability is usually only slightly lower than the among-batch variability. For comparison purposes, the MQOs were considered to be appropriate for both within-batch and among-batch variability. Imprecision of sample homogenization and subsampling efficiency at the sample preparation phase was assessed using data from the PLHD samples.

A primary feature of precision objectives for solid media like soil is the two-tiered system of characterizing MQOs (9). Some parameters, especially those in the middle to upper portion of the known concentration range, are best evaluated when the acceptable imprecision limits are variable with concentration and are expressed as a relative standard deviation (RSD) in percent. Other parameters, particularly those in the lower portion of the known concentration range, are best evaluated when the acceptable imprecision limits are absolute and are expressed as a SD in reporting units. This approach avoids setting restrictive precision objectives for low concentration soil samples, which generally are more difficult to extract and analyze with a high degree of relative precision.

The concentration scale of the samples is divided into two ranges or tiers separated by a calculated value called the knot (9). A knot value is used to distinguish low-concentration samples from median- and high-concentration samples. Most parameters have a distinct knot value which is determined by dividing the imprecision objective for the lower tier by the imprecision objective of the upper tier and multiplying by 100. The lower tier concentration range below the knot defines the region of the data in which the acceptable imprecision limit is an absolute value and is expressed as a fixed (constant) SD in reporting units. The upper tier of the concentration range above the knot defines the region of the data in which the acceptable precision limits vary directly with concentration and are expressed as %RSD. Imprecision below the knot can rise to quite high levels (if expressed as %RSD) and still satisfy the MQO as SD.

Accuracy. Accuracy is the degree of agreement between an observed value and the true or accepted value of a characteristic. Using data from the ALMR samples, the QA staff investigated accuracy from the perspectives of bias and laboratory trends. Analytical bias was considered to be the quantitative measure of inaccuracy, and laboratory trends served as quantitative and qualitative evaluations of laboratory performance over time. A range of acceptable ALMR values for each parameter was defined by a 95 percent confidence interval accuracy window. The window was calculated as two times the SD of extensive ALMR replicate aliquot analysis conducted by the referee laboratory prior to initiating the routine analysis. From a contractual compliance standpoint, any ALMR observation that occurred within an accuracy window (i.e., between the lower limit (LL) and upper limit (UL)), was considered to be acceptable (Fig. 1).

Fig. 1

The ALMR sample data were also examined for trends that could result from instrumental drift or other problems that might have occurred at the laboratory over the course of the analysis. For this purpose, standard control charts of the ALMR data were plotted in a temporal sequence of batch analysis (Fig. 1).

The external evaluation of accuracy by the QA staff was, by necessity, kept confidential to protect the integrity of the accuracy windows for the soil reference samples. For internal control of accuracy by the laboratory, an ALCR sample with established accuracy windows was provided. The laboratory staff plotted data on control charts to evaluate performance with respect to established confidence intervals. These charts were used to identify systematic or random bias during batch analysis.

Completeness. The laboratory was required to complete the specified processing tasks (criterion = 100 percent completeness) on all soil samples received batch-by-batch as identified on chain-of-custody tracking forms. Analytical completeness (criterion = 95 percent) was evaluated using routine sample data from the verified and validated data bases.

CONCLUSIONS

Quality assurance procedures were efficiently optimized and applied. The results of the study showed that the predefined MQOs were satisfied for detectability, precision, accuracy, and completeness. The quality of the data was thereby assured at the specified levels of acceptability established by the users. In conclusion, the quality assurance concepts first used by nationwide EPA programs were successfully adapted to the site-specific DOE project.

ABSTRACT
The primary objective of this project is to develop and demonstrate a close-coupled barrier for the containment of subsurface waste or contaminant migration. A close-coupled barrier is produced by first installing a conventional cement grout curtain followed by a thin lining of a polymer grout. The resultant barrier is a cement-polymer composite that has economic benefits derived from the cement and performance

benefits from the durable and resistant polymer layer. The concept of close-coupled barrier technology is the combination the two technologies that were developed at Brookhaven National Laboratory (BNL) and Sandia National Laboratories (SNL).

A full-scale demonstration barrier was installed at a cold site at the Hanford Geotechnical Test Facility, 400 Area, Hanford, Washington. The composite barrier was emplaced around and beneath a 15,000 liter tank. The tank was chosen to simulate a typical waste form that exist within the DOE Complex. The stresses induced on the waste form were evaluated during barrier construction. The barrier was constructed using conventional jet grouting techniques. Drilling was completed at a 45 angle to the ground, forming an ice cream cone shaped barrier. One row of cement columns was grouted in a circular pattern followed by a second row of columns between and tangential to the first row, in a honeycomb fashion. The primary barrier was placed by panel jet-grouting with a dual wall drill stem using a two part polymer grout. The polymer chosen is a high molecular weight acrylic manufactured by 3M Company. This paper will discuss the installation of the close-coupled barrier and the subsequent integrity verification.

INTRODUCTION

Numerous historical waste disposal sites located throughout the US Department of Energy (DOE) Complex have resulted in contamination of the subsurface. The waste sites include; underground storage tanks, piping systems, vaults, landfills, and other structures containing hazardous and mixed wastes. Consequently, efforts are being made to devise technologies that provide containment of waste sites either as a safety net to "catch" future contaminant leakage/migration or as an interim step while final remediation alternatives are developed. Subsurface barriers can increase the performance of the waste site and reduce or prevent the possibility of contaminant migration into local geologic media or groundwater. In addition to preventing contamination (and resultant clean-up costs) such in-situ treatment could result in large cost savings and reduced worker exposure, compared to conventional restoration costs (e.g., excavation, re-treatment and re-disposal of the waste). In addition, the legal ramifications for not treating many of these waste sites could be detrimental to the responsible parties.

The primary objective of this project is to develop and demonstrate a close-coupled barrier technology capable of containing waste forms within their existing subsurface transport, disposal, or storage structures. The containment will be a multibarrier of a cementitous grout followed by a polymer grout. The two grouts will be placed in a close-coupled fashion such that the polymer barrier is bonded to the cementitous barrier. The close-coupled barrier is produced by first installing a conventional cement grout barrier followed by a thin lining of a polymer grout. The resultant barrier is a cement polymer composite that has economic benefits derived from the cement and performance benefits from the durable and resistant polymer layer. The polymer barrier is thin (0.15 to 0.3 meters) and serves as the primary barrier to contaminant mobility. The cementitous barrier is thick (1.0 to 2.0 meters) and serves as a secondary barrier to contaminant mobility. It is essential that materials (grouts) and emplacement techniques are compatible; therefore, they must be developed and demonstrated simultaneously. This is not a trivial issue. Barrier materials must simultaneously be emplaceable, i.e., compatible with emplacement equipment and site geology, withstand a wide

variety of chemical, thermal, physical and radiological conditions, and meet acceptable longevity requirements. The concept of close-coupled barrier technology is the combination the two technologies being developed at Brookhaven National Laboratory (BNL) and Sandia National Laboratories (SNL).

BNL has been developing improved polymer-grout barrier materials for applications where impermeability and long-term durability are required (1,2). These materials have been used extensively in many commercial applications such as sewage and brine handling systems and electrolytic baths. Polymer grouts are candidates for high quality barrier materials due to their impermeability to gases and liquids, combined with their resistance to radiation, acidic, and alkaline environments (3). However, improved chemical and/or physical durability and performance increases the cost of the barrier grout.

SNL has been investigating placement methods and cementitious grouts for subsurface barriers. During the summer of FY94 SNL placed several pilot scale jet-grouted cement columns at a clean site near the Chemical Waste Landfill at Sandia. At the same time BNL was invited to demonstrate a polymer grout using the same placement equipment.

For a barrier where zero tolerance in leak rate is required it would be nearly impossible to achieve this goal using a cementitious grout. Large castings of hydraulic cements result invariably in cracking due to shrinkage, thermal stresses induced by the hydration reactions, and wet-dry cycling prevalent at arid sites. The improved, low permeability, high integrity polymer materials under investigation by BNL could achieve the permeability and durability goals, but might be costly. A joint venture was proposed by Brian Dwyer of SNL, John Heiser of BNL, and Steve Phillips (grouting contractor) of Westinghouse Hanford Company (WHC). SNL could design an economical cement grout curtain that would be used as a backdrop for the polymer curtain. A cementitious "bath tub" would be formed and the inside lined or flooded with a polymer binder. The resultant containment is a multibarrier of a cementitious grout followed by a polymer grout. The final composite barrier would have cost benefits from using mostly portland cement grout and have the performance benefits of the polymers from the inner lining.

Close-coupled barrier technology is applicable for final, interim, or emergency containment of subsurface waste forms. Consequently, when considering the diversity of technology application, the construction emplacement and material technology maturity, general site operational requirements, and regulatory compliance incentives, the close-coupled barrier system provides an alternative for any hazardous or mixed waste remediation plan.

This demonstration is currently funded by the Landfill Stabilization Focus Area (LFA) with roots in what is now the Plumes Focus Area (PFA). For the LFA close-coupled barriers have many applications. They can be used to contain buried waste and will provide a lower permeability, more durable and chemically resistant barrier than cement grout alone. The polymers are not expected to crack as easily as cement (wet-dry cycling) or slurry walls (solvent or organics). Close-coupled barriers are also useful in hot spot retrieval for containing contaminants while excavation and removal take place and may serve as shoring reducing the amount of contaminated soil. Utilization by PFA related projects include sealing off a source term (e.g., sealing a leaking UST or containing a subsurface spill of solvent) and preventing continued growth of a plume; thereby,

fixing the volume of waste. A data subset of the technology developed from the close-coupled barrier demonstration will include grouting with polymers. Using polymers by themselves will also prove useful to the DOE complex. Plumes or source terms can be surrounded by an inexpensive (e.g., AC-400 acrylate grout) to improve remediation efficiency for such technologies as in-situ air stripping of VOCs.

BACKGROUND

During FY94 small scale configurations (v-trough, cone, and 7x7 matrix) using cementitious grouts were installed via jet grouting. A single column was installed using a polymer grout. The FY95 demonstration installed a conical configuration barrier that is large enough to simulate numerous real sites. The cement and polymer were installed to form a close-coupled or composite barrier. The barrier was constructed to surround a simulated waste, a small (15,000 l) tank (see Fig. 1). The tank was chosen as a typical waste form that exist within the DOE Complex and also allows access to the subsurface inside the barrier for testing and monitoring.

Fig. 1

Test site

The site selected for the field-scale demonstration is the Geotechnical Test Facility (GTF) in the 400 Area ("Little Egypt") at the Hanford Site near Richland, Washington. This site was selected for several reasons: in geotechnical terms it is typical of many DOE facilities, the GTF was fully characterized and permitted for such a demonstration, the grouting contractor and required instrumentation and equipment (e.g., accelerometers, steel tank, etc.) are located nearby (eliminating mobilization/de-mobilization costs). The GTF was completed in FY82. It was originally designed to test and demonstrate burial ground subsidence control methods. The site is NEPA approved and well characterized and is described in a report Construction and Preliminary Description of a Geotechnical Test Facility at the Hanford Site, Richland, Washington by Phillips and Fischer (Rockwell Hanford Operations SD-RE-TI-048). Potential end users were identified and include BNL (chemical and glass pit remediation), INEL (hot spot retrieval) and Hanford (close-coupled barriers for UST leak repair). The GTF (Hanford) soil is a coarse sand to gravel; BNL is a coarse sand, free of clay lenses or cobble; and INEL is an alluvial/eolian deposit consisting of fine clay sized silts to coarse gravels of carbonaceous origin overlying basalt.

Jet grouting has been accomplished in all of these soil types. Soil type affects the effective diameter (jetting distance) of the column, for example in a clay soil the jetting distance will be slightly reduced due to the energy absorbing characteristics of clay. This effect will be minimal and in the worst case will require slightly reduced spacing of the installation bore holes (columns) or increased jetting pressures. The biggest impediment soil type could impose to jetting would be large cobble that could block the jetting pathway, which could result in a gap in the barrier. It is anticipated that with a close-coupled approach the cobble will become part of one or both of the barrier layers (since the jetting would occur parallel and perpendicular to the cobble; column jetting followed by panel jetting). Therefore the success of the demonstration was virtually independent of the test site soil type.

Prior to the demonstration the site has been prepared by the subcontractor. This includes the burial and backfill of a 15,000 liter tank and the installation of monitoring equipment. Eight monitoring wells

(every 45) were installed inside and outside the area to be enclosed by the barrier. These wells will be used for verification of the barrier integrity using perfluorocarbon tracers and for moisture determinations during water infiltration testing.

BARRIER INSTALLATION

This project demonstrates a systems approach to construction of a subsurface barrier. This includes the integration of barrier materials, emplacement equipment, verification techniques, and post monitoring instrumentation to produce a close-coupled engineered barrier.

The barrier was constructed using conventional jet grouting techniques. Jet grout curtains are constructed by injecting the grout through a pipe into the subsurface. The pipe has a drill tip on it which is used to drill the initial borehole. The pipe is then rotated while injecting the grout and slowly withdrawn from the ground. The high velocity jet masticates and intimately mixes the soil and grout which results in a column ~1 meter in diameter that resembles a pancake stack. The technique requires a pumpable grout that can be injected at pressures up 5-6,000 psi through a small orifice, typically 1 mm. This limits any aggregate additions to fine particle sizes. Most often, the jet grouting uses a low viscosity grout (<50 cps), and incorporates only the existing soils for aggregate. Jet grout curtains can be vertical using conventional drilling, or may be angled, or horizontal, using directional drilling.

The secondary cement layer was installed using column jet grouting as described above. The primary polymer layer was installed using panel jet grouting to reduce grout costs. Panel jet grouting is a simple refinement to conventional jet grouting. The tool is turned back and forth only a few degrees forming a bow tie shaped panel, rather than rotating the jetting tool 360 and forming a cylindrical column. This forms a thin panel, typically 30-40 centimeters wide. Panels are laid side by side with a slight overlap in order to form a continuous barrier. This method requires only a fraction of the grout volume compared to the volume of grout required for a full column.

For the demonstration the drill rig was a Casa Grande C6 unit owned by the Westinghouse Hanford Company. This is a track/trailer mounted jet grouting rig and is depicted in Fig. 2. The cement layer was installed during the summer of 1995. The complete installation of this layer took approximately one week. Drilling was completed at an approximately 45 angle to the ground, the columns are ~28 feet long forming an ice cream cone shaped barrier (see Fig. 1). A row of 60 cement columns was grouted in a circular pattern followed by a second row of columns in front of and touching the first row in a honey comb fashion. Columns were placed 24 inches on center and were ~30 inches in diameter producing a barrier 3-4 feet thick. The final cement barrier is ~40 feet in diameter at the top and extends approximately 20 to 22 feet below grade. This cement layer serves foremost as a backdrop for the polymer layer and secondly as a redundant, albeit less durable, barrier.

Fig. 2

During the construction phase the stresses induced on the waste form were evaluated. Tank wall and floor stress/strain relationships were determined using extensiometers, strain gauges, inclinometers, accelerometers, earth pressure cells, and precision leveling. This is an important part of a barrier emplacement because a miscalculation of the forces exerted on the waste form or structure could result in damage to

the waste form and unplanned releases. No undue forces were observed during the cement layer installation.

Following the installation of the cement layer a novel technique for checking barrier integrity was employed. This method involves the use of gaseous tracers to locate and size breaches and may provide estimates of the barrier diffusivity. The proof-of-concept demonstration of this technique was performed on the cement layer prior to lining the barrier with the polymer. This was done because the likelihood of a crack or gap occurring in the cement layer was greater than in the composite, final barrier. Verification of the polymer/cement composite barrier will be completed in March. A brief description of the technology is given later (see Integrity Verification) and a more complete synopsis can be found in Sullivan et al (4) or Heiser (5).

The primary barrier was to be placed by panel jet-grouting utilizing a two-part polymer grout. The polymer chosen is a thermosetting, high molecular weight acrylic manufactured by 3M Company. 3M provided laboratory formulation and testing to meet the specific needs of the grouting demonstration. They also provided expertise in the field during the construction phase of the demonstration. The resin is polymerized using a catalyst (benzoyl peroxide) in combination with a promoter (N-ethyl, N-hydroxyethyl, m-toluidine). The promoter was mixed in with half the monomer resins (part A) and the catalyst mixed into the second half part B). Two separate tanks held parts A and B and two separate pumps were used to deliver the fluids for grouting. The polymerization reaction begins when parts A and B mix together in the ground. To facilitate jet-grouting of a two part resin the drill rig would require modifications. Off-the-shelf dual wall drill pipe was used so that the two separate grouting media could be simultaneously injected and therefore, the two fluids mixed together in the soil only after leaving the drill stem. The mixing occurred as part of the soil mastication/mixing that occurs from high pressure jetting. Prior to installing the polymer liner the drill rig modifications had to be tested using the polymer grout.

BNL was also involved in a parallel project at Idaho Engineering Laboratories (INEL). This project was to demonstrate in-situ stabilization of buried waste using polymers (see Loomis et al in this proceedings). At this demonstration modifications to the casa grande drill rig were completed. The modifications included the installation and shakedown of a dual wall drill stem, flow metering devices and a low pressure pump. These modifications allow the jet grouting rig to deliver two separate grouts simultaneously. The acrylic resins were injected in two parts. One part contained acrylic resins mixed with the catalyst and the other part contained resins mixed with the promoter. Polymerization of the resins initiates only when the promoter and catalyst are mixed. By delivering the two parts separately the polymerization reaction begins only after the resins leave the drill stem and are mixed in the soil. The system was tested by drilling and injecting a test column in undisturbed soils.

The following day the column was excavated. The column was 16-18 inches in diameter as expected based on results of column grouting using cement in earlier field tests at INEL. The polymer column was more uniform from top to bottom, than the pancake stack seen for cement grout under similar conditions. The column was removed and photographed (Fig. 3). Following the test column, two pits of simulated buried waste were stabilized using the polymer grout with jet grouting. Grouting went smoothly with and both

pits were completed in one day (originally two days were allocated). Results of this field trial were better than expected and proved the equipment would perform properly for the barrier demonstration at Hanford.

Fig. 3

The grouting rig was returned to Hanford for installation of the polymer layer of the close-coupled barrier. The polymer layer was installed via panel jet grouting at a 45 angle, closely following the inner surface of the previously installed cement barrier. The polymer was the same two part system used at the INEL field tests. The resins were delivered to the site by 3M in two lots. Lot A was prepromoted resins (0.3 wt% N-ethyl, N-hydroxyethyl, m-toluidine) and lot B was plain resins. The benzoyl peroxide catalyst (50% active) was added to the lot B drums (16 lbs./55 gal. drum) one to four days prior to use. Each part was transferred to separate holding tanks for delivery to the jetting pumps (see Fig. 4). Flow meters were used to monitor the flow rates of each part thus assuring the proper mix ratio (1:1) of the two parts and that the correct amount of grout was delivered. As a backup to the flow meters the storage tank levels for each part were also monitored.

Fig. 4

The viscosity of the polymer grout resins was near water. This necessitated the lowering of the gel time of the resin mix, additional promoter and catalyst were added to reduce the gel time from 180 minutes to 50-60 minutes. This was done to allow the grout to cure before too much "run-out" occurred. In test panels injected with a 180 minute cure time the resins spread out more than anticipated due to the coarse (near gravel) nature of the sandy soil and the very high porosity (40-45%). A second set of panels injected with a 60 minute gel time resulted in an acceptable column and minimal run-out. For future installations it would be desirable to use a thixotropic agent to increase the viscosity of the resins and thereby reduce or eliminate any run-out. This is a preferable method for two reasons, first the same effect is accomplished but the resin requirements are slightly reduced by the addition of the thixotrope. Second, an more important the gel time could be left at the longer times. This reduces the absolute temperature rise during the polymerization. For a fixed amount of resins the slower the polymerization process takes the lower the temperature. There is a fixed number of watts available from the polymerization reaction and the peak exothermic temperature is dependent on how quickly those watts are released.

Cost

DOE has about 3000 hazardous waste landfills, the representative site is approximately 2 acres. Potential cost savings of close-coupled barrier technology range from a few million to tens of millions per representative 2 acre site.

Subsurface barrier costs vs. Remediation costs for a representative 2 acre site, 20 feet deep

Type of Corrective Action	Estimated Project Cost in $/cubic meter	Approximate Project Cost
Subsurface Barrier Systems Under Development		
Close-coupled Polymer/ Cementitious Barrier**	$24	$1,700,000
Cryogenic Barrier (6)	$90	$6,400,000
Remediation of Organic Compound Contaminated Site		

Thermally Enhanced Vapor Extraction (7)	$150	$10,700,000
Excavate and Treat (6)	$590	$41,900,000

**Project cost data

INTEGRITY VERIFICATION

It is recognized that no suitable method exists for the verification of an emplaced barrier's integrity (5). Because of the large size and deep placement of subsurface barriers detection of leaks is challenging. This becomes magnified if the permissible leakage from the site is low. Detection of small cracks (fractions of an inch) at depths of 100 feet or more has not been possible using existing surface geophysical techniques. Compounding the problem of locating flaws in a barrier is the fact that no placement technology can guarantee the completeness or integrity of the emplaced barrier. In jet grouting the borehole may become misaligned or the jet can be partially obstructed by cobble or varying soil types/densities, leaving a gap in the final barrier. Panel jet grouting may leave gaps between panels and/or at the junctions of horizontal and vertical barrier walls and may be thinner, and thus more prone to cracking. Additionally at the time of gel formation separations or "tears" may occur if localized settling takes place.

As a subtask to the barrier emplacement this project demonstrated a method to verify the continuity of the barrier. Perfluorocarbon tracers (PFT) will be used to locate breaches in the barrier. It is expected that the demonstration will provide a proof-of-concept for gaseous tracer verification of barrier integrity and will give an estimate of the resolution of the technology.

PFT technology consists of the tracers themselves, injection techniques, samplers and analyzers. PFTs have negligible background concentrations of PFTs in the environment, consequently, only small quantities are needed. The tracers are nontoxic, nonreactive, nonflammable, environmentally safe (contains no chlorine), and commercially available. PFT technology is the most sensitive of all non-radioactive tracer technologies and concentrations in the range of 10 parts per quadrillion of air (ppq) can be routinely measured. The PFTs technology is a multi-tracer technology permitting up to six PFTs to be simultaneously deployed, sampled, and analyzed with the same instrumentation. This results in a lower cost and flexibility in experimental design and data interpretation. All six PFTs can be analyzed in 15 minutes on a laboratory based gas chromatograph. Low detection limits allow detection of very small breaches in the barrier. Breaches will be located by injecting a series of PFTs on one side of a barrier wall and monitoring for those tracers on the other side. The injection and monitoring of the PFTs will be accomplished through vadose zone monitoring wells. The amount and type of tracer detected on the monitoring side of the barrier will determine the size and location of a breach. It is easy to see that the larger the opening in a barrier the greater the amount of tracer that transports across the barrier. Locating the breach requires more sophistication in the tracer methodology. Multiple tracer types can be injected at different points along the barrier (both vertical and horizontal). Investigation of the spectra of tracers coming through a breach then gives a location relative to the various tracer injection points.

The initial verification of the cement layer was completed in October 1995. Results were promising (see Sullivan, Gard and Heiser (4) in these proceedings). Verification of the polymer/cement composite barrier will

be completed in January and should provide a method of determining breaches in a barrier and perhaps estimates of the diffusion characteristics of the barrier.

CONCLUSIONS

This project has successfully demonstrated the feasibility of installing a close-coupled, composite barrier. Close-coupled barriers are applicable to final, interim, and emergency loss of confinement conditions. The technology is applicable to any buried or surface waste form that has the potential to release mobile contaminants. Unlike many other subsurface barrier technologies, close-coupled barriers are applicable to a wide range of waste materials and geohydrologic conditions. This is extremely advantageous because nearly every subsurface barrier has site specific conditions that require the flexibility offered by this technology, more specifically this technology offers an ability to place barrier materials that are compatible with virtually any waste form in almost any geologic setting.

End users for this technology include any DOE, state or commercial facility that has buried waste that may release contaminants to the environment at unacceptable levels. Specific end users have been identified and include Idaho National Engineering Laboratory (INEL), Brookhaven National Laboratory (BNL) and the Hanford reservation. INEL and BNL are interested in the full subsurface close-coupled barrier technology. Letters of support of the demonstration have been obtained from Lockheed Idaho for INEL and the DOE area office for BNL. Hanford has expressed interest in the use of polymers to form a close-coupled barrier. This technology could be used to seal leaks in the underground storage tanks at Hanford.

For future installations it would be desirable to use a thixotropic agent to increase the viscosity of the resins and reduce or eliminate any run-out. This reduces the resin requirements and the peak exothermic temperature during the curing of the grout.

Perfluorocarbon tracers will allow locating and sizing of breaches at depth. The technology has regulatory acceptance and is used commercially for non-waste management practices (e.g. detecting leaks in underground power cables). This technology has been used in a variety of soils and locals and will be applicable to the entire DOE complex as well as commercial waste sites. The major use of tracers will be to verify placement continuity of a freshly emplaced barrier and to re-check corrective actions that may be used to seal or repair a breach. It may also be useful to periodically check a barrier to determine the long term integrity of the walls. This would certainly be beneficial if a cementitious grout (portland based) barrier were used. Cementitious grouts are prone to cracking from various degradation modes including wet-dry cycling which is prevalent at many of the DOE sites (e.g. Sandia and Hanford). Tracers would allow determination of performance losses in containment over the life of the barrier.

ABSTRACT

A proprietary chelating polymer has been synthesized with a high affinity for lead. Batch experiments show the chelator's ability to reduce lead contaminated levels to below EPA requirements in a single washing step. In order to effectively investigate the process feasibility of soil remediation of lead contaminated soil with this polymer, soil transport characteristics must be known. Column experiments using radiolabeled chelator yield information pursuant to vital parameters needed for feasibility studies. Preliminary data suggests that the chelator has a low affinity for quartz.

INTRODUCTION

Lead is listed as a contaminant on roughly a third of the sites on the National Priorities List; in the past, standard protocol for cleaning lead contaminated soil included off-site disposal, solidification and stabilization or capping. These methods of cleanup are not environmentally sound and not permanent solutions. As a result, investigations into treatment alternatives have found chelation technology as a viable choice for lead removal. The advantageous qualities of such an approach include the recovery of lead as a natural resource, the restoration and redeposition of the soil, and the permanence of the solution. Pursuit of this alternative resulted in the development of a proprietary water-soluble polymer, or chelator, with a high affinity for lead by collaborators at Los Alamos National Laboratory (LANL). Batch experiments have shown that the chelator is soluble over a wide pH range, has a high specificity for lead, and is able to remove lead to below EPA requirements. However, before developing the full scale process, investigations of the chelator's transport characteristics through soil must be completed. Column experiments run using radiolabeled

polymer provide information regarding the polymer's transport through soil.

THEORY

The transport of the water soluble chelator through columns will be driven primarily by fluid motion. This condition gives rise to two macrotransport mechanisms 1): convection (also called advection) and dispersion, a diffusive-like process that comes about due to the myriad and tortuous pathways through the column interstices.

Accordingly,conservation of the species will be described by a convective-dispersion equation of the form:

Eq. 1

where jP, the flux of the dissolved polymer, is given by

Eq. 2

and RP is a source/sink term that accounts for processes, such as attachment to soil particles and metal binding, that can alter the local concentration of chelator cP. In Eq. (2), u is the spatially averaged interstitial fluid velocity and DP is a dispersion coefficient. The radiolabeled column transport studies will provide parameters governing adsorption and desorption characteristics of the chelator under the test conditions.

METHODS

Polymer Synthesis

Synthesis is done in small reaction batches of approximately 300 ml. The commercially available base polymer (MW 600 to 750,000) is functionalized to create the desired chelating polymer. Currently, the synthesis process is under patent review. For the column experiments requiring radiolabel, the base polymer is simply functionalized with reactants containing radiolabel. The reaction mixture is then ultrafiltered with a 10,000 molecular weight cut off (MWCO) filter to remove all unused reactant, radiolabel and polymer of low molecular weight, yielding a homogeneous mixture.

Polymer Yield and Quantification

Copper tests are done to quantify the reaction product using a spectrophotometer. Samples and standards are prepared by combining 0.5 ml of 0.1 M copper sulfate ($CuSO_4 \cdot 5 H_2O$), 2 ml Orion pH storage solution and an appropriate amount of sample or chelator stock solution in a 25 ml volumetric flask. The solution is brought up to 25 ml, and a standard calibration curve of absorbance (284 nm) versus polymer concentration is established for chelator concentrations of 0, 10, 50 and 100 ppm. This linear relationship is then used to quantify the chelator concentration of the prepared samples.

Lead concentrations are found by using an inductively coupled plasma unit (ICP) at LANL. After ICP calibration for lead, samples are injected into a chamber where they are exposed to argon plasma at temperatures of 6000 to 10000 K, and atomic emission spectra are analyzed using photo multipliers. This quick and efficient technique has its lowest detection level for lead less than 1 ppm.

MARK Columns

MARK column experiments, in which the bulk of experiments were run, were developed at the University of Arizona (2) and have been used effectively to investigate factors affecting the transport of biocolloids through saturated porous media. The column itself is the bottom barrel of a 3 ml syringe with 0.8 cm ID. The syringes are prepared by inserting a 0.8 cm GF/D filter (Whatman, 2.7 mm nominal pore size) into the bottom of the

syringe barrel. The syringe is then packed with porous media--sand, coated sand or soil. The medium is typically stirred to remove trapped air, ensure homogeneity and provide an even surface at the top of the barrel. The barrel is then rinsed with water of the same ionic composition of the test solution (dependent on experimental objectives) until there is no pH change across the column. The column is now fully prepared.

Chelator transport experiments are initiated by adding a known volume (between 0.4 and 40 ml) of the 0.5% test solution containing radiolabeled polymer at the top of the packed mini-column. The flow conditions are manipulated to ensure laminar flow. The flowrate for all experiments was 4 ml/min. The column is then rinsed with solution of the same ionic strength to remove residual, unattached label from the column pores. The procedure permits tightly controlled application of soluble radiolabeled chelator, semi-continuous measurement of labeled chelator in the column filtrate, and (after sectioning the column) measurement of retained labeled chelator in the column media as a function of bed depth. Radiolabel counts of soil slices and column effluent are made using a Beckman liquid scintillation counter.

As currently configured, the procedure has produced reproducible measurements of radiolabeled microorganisms that are retained on soils or sediments in mm-scale sections of sand columns. In the context of any appropriate transport/reaction model, such data will support parameter estimation, model calibration and prediction for the purpose of large-scale reactor design, pursuit of environmental objectives and design of in-situ remediation procedures.

RESULTS

The chelator was synthesized and tested by collaborators at LANL. Binding capacity tests showed that 10 mg of polymer bound approximately 4 mg of lead. Preliminary soil extraction batch experiments were performed in which 2 g of lead-contaminated Cal-West soil and 8 g of water containing chelator were combined in a sealed tube and agitated for 24 hours. Soil and water were then separated and both were analyzed for lead using ICP. After one extraction, the chelator lowered residual soil lead levels below EPA standards (see Fig. 1), as determined by the Toxicity Characteristic Leaching Procedure (TCLP). Two additional extractions were performed which demonstrated that lead can be removed to a level of less than 1 ppm, even when the initial lead concentration is 6000 ppm. Once the chelator was known to effectively remove lead, the specificity of the chelator for lead was determined. Again, Cal-West contaminated soil was extracted and the concentrations of Ca, Fe, Mn, Mg and Pb were determined both for the liquid phase containing the polymer and the solid or soil phase. As shown in Fig. 2, the chelator is highly specific for lead. The chelator bound 97% of the lead present and below 5% of the Mg, Fe and Mn present. Unfortunately, 9% of the Ca present was also bound by the chelator, however this Ca binding did not appear to affect the ability of the chelator to remove Pb, the target metal. Due to the success of these soil batch experiments, the process for synthesizing this chelator has been submitted for patent review(3).

Fig. 1

Fig. 2

Upon completion of the batch extraction experiments, column experiments were performed to determine the feasibility of using this water-soluble chelator for soil washing applications. These experiments were done in

MARK mini-columns, which measure the fraction of polymer retained in the sediment as a function of bed-depth. The first experiments were done using and ideal soil matrix of quartz sand particles (145 mm average diameter) and 5 pore volumes of chelator solution. No contaminants were present in the bed. As show in Table I, the polymer had a very low affinity for the quartz, less than 1% adhesion under the given flow conditions. Since this polymer is water soluble, this result was anticipated. Examining the concentrations of polymer as a function of depth (Fig. 3) for the 5 pore volume case, it was difficult to determine whether or not the polymer was exhibiting first order adsorption with no desorption. Thus, the volume of the test solution was increased by an order of magnitude to obtain a higher amount of polymer adhesion to the quartz and thus more accurate data.

Fig. 3

When 50 pore volumes of polymer solution were used, approximately the same total amount of polymer bound to the quartz as was observed for the 5 pore volume experiment, see Table I. This suggests that the adsorption is not first order at steady state, instead there may exist preferred binding sites for the polymer and once these sites are saturated, no additional polymer will adhere to the quartz surface. The other possibility is that the flow rate of 4 ml/min is too fast to allow for sufficient binding of the polymer to the surface.

To verify these results the following experiments will be performed. First, and equilibrium isotherm will be generated to determine how much polymer will bind to the quartz surface. This information will verify if the polymer has an extremely low affinity for quartz and if the flow rate was simply too fast to allow for adhesion. Secondly, smaller amounts of polymer solution (0.5 to 1 pore volume) will be used in the MARK experiments to determine if indeed there are preferred binding sites on the quartz surface which are saturated by the polymer. Once these quartz experiments are complete, the water and soil chemistry will be made more complex in a step-wise fashion and further MARK experiments will be performed prior to pilot-scale soil remediation experiments.

Table I

CONCLUSIONS

The water-soluble chelator synthesized at LANL shows tremendous potential for remediation of soils contaminated with lead. The chelator has a high binding capacity for lead; it is highly specific for lead compared to other common metal ions found in soil. Transport experiments performed in MARK columns demonstrate that the chelator has a low affinity for quartz. Further experiments will involve determining the effects of Pb, other metal ions and soil type on chelator transport. The long range goal is to perform an in situ test remediation study in which this chelator will be utilized to was or remove Pb to below EPA requirements.

ENERGY CONSIDERATIONS AND SOIL TEMPERATURE CHANGES DURING SOIL VAPOR EXTRACTION

David Casey

ABSTRACT

Soil vapor extraction (SVE) is a widely used remediation technology for sites contaminated with volatile organic compounds (VOCs). In addition to removing VOCs, SVE can produce secondary effects on soil temperature and moisture content. Soil temperature is important because it controls the vapor pressure of VOCs and the mass transfer rate out of stagnant, low permeability zones in the soil. Soil moisture content affects the removal efficiency of SVE by decreasing the permeability of the soil, by heating or cooling the soil in response to latent heat effects, and by affecting the partitioning of the VOCs. A comprehension of the importance of temperature and moisture content will result in a greater understanding of the energy fluxes associated with soil venting. This is crucial to the development of an optimal design. In this work, a simple model for the enthalpy balance during SVE was used to examine several processes leading to changes in soil temperature and moisture content.

INTRODUCTION

Soil venting or soil vapor extraction (SVE) is frequently used to remediate soils contaminated with volatile organic compounds (VOCs) such as gasoline or chlorinated solvents. The efficiency of a soil venting system is dependent upon the achievable flow rate (1), presence of heterogeneities (2), VOC vapor pressure, and reaction kinetics. Although simple sites with homogeneous materials and uniformly distributed high vapor pressure compounds can be rapidly cleaned in theory, most sites are complex. This leads to initially rapid removal rates followed by a long tail of lower contaminant removal. Cleanup problems at complex sites are the source of a variety of research studies into the enhancement of site remediation.

One potential method for enhancement of soil venting is increasing soil temperatures. Higher temperatures lead to a more rapid diffusional release of VOCs (3) by increasing the vapor pressure. Since the diffusion equation is linear, the diffusional removal rate from stagnant zones is directly proportional to vapor pressure. Henry's Law constants that govern partitioning between aqueous and vapor phases may be important (2). Examination of Henry's Law constants (4) indicates that higher temperatures lead to greater partitioning into the vapor phase for most VOCs. Soil temperature is important when coping with stagnant zones in the soil. Since diffusion rates increase with a rise in temperature, a

higher soil temperature will remove VOCs from stagnant zones faster. Soil temperature also affects bioventing. A rough rule of thumb is that each ten-degree Celsius rise in temperature doubles microbial activity. Thus, moderate elevation of the soil temperature could result in faster biodegradation of contaminants (5). In summary, moderate increases in soil temperature can facilitate cleanup in several ways: raising vapor pressure of residual VOCs, speeding up diffusional removal from stagnant zones, favoring partition from soil moisture into soil air, and promoting microbial activity.

Because of the relationship between soil temperature and cleanup efficiency in soil venting and bioventing, a number of methods have been developed to raise soil temperature. The US Environmental Protection Agency (EPA) has funded studies on methods including injection of heated air, steam injection, and radio frequency heating of the soil (6). Most of these methods have the disadvantage of being energy and capital intensive. The purpose of this contribution is to examine some of the energy relationships leading to temperature changes in the soil during venting and to explore the feasibility of low cost soil heating. Some of the factors in soil venting influencing soil temperature are discussed, followed by the application of a simple mathematical model to a hypothetical contaminated site located in Lexington, Kentucky.

The energy terms important to SVE are: sensible heat, latent heat of vaporization of water and contaminants, vacuum related evaporation, pumping related energy, and biodegradation. As air flows from the atmosphere to the soil, it is heated or cooled to soil temperature. Simultaneously, the moisture in the air equilibrates with the soil moisture and the temperature of the water vapor changes to that of the soil.

Air moves through a soil venting system from high to low pressure, expanding in the process. Lower pressure causes an increase in volumetric flow rate of air and, consequently, an increase in the mass of water vapor exiting the system. The water vapor flux increases inversely with pressure because the partial pressure of water vapor is set by the soil temperature. Vacuum evaporation causes drying and cooling of the soil, especially if the total pressure in the exit well is low. Any volatilization of contaminants would further cool the system.

Pumping of air through the system may lead to energy changes depending upon the method of pumping. Flow of air through porous media in response to a pressure drop is analogous to the Joule/Thompson expansion of classical thermodynamics - an isenthalpic process (7). For an ideal gas, there is no net energy change in passing through the soil or well screen.

In areas of high microbial activity, biodegradation has been reported (8) to lead to increases in soil temperature on the order of 0.028 to 0.065C/day. This effect was found to be more likely in low flow rate regions rather than in high flow rate areas.

MATHEMATICAL MODEL

A simple mathematical model was used to examine a portion of the energy relationships at a hypothetical field site located near Lexington, Kentucky. The mathematical model is limited to the processes of interest. Biodegradation and latent heat effects from contaminant volatilization are excluded from the simulations in order to focus on the latent and sensible heat changes from air and water vapor. Both biodegradation and contaminant volatilization are site and contaminant specific and, therefore, are important in select situations. The model considers a

single control volume (i.e., spatial variations in temperature in the soil are ignored) with one dimensional flow. The simple model gives less detailed information than a full finite difference code. The primary advantage of the model is that a specific geometry for the system does not have to be defined; only the flow rate per unit volume, input pressure, input moisture content, exit pressure, initial conditions in the soil, and heat capacity of the soil are utilized.

Many system geometries could approximate the model's input assumptions. The system could consist of: a) a network of injection and extraction wells in low permeability soils, b) a single extraction well with multiple injection wells in high permeability soils, c) linear air flow between trenches, and/or d) flow between horizontal wells and the surface. The common factor of these geometries is that the simulations assume that the properties of the input air are either known or controlled and that the flow is one dimensional.

The goal for a SVE system, attempting to promote soil heating, is to minimize heat flux out of the system while allowing sufficient time for heat conduction to warm low permeability zones in the soil that are normally resistant to remediation by venting. Heating of low permeability zones should enhance the rate of diffusion of contaminants out to the high permeability regions for removal.

The equation for temperature change of the soil is:

Eq. 1

E = energy imparted by the latent and sensible heats (kJ/s)

V = volume of soil taken as 1 m3

rCp = density of soil times heat capacity of soil, 2.3106 J/m3/K (Jury et al, 1991)

T = soil temperature, C

t = time, s

All simulations assume one atmosphere (1.013 105 Pa) for input air and 0.9 atm in the extraction well. Integration is performed in a series of hourly steps based upon the meteorological data (temperature and humidity) from the National Weather Service, modified as stated in each simulation. Enthalpy and vapor pressure along with flow rates and pressure drops give the net energy flux, (E), into or out of the system. The "lumped" model accurately represents the system over long time periods but cannot consider spatially variable temperature changes.

It is useful to examine the energy dynamics of soil venting using humidified input air prior to viewing the full simulation. The total energy imparted to the soil per cubic meter of air (at soil temperature and one atmosphere pressure) flowing through the system is shown in Fig. 1 as a function of temperature and relative humidity of the injected air.

Fig. 1

The soil temperature in Fig. 1 is assumed to be 15 C. For input air at 100% relative humidity (i.e., humidified input air), the energy balance becomes positive when the input air temperature is slightly above the soil temperature. The slight negative energy flux at 15 C and 100% relative humidity (~ -3 kJ/m3) is caused by vacuum evaporation. Input air at 50% and 0% relative humidity is less energetically favorable and only provides a net heating of the soil system at temperatures significantly above the soil temperature. For this reason, the injection of warm dry air is ineffective in warming the subsurface. Figure 2 gives the number of soil volumes of humidified air (at atmospheric pressure and soil temperature) required to change the soil temperature one degree Celsius.

Fig. 2
The results are given for three different values of soil temperature (5, 15, and 25C) as a function of input air temperature. Figure 2 illustrates that the temperature of the input air is generally more important than pumping rates in leading to warming of the soil. As the temperature of the input air increases, warming becomes much more rapid (i.e., requires fewer soil volumes of air) and nearly independent of the soil temperature. The sharp dependence on input air temperature is caused by nonlinearity in the saturation vapor pressure curve for water. Warm air holds much more water vapor, and thus thermal energy, than cool air. Significant warming rates (i.e., greater than 1C/50 soil volumes of pumped air) occur when the humidified input air is only slightly (15-20) warmer than soil temperatures. The small degree of temperature difference required for soil warming can be provided by several energy sources including: diurnal atmospheric temperature variations, seasonal atmospheric temperature variations, solar heating, and waste heat from industrial processes. Solar heating, for example, is very efficient for low temperature rises. The second figure can be used to compare expected soil warming rates by humidified air with other processes such as heating from biodegradation and cooling by evaporation of contaminants.
SIMULATIONS
Four simulations were performed for a site near Lexington, Kentucky for a period of one year. All the simulations assume a pumping rate of five soil volumes per day at atmospheric pressure and soil temperature. Initial soil temperature is taken as annual average air temperature and initial volumetric moisture content as 0.1 m3 of water/m3 of soil. Figure 3 shows the soil temperature as a function of time for the four simulations. The ambient temperature data is shown in gray. The temperature curve labeled "a" represents ordinary venting of the soil and serves as the reference (control) case for comparison. All of the alternative venting scenarios result in higher temperatures than the control. In simulation "b", the ambient air is heated 40C prior to being pumped through the system. Curve "c" shows the result of heating the input air 40C and saturating it at this elevated temperature. The "d" curve represents an input that is heated 20C, saturated, and heated 20C more.
Fig. 3
Figure 4 gives the predicted soil volumetric moisture content. The control case (ambient conditions) causes a net drying of the soil, primarily from vacuum expansion related drying whereas the humidification cases result in a slight increase in moisture content. Soil drying for normal venting in the simulation is minimized by venting during the warmer months where the normally humid summer air in Lexington condenses in the cooler soil. Venting in the fall and/or winter months, particularly when air temperatures fall below soil temperatures, results in more rapid soil cooling and drying. Changes in soil moisture content track very closely with soil temperature changes, indicating the importance of latent heat of vaporization. Although not shown, other techniques such as pumping only during the hottest portion of the day and simple heating of the air without humidification have been tried. They are of limited effectiveness because the latent heat dominates the energy balance in most cases (Fig. 1).
Fig. 4
DISCUSSION

One of the most important observations is that humidification of the input air does not significantly saturate the soil with water. If the soil were saturated, air permeability would go to zero and the methods proposed would not be effective. The small change in volumetric water content is related to the thermodynamic properties of water. The high value of the latent heat of vaporization of water causes a rapid temperature rise in the soil with only a small volume of condensation water. The change in volumetric water content per degree temperature rise in the soil is given by:

Eq. 2

(hwv - hwl) = latent heat of vaporization of water (~2.4106 J/kg)

rw = density of water (1000 kg/m3)

This equates to a ~10-3 increase in soil volumetric moisture content per degree increase in temperature. Increasing soil temperatures by 10C, for example, only increases the volumetric moisture content by 0.01, an insignificant amount. As soil temperature increases, the vapor pressure of contaminants in the soil increases, resulting in more rapid removal of moisture from the system. For this reason, change in water content of the soil by humidification is self limiting as moisture flux out of the system rises to match input moisture flux. An additional factor is that normal venting tends to dry the soil because of vacuum expansion.

As illustrated, raising the temperature and relative humidity of the input air is an efficient way of heating the soil. Alternative methods of heating and saturation are widely available. Low grade waste heat and low quality waste steam are available at many industrial plants. Solar energy is also available.

For example, one could use the calculations illustrated herein with a smart solar powered remediation system that would inject fresh humidified air when energetically favorable (e.g., when the atmosphere is warm and/or the sun is shining) and recycle scrubbed air from the subsurface during periods when injection of fresh air would result in soil cooling. Warming the air to higher temperatures prior to injection results in greater rates of soil warming than shown in the simulations (Fig. 2), even at very low flow rates.

By significantly warming the soil, relative to normal venting, the enhancement methods suggested can potentially lower cleanup times. The improvement is anticipated to be particularly significant during the long tail period of cleanup dominated by diffusion from stagnant zones, slow kinetics, and other non-ideal conditions that generally control clean-up times. Even when enhancement is not applied, scientists and engineers should benefit from better understanding of SVE caused changes in subsurface temperature.

ABSTRACT

The position of mercury contamination was determined and content of mercury in solid and pore waters was estimated on the artificial range in Sergiev Posad brunch of Mos NPO "Radon". The range contain 82.6 g of mercury in solid and 172.3 mg of mercury in pore water. The desorption of the mercury by the H+ ions in laboratory experiments was studied. Special laboratory research with electrokinetic cell demonstrated, that mercury in the hole water have cation form.

Electroosmosis and electromigration provide transport desorbed ions between electrodes. The construction of metal collector with cationexchangable membranes gave possibility accumulate up to concentration 1 mol/l. The metal collector was tested during 1 month (current 1 A, potential ~ 30 V). In natural condition was collected ~ 100 mg mercury. Desorption solution must be introduce in order to receive practical results.

INTRODUCTION

The mercury belongs to the group of heavy metals (Hg, Pb, Cd, As, Zn), distinguished by high anthropogenic background. These metals are very toxic and suppress the life of animals and plants (1).

Anthropogenic mercury discharged into environment comes from several global sources: fossil fuel combustion, chloralkali factories, mining industries.

Mercury and its compounds are actively used in an electro-technical industry, pharmacology, medicine, vacuum technology, scientific researches. Therefore the territories around large industrial centers are heavily polluted by mercury.

Electrokinetic soil processing uses low-level direct current (on the order of ampers per square meter of area) is perhaps one of the most promising in situ decontamination processes capable of removing heavy

metals and radionuclides from soil. The significance of the technology appears to be in its projected low operation cost and its potential applicability to a wide range of contamination situation (2).

The procedure of the electrokinetic decontamination is realized in three stages: 1) transformation of a polluting impurity in the soluble forms (anions, cations or neutral atoms), 2)moving of an impurity by electrical current in the anode-cathode space, 3) accumulation of polluting impurity in the collector of metals.

In the present research problems, arising from practical realization of these stages, are considered.

OBJECT OF RESEARCHES AND Hg ANALYSIS

The improvement of Hg decontamination technique was carried out in Sergiev Posad branch Mos NPO "Radon", located in 90 km north-east from Moscow.

An artificial hole (the size 7 x 7 x 1,2 m) has been dug out in the moraine clays and filled up by sand. Physical properties of clay and sand are listed in Table I.

Table I

Very low filtration coefficient of hard moraine clay limits washing by atmospheric precipitation and underground water flows. The granulometric composition of sand and clay are shown in Fig. 1.

Fig. 1

The sand consists of Al_2O_3 and SiO_2 (~80%), oxides of iron (~6,%), carbonates (~4%), oxides Na and K (~3%). Acided by HNO_3 up to pH 2-3 a solution of nitric mercury in natural water has been entered in the hole from 6 m3 capacity through a punched steel pipe, laid in the central part of the hole at the distance of 20 cm from the bottom in October 1992 (Fig.2).

Fig. 2

In result of natural processes (washing by atmospheric precipitation, change of forms, diffusion, sorption) stationary distribution of Hg around the steel pipe at the distance of no more than 40 cm and restricted by the hole bottom has been formed (Fig.2).

The highest concentration has been reached directly near the pipe. The typical character of vertical distribution of concentration of dissolved and suspended mercury is the same, it means that distribution of dissolved mercury is controlled by exchange reactions, but diffusion processes certainly promote mercury redistribution.

The quantitative chemical analysis for the mercury was performed by atomic absorption spectrophotometric measurement.

Mercury was extracted by tioether from 0.5 l of pore water, after filtration tioether was diluted by nitric acid, limit of detection is 0.0005 mg/ml. Mercury from 2 g of solid samples was extracted by treatment of the sample by nitric acid, limit detection is 0.2 mg/g .

In order to reveal position of Hg contaminant content of mercury in 112 liquid and 112 solid samples from 28 position and 4 different depth (60,80, 100 and 110 cm) was analyzed.

Simple calculations show that hole contains 82.6 g of mercury in solid state and 172.3 mg of mercury in liquid state, average value of distribution coefficient (Kd) is ~300 ml/g .

PROCESS OF DESORPTION

The adsorption of Hg on the surface of the solid can be described by the exchange reaction of two species (Hg and X) between their aqueous solution (aq) and solid (s) (3).

Eq. 1
The rate of change of the concentration of Hg is:
Eq. 2
where Hg(aq), Hg(s), X(aq), X(s) - concentration of species dissolved or suspended in aqueous solution (moles/ml);
K1 and K-1 forward and backward reaction rate constants respectively.
Assuming a first order reaction kinetics for a steady state we have:
Eq. 3
Kap - apparent equilibrium constant.
For real systems we must use the thermodynamic activities instead of the concentration, using the conventional relationship between activity, concentration and activity coefficient.
The activity of the dissolved species is a(aq) =C(aq)g , where g is the molal activity coefficient, C(aq) is molal concentration. Activities of the adsorbed specie is a(s) = c(s)l , where c(s) is mole fraction, l-is the activity coefficient in the adsorbed state. The activity coefficients of ions in solution g can be estimated from Debye-Huckel (4) and related equations, but for the activity coefficients of adsorbed species l there is no comparable method and the equilibrium constants Kap are known only for several specific systems (4).
Coefficient Kd is usually used in practice
Eq. 4
Kd - distribution coefficient at steady state [ml/g]
Cp - concentration of solid in aqueous solution [g/ml].
Kd (opposite from Kap) is not on equilibrium constant and can vary as pH, solution composition, physical and chemical properties of suspended particles change.
It is common practice to express the desorption results of metals in terms of the "% desorbed". Experimental measurements are certainly the most reliable way to find out the type of exchange or desorption that takes place in the given solution-solid system under the given conditions.
The desorption of mercury in our laboratory experiments was studied by the H+-ions. We used contaminated soil from the hole; the concentration of mercury in the soil is 4.1 mg/kg. Known amounts of contaminated soil (usually 2 g) were added to 50 ml of hydrochloric acid solution from 0.01 N to 10 N. The desorption was studied both in hydrochloric acid solution and in distilled water and natural water from the hole. Ca2+ (79%), Mg2+ (14%), (Na++K+) (7%) are basic cations of natural water; HCO3-(84%), SO42-(14%), Cl- (2%) are basic anions. Total mineralization is 230 mg/l. The solution with contaminated soil was mixed constantly during 4 hours. After this solution was filtered and concentration of mercury was measured on the filter and in the solution. The results are presented in term h (Table II)
Eq. 5
C(aq) mercury content in filtrate,
Co(s) mercury content in solid before experiment.
Table II
Actually we may transfer considerable part of mercury in solution only after treatment by 1 N solution of hydrochloric acid.
FORMS OF Hg
Special laboratory research to detect mercury form was realized. Plastic 15 l volume electrokinetic cell was filled with natural water from the hole (Fig. 3). 0,3 mg of mercury (HgNO3) and nitric before pH=3 were

added. Solution was mixed carefully for several days. Stainless steel anode and the cathode collector of metals with 2 cationexchangable membranes were place in the cell. During 24 hours for I=0.7 A collector of metals collected 75% of mercury. Mercury in the hole water had cation form.

Fig. 3

TRANSPORT

Mass balance across the system and the assumption of constant flow rate for the bulk fluid (without adsorption, desorption, chemical reaction) describes the movement of different species of medium by the Eq. (5)

Eq. 6

C - mass of solute per unit volume of solution,
z - charge on the ion,
F - Faraday`s constant (96485 coulombs),
R - universal gas constant,
T - temperature (oK),
Y - electrical potential,
D - diffusion coefficient,
x - flow direction,
V - average seepage velocity.

The first, second and third terms on the right-hand side represent the diffusion advection and migration components respectively.

Advection may be used for decontamination, but if the velocity of advection is too large, this process demands very much quantity of desorbent. By advection ions and neutral atoms may be removed.

Electrokinetic is the movement of water (electroosmosis), ions and polar molecules (electromigration) between two electrodes under the action of an applied direct current electric field.

By electroosmosis we may move ions and neutral atoms. In electroosmosis, the flow rate qos [cm3/s] conventionally related to current I (A) by empirical relationship:

Eq. 7

kI - coefficient of water transport efficiency [cm3/A s].

Practically kI change within the limits 10-4 - 10-5 [cm3/A s]. It means that for I = 1 A qos change in interval 0,1 - 1 cm3/s and electroosmosis may have very important role in the decontaminated processes.

Electroosmotic flow could be induced and sustained in all soil types. Electroosmotic flushing is dependent mainly on soil mineralogy.

The flow rate of electromigration qel is:

Eq. 8

Grady is the fundamental parameter, which determine quantity of flow.

Current (I) is sum of separate ions currents

Eq. 9

li - molar conductivity of separate ion.

Cations of Mg2+ and Ca2+ is the basic for the natural hole water and just they determine the molar cations conductivity. For solution of electrolytes l may be estimated by using Nernst-Einstein equation:

Eq.10

where D for some ions may be found in (4); for most of ions (except H+ and OH-) l changes in small intervals (40-80 . 10-4 W-1 m2 mol-1), lH+ =349 . 10-4 W-1 m2 mol-1, lOH-= 197,6 10-4 W-1 m2 mol-1

The maximum meaning of current is dependent on construction of electrodes and ordinary it is no more then 1-2 A.

Steady state of current may be disturb by 2 phenomenons.

1. The primary electrode reactions are:

$2H_2O - 4e^- = O_2 + 4H^+$ (anode)

$4H_2O + 4e^- = 2H_2 - 4OH^-$ (cathode)

Subsequently the hydronium ions produced at the anode migrate toward the cathode and the hydroxide ions produced at the cathode migrate toward the anode. Acid front migration is beneficial for metals extraction from soil. The pH conditions varied at any time during the treatment and can have a significant influence on the local conductance. pH = 12 near cathode region can limit the movement of the metals.

2. In due time the electromigration lead to accumulation of the different sign ions near electrodes and, as consequence, the diffusion act opposite electromigration. It is obvious, that electromigration shell be equal to diffusion , then process of decontamination shall be finish.

In order to overcome this two undesired phenomenons special construction of metal collector was used.

THE COLLECTOR OF METAL AND PRELIMINARY EXPERIMENTS

Schematic construction and hole position of the cathode metal collector is given in Fig. 4. Clear plastic was used for all collector parts. Cationexchangable membranes are placed at each end. Electrode chamber is 2.7 l in volume. Electrode with surface area of 70 cm^2 was constructed of titanic pipe with a 1cm diameter. In all preliminary experiments a constant current 1 A was applied across the electrodes, potential (~ 30 V) was changed in due time. Cationexchangable membranes fixed cations in the collector volume, concentration limit of membrane is 1 mol/l, it means, that solution in collector (natural water from hole) must be change within 3 days.

Fig. 4

In order to neutralize generation of OH^- ions, hydrochloric acid was added in the collector in accordance with rate of primary electrode reaction.

The desorption solution on the first step research is not used and practical possibilities of metal collector was studied. The system worked successfully within one month from 17 August to 15 September 1995. Mainly ions of Ca^{2+} and Mg^{2+} was accumulated in collector of metals. Results of 6 cycles are presented in Table III.

Table III

At an average 1 amp-hr may collect 0.62+0.08 g of cations in collector. The mercury is not revealed in the collector solutions in the limit of detection, but mercury (~ 100 mg) in the end experiment in cationexchangable membranes was fixed. Very low migration quality of mercury was caused by content of natural water in hole (high content of bicarbonates). Experiments with introduction desorbed solution in contaminated soil shall be realized next summer.

CONCLUSION

1. The position of mercury contamination and mercury content in solid and pore water on the artificial range in Sergiev Posad brunch Mos NPO "Radon" were estimated.
2. The desorption of mercury carried out in laboratory by H^+ ions was studied.
3. Mercury in the natural waters of range had mainly cation form.
4. The cathode metall collector was constructed and tested on the range.
5. Desorption solution must be introduced to receive practical results.

ISOTOPIC ANALYSIS OF URANIUM IN CONTAMINATED SOILS BY GAMMA RAY SPECTROSCOPY

James A. McHugh
Hilbert Associates, Inc.
640 Maple Avenue
Saratoga Springs, NY 12866

ABSTRACT

The total uranium radioactivity concentration (Bq/g) of soils contaminated with enriched uranium can be determined by gamma ray spectroscopy, as opposed to alpha spectroscopy. The gamma spectroscopy method saves considerable time and reduces expenses associated with site characterization and remedial activities. Uranium 234 is the dominant contributor to the radioactivity of enriched uranium (e.g. the U-234 represents greater than 90% of the total uranium radioactivity for uranium at 6 weight percent U-235). Since U-234 is an alpha emitter with no practical gamma yield, alpha spectroscopy is the usual method of choice for the analysis and characterization of soils contaminated with enriched uranium. However, gamma spectroscopy can be used to determine the U-234 concentration (or the total uranium concentration) by using the fact that the U-234/U-235 ratio is nearly invariant for a particular uranium contaminant source. This fact, coupled with accurate U-235 and U-238 measurements by gamma ray spectroscopy, provides a method that meets the site specific remedial investigation sensitivity, accuracy and sample analysis turn-around time requirements. The gamma spectroscopy method is nondestructive, fast, and reliable. A sample turn-around time of 10 minutes can be achieved for a U-234 minimum detectable concentration (MDC) of 0.12 Bq/g (3.4 pCi/g) at a 95% confidence level. A range of uranium contamination levels and contaminant enrichments were encountered in this study: uranium concentrations of 0.03 to 20 Bq/g (1 to 540 pCi/g), and enrichment levels to 6 weight percent U-235. The accuracy and success of the method is dependent on the use of uranium calibration standards (as opposed to multinuclide gamma standards), and applying all appropriate gamma emission interference corrections. The methodology was

validated by comparing 45 soil gamma spectroscopy analysis results with the alpha spectroscopy results performed on the same set of samples.

INTRODUCTION

The need to provide a fast turn-around method for the analysis of uranium radioactivity in soil contaminated with enriched uranium prompted the selection of high resolution gamma ray spectroscopy. Gamma spectroscopy can be used to determine the U-234 concentration (or the total uranium radioactivity concentration) by using the fact that the U-234/U-235 ratio is nearly invariant for a particular uranium contaminant source. The method is nondestructive, sensitive, fast and has been adapted for field/mobile laboratory use. It provides a near real time analytical method to support on-site decisions/actions relative to characterization and the control of remedial activities. The analysis of 450 samples (supporting a recent site characterization) demonstrated the value of the method in saving time and characterization costs. Projected savings amounted to fifty percent in analysis costs compared to alpha spectroscopy, and considerable savings in field sampling and excavation time because a potential need for a future mobilization was eliminated by having analytical results immediately available.

The analysis of uranium in environmental samples by gamma ray spectroscopy is complicated because it requires the use of a number of low energy gamma emission lines, the correction for the U-235/Ra-226 interference at 186 keV, and the correction of a number of other interferences. These complications are a principal reason the method is not widely used for uranium isotopic characterization in environmental soil/material analyses. However, the isotopic characterization of enriched uranium materials (particularly as it relates to control of fissile materials) has been extensively studied and applied (1).

The gamma spectroscopy method can provide analytical information on many radionuclides, in addition to uranium. This broad analytical capability is a valuable asset since it avoids duplication of radioanalytical capabilities. This gamma ray spectroscopy application is the focus of this report because of its importance to characterization and remedial activities. It is fast and reliable, and can save considerable time and expense associated with these activities.

METHODOLOGY AND PROCEDURES

Sample preparation is simple, does not involve chemical processing, and is accomplished by placing (in the field or laboratory) the selected soil sample into a standard geometry counting container. The nominal 500 cm3 Marinelli container was used in this study; the soil sample was mixed prior to being placed in the counting container to ensure a degree of homogeneity. The container was filled completely with soil; about 700 to 1000 grams is typical and depends on soil/material porosity and water content. The analysis of a large sample is desirable to ensure a representative result from the sample location. This sample size is in contrast to chemical or alpha spectrometric methods that utilize about 1 gram, or at most 10 grams, for an analysis. Therefore, success of these later methods depends on careful homogenizing and sampling of the initial sample material.

The mobile high resolution gamma spectrometer system includes a Canberra thin window intrinsic germanium detector (with an energy resolution of 2.1 keV and an efficiency of 20% relative to NaI), a Canberra graded four inch lead shield, an Aptec multichannel analyzer/computer interface card, Aptec preamplifier and high voltage hardware, and Aptec gamma

spectroscopy software for spectroscopic data reduction and quantitation (2,3). The system and other supporting equipment is housed in a mobile trailer provided with atmospheric control for all weather operation. All the gamma spectroscopic measurements reported in this work were performed with this system.

The gamma efficiency calibration of the system was performed using a simulated soil matrix containing a well characterized natural uranium ore standard. The calibration standards were prepared by mixing a weighed quantity of a finely ground uranium ore standard(4) with a simulated soil matrix material; the mixture was thoroughly mixed to ensure uniformity, and then quickly solidified. The uranium ore was of an age where all the U-238 progeny are at, or very near, secular equilibrium. This provides a standard containing all the principal radionuclides of interest (U-238, U-234, U-235, Ra-226, and their progeny). By calibrating the system with the exact radionuclides and gamma energy lines used for the sample analysis, one eliminates quantitation errors related to decay scheme/efficiency complications, and errors associated with the nuclide gamma yields and the fitted/calculated efficiency vs. energy curve for the gamma detector system. The fact that these uncertainties are eliminated improve the accuracy and precision of the measurement, and are key to the overall success of this method.

The uranium (U-234, U-235, and U-238) isotopic radioactivity is derived from measurements of the U-238 and U-235 content of the soil or environmental material. The U-238 concentration is obtained from Th-234 (and at higher concentrations Pa-234m). These progeny are in secular equilibrium with U-238 and can be used as a measure of U-238 for uranium materials that were processed/separated more than 200 days earlier. This is the usual situation encountered for old or inactive sites where characterization and remedial actions are desired. The U-235 concentration is obtained from the several U-235 gamma emission lines; the principal 186 keV line of U-235 requires correction for interference from Ra-226; the radium contribution amounts to about 50% of the U-235 peak area in natural uranium sample with all progeny in equilibrium. The U-234 concentration is derived from the measured U-235 concentration and the nominal U234/U235 activity ratio for the project site. Table I provides nominal U-234/U-235 radioactivity ratios for various uranium-235 enrichments(5,6). The enrichment process (gaseous diffusion, electromagnetic, centrifuge or laser methods) determines the nominal ratio, and variations can be expected. Since gaseous diffusion is the source of most of the enriched and depleted uranium, these nominal ratios reflect this dominant source. The U234/U235 activity ratio is not a strong function of uranium 235 enrichment. A U234/U235 ratio of 22 to 25 is typical for most situations where low enrichment uranium is involved. The U-234/U235 ratio for a site can be obtained from a knowledge of (a) the U-234 and U-235 isotopic compositions of the uranium materials processed or handled at the facility, (b) an isotopic characterization of contaminated materials (alpha or mass spectrometric), or from the gamma spectrometric measurement of U-235/U-238 ratio and a nominal U-234/U-235 value from Table I. The best approach is to characterize the isotopic composition of the contaminated media by one of the direct methods. This provides the needed U-234/U-235 ratio, and also provides an independent verification of the gamma spectroscopy results. This direct measurement (e.g. alpha spectroscopy) would be performed on a limited number of samples, and would be part of a QA/QC data validation protocol.

Table I

The key interference corrections that are necessary to ensure the accuracy and reliability of the uranium isotopic radioactivity measurements involve the 186 keV and 92 keV gamma emission lines. The 186 keV spectral peak is a combination of U-235 and Ra-226; lesser contributors to this peak are Th-237 and Pa-234. For most situations, these lessor contributors can be ignored. The correction for the Ra-226 contribution is derived from the measured Pb-214 and Bi-214 concentrations. The Pb-214 and Bi-214 are progeny of Ra-226; when secular equilibrium conditions exist, their individual concentrations equal the Ra-226 concentration (Bq/g). For the typical situation where processed uranium is the principal radiological contaminant, the radium source is natural occurring radium in the soil. Soil samples placed directly in the counting container and sealed in the field are very near equilibrium. No significant loss of Rn-222 (3.82 day half life) occurs in this situation; the majority of Rn-222 is trapped in the naturally occurring uranium mineral grains or soil matrix constituents. Also, the sample material is not significantly disturbed in the preparation step, compared to drying and grinding of the sample. For situations involving radium contamination from a uranium processing, or radium recovery operation, or some form of aggressive sample preparation, one needs to establish the state of secular equilibrium for the immediate progeny of Ra-226 in the sample. This is easily done by monitoring the Pb/Bi-214 as a function of time for the particular site soil/contaminant situation. The delay time required between sample preparation and analysis can then be established. No delay was found to be necessary for the soil/contaminant condition at the site that was the subject of this study. If the equilibrium with Ra-226 progeny is not attained, the Ra-226 correction is underestimated, and as a result, the interference corrected U-235 value is biased high. Therefore, the U-235, U-234 and total uranium radioactivity values will all be biased high, which provides a degree of conservatism that avoids the situation of underestimating the contaminant radioactivity concentration.

The 93 keV spectral peak is a complex peak involving two lines of Th-234, and contributions from Ac-228, U-235, and Th-231. The Th-234 gamma emissions provide a measure of the U-238 in the sample. The Ac-228 is a major correction when Th-232 is present in the soil naturally or as a contaminant. The interference correction for Ac-228 is determined from the measured Ac-228 concentration (using other prominent Ac-228 spectral peaks) and other Th-232 progeny (Pb-212 and Tl-208), if secular equilibrium is established. The U-235 and Th-231 contribution at 93 keV is obtained from the measured U-235 concentration; Th-231 is a short lived immediate progeny of U-235, and is a minor contributor to the complex peak. The actual interference contribution is derived from the contributor concentrations (described above) and their respective gamma yields, together with the gamma yield of the subject line and it's uncorrected concentration (Bq/g). These data provide the necessary information to obtain the final interference corrected result. The 63 keV emission line of Th-234 is also used for quantitation of U-238 when the U-238 concentration is significantly above the minimum detectable concentration (MDC).

The detection sensitivities for the uranium isotopes or progeny permit low level radionuclide concentrations to be measured. The specific situation depends on the general and normal uranium background spectra

for the materials/soils under investigation, and the count interval for the specific sample. For a typical screening analysis situation (about 3 samples per hour, or one sample every 16 minutes), the uranium radioactivity minimum detectable concentrations (MDC) are given in Table II. The MDC is provided at the 95% confidence level and is calculated from the spectral data using standard methodology developed by Currie (7).

The detection sensitivity and MDC of a measurement is strongly influenced by the method background and interferences, and refers to the statistically determined quantity of radioactivity that can be measured at a selected confidence level. Detection sensitivity at the 95% confidence level is defined as that level above which there is less than a 5% probability that radioactivity will be reported present when it is really absent (, or Type I error), or reported absent when it really is present (, or Type II error). Minimum detectable activity (MDA), or minimum detectable concentration (MDC), is common terminology used when estimating the minimum activity or concentration level which can practicably and reliably be measured under the defined sample and analytical conditions. The MDA and MDC are not the detection levels of the method, but values greater than the detection level (7). The derivation of the MDC is based on the Type II error of escaping detection when activity is present. The MDC values provided in Table II represent the average of individual MDC's determined from the net count/statistical analysis of the spectral data gathered for individual soil samples. The method detection level and the MDC can be lowered with longer count periods; or one can achieve a greater sample throughput with a shorter count period, assuming the MDC for the short count is consistent with characterization or remedial objectives. For some remedial activities where a uranium action guideline of 30 pCi/g is used, one can set the analytical conditions such that the U-234 MDC is 0.13 Bq/g (4 pCi/g), and perform a screening analysis every 3.5 minutes using this method. See Table II.

Table II

RESULTS

The U-238, U-235 and U-234 radioactivity concentrations were determined by the gamma spectroscopy method described above for 450 soil samples. These samples were taken as part of a site assessment/characterization investigation, and involved surface and subsurface soil sampling. Uranium materials processing (involving enriched, normal and depleted uranium) was the principal source of the radiological contamination at the site. the capability to provide analytical results within one to two days was required; timing was dictated by the specific need to support control and direction of the site investigation. This particular timing could not be met using the alpha spectroscopy method, but could be met by this gamma ray spectroscopy method, and also, without having to move the mobile gamma spectroscopy laboratory to the site of the investigation.

The uranium isotopic results were validated by alpha spectrometric analysis; 45 samples were selected from the group of 450 samples previously analyzed by the gamma spectroscopy method. The validation samples were sent to an independent laboratory for uranium isotopic analysis by alpha spectroscopy. The laboratory removed a representative aliquot of soil from the sample container (about 1 gram). No drying or homogenizing of the sample was performed prior to selecting the sample for chemical processing and analysis. This introduces an added source of

variability to the alpha spectroscopy results compared to the gamma spectroscopy results. The gamma spectroscopy method is averaging the gamma emissions over about a 1000 gram sample; this provides a more representative result for the total sample volume.

The 45 samples ranged in total uranium content from 0.03 to 20 Bq/g (0.8 to 540 pCi/g). The samples also represented a wide range of U-234 content because of the enriched uranium contaminant source. The observed U-234/U-238 radioactivity ratios varied by a factor greater than 10 (from 0.7 to 8). The paired results for the 45 samples provided a basis for comparison of the two methods. A U-234/U-235 radioactivity ratio of 22 was used to calculate the U-234 content from the measured U-235; this ratio is site specific and based on an evaluation of the alpha spectrometric results for this site. The alpha spectrometric results averaged 19.3 with a standard deviation of 2.9. The paired comparison of results for the two methods is given in Fig 1. The data has been plotted without including the method error estimate of each measurement pair to clarify presentation of the information. In general, the 95% confidence level counting statistics error (the dominant contributor) for the gamma spectroscopy method, and the particular analytical conditions, ranges from 15% at high concentrations to 35% at low concentrations. For the alpha spectroscopy results, the range is 15% to 50%. The overall agreement between methods for U-238, U-235 and U-234 is good considering the large differences in sample sizes, and the fact that no additional sample homogenization was performed on the sample for alpha spectrometric analysis.

Fig. 1

Fig. 2

In addition, the U-235 weight percent was calculated for the gamma spectroscopy and the alpha spectroscopy results. The paired results for this calculation are given in Fig. 2. The agreement in U-235 weight percent (between the two methods) is also good, considering it is a ratio of measurements which has a larger error caused by the compounding of the individual measurement errors.

Statistical tests of the data pairs were performed to evaluate the extent of agreement for the methods (8). The Pearson product moment correlation coefficient provides a dimension less index (that ranges in absolute value from 0 to 1) to measure the extent of a linear relationship between two data sets; the index is derived from the linear regression line fitted to the data points. The Pearson correlation coefficients for U-238, U-235, U-234 and total U results sets were 0.99, 0.82, 0.92 and 0.92, respectively. This indicates a strong linear correlation, as expected. A test of the significance of the differences in the paired results for the 45 samples (using the Paired Difference Method) shows no significant bias between methods at the 95% confidence level for the complete data set. A test of a reduced data set of the pairs obtained by discarding pairs at high and low concentrations to minimize the possible effects of homogeneity and the larger errors at low concentration showed a small positive bias for the U-234 pairs at the 95% confidence level. This small positive bias is the result of using a value of 22 for the U-234/U-235 ratio (to convert U-235 to U-234 for the gamma spectroscopy method) compared to a value of 19.3, which is the average of the alpha spectroscopy results for the site samples. The value of 22 represents the average plus the standard deviation of the alpha spectroscopy results; this provides a degree of conservatism in the U-234 content of the soil

samples and is the cause of the small positive bias indicated by the Paired Difference Method test.

SIGNIFICANCE OF RESULTS

A practical example of using gamma ray spectroscopy to provide isotopic and total uranium radioactivity measurements in soil contaminated with enriched uranium has been demonstrated. The use of a constant U-234/U-235 site specific radioactivity ratio is satisfactory to provide a reliable assessment of U-234 content using gamma ray spectroscopy. This methodology should be considered as an important assessment tool for the characterization and remediation of radiological situations involving normal uranium, enriched uranium and depleted uranium. The principal advantages can be summarized as follows:

The method is nondestructive and the cost per analysis is low compared to alternatives (40 to 75% less); and the QA/QC for this methodology is less cumbersome and more direct compared to chemical or wet radiochemical analyses.

Large sample volumes are directly analyzed, thus providing analytical information that is a better representation of the field sampling location, and less dependent on homogenizing the sample compared to methods that involve chemical processing.

The sensitivity of the method for uranium isotopes permits low level concentrations to be measured; the method is an alternative to alpha spectroscopy for uranium concentrations near or above 0.03 Bq/g (1 pCi/g).

Sample analysis turnaround can be as short as 10 minutes for a field located/mobile laboratory, to 1-3 days for the off-site laboratory. The analytical productivity is controlled by the specified MDC; a throughput of 20 to 50 samples per day can be expected using one spectroscopy system.

Quantitation of other observed gamma emitting nuclides can be performed on the same sample with no significant increase in the cost per sample.

HEAP LEACH PROCESS FOR REMEDIATION OF PLUTONIUM- AND AMERICIUM-CONTAMINATED SOILS

William R. J. R. Turney
Jason J. Kitten
Bradley S. Schake
Caroline F. V. Mason
Ningping Lu
Los Alamos National Laboratory

ABSTRACT

As an extension of previous successful studies for remediation of uranium-contaminated soil using adaptation of the heap leach process, results documenting the removal of plutonium and americium from soils are reported. In addition, results of leaching schemes from soils co-contaminated, not only with plutonium and americium but also with uranium, are reported. The first soils tested that contained plutonium and americium as contaminants were obtained from the Rocky Flats Plant site in Colorado, whereas soils that contained uranium, in addition to plutonium and americium, were obtained from the site of the former plutonium processing facilities at Los Alamos National Laboratory (which were active from 1945 to 1978). Heap leach has proved to be a relatively fast, low-tech, economical solution for the remediation of plutonium- and americium-contaminated soils at laboratory scale.

Using different leach reagents, more than two thirds of plutonium and/or americium present in the soil samples were successfully removed using the heap leach process. Uranium was also removed. Leach solutions used in experiments consisted of various compositions of citrate, bicarbonate, and/or dithionite. Comparative studies of the different reagents are reported and the results from Rocky Flats and LANL are compared.

The laboratory experiments show promise for remediation of soil by a simultaneous leach of multiple radionuclides.

INTRODUCTION

Several sites exist in the Department of Energy (DOE) complex with plutonium (Pu), americium (Am), and or uranium (U) soil contamination, including the former Rocky Flats Plant (RFP) and Feed Materials Production Center (FMPC) sites in Colorado and Ohio, respectively, and the Los Alamos National Laboratory (LANL) in New Mexico. Uranium-contaminated soils also exist, among other places, in the Czech Republic. Plutonium was previously successfully leached in the laboratory from soils samples from the Rocky Flats Plant (1). Soil samples from the RFP were from an area where drums containing Pu and Am contaminated liquids were stored and subsequently leaked. (The liquids consisted mineral, pump, and hydraulic oils. Other liquids in the drums included carbon tetrachloride, trichloroethylene, perchloroethylene, and ethanolamine.) Pu and Am were the primary alpha emitting radionuclides in those samples. Uranium was also successfully heap leached from uranium-contaminated soils from the FMPC (2), from the Czech Republic, and from LANL (3). Uranium contamination of soils from the FMPC was the result of both aqueous liquid spills and airborne emissions.

Simultaneous leach of U, lead (Pb), and beryllium (Be) from LANL soils was accomplished as well (4). The uranium-contaminated soils are associated with a non-nuclear firing site where highly oxidized depleted uranium (DU) metal came into contact with the soil surface. Simultaneous leach of Pu, Am, and U, however, has not heretofore been reported.

Actinides (such as Pu, Am, and U) tend to have a strong affinity for minerals in most soils (1). The mechanisms that normally dominate radionuclide sorption are surface complexation and ion exchange. Since the radioactive metals are Lewis acids (i.e., acquire electrons to reach an inert state), complexants that act as Lewis bases (i.e., have electron pairs that can be shared with the metal) can be utilized to leach Pu and Am from contaminated soils.

Triay (1) used several leach solutions for the removal of Pu and Am from RFP soil samples in batch desorption experiments. Those leach solutions consisted of various concentrations and mixtures of sodium citrate, ascorbic acid, sodium ascorbate, sodium dithionite, sodium persulfate, sodium bicarbonate, hydrogen peroxide, sodium hypochlorite, sodium hydroxide, sodium ethylenediaminetetraacetic acid (EDTA), and diethylenetriamine pentaacetic acid (DTPA). Best plutonium removal (62%) was attained with 0.1 M sodium citrate (Na3C6H5O7) + 0.1 M sodium dithionite (Na2S2O4) leach solution at 20C. Best americium removal (77%) was with 0.3 M + 0.01 M sodium bicarbonate (NaHCO3) + 0.5 M Na2S2O4 leach solution at 20C.

Turney (2) utilized 0.5 M NaHCO3 in unsaturated heap leach for removal of greater than 90% removal of uranium (U) from the FMPC soils at room temperature. Kitten (3) successfully removed U from the Czech Republic soil samples by use of unsaturated heap leach with 0.5 M leach solution at room temperature. Dander (4) used 0.5 M NaHCO3+ 0.1 M leach solution in unsaturated heap leach at room temperature for removal of U and Pb from LANL soils. Dander (4) also used 1.0 M acetyleacetone (C5H8O2) leach solution for removal of Be from the LANL soils by heap leach.

EXPERIMENTAL PROCEDURES

Based upon the work of Triay (1), Turney (2), Kitten (3), and Dander (4), the objective of this study was to investigate the removal of U, Pu, and/or Am simultaneously from LANL and RFP soils by use of unsaturated heap leach with leach solutions consisting of different combinations of 0.1 MNa3C6H5O7, 0.1 M NaS2O4, and 0.5 M NaHCO3.

Samples from LANL were taken from locations at the former plutonium processing facility, and included soils from beneath (denoted 3S) and near (denoted 27a) a former uranium processing laboratory and from building debris (denoted BD) associated with the decontamination and decommissioning of that facility. Soil samples from the RFP were the same as those samples described above.

The leach solutions used in the various experiments are shown in Table I.

Table I

Soil samples were all ~ 60 g and were heap leached in a downflow direction in 60 mL glass columns in an unsaturated environment (Fig. 1). Experiments were conducted at room temperature. Leach solution application rate was 0.012 mL/cm2/min (0.012 cm/min).

Fig. 1

Radioactive decay of Pu and Am emits primarily alpha radiation. Post-leach solutions were analyzed for Pu and Am by use of a liquid scintillation counter (LSC) that measured only gross alpha radiation. As such, LSC determined the total activity Pu and Am in solution. That activity is reported here as pCi/g. Post-leach solutions were analyzed for uranium by use of kinetic phosphorimetry analysis (KPA). Uranium is reported as mg U/kg soil.

RESULTS AND DISCUSSION

Alpha radioactivity was removed from both RFP and LANL soils with (1) sodium bicarbonate (hereafter referred to as bicarbonate, or B) and (2) sodium citrate and sodium dithionite (hereafter referred to as citrate-dithionite, or CD) leach solutions. Gross alpha of untreated RFP samples used in the experiments ranged from 45 pCi/g to 67 pCi/g. Approximately 10 pCi/g gross alpha was removed from the RFP samples by use of bicarbonate, and ~ 40 pCi/g gross alpha removed by citrate-dithionite leach solution. This suggested between 60% and 89% of the gross alpha activity was removed by the citrate-dithionite leach solution (see Fig. 2). Bicarbonate solution removed from 15% to 22% of the gross alpha activity in the RFP samples.

Fig. 2

While the bicarbonate solution removed up to 22% of the gross alpha activity in the RFP samples, bicarbonate solution removed nearly 70% of the alpha activity associated with the building debris samples from the LANL site (Fig. 3).

Fig. 3

Cumulative U removed from building debris samples from LANL was greatest with citrate-dithionite leach solution (Fig. 4). Sodium citrate-sodium dithionite-sodium bicarbonate (hereafter referred to as citrate-dithionite-bicarbonate, or CDB) removed less than 50% of what the citrate-dithionite leach solution did. Bicarbonate leach solution removed about 40% of the amount of uranium that the citrate-dithionite leach solution did. Sodium citrate-dithionite leach is solution was more effective for the removal of Pu and U than bicarbonate and CDB leach solutions.

Fig. 4

Dithionite is a strong reducing agent that will reduce oxidized plutonium (Pu(VI) and Pu(V)) to its more reduced oxidation state (Pu(IV) and Pu(III)). Dithionite will also reduce U(VI) to U(IV). At reduced oxidation states Pu and U will form strong complexes with citrate ions (5,6). The formation of citrate-Pu and citrate-U complexes would enhance the solubilities of reduced Pu and U and, thus, accelerate the removal of Pu and U from the soils.

A total of 37 mg U/kg was removed from the 27a LANL soil (Fig. 5). Uranium concentrations of 027a samples ranged from 8 to 231 mg U/kg. It is noted that RFP samples were soil samples containing clay, silt, and sand size particles. Building debris samples from the LANL consisted of cement (pH ~ 11) and were gravel sized with little, or no, clay, sand, or silt sized particles. Characterization of soils from the FMPC showed the U contamination in the soil (soil pH ~ 7) was associated with the clay sized particles (7). Large surface areas and strong electrostatic attractions make this scenario possible (8).

Fig. 5

CONCLUSIONS

The results of the experiments performed indicated that Pu, Am, and U can be removed simultaneously by the use of the 1) bicarbonate, 2) citrate-dithionite, or 3) citrate-dithionite-bicarbonate leach solution in unsaturated heap leach. Almost 70% of gross alpha activity associated with building debris from the former plutonium processing plant at the Los Alamos National Laboratory was removed by bicarbonate leach solution. As much as 89% of the gross alpha associated with soil samples from the Rocky Flats Plant soil samples was removed by the unsaturated heap leach method with sodium-citrate-dithionite leach solution. Uranium was also

removed simultaneous from the LANL samples during the leach process. The results show promise for remediation of soil by a simultaneous leach of multiple radionuclides.

ABSTRACT
Uranium mill tailings resulting from an acidic treatment were sampled at a Cogema site (Jouac, France) and separated into 5 particle size fractions by wet sieving. The morphology, the chemical and mineralogical compositions as well as radium-226 content were determined for bulk tailings and 2 selected fractions. The coarse particles were shown to be rough shaped and to form important aggregates when fine particles were present. Quartz, mica and feldspars were identified as the major components of the investigated materials in addition with clay for the fine fraction, but mineralogy and particle size fractionations were found to be dependent characteristics. Although the fines contained more radium than the coarses, direct correlation did not exist between radium concentration and particle size.
An experimental procedure was developed to determine radon emanating power using a sweeping type of collection. Measurements were performed at various moisture content and showed a slight effect of water on radon emanation from the coarse fraction while the emanating power of saturated bulk tailings and saturated fine fraction were respectively about 5 and 3 times those from dried materials. The apparent influence of size fractionation on radon emanation was found to be small for wet tailings. However, this study indicated that interferences between the properties of mill tailings may hide their respective effect on radon emanation process.
Key Words : Uranium mill tailings, radon-222, emanating power

INTRODUCTION

The uranium extraction from ores leads to large amounts of mill tailings, presently about 50 million tons in France. Although more than 90 percents of the uranium is generally extracted, those materials still contain radionuclides as thorium-230 and radium-226, which generate a radioactive

gas, radon-222. Without protective action, the dose associated with the ingestion and inhalation of short-lived decay products of radon may be high enough to cause concern for health of populations living in the vicinity of an uranium mill tailings (UMT) disposal. Knowledge of the radon source term is therefore required in order to assess its environmental impact. In the remainder of this paper the term "radon" will refer to radon-222 isotope. Release of radon to the environment involves two steps, escape from the individual particles in which it is formed and migration through the bulk medium to the free surface. Emanation is not to be confused with exhalation. Emanation only refers to the escape of radon from individual particles to the free pore space, whereas exhalation relates to macroscale radon release. The free pore space includes, in addition to the interparticle pores, the intraparticle pores that allow all radon atoms which enter it to diffuse out of the particle. In this paper, we treat the radon emanation and do not consider radon exhalation. The radon emanating power EP (also called emanation factor, emanation coefficient, escape to production ratio and radon leakage (1)) is defined as the ratio between the number of radon atoms entering the free pore space and the total number of radon atoms formed. The emanation of radon from various types of materials have been reviewed by Tanner (1,2). Four mechanisms have been proposed to account for radon emanation from solids. The recoil energy (86 keV) gained by the radioactive decay of radium-226 allows radon-222 atom to cover a finite distance, named the recoil range (40 nm in minerals, 100 nm in water, 65 m in air). The radon atom may therefore end its recoil in the free pore space. This mechanism is referred to as direct recoil. A second mechanism which may contribute to the emanation is diffusion through the solid matrix. It concerns the radon atoms located at the surface of the particle and becomes significant for very small particles with high diffusion coefficient (of the order of 10-16 cm2s-1). This mechanism is not likely for minerals, as has been reported by most of the investigators. A further mechanism which may be considered is the so-called indirect recoil : the radon atom goes through the free pore volume by recoil, lodges in the opposite pore wall and is released at a later time in the free pore space. Finally, the knock-out effect, as has been summarized by Semkow (3), has been proposed to explain high emanating powers of some substances which decompose easily into H2O or CO2, like hydroxides and carbonates.

Bossus (4), Semkow (3) and Morawska (5) have developed theoretical models of radon emanation from single mineral grains. The grain geometry was simplified for the sake of calculations. Bossus has considered the simplest case of a smooth sphere without any inner porosity. Morawska has included cylindrical pores of same diameter, parallel in each planes and Semkow has come close to the real structure of minerals with, among other things, a roughness surface concept. But UMT are produced by grinding rocks and have not a regular crystal structure. They are much more complicated than assumed for the models. Moreover, the parameters involved in those models (recoil range, intraparticle diffusion coefficient, shape of the surface, intragranular pore size, radium localization) are difficult to investigate with experimental methods. Emphasis was given to the recoil mechanism in those models, the diffusion through the solid phase being considered as negligible. Grain aggregation nor radon embedding into neighboring grains were included, so that those models might be seen as basis for a more complete model of emanation from

materials. Those models give important information about radon emanation from individual particles but cannot be used to determine the emanating power for UMT.

Elsewhere, numerous experimental studies (6-10) have been conducted on radon emanation from rocks, soils, minerals, or building materials for most of them. EP have been found to depend on physicochemical factors such as particle size, specific surface area, moisture content and temperature. The radon emanation from common accessory minerals have been shown to be very low (6). There are fewer published data on EP for UMT. The reported values (11-13) for UMT originating from various types of ores and treatments range from 0.07 to 0.31. Landa (12) has demonstrated that no consistent pattern enabling the prediction of EP of tailings on the basis of ore type was evident. The author has also shown that where wet sieving of UMT has occurred, fines tend to have somewhat EP than the coarse tailings. Studies by Strong (11) indicated that increasing moisture content enhances EP of Australian tailings, but different correlations - linear or more complicated - have been found between water content and EP depending on the type of the investigated materials. The various approaches taken to the problem and the lack of experiments descriptions make in fact comparisons difficult between all of this studies. The generalization of a given parameter effect on radon emanation to any UMT requires therefore further investigations.

The main objective of this laboratory study was to provide the magnitude of radon EP for one type of French UMT. Experimental measurements were also undertaken to assess the effect of the two factors that could be controlled in the investigated material, moisture content and particle size. The method used to separate UMT into particle size fractions, physicochemical properties of the bulk material and of two selected fractions are described in a first part. The experimental procedure to measure EP and the results obtained are presented in a second part.

MATERIALS

To avoid misunderstandings, it should be specified that "dry" materials refers to materials dried at 105C and cooled in a desiccator. The moisture contents are reported as the weight fraction of water, determined by subtracting the weight of the dry tailings from the weight of the moist tailings and dividing the difference by the weight of the moist tailings.

Sample Collection and Preparation

Tailings were collected at an active, acidic-leach uranium mill at Jouac in the Limousin, center of France (Socit des Mines de Jouac, COGEMA's subsidiary). They derived from granitic ores from Margnac (~80%) and La Besse (~20%), both next to Jouac. The processing, which included mechanical (f(95%) < 500 mm) and chemical (H_2SO_4, 130 kg per ton) treatments had removed about 98% of the initial uranium content. Tailings were sampled on filters before to be mixed with chemical slurries on the 17-05-94. Afterwards the moist tailings (19 wt %) were dried at 105C, hand crushed and stored per 1000 g aliquots in sealed containers at ambient temperature. The resulting material - called bulk tailings- were homogenized prior to sampling for any use (3D-mixer, Turbula). The bulk tailings had a mean moisture content of 0.3% at room temperature.

Size Fractionation

A wet sieving procedure has been derived from the one proposed by Landa (12).100 g aliquots of bulk tailings were shaken overnight (62 rpm) in 700 ml of deionized water and then submitted to ultrasonic waves for 30

mn in order to disrupt aggregates. The slurry was put through a nest of 20 cm in diameter stainless steel sieves (500, 200, 125, 45 mm diameter opening). The nest was mechanically shaken for 2 mn using an electric sieve vibrator (500 excursions per minute, with intermittent tapping). The material on the 500 mm sieve was abundantly washed with a fine stream of deionized water (1000 ml minimum). The fractions on the 4 sieves were washed one after the other above the nest of lower sieves and dried at 40C. The particles passing the 45 mm sieve were collected by centrifuging (59600 m s-2, 45mn) the entire slurry volume. These fine solids were dried at 105C and the clods were hand crushed to pass a 125 mm sieve. The particle size fractions resulting from that wet sieving are presented in Table I with size limits or theoretical cut diameters and weight proportions (percent of total weight). About 6.5% of the bulk tailings are water-soluble materials removed during the wet dispersion and sieving processes.

Table I

Particle Size Distribution

Fractions #2 and #5 were selected to test for the effect of particle size on radon emanation. We will therefore focus hereafter on the physicochemical properties of those fractions, as well as bulk tailings. The particle size distribution of fractions #2 and #5 were determined using a laser granulometer (CILAS HR850). The apparatus works in the range 0.1 to 600 mm and does not accept particles with diameter greater than 600 mm. Hence bulk tailings were sieved on a 500mm sieve before analyses. Table II summarizes some characteristics of the particle size distribution with the median diameter - by which is meant that 50% by volume of particles have a diameter smaller than this median diameter or f(50%) - as well as f(10%), f(90%) and the mean diameter. The reported results are averaged over at least 3 measurements.

Table II

Fraction #2 had a median diameter of 300 mm with 30% (volume) maximum of particles with diameter smaller than 200 mm and 7% (volume) maximum with diameter above 500 mm. Fraction #5 had a median diameter of 10 mm with at least 95% (volume) of particles with a diameter smaller than 45 mm. The apparent gap between the real particle size distribution of the investigated materials, the one determined with the granulometer and the theoretical sieving cuts might in fact be due to the shape of the particles. They are particularly rough indeed, most of the time without real similarity with ordinary geometric shapes (see Fig.1), when the separation and the analysis method are based on spherical particles hypothesis. It was then difficult to assess the real size distribution of those materials.

Morphologies

Small amounts of bulk tailings and fractions #2, #5 were deposited under a stereomicroscope without any sample preparation. Although the images observed by optical microscopy did not allow to probe details of the particle shapes or surfaces, they were sufficient to illustrate the complexity of UMT morphologies (see Fig.1).

The observation of fraction #2 (Fig.1c) showed various and not regular particle shapes and allowed to recognize crystalline structure such as quartz, mica and feldspar. The sample also included polycrystalline particles as can be seen in Fig.1c-d. The particle size distribution of fraction #2 appeared relatively wide. This is in agreement with the results obtained using a laser granulometer. Nevertheless, evidence was

given that no fines were aggregated with those particles. The particles in fraction #5 aggregated together in slightly larger entities as well as much larger ones (Fig.1b). The thickness of those aggregates did not allow to have a sharp image of the whole, but small and large cracks could have been observed. The surface of the fines could not have been examined. However, a rough estimation of the specific surface area was performed using methylene blue method (NF 18-592) and yielded 65 m2g-1. As could be expected, very important aggregation occurred in bulk tailings (Fig.1a - much smaller particles aggregated at the surface of coarse ones). This might suggest the presence of cementing phases between the particles in the materials.

Fig. 1

Chemical and Mineral Composition

Table III presents the chemical composition (major elements) expressed in % of oxides. Complete chemical analyses including minor and trace elements were also performed but did not give interesting information with regard to the present study. The analyses were carried out by Inductively Coupled Plasma / Mass Spectrometry (ERM, Poitiers, France). Table IV summarizes the semi-quantitative estimate of main identified minerals from chemical composition and X-ray diffraction analyses. Fe-bearing phases might be oxi-hydroxides or sulphurs.

Table III

Table IV

The particle size separations actually led to variations in the resulting fractions composition but no clear cut selection was made. Generally speaking, the same phases were found in bulk materials and fractions #2, #5 : mica, quartz and feldspars. The strong mechanical and chemical treatments involved by uranium extraction have led to a relatively homogeneous mineralogy (except for clays) with particle size. Nevertheless, mineralogy and particle size were not independent properties of the investigated materials.

Activity Concentration of Radium-226

Radium concentrations were determined by gamma ray spectrometry (214Bi ray). 15 to 25 g samples of bulk tailings or size fractions were sealed in 20 ml boxes and left for a minimum of 38 days for equilibrium to be reach between radium and progenies. The samples were then counted on a hyperpure germanium detector for 12 hours. The results shown in Table V are the average values over measurements on at least 3 different samples of the same material.

Table V

The radium concentration of the fractions increased with decreasing particle size, as have been reported by other investigators (5, 12), by more than a factor of 10 between the coarse and the fine fractions in the present case. However, fractions #1, #3 and #4 presented a radium concentration of the same order of magnitude than fraction #2 and no direct correlation between radium content and particle size fractionation was found in the present study. It is of interest to note that the fine particles (<45 mm) which did not pass a 125 mm sieve after drying and crushing contained 320 Bqg-1 and had a median diameter less than 1mm. The major part of cementing phases contained in the bulk materials might in fact be hold in this subfraction.

RADON-222 EMANATING POWER

Experimental Procedure

A known mass of tailings, dried at 105C and cooled in a desiccator, was deposited in a glass reactor (800 ml) to form a thin layer of thickness less than 1 cm. To avoid problems with hysteresis in the uptake of water (8), the sample was first supersaturated with deionized water (several millimeters of water above the layer surface) for at least one night. Water was then removed stepwise by evaporation at room temperature, so that experiments were started with saturated materials, carried on with intermediate moisture contents and finished with the sample dried at 105C (inside the reactor) and cooled in a desiccator. For radon measurements, the reactor was inserted in the setting up depicted in Fig.2. The surface of the sample was swept by an inert gas (N2, 1 lh-1), which carried the emanating radon to a collecting bag (20 l). If the investigated material was wet, the inert gas was first saturated with water by bubbling in a saline solution in order to avoid any drying up of the layer. A small fan prevented radon from accumulating above the layer. In such conditions the system was assumed to be at the atmospheric pressure. Temperature and relative humidity of the system were controlled by a probe all along the experiment. 7-9 hours were required before the system to reach a steady state as regard to radon concentration, depending on the sample type. After a sufficient time, the collecting bag was sampled using 2 evacuated scintillation cells (500 ml). These scintillation cells have been constructed by Algade (Bessines, France) and were standardized by air-bubbling in radium-bearing solutions. The scintillation cells were left for a minimum of 3 hr (for the secular equilibrium to be reach) and then counted for 2 hours using flask counters (PABS, Electronic Laboratory, CEA-
Far) and standard electronics. The gas circuit was then closed for a short time (<1 mn) in order to empty the collecting bag and opened again to allow gas collection. A second sampling was then performed about 2 hours after the first one.

Fig. 2

The values of the emanating power (EP) are calculated by Eq. 1 :

Eq. 1

The uncertainties on EP values were estimated according to a recommendation (INC-1) from the french NSB (BRPM). These uncertainties consist of a "systematic" component estimated by classical statistic methods on the basis of one standard deviation (gamma ray countings) and a "random" one, estimated from the maximum uncertainty of each parameter. The mean uncertainty on EP was 13%, the larger contribution being introduced through the dependence on gamma-ray spectrometric determination of radium concentration.

The thickness of the layer had to be chosen in order to allow all the emanating radon atoms to reach the surface, that is to avoid a loss of radon atom by decaying during the migration process. For this purpose, radon concentrations were measured from 10, 20, 30 and 40 g samples of moist (30%) bulk tailings. The same test was performed from 10 to 60 g on particle size fractions #2 and #5. The EP were found to be constant with these layer thicknesses. This is reinforced by the radon diffusion lengths reported in the literature (1, 14) as ranging from 0.1 to 3 meters. The effect of moisture content on EP was then performed with 30 g samples of bulk tailings and 40 g samples of fractions #2 and #5.

RESULTS AND DISCUSSION

Table VI presents the means of EP measurements for different values of moisture content of bulk tailings and particle size fractions #2 and #5.

They are plotted versus moisture contents in Fig. 3. Those results were obtained with stepwise evaporation from one saturated sample of each investigated material. The other EP measurements performed for sweeping time and thickness determinations were consistent with those series of results.

Table VI

Fig. 3

EP of bulk tailings was found to increase sharply with moisture content in the range 0 to about 5%. Measurements have not been completed with moisture content close to water saturation but the existing results suggested that EP did not vary so much between 5 and 16% moisture content. EP of fraction #5 increased also but slighter with moisture content in the range 0 to about 10% and then reached a plateau to complete water saturation. The ratio EP(wet)/EP(dry) was 4.75 for bulk tailings and 3 for fraction #5. They were relatively high values compared with the typical ones between 1 to 4 reported by Semkov (3). This water effect can be qualitatively explained by the direct recoil mechanism of radon emanation and the difference between the radon recoil range in air (65mm) and in water (100 nm) (1). When air fills the free pore space, the recoiling radon atoms may be embedded in an opposite solid surface. On the other hand, when water is present in the pores, many recoiling radon atoms will stop in it and increase the EP. In contrast, EP of fraction #2 was rather constant with moisture content up to 15% and then increased slightly to the saturation limit. This observation suggests that the pore sizes might be sufficiently large so that the recoiling radon atoms will stop in it, no matter if air or water fills the pore. The very low EP value measured for the dry bulk tailings may also be explained by the effect of pore size. As have been seen in studying the nature of those materials, they were composed with very fine particles and water-soluble compounds. When evaporating water from the sample, those particles were drawn closer to each other as well as to the larger particles than they were at higher moisture contents. This was confirmed by the increasing apparent densities from 0.60 g cm-3 for the wet sample to 0.85 for the dried one. The radon EP would therefore decrease because of the increased probability of the embedding process to occur. Cemented crusts were formed on the surface of the sample when drying the sample. This might also have led to a loss of radon by decaying before to reach the sample surface.

With the exception of the dry state previously discussed and generally speaking, no clear effect of size fractionation on radon EP was observed (Fig.3) Although radon concentrations measured from fraction #5 were much higher (8800 Bq m-3) than from other samples (2800 Bq m-3 maximum), its EP was only slightly higher than that of bulk tailings or fraction #2. Contradictory results exist in the literature : Greiner (8) did not measured any effect of particle size on radon emanation while Baretto (6) did. However, comparison with results obtained from coals or single minerals should in fact be avoided because variations in the particle size of UMT have been shown to involve changes in other properties of the materials such as their mineralogical compositions. The present study indicates therefore that it would be more suitable to consider the effect of the size fractionation rather than the particle size one for such materials. Moisture content might also interfere with chemical properties such as the localization of radium. Conclusions about the effect of a given parameter on radon emanation are in fact difficult to draw because

of relations of dependence between UMT properties. In these conditions, the contribution of the different emanation mechanisms previously reviewed could not have been further assessed.

ABSTRACT
Uranium mining and milling have left behind great amounts of tailings containing both radionuclides (radium and uranium) and toxic elements (arsenic, lead, nickel,...) which may be released through aquatic pathway. The main exposure from uranium mill tailings is currently the inhalation of radon daughters. The contaminants release towards subsurface compartment and groundwaters is not of concern at present date. Nevertheless, potential modifications of such release in the long term have to be evaluated.
An uranium mill tailings site impact assessment related to aquatic pathways involves at first a complete definition of the source term (contaminants inventory, determination of the mechanisms responsible of their mobility in the tailings). The second step is the understanding of the numerous processes involved in the weathering of the tailings (pH and redox buffers, dissolution and precipitation of minerals).
In this paper, we present data obtained for the Lengenfeld site (located in the south of Dresden in Germany) which contains 300,000 m3 of tailings deposited 30 years ago and covered with 5 to 10 meters of sandy soil. No information was available about uranium ores, milling treatments and disposal conditions. From six drillings performed on the site, samples of the cover, the tailings and the underlying soil have been analyzed. From the results, we can assume that the tailings are issued from granitic and/or sedimentary ores which have been attacked by an alkaline solution (Na_2CO_3, $NaHCO_3$). The comparison with a well known site containing similar residues (basic treatment) may be used to improve present knowledge of the evolution of the Lengenfeld tailings. The analysis of the tailings, specially the determination of the amounts of the different minerals present at different depths, has allowed to point out a beginning of weathering through dissolution and precipitation reactions. The experimental data will be compared to simulations performed by means of geochemical codes, based on thermodynamic equilibrium.
Key Words : uranium mill tailings / radium / uranium / geochemical modeling
INTRODUCTION
For more than a quarter of century, tailings and waste rocks resulting from uranium mining and milling operations have been deposited in impoundment areas throughout the world (about 50 millions of tons until 1991 in France)(1). The tailings issued from milling and chemical processes have the texture of a fine sand and represent about 98% by volume of the extracted material with 85% of the radioactivity found in the original rock. Many of the remaining radionuclides have very long half-life times (80,000 years for 230Th and 1,600 years for 226Ra). As a result, although the radioactivity may be very low, some radiological hazards can be considered to last forever. Moreover, the uranium ores generally contain metallic elements (arsenic, copper, cadmium, silver, lead,...) which remain in the tailings. These elements may cause concern for health, and environment for long periods of time because of their permanent toxicity. The health hazards occur in a number of pathways via radioactive gas or dust inhalation, external exposure and through contamination of surface and groundwater. The radionuclide concentrations in waters are controlled partly by the tailings which act as a source

term, and partly by the hydrochemistry resulting from the mixing of surface, tailings and shallow waters.

This work is devoted to the term source definition considering the aquatic pathway. This includes the determination of the amounts of contaminants present in the tailings and the mechanisms responsible of their release in the geosphere. Their knowledge requires a complete characterization of the tailings, the surface layer and the underlying soil.

HISTORY AND DESCRIPTION OF THE LENGENFELD SITE

The uranium mill tailings site is located in Lengenfeld (Vogtland) at 120 km of Dresden in the east part of Germany. It is closed to the uranium ore mill, which has been in production from 1946 to 1961. The mill and the tailings site were managed by Wismut Society. Until 1991, no details about the organization and the productivity of Wismut were available. After the German unification and because of public pression, some information have been obtained from Wismut's old workers, specially concerning the amounts of uranium produced in east Germany (220000 tons between 1946 and 1989) (2). But the origins of the uranium ores and the milling processes are still unknown.

In Lengenfeld, the tailings (volume of about 300,000 m3) have been deposited 30 years ago in a valley whose river has been diverted in the east part of the site. These residues are surrounded by a dam and covered by a 7 meters thickness of sandy soil.

EXPERIMENTAL PART

Field Experiments

Six boreholes drilled from 0 to 20 meters deep have given a total of 60 core sections including surface layer, tailings and underlying soil (Fig. I). The water table is very close to the surface layer and the cut cores were saturated in water. These solutions in contact with solids have been obtained by pressing down with a 100 bars squeezer. After a filtration through 0.22 mm pore size filters (Millipore), the pH of the solution was immediately measured with a Portatest 655 pH-meter equipped with an Ingold combined electrode, and then was adjusted to 1-2 with Merck 65% Suprapur HNO3 for further analysis.

Fig.1

Laboratory Experiments

Eq. 1

Solid analysis : A laser apparatus (Cilas HR850) was used to measure the distribution of the particles as a function of their size. The chemical and mineralogical composition were determined for several samples of surface layer, tailings and underlying soil. Radionuclides contents (226Ra, 238U and 210Pb) were measured by g spectrometry with a high resolution hyperpure germanium spectrometer. The detection limits (DL) were 0.1 Bq.g-1 for 226Ra, 0.7 Bq.g-1 for 238U and 0.4 Bq.g-1 for 210Pb.

Solution analysis : classical chemical analysis were performed on solutions obtained at different depths. 226Ra and total uranium were analyzed respectively by 222Rn emanometry (DL = 20 mBq.l-1) and laser fluorimetry (DL = 20 mg.l-1).

MODELING

The numerical simulation of geochemical reactions has been performed with the code chimere (3) and the software The Geochemist's Workbench (4). Both are founded upon thermodynamic equilibrium in aqueous solution in order to deal with species speciation in solution, dissolution-precipitation of minerals or sorption reactions. The thermodynamic

database of The Geochemist's Workbench is based in large part on the supcrt data compilation and on the Dzombak and Morel data set (4). Whereas, the chimere thermodynamic database originates from data compilation achieved within the European Communities chemval project (5).

RESULTS

Analysis have been conducted on numerous samples and only a mean composition of each component (surface layer, tailings and underlying soil) is presented in Table I.

Surface Layer

The mineralogical phases are mainly quartz (65%), micas (7.5%), fluorite (9.5%) and carbonates (3.5%). Kaolinite and feldspars appear as minor components (respectively 2.5% and 1.5%). High amounts of barium (closed to 10,000 ppm) have been determined in all samples of this layer. The particles mean size is closed to 150 mm.

The evolution of the cores colour (greenish to reddish) occurring during the two hours following the drilling is probably due to the oxidation of ferrous ions in the presence of oxygen. A detailed analysis of iron in the solid has shown that this element is present partly as ferrous ions (40% of the total iron) and partly as ferric ions (60% of the total iron). Organic carbon has been detected in solid samples (0.1% in weight) and is probably responsible for the weakly reducing conditions of the surface layer.

Considering the water table, the first centimeters of the surface layer (below one meter deep) constitute probably an unsaturated zone in which precipitation/dissolution reactions can take place because of water evaporation. Therefore, the high concentrations measured at this depth are not representative of the covering layer.

Table I

Solutions and solids obtained at different depths in the surface cover have been analyzed (Table II and Table III).

Table II

Table III

Calcium, magnesium and sulphate concentrations decrease with depth while sodium and potassium concentrations increase, iron concentration remaining constant. The pH increases slightly (7.0 to 8.2). Several processes can be involved to take into account these variations like ion exchange, dissolution and/or precipitation of mineral phases, sulphates reduction. Different hypothesis have been tested through speciation modeling. The solution compositions have been introduced into the two geochemical codes under the following constraints: pH fixed to the measured values and redox potentials Eh slightly below 0 mV. In both cases, the total concentrations in calcium, magnesium and carbonates are mainly controlled by the carbonate phases, calcite $CaCO_3$ and dolomite $CaMg(CO_3)_2$. The carbonates also act as pH buffers.

Of course, the computed total concentrations in calcium, magnesium are dependent on the equilibrium constants introduced in the geochemical database. The solubility constant of calcite is well known ($K_s = 10^{-8.3}$) indeed. But large discrepancies occur in literature data for the dolomite solubility product ($K_s \sim 10^{-16.5}$ to $10^{-19.5}$). In fact, dolomite found in nature is seldom pure (stoichiometric composition) because of the incorporation of numerous divalent cations (Ca^{2+} in most of the cases), leading to the formation of a magnesian calcite ($Ca_xMg_{(1-x)}CO_3$). For solutions in equilibrium with both calcite and dolomite, the $[Ca^{2+}]/[Mg^{2+}]$ ratio is constant and equal to 1.3, which corresponds to

the solubility ratio (with a solubility constant for dolomite about 2x10-17). The variations observed in the different samples may be due to the evolution of carbonate phases between two pure phases (calcite and dolomite) through the formation of solid-solution (6).

Tailings

Several samples obtained at different depths have been analyzed and their chemical compositions are presented in Table IV.

Table IV

The mineralogy of the tailings is quite different from those of the surface layer with high amounts of micas (35%) and feldspars (7.5%). Carbonate is present only as dolomite (7.5%) and 60% of iron is present as ferrous ion. Organic carbon amount is higher than in the surface layer and is probably responsible for the reducing conditions found within the tailings (a colour evolution, from greenish to reddish, has also been observed on the cores after drilling). In the opposite of the surface layer, a very low amount of sodium is measured in all the tailings samples. The clays amount is significant with kaolinite (9%) and swelling clays (2.5%). The granulometry of the tailings is quite homogeneous and the mean particle size is closed to 10 m. This particle size has forbidden any more detailed mineralogical studies through microscope observations. Therefore, considering the results presented above, it is not possible to conclude about the origin of the ore (granitic or sedimentary). Keeping in mind that this mill facility has been chosen because of the existing structure and the important railway network, we can assume that all kinds of ores have been treated in this mill inducing a possible heterogeneity in the tailings.

The radionuclides contents are presented in Table V.

Table V

The concentrations of 226Ra, 238U and 210Pb decrease slightly with depth, but these variations are not significant. In the ore, the two ratios 238U/226Ra and 226Ra/210Pb are closed to the unity because of the secular equilibrium. Whereas in tailings, uranium has partly been removed in consequence of the ores treatment and thus the secular equilibrium between 238U and its daughters has been disrupted. From these data, an estimation of the extraction yield gives a value of 84% which is relatively lower than those obtained in France (between 93 and 99%).

The volumes of solution obtained by squeezing are very low (less than 20 ml in most of the cases) and only few elements have been analyzed (Table IV). Among others, the bicarbonate contents in solution still remains to be measured by this method. However, charge balances and in field results from boreholes lead to carbonate concentrations which are close to 10-2 mol.l-1.

High concentrations of sodium (6x10-2 mol.l-1) with high pH values (closed to 10) are obtained. These data suggest that a basic treatment has been applied to the uranium ores, the chemical reagent being probably NaHCO3. Such a treatment is usually applied to sedimentary ores combined with a more pronounced milling than for granitic rocks. For example, the mean size of tailings obtained in Lodve (sedimentary ores in France) is 17 mm (7). The particle size measured for Lengenfeld tailings is in good agreement with a basic treatment. However, this result is insufficient to assert that all the ores were issued from sedimentary rocks.

Only two radionuclides, U and 226Ra, have been measured in solutions (Table V). The distribution coefficients of radium (closed to 20,000 l.kg-1) are in the range proposed in the literature (7). The

radionuclides concentrations differ strongly between the two samples with an increase of pH with depth. The chemistry of radium (as all the alkaline earth elements) is dominated by their ease of oxidation and the ionic nature of their metal-oxygen bonds. Only the divalent stable form is known. Geochemical simulations show that concentrations in anions (such as SO42-, Cl-, OH-) as are not high enough to form complexes with radium. This element is thus mainly present as the divalent species Ra2+. The chemistry of uranium is more complex because of the multiplicity of oxidation states, organic and inorganic complexes and insoluble compounds.

The estimated permeability is about 10-11 m.s-1, which induces a very low water flow. In these conditions, we can reasonably assume that equilibrium between solid and solution is reached in any point of the tailings. A first modeling of the water-rock interactions within the tailings has been performed under the constraint that pH values were fixed to the measured ones. As previously discussed, the alkaline leaching of the uranium ores has led to a pH which is about 10 and to a Na2CO3 solution type. The magnesian calcite, through precipitation-dissolution reactions, acts as a pH buffer and controls the calcium and magnesium solution composition. The perennity of this pH buffer is ensured in tailings by a high carbonate contents and a low permeability. Although the high content in organic matter measured in the tailings is probably responsible for the perennity of the reducing conditions, redox in solution is often controlled by Fe(II)/Fe(III) reactions. The Fe(II) content in the tailings is relatively high. Thus, for the solution compositions encountered within the tailings, the following reaction seems to be reasonable: FeCO3(s) + 3 H20 Fe(OH)3(s) + HCO3- + 2 H+ + 1 e-. The combination of this reaction and of the total iron concentration measured in solution leads to a redox potential Eh which is - 220 mV. Regarding the uncertainty about the bicarbonate content in solution, another mechanism can be proposed for such a high pH: Fe(OH)2(s) + H20 Fe(OH)3(s) + H+ + 1 e-. This reaction gives a Eh which is quite similar to the previous one, about - 250 mV.

The stability of alumino-silicate minerals has also been computed relatively to the low temperature and the chemical aqueous conditions found in the tailings. For such an alkaline pH, a sequence of stability can be propounded: micas and swelling clays > kaolinite, quartz and Na-K-feldspars > SiO2(am) and Ca-feldspars. This is just a theoretical proposal based on thermodynamical considerations, and which needs to be confirmed by further experimental studies.

For such reducing conditions and high carbonate contents, it appears that uranium is present as an anionic species UO2(CO3)34- at pH equal to 10.2 (> 10) (8). But for pH < 10, the most stable form of uranium is the tetravalent state which tends to precipitate as UO2, xH2O. Therefore, for the sample obtained at 9 m (pH = 10.2), uranium is present as an anionic species, weakly sorbed on solids. For the sample obtained at 11 m (pH < 10), uranium concentration in solution is controlled by the solubility of UO2, xH2O, inducing a lower concentration in solution. These modeling data are in rather good agreement with experimental results.

Radium is present at trace level in the tailings, respectively 1.60x10-10 mol.l-1 at 9 m and 3.25x10-11 mol.l-1 at 11 m. So, it cannot precipitate as a pure solid compound. The behavior of radium in these samples can be controlled by different processes : sorption onto solids, cation exchange on clays and co-precipitation on carbonate phases. With acid uranium mill

tailings, stress has been put on the co-precipitation with barite ($BaSO_4$). In Lengenfeld, the geochemical modeling indicates that the SO_4^{2-} aqueous concentration is not high enough for such a process to occur. On the contrary, the interaction of radium with carbonate phases (especially on magnesian calcite) is not well-known and further attention has to be paid on it because of the chemical behavior analogy of Ca, Mg and Ra.

Underlying Soil

Few samples have been analyzed (Table VI). The characteristics of the solid phases are quite representative of a river sand : wide range of particles size (2 to 500 mm), smooth shapes of these particles and high content of silica.

The amount of carbonate is lower than in the tailings but the amount of clays is quite similar. The sodium concentration is higher in the soil than in the residues.

Table VI

Radionuclides concentrations have been measured in this layer up to a depth of one meter (Table VII).

Table VII

The $^{210}Pb/^{226}Ra$ ratio is about 0.9, which is slightly lower than in the tailings. The contamination plume measured in the underlying soil may be due to the migration of small tailings particles or to the migration of uranium and radium as ionic species. The $^{238}U/^{226}Ra$ ratio is higher (0.60) in the soil than in the residues (0.18). Within the tailings, the distribution of particles sizes is narrowly centered on small radius. And so, the distribution of Ra and U relatively to the particle size is probably quite homogeneous. Therefore, the contamination in the underlying soil is not only induced by the migration of small particles. In this case, the ratio would be the same than in the tailings. The discrepancies observed for the different samples are probably due to the combination of the two processes: migration as particles and as ionic species. During migration in solution, sorption and precipitation reactions are different for Ra and U, and a shift between the Ra and U migration fronts occurs.

Only one solution has been analyzed and the data are presented in Table VI and Table VII. The pH is lower than in the residues (8.3) and no uranium is detected in this solution. This result is in good agreement with the uranium speciation. In reducing conditions, for $pH < 10$, uranium is present at the tetravalent state and precipitates as UO_2, xH_2O. Therefore, the concentration level in solution is lower than the detection limit. The distribution coefficient KD of radium in underlying soil is about $1x10^4$ $l.kg^{-1}$. The radium is always present as a divalent cation which can be sorbed on solids like clays, feldspars and micas. Few data are reported in literature (10, 11) and it is difficult to elucidate the mechanisms responsible of this high KD value.

DISCUSSION

Over centuries, the rich deposits of metallic ores in the Vogtland county were mined intensively. Wolfram ores currently are encountered and surrounded with barite veins. After the extraction of this metal, the residues are mainly constituted with sands containing barite. Before to be devoted to the treatment of uranium ores, the plant located near the site was used for wolfram extraction. Therefore, it is not surprising that this sand, probably present in high quantities in the near environment, as a covering layer. The modeling indicates that solution composition is partly controlled by carbonate phases. Calcium and

magnesium concentrations being different in the three samples obtained at different depths, one can assume that the carbonates phases which control the system are slightly different at the different levels (calcite, dolomite, magnesian calcite). The permeability of this layer (assuming a granulometry closed to 150 mm) is about 5x10-8 m.s-1 and it is possible that an evolution of the system (dissolution and precipitation processes) occurs, inducing variations in major elements concentrations. More detailed characterizations of these carbonate phases will allow a more accurate modeling of the covering layer system. This is an important topic for the prediction of the solution composition issuing from this layer and flowing down the tailings.

The tailings are constituted of very fine particles (10mm) in contact with reducing basic solutions (pH > 10). Considering the solution composition, we have assumed that a basic treatment (probably NaHCO3) has been applied to extract uranium. In these conditions (reducing medium, pH > 10), the solution composition is controlled by carbonates (magnesian calcite), by Fe(II)/Fe(III) reactions, and by slower and more complex organic matter and alumino-silicates evolutions. Uranium is present as an ionic carbonate species ($UO_2(CO_3)_3^{4-}$). As soon as the pH slightly decreases (< 10), uranium precipitates as UO_2, xH_2O, inducing a lower amount of mobile uranium. Considering these data, one can assume that as long as carbonate phases will be present in the tailings, the pH will be fixed at a value closed to 10. In these conditions, uranium will be present as an anionic mobile species. But after a full consumption of this solid, the pH will decrease and uranium will become less mobile due to its precipitation.

The speciation of radium in solution is easy to predict but few data about its sorption onto different kinds of solids are available. Therefore, complementary studies have to be conducted on the sorption mechanisms which may be responsible of the retardation factor of radium in the migration process.

Finally, the analysis of few samples of the underlying soil has shown that the radionuclides have soon reach one meter of depth. It is difficult to elucidate the mechanisms responsible of this plume. However, the $^{238}U/^{226}Ra$ ratio was sufficiently different from those measured in the tailings to led us to assume that this plume cannot be due to the single movement of fine tailings particles. More probably a combination of several processes is involved.

This study has also allowed to build a part of the history of the site. A basic chemical treatment has been applied to different kinds of ores which have been submitted to an intensive milling. Therefore, a comparison with others sites containing analogue residues will be possible, in order to improve our knowledge on the history of this site. Moreover, the tailings have been deposited in this valley 30 years ago. They are saturated with water and we can assume that the weathering of the solids have soon begun. Particularly, the microscopic observations of the different minerals will bring some information on the behavior of radium in these weathering process (incorporation, surface sorption). These data are necessary to predict the long term behavior of the contaminants and therefore, to build a strategy for the long term management of this kind of residues disposal.

ABSTRACT

An integrated analysis of a tailings impoundment, ECARPIERE (Western part of France) was performed in order to get a good understanding of the behavior of radionuclides and associated heavy metals.

Three drill holes performed on the tailings impoundments (former open-pit and ring dyke) give a good outline of the mineralogical and geochemical modifications accruing in the tailings which, in some cases, have been stored for nearly 40 years.

Mineralogical and geochemical investigations of the solid fraction and isotopic charac
terization of the tailings pore water were made from the top to the bottom of the storage all along the drillcore ; they lead us to the conclusion that the stored tailings have undergone a significant diagenesis.

Mineralogical Modifications consist of :

- precipitation of new mineralogical paragenesis: smectite, gypsum, barite, hexavalent uranium minerals ...,
- dissolution of residual minerals such as sulfides, feldspars, biotite, monazite, etc....
- close relationships between some heavy metals, radionuclides and the newly formed minerals.

Leaching Test performed on both stored and fresh tailings lead to the same conclusions as mentioned above. The radionuclides and associated heavy metals releases are higher in a fresh tailings than in a stored one ; development of smectite does not appear in fresh tailings.

The 230 Th/226 Ra and 226 Ra/210 Pb ratios are in desequilibritum in the acidic tailings.

The main conclusion of these studies is: a tailings impoundment is not inert, deep modifications appear short time after the deposit especially in the saturated zone of the tailings. These modifications will have an influence on the mobility of the radionuclides and heavy metals in the tailings and consequently on their release toward the environment.

INTRODUCTION

Uranium mining activities started in FRANCE in the early fifties and during more than 40 years 70.000 tons of uranium have been produced; uranium was mined in there main uranium districts located in hercynian leucogranites, permian black shales and tertiary sandstones. These deposits are mainly vein types, episyenite body and stratoid lenses. Uranium was recovered by dynamic or static leaching using acidic and alkaline solution, 46M.Tons of waste (29 M.Tons of tailings and 17 M.T of heap leaching wastes) were produced and stored on the mill sites or in the vicinity of them.

In order to reduce the impact of our mine sites (openpit - underground mines, tailings impoundments, mill facilities, heap leaching dumps) remediation works have been undertaken on the 170 mine sites with the following principles and objectives :

Principles:

Highest efficiency
Final impact must comply with regulatory constraints
Residual impacts are made as low as reasonably achievable
Large information and participation of the public.

Objectives:

Long terms stability of the remediated area
Prevention of intrusion
Control and limit the long term radiological impact
Choice of natural barriers to rely on passive controls and reduce future technical supervision requirements

Reduction of the total land consumption and need for institutional control

Integration into the surrounding landscape, and if possible future use of land

Project technically and economically workable.

Ecarpiere Uranium Deposit

ECARPIERE is located in VENDEE W.FRANCE

Mining (underground - open pit) 1953 - 1990

Milling (9300 kt 1,5 /) 1957 - 1991 (acidic treatment)

Heap leaching (4000 kt 0,4 /) 1967 - 1991

- Remediation 1991 - 1995 (Recontouring, Cover, Drainage + Water treatment)
- Open pit mining.....115 ha
- Mill.....6 ha
- Heap leaching facilities.....16 ha
- Underground mining installations.....12 ha
- Heap leaching waste dump.....9 ha
- Mill tailings impoundment.....73 ha
- Waste water collecting zone.....9 ha

Tailings (7 M tons) from l'ECARPIERE have been stored behind a ring dyke for more than 30 years; to reduce radon emanation and water infiltration the tailings are covered by a multilayer cover.

PETROGRAPHY AND MINERALOGY

There drill holes (C1 - C2 - C7) were performed on the tailings impoundments in order to get a representative sample which allowed us to study the petrography, mineralogy and geochemical characteristics of the tailings from the top to the bottom.

Two types of minerals can be observed :

The main clastic minerals representing the nature of the initial hostrock and the ore paragenesis; these minerals are : quartz, feldspars (Na - K), muscovite, biotite, smectite1 (Al rich), calcite, zircon, pyrite, monazite, tourmaline, fluorite, iron and titanium oxides ; other rare minerals such as marcasite, covellite and graphite are sporadically found.

The second type of minerals can be considered as authigenic, they appear as a cement in all the samples ; gypsum, barite, jarosite, uranium phosphate, uranium vanadate, uranium lead silicate, aluminous rare earth phosphates, iron oxydes and hydroxides, iron phosphate, amorphous silicate and smectite 2 (Fe rich). All these minerals cristallize after deposition of the tailings and a mineralogical zoning can be observed from the top to the bottom of the storage : the smectite to illite ratio increases with depth.

There is a close relationship between the percentage of clay minerals and the radionuclides (226Ra) content.

The dissolution of pyrite, the formation of ion oxyhydroxides around clastic and authigenous minerals, the recrystallization of hexavalent uranium minerals and the development of Fe smectite indicate the diagenetic evolution of the tailings. All these authigenic minerals are not observed in fresh tailings coming from the mill.

LEACHING TEST DATA

Leaching Data

Results on the contaminant releases from the cored mill tailings show that sulphates (mainly gypsum) are mobilized. Uranium and other heavy metals are not released.
The release of 226 Ra is correlated to gypsum and not to barium. After gypsum is totally leached, radium mobility is weaker.
Some tests were carried out in the same conditions on a fresh and stored mill tailings of a Limousin plant (same acid hydrometallurgical process). They revealed the same significant difference towards the mobility of 226 Ra.
In fresh mill tailings, 226 Ra is released in significant amounts, even after the sulphates leaching, whereas it is much lower in an aged mill tailings sample. As mentioned above no recrystallization of authigenic minerals such as smectite, gypsum, barite etc..... have been described in fresh samples.
This behavior can be explained by the diagenesis that the tailings have undergone during their storage.

GEOCHEMISTRY

Major and Trace Elements Data From the Solid Tailing Samples

The geochemistry of the tailings depends on 1) the nature of the ore, 2) the chemicals added during the milling process such as H_2SO_4, $NaClO_3$, and $CaCO_3$ and $Ca(OH)_2$ and 3) possible elements added through water treatment such as Ba.
A relatively regular evolution with depth is noted. The Mg, Ni, V, Cr, Co, Cd, Ti and Fe contents increase from the base to the top of the tailings pile whereas the Cs, Be, Bi, Ge, In, Ga, Rb, Sn, Ta, W and Nb contents decrease. This reflects a change of the processed ore type from hosted granitic ore to hosted metamorphic ore.
The behavior of Ba, Mo and Sr is variable and there is no relation between Ba and K_2O. This is probably due to the occasional addition of sludges resulting from the water treatment on the top of the tailings.
In solid tailings sample, 226 Ra is best correlated with PO_4.

Geochemical Data From the Porewater Samples

The shape of the vertical profile of radium is roughly similar to the gamma ray profile and to the Sr profile. They linearly increase from the top to about 14 meters deep and then decrease in the water satured zone. At this depth, there is also a higher Ba and U content in the water coupled with a depletion in the solid fraction.
Some elements increase with depth such as Si and Al. For several elements the last two porewater samples are different.

URANIUM SERIES DISEQUILIBRIUM

Analytical Methods

The 238U, 230Th, 226Ra and 210Pb activities were measured by gamma spectrometry on 20g of dried samples.

238U, 230Th, 226Ra and 210Pb Activities

The 238U, 230Th, 226Ra and 210Pb activities vary from one layer to another.
As an example for C1, the average activities of the mill tailings are :

- 1475 Bq/kg of 238U,
- 23900 Bq/kg of 230Th,
- 20500 Bq/kg of 226Ra,
- 25400 Bq/kg of 210Pb.

The residual 238U activity represents from 1 to 12% compared to the activity of 230Th.
It increases at the bottom of the tailings.

The 230Th/226Ra and 226Ra/210Pb activity ratios deviate from 1 in the mill tailings. In the C1 and C2 holes the 226Ra/210Pb activity ratio increases with depth from about 0.75 to 0.95 whereas in the third one it remains constant at about 0.8.
The disequilibrium rapidly reverses in the substratum and the activities decrease drastically. The 230Th/226Ra activity ratio are higher than 1 in the mill tailings and strongly increase in the surface altered zone of the granite, just below the tailings.
The values of 226Ra/210Pb ratio below 1 indicate that the isotopes have been leached differently in the tailings.

CONCLUSION

The main conclusions from this study are

1. The mill tailings have undergone a significant diagenesis during the last 30 years with the neoformation of minerals (smectite, gypsum, barite, hexavalent U-minerals) and the dissolution of residual minerals (pyrite, feldspars ?...).
2. The 230Th/226Ra and 226Ra/210Pb activity ratios are in disequilibrium in all the mill tailings indicating a different behavior of the radio-isotopes during diagenesis. The radium content of the porewaters range from 1Bq/l to 12Bq/l.
3. The leaching behavior of radium and other metals is different in fresh and stored tailings.
4. The geochemical characteristics of the porewater in the unsaturated and the saturated zones are different and the contact is the location of some metals deposition.

ACKNOWLEDGMENTS

This study was undertaken under a CCE contract entitled FISRAMUT.

ENVIRONMENTAL DISTANCE LEARNING AWARENESS TOPICS FOR DOE, INDUSTRY AND UNIVERSITIES

Connie Callan
National Environmental Technology Network (NETN)
The University of New Mexico

Technical Training Materials Using the Latest Instructional Systems Development (ISD) Technology

ABSTRACT

Most organizations are experiencing changes which include downsizing, funding cutbacks, shifts in workforce, new missions, new funding sources which demand a swift reaction to train or re-educate the workforce. Those organizations that continue to remain competitive have been able to accommodate to the changes imposed by a technological society using technical training materials incorporating the latest Instructional Systems Development (ISD) technology.
Only 10% of all trainers are familiar with the latest technology in distance education. The remaining 90% prefer traditional tools for

teaching and training (stated at a '95 American Society of Training and Development [ASTD] Conference). Recently, NETN broadcast a "meeting of the minds" to teachers across the U.S., wherein academics came together to discuss the pros and cons of technology and media in the classroom. They determined that chalkboards, flip charts, and pen and pencil tests far outranked ISD technologies such as interactive advertising on television, CD-ROM-based training, in popularity and usage. Yet today's workforce is exposed to new technologies and their uses on a daily basis. Talk show hosts use video telephones, industrial moguls are experimenting with selling products using interactive advertising on television, and business executives have equipped their satellite offices with videoconferencing equipment to cut down on travel time. More and more information from executives and their employees is prepared and presented in new formats involving multi-media.

Environmental issues have had such a substantial impact on the way we live and do business over the past several years, it is imperative that up-to-date training is available. This training must be easily accessible and affordable. Distance Learning using ISD meets this criteria.

INTRODUCTION

Only 10% of all trainers are familiar with the latest technology in distance education. The remaining 90% prefer traditional tools for teaching and training (stated at a '95 American Society Training and Development [ASTD] Conference). Recently, NETN broadcast a "meeting of the minds" to teachers across the U.S., wherein academics came together to discuss the pros and cons of technology and media in the classroom. They determined that chalkboards, flip charts, and pen and pencil tests far outranked ISD technologies such as interactive television, CD-ROM-based training, in popularity and usage. Yet today's workforce is exposed to new technologies and their uses on a daily basis. Talk show hosts use video telephones, industrial moguls are experimenting with selling products using interactive advertising on television, and business executives have equipped their satellite offices with videoconferencing equipment to cut down on travel time. More and more information from executives and their employees is prepared and presented in new formats involving multi-media.

It is incumbent upon both the student and the employee to stay abreast of the new communication technologies. With the digital revolution, anything can be rearranged, cut apart, and mixed with anything else that is digital. It is possible to create a digital manual that can be called up on a home computer. So many things are possible: interactive television, video phone calls, long distance learning. The question that must be answered first is what will the audience members readily accept? The questions of cost, duration, quality and effectiveness must follow, and be answered in light of the changing mission, culture, and objectives. Traditional classroom/workshop training methods, while familiar and proven, cannot supply training that crosscuts all EM components with the same efficacy as ISD technologies. The computer literacy of the workforce is on the rise, and the availability of travel/training dollars is in decline, thus ISD technologies are the best hope for softening the culture shock of organizational change, as well as using the existing skills of the workforce in the most efficient manner possible, while demonstrating considerable cost savings. As Secretary Hazel O'Leary pointed out in her May 3, 1995 address, an annual savings of $175 M can

be achieved for DOE in part by the use of videoconferencing (an ISD technology) for training.

Just as on-line software companies are struggling today to define themselves, to come up with something distinct that will make them stand out, so too, must learning programs carry a distance and unique label, focusing on both the network and the content. Learning objectives must not only be delivered by the latest technology but produced in a visually (if the technology is television) exciting manner.

In the business arena marketing strategies have moved from highlighting the technologies to heralding the services. The spotlight is now upon the customer. At NETN, we always begin with the customer.

The University of New Mexico has established a history of ISD technology courses for two national laboratories in the Albuquerque area: Sandia National Laboratory and Los Alamos National Laboratory. These full-credit academic courses are broadcast to 30 industry sites in the Albuquerque area via a line of site microwave antenna utilizing an instructional television fixed system (ITFS). Over 60 engineering courses are broadcast each semester, establishing UNM as a leader among universities with total quantity of academic course broadcast. Selected academic courses are also broadcast through the National Technological University (NTU) in which UNM is honored to participate as a member university supporting their national engineering curriculum utilizing distance education. As Lionel Baldwin, NTU President stated at a recent meeting, NTU has become a "virtual" university.

The following phases are suggested to identify, modify, and develop technical training materials (distance learning, computer-based training, video-based courses, interactive television courses, etc.) to maintain an informed, effective DOE workforce. The process will facilitate selection of the most appropriate ISD technology based on material, audience, budget, and timeframe.

Research/Data Collection

Conduct a needs assessment of receiving locations by utilizing comprehensive survey methods including telephone, facsimile machines, computer, electronic mail, etc. Using the strategy to study the technology most effective for education and training, the material can then be customized to fit the exact needs of the intended audience.

Hardware Inventory and Trainers

Implement the same comprehensive technological survey techniques to assess the equipment inventories at the receive sites, which would be used to determine the methods of receive capability. The hardware would facilitate accessible technologies in five major areas:

a) Originating Site - Broadcast Capabilities, Uplink/Broadcast/Production
b) Receiving Field Offices - Receiving Capabilities/Downlink/Monitors/Phones/Faxes/Computers
c) Training Rooms - Physical Room Arrangements/ISD Equipment Available
d) Individual Work Stations - How many and composition at each facility
e) Trainers - To participate (EM & Field)
  - Background of experience in ISD
  - Organizational reporting issues
  - Time available to participate in new and innovative ISD training opportunities

Audience Evaluation

Evaluate ISD technologies available to all levels and organizations to determine the access and availability to every individual as well as

groups. Establish Advisory Group composed of trainers from field offices, representatives, and contractors to oversee projects. Technologies surveyed will include traditional chalkboards, as well as computer programs, faxes, modems, VCR's, and monitors, CD ROM capability, Internet, electronic mail, two-way interactive computers, and downlink of satellite feed.

Competency Level of Employees

Employees will be evaluated for basic understanding of equipment usage by the following: a) determining employee preference for and use of instruments/media, b) testing on familiarity with equipment, and c) logging usage of various technologies

Competency Level of Trainers

Trainers/facilitators will receive evaluations parallel to those of employees to determine their competency and skill in using the various technologies for general business purposes. Trainers would appropriately demonstrate the same or greater competency and skill as the average employee.

ASSESSMENT OF ISD ACCESS AND FAMILIARITY WITH TECHNOLOGY

After completing the assessments determining general business usage of ISD technologies by employees, basic training would be initiated to achieve a common skill level on all the media identified for use by trainers for ISD technology training. It is essential to consider the preferences of both students and trainers in identifying these courses. After the control group has been established in which the media/technology/instrument of teaching is the tool, a survey of courses currently initialized and developed would be compiled. A small number of target, sample courses (with a mix of student levels) would be established as a pilot project. A survey instrument would be developed to determine the elements that would result in effective training. Various ISD technologies would be introduced to existing courses to discover their effectiveness for participants at various skill levels.

EQUIPMENTAL DESIGN EVALUATION

An experimental design would be developed to include concurrent evaluation of both a control group (the group that takes the course without the new introduction of ISD), and an experimental group (introducing the newer ISD for evaluation).

Qualitative evaluation of training would include (but not limited to): utilizing the new skills in the job (changing the way they are currently doing their work as a result of the training), and basic comfort level of employers with the new ISD training technology.

Quantitative issues evaluated would include the number of employees taking the course in what period of time, the test/evaluation scores, and the basic knowledge tests comparing the results of pre-test and post test. Different learning styles/preferences of various groups include: ethnic background and gender, geographic location, and workers job descriptions/titles relative to ISD preference.

CONCLUSION

In addition to learning about the technology, familiarity with the software packages used is important for those who will be anxious to improve their presentation skills. There are many software packages (Adobe, Persuasion, Microsoft PowerPoint, Gold Disk Astound) that are suitable for multi-media presentations. Training will depend upon the time and expertise available by both the customer and the trainer. Presentations have progressed beyond placing transparencies on an

overhead projector or writing (with one's back turned to the audience) on a chalkboard. Today live and full color video can be incorporated in a presentation, along with computer demonstrations and interactive modes. Exploring the technologies available is important in today's changing society.

Standardizing training materials by converting to ISD formats would assure quality and content of material, and maintain a consistency of message within the customers area. ISD technologies can help students cope with the culture shock of technological change, and assist them in using their existing skills in the new, high-tech environment. Computer-based learning methods are similar in presentation to traditional methods, thus aiding student receptiveness to new technologies. Students can work at their own pace and in their own style with the adaptable ISD technologies, thereby reducing the impact of individual levels of competence. Dissemination of information via telephone, cable, satellite and television should be considered with the audience in mind. A criteria for selection of the technology should include cost, duration (is the technology likely to change quickly), quality and acceptability.

The outcome of this phase approach is projected to concur with existing research literature on ISD technology. However, this approach considers the employees' unique work environment as well as the effect of decentralization of responsibilities, and the types of training necessary and desirable skills. A variety of options could include the combination of several technologies, and the length of the learning process.

Combining the human and the hardware in the system is of the utmost importance. Today the ability for interaction is growing, thus coming closer to the ideal communication situation: one-on-one human communication where the element of direct feedback is present.

The phased approach can facilitate a "mix and match" technology reflecting the resiliency of government and industry in adsorbing and retraining current and new employees. The survey and assessments ensure the appropriateness of the material to the technology and determines the preferred choice of instructors and students. There is no one tool that can solve all problems of information dissemination. It is best to arrive at a degree of competency on an arsenal of tools, to include both the familiar and the unexplored. With timelines, budget, priorities, audience size, necessity, and the availability of technology, clearly defined, ISD technologies can be implemented to help institute necessary change in mission and culture, and while lining up with Secretary O'Leary's goal of saving millions of dollars and maintaining a highly effective and well-trained workforce. ISD technology is a means to such goals.

IDENTIFICATION OF UNLABELED GAS CYLINDER CONTENTS FOR PROPER WASTE CHARACTERIZATION

Mitch Jacoby
Emergency Technical Services Corporation
Schaumburg, IL

ABSTRACT

The management of waste gas cylinders with unidentified contents is an issue of far reaching significance. Directly involved and potentially at risk are thousands of workers at DOD, DOE, commercial and academic facilities where poor storage practices of waste gas cylinders have continued for decades. It is largely accepted that proper

characterization of the cylinder contents calls for a chemical analysis. Criteria for these analyses have been discussed in Section 5.3.3 (Compressed Gas Cylinder Handling) of EPA Publication 625/R-93/013 (Approaches for the Remediation of Federal Facility Sites Contaminated with Explosive or Radioactive Wastes). The Publication states that examination of the cylinder's exterior (color, markings, etc.) is insufficient for identification of the contents. Rather laboratory techniques such as Infrared spectroscopy (IR), gas chromatography (GC) or mass spectrometry (MS) are required. Though it is widely agreed that spectroscopic analysis of the unknown material is essential, this paper will argue that confident identification of the unknown requires chemical expertise and cylinder expertise. Analyses based solely on GC, MS, IR or any chemical data can lead to incorrect identification of the unknown regardless of the analyst's skill in spectral interpretation. The erroneous conclusion will lead to incorrect waste classification and may cause serious worker injury.

INTRODUCTION

Compressed gas cylinders are routinely used at an enormous number of industrial, commercial, military and research facilities. The great majority of cylinders undergo the intended cycle: test, fill, use, return (recycle, dispose), retest, refill... etc. Cylinders managed this way tend to remain clearly labeled and pose none of the special problems of those with unknown contents. The "unknowns" are usually old, abandoned containers whose labels are missing or have become illegible due to poor storage practices. This includes those left to rust in factory corners and university basements or those waiting for years "to be processed" at gas facilities. Also included are cylinders that have been damaged by fire or natural disasters, and those excavated from chemical "cemeteries" at government remediation sites. But even clearly labeled home-made cylinders or those with modified valves should be considered to have suspicious and potentially dangerous contents, especially if the labels are hand written. Cylinders bearing contradictory signs, such as conflicting labels or the presence of liquid where none should be present must be considered unknown as well.

The dangers associated with gas cylinders arise from the fact that these sturdy containers are used to store materials under high pressure as well as many of the most reactive, and most toxic low pressure compounds (see Table I). Further, it must be recognized that cylinders are not just used for pure gas storage. Cylinders have also been used to package liquified compressed gases, liquids, solids and a great number of commercial, industrial and specialty mixtures. Together with the durability of the package, which generally exceeds the durability of the label and valve, it is clear that old, unmarked cylinders with failing valves may contain any of a large number of hazardous materials. The safe management of such cylinders calls for a three step analysis: 1) a detailed inspection of the cylinder and its valve, 2) a chemical analysis of the cylinder's contents, and 3) an evaluation of everything learned from the first two steps to determine if the clues paint a consistent picture.

CYLINDER EVALUATION

Before laboratory work begins, it is important that the cylinder be examined by a specialist for clues about the intended contents of the cylinder. This requires being able to identify and interpret cylinder markings as well as recognizing the cylinder and valve construction materials - eg. steel, brass, stainless steel, Monel etc... The analyst

must be able to identify the valve outlet's Compressed Gas Association (CGA) designation and recognize whether the valve is the packed or packless type. It must be noted whether a pressure relief device is present and, if so, where it is located and whether it is the plug, disk or valve type. It is important that all of this information be noted, as the following example illustrates: a rusted cylinder with a crumbling label was found at a DOE facility. The external, left hand threaded valve outlet was measured and correctly identified as a CGA 350. This outlet has been designated for use with many flammable gases. Had the cylinder evaluation been concluded at that point, the contents may tentatively have been identified as methane or ethane because the remaining portion of the label seemed to bear the letters "ane." Further inspection of the valve showed that no pressure relief device was present. This additional fact indicated that the cylinder was intended for toxic, flammable gas service. Accordingly, the contents were tentatively identified as silane. Laboratory results confirmed this. Of course, one can not be certain what a cylinder contains until the laboratory analysis is completed. But the knowledge that a cylinder may be leaking silane instead of methane not only simplifies the work, it may also prevent serious worker injury.

SAMPLE COLLECTION AND MANIPULATION

In the Field

The preferred way to collect a sample of an unknown gas is to bring the unidentified cylinder to the lab. Doing so eliminates uncertainties in the following; the original cylinder's pressure, the ambient temperature and pressure, and the state(s) of matter in the original cylinder eg. gas only, gas and liquid... In most cases, though, this is not allowed by the U.S. Department of Transportation. Once transferring becomes necessary, it should be done with careful attention to safety issues and in such a way that the sample is truly representative of the unknown. That means the manifold (the system of valves and tubing) through which the sample is transferred, and the receiving vessel be properly cleaned and evacuated. Likewise, the materials from which the manifold components are made and even the valve lubricants must be judiciously chosen for compatibility. The fact is, many highly reactive materials will be chemically altered by the presence of small amounts of air or water or on contact with so-called non-reactive polymers. The result is that the micro sample that finally reaches the spectrometer may not be the same as the remainder of the unknown.

In the Lab

Gas samples are best handled with a manifold. This stands in contrast to liquids and solids which often are prepared as solutions and delivered to analytical instruments using syringes. The idea is to attach the cylinder to the manifold in a leak tight fashion and deliver the sample to each of the instruments via plumbing - not by walking through the lab with the sample in hand. The manifold should be located in a forced-air fume hood and be equipped with gauges for coarse and fine pressure/vacuum measurement, emergency backup valves and check valves, a finely controlled needle valve, and chemical scrubbers on both the vent and vacuum side. The sampling manifold should be constructed according to the same guidelines as the transfer manifold, with careful thought given to chemical compatibility. A separate manifold should be freshly passivated and used any time the unknown is suspected of being a potent oxidizer eg. fluorine, oxygen difluoride, chlorine trifluoride or other interhalogen

compounds. The reaction of strong oxidizers with most organic compounds (oils, grease, residue from last sample) is generally explosive.

CHEMICAL ANALYSIS

For an analysis to be done correctly, it must be recognized that cylinders may contain gases, liquids, solids, or combinations of materials in different states (see Table I). Further, there may be an equilibrium between the states, such as that with liquid and gaseous ammonia. Or there may be no gas-liquid equilibrium, as with nitrogen and pyrophoric liquids. Or there may be more complex equilibria at work, such as those between liquid phosphine, gaseous hydrogen and gaseous phosphine. Because of these equilibria, it is possible that a cylinder with high pressure may actually be almost empty, whereas one with no pressure may be full. All of this must be considered in order to properly interpret the results.

Table I

Confident identification of the gas in an unlabeled cylinder is best achieved by using two unrelated spectroscopies. The best tools known to the author for this purpose are Infrared (IR) spectroscopy and mass spectrometry. Gas chromatography is certainly an important analytical technique but it is by no means the starting point of unknown gas analysis. The principle reason is that GC data provide quantitative, not qualitative information. Analysis of the liquid or solid may also be done spectroscopically or may require wet chemistry methods.

Infrared Spectroscopy

A Fourier transform infrared (FTIR) spectrometer, equipped with a robust gas cell, is ideal for unknown gas analysis for several reasons. To begin with, the vast majority of materials packaged in cylinders are IR active . Further, the computer, which is present in all FT-type instruments, makes it simple to scan a sample -say 30 times, signal average, display, and store the result to computer memory in less than five minutes. The same computer can be used to quickly compare the sample spectrum to spectral libraries in search of a best match. To be done effectively, the libraries should contain 10,000 gas phase spectra and an additional 10,000 or so condensed phase spectra. Such libraries are available commercially.

Once the library search results are presented, however, the analyst must decide whether the results are believable. For non-reactive, pure compounds spectral interpretation is straightforward. The job is more difficult with non-absorbing or weakly absorbing materials and with mixtures. "Mixtures" includes compounds deliberately mixed by the chemical supplier, materials deliberately or accidentally mixed by the previous user, and the reaction of the sample with manifold residues. Very little deviation from a library spectrum is all that is required to make the search results confusing. Clearly the analyst must be skilled in spectroscopic interpretation.

There are several shortcomings with the use of IR for unknown gas analysis. To begin with, not all materials are visible in the IR. The diatomics, hydrogen, nitrogen, oxygen, fluorine, chlorine and bromine are invisible. Likewise, the Noble gases, helium, neon, argon, krypton, and xenon are invisible. Further, compounds that are related structurally or chemically, like propane and butane, are quite difficult to distinguish. Next, the absorption strength of all compounds is not equal. For example, dichlorodifluoromethane (a refrigerant) absorbs very strongly at low concentration. A much higher concentration of hydrogen cyanide (highly

toxic) is required to observe the same size signal. Therefore, mixtures of compounds with differing absorption sensitivities will be disproportionately represented in the spectrum. The only way to know the true concentrations is to compare the sample spectrum to a reference mixture spectrum. It follows that if a weakly absorbing gas is present in a mixture at low concentration, it may be missed altogether.

Mass Spectrometry

As mentioned above, it is important that a second, unrelated analytical technique be included before reaching a final conclusion. Mass spectrometry (MS) is an excellent candidate for this position for three reasons. 1) MS is an extremely general technique - useful for the detection of hundreds of thousands of compounds, 2) it is not "blind" to any of the gases listed in the previous paragraph and 3) as required, the principles of operation are completely unrelated to those of IR spectroscopy.

Standard benchtop mass specs equipped with electron multiplier detectors are sufficient for the job. Likewise, the so-called "mass spec detectors," basic, computer operated mass specs that are marketed as detectors for gas chromatographs, are also quite adequate, but modifications must be made to accommodate direct sample introduction. As with the IR, multiple scans are easily averaged and the result compared to commercial libraries. One of the more common libraries has roughly 70,000 spectra. Once again, the computer search algorithm will assign a low match quality if the sample and reference spectra do not match very closely. Analysis of a cylinder of tetrafluorosilane (SiF_4), for example, contaminated with a little moist air will give a single (confusing) mass spectrum that combines all the features expected for SiF_4, in addition to those of hydrogen fluoride, oxygen, nitrogen, carbon dioxide, water and the minor components of air. It is essential, therefore, that the analyst be skilled in spectroscopic interpretation.

RECONCILIATION OF CYLINDER EVALUATION AND CHEMICAL ANALYSIS

After interpreting the chemical data, it is imperative to review the cylinder evaluation to determine if the results are consistent and if there is a need for chemical analysis of the condensed phase. There are innumerable examples of how failure to properly reconcile all observations can lead to an incorrect conclusion and disaster. Here are two:

Example 1 A low pressure cylinder containing liquid is too large to be transported as an unknown (USDOT guidelines). A gas phase sample is collected and brought to the lab for analysis. The results are reported as a few percent ethane in nitrogen at <5 psig. The incorrect conclusion is that the sample and original cylinder contain ethane in nitrogen. This is either a calibration mixture or accidental contamination. A disposal or recycling plan should be developed according to the flammability limits of ethane.

A careful cylinder evaluation would reveal the following inconsistencies: neither ethanenor nitrogen tend to be packaged in low pressure cylinders. The cylinder contains liquid and has a 5 psig head pressure, yet the equilibrium vapor pressure above liquid ethane is 543 psig @ 70oF. The correct response is that the gas phase sample is not representative of the liquid. This cylinder may contain a pyrophoric material such as an ethyl aluminum compound. Suppliers typically ship these liquids in low pressure cylinders slightly pressurized with nitrogen. It is common to find a little methane gas above trimethyl compounds, ethane gas above

triethyl compounds, etc... Opening such a cylinder in the presence of air will cause a spectacular fire, spontaneously. A chemical analysis must be done directly on the liquid phase.

Example 2 A small, 30 year old cylinder with a CGA 320 outlet is known to contain liquid. Laboratory analysis clearly indicates the cylinder contains methyl chloride. This is determined by two factors: 1) the close match of the unknown FTIR spectrum with reference spectra (Fig. 1) and 2) excellent agreement of the measured vapor pressure (59 psig @ 70oF) with the literature value. The hasty conclusion would be the following: based on the certainty of the spectral results and the match with the expected vapor pressure, the cylinder contains compressed, liquified methyl chloride. Handle accordingly.

An experienced cylinder analyst would note that CGA 510 or 660 outlets are typically used for methyl chloride. The absence of the prescribed outlet for this compound may indicate that the cylinder contains an additional low pressure material not observed in the gas phase. Pesticide manufacturers often included methyl chloride as a propellant for the "active" ingredients. The mixture was packaged in cylinders often fitted with CGA 320 outlets. For example, 5-10% mixtures of highly toxic organo-phosphates in methyl chloride have been marketed under the trade names Phosdrin or Nifos T. These compounds have LD50s of 1-2 milligrams per kilogram of body weight. A proper analysis requires checking for a second component. To do so, the cylinder should be inverted in a laboratory fume hood and a few drops of liquid carefully delivered. Failure of the entire sample to evaporate instantly indicates a material other than methyl chloride is present. The FTIR spectrum of the residual liquid (Fig. 2) verifies the presence of the toxic material. Clearly even a skilled chemist who lacks cylinder experience is likely to conclude the analysis with the identification of methyl chloride. If the precautions taken during the disposal of this improperly identified cylinder are suitable only for methyl chloride, the workers are likely to be poisoned.

Fig. 1

Fig. 2

These are some examples of how a disaster can arise from incorrect conclusions based upon sound scientific information. It is clearly seen then, that in order to properly and safely manage cylinders with unidentified contents, it is essential that a thorough chemical analysis go hand in hand with a thorough cylinder analysis.

PROACTIVE PUBLIC INVOLVEMENT STRATEGIES FOR THE ENVIRONMENTAL RESTORATION PROJECT AT LOS ALAMOS NATIONAL LABORATORY

Marja Shaner
Los Alamos National Laboratory
P.O. BOX 1663, MS J591
Los Alamos, NM 87545
505-665-7112

ABSTRACT

The Resource Conservation and Recovery Act mandates formal public involvement at the corrective measures stage of any environmental restoration activity. At Los Alamos National Laboratory, the Environmental Restoration Project has exceeded legislative requirements in its approach to public involvement.

However, formal public meetings are not particularly successful, especially in an area of substantial economic and racial diversity. In the past, activists have monopolized the Laboratory's formal public meetings.

To ensure that a broad cross-section of the public participates, the Environmental Restoration Project at Los Alamos has developed an approach that involves a much broader variety of stakeholders in making recommendations on various remediation activities. This approach consists of attending community meetings and familiarizing different constituencies with the purpose and goals of the Environmental Restoration Project. Attending community meetings has helped Los Alamos and our neighbors build a more positive relationship based on mutual respect and trust.

As a direct result of this different approach, community representatives have volunteered to participate in a focus group that will work together on issues of concern and interest.

PROACTIVE PUBLIC INVOLVEMENT STRATEGIES FOR THE ENVIRONMENTAL RESTORATION PROJECT AT LOS ALAMOS NATIONAL LABORATORY

Located in the northern mountains of New Mexico, approximately 32 miles northwest of Santa Fe, Los Alamos National Laboratory occupies a unique position in the Department of Energy's nuclear complex. It was at Los Alamos during the "Project Y" years that scientists from Europe and the United States worked together to develop and test the first nuclear weapon, thus heralding the beginning of the "nuclear age."

Development of the first nuclear weapon also initiated the problem of addressing the radioactive and hazardous waste generated by this project. Although the dangers of acute radiation were known at that time, no one knew with any certainty the environmental problems that could be created if waste products were buried for extended periods of time. The long-term health and environmental effects of liquid waste drained into the canyons also was not known. The canyons that cross the Los Alamos National Laboratory site all flow to the Rio Grande.

Los Alamos National Laboratory and Los Alamos county are surrounded by the communities of Santa Fe, Espaola, and several Indian Pueblos, the closest of which are San Ildefonso Pueblo, Santa Clara Pueblo, San Juan Pueblo, and Cochiti Pueblo all located adjacent to the Rio Grande.

To address past releases from research and development activities at the Laboratory, the Department of Energy in 1989 established the Environmental Restoration Project (ER Project). The ER Project established the following goals:

to protect human health and the environment from exposure to releases of hazardous and mixed wastes from historical treatment, storage, and disposal practices at the Laboratory;

to meet the environmental cleanup requirements of the Laboratory's permit to operate under the Resource, Conservation and Recovery Act (RCRA), specifically Module VIII, which governs ER Project activities (Module VIII was issued in May 1990 and modified in May 1994); and

to perform timely and cost-effective cleanup activities.

Module VIII requires the Laboratory to establish a community relations plan for the ER Project. The following elements were required as part of the community relations plan:

1. establish an active mailing list;
2. conduct informal public meetings;

3. prepare fact sheets, news releases, work plans, final reports, and quarterly progress reports;
4. establish a public information repository and reading room;
5. place updated materials in the information repository and reading room;
6. conduct public tours and briefings, and solicit public concerns;
7. prepare quarterly technical progress reports for the Administrative Authority; and
8. establish procedures for immediate notification of San Ildefonso Pueblo or other affected parties in case of a newly discovered off-site release that could have a potential impact.

In addition to the requirements of the Hazardous and Solid Waste Amendments (HSWA) permit, the ER Project follows the requirements of the Comprehensive Environmental Response, Compensation and Liability Act (Superfund) by establishing an administrative record for the ER Project. The Laboratory also follows the public involvement requirements under Superfund, although it is not a Superfund site.

The first public information meeting for the ER Project was held in May 1992 at three locations: Santa Fe, Espaola, and Los Alamos. The format of these meetings was informal: It consisted of an open house with project exhibits and staff available to answer any questions. A limited amount of time was available for a general briefing and a question and answer period. An average of three meetings each year were held until March 1994. These meetings were different from the formal public hearings mandated by the HSWA permit. Although initial attendance at these public meetings was good, attendance decreased significantly during 1994. The public meetings generally attracted representatives of special interest groups whose agendas did not necessarily include environmental cleanup issues. The ER Project felt that in holding these public meetings it did not really reach its intended audience. As a result, the ER Project decided that this approach was not cost effective and discontinued these meetings; it also decided to find an approach to reach a broader section of the interested public, including state regulators, local government officials, community service organizations, Indian Pueblos, and ordinary citizens.

In its first effort, the ER Project conducted a day-long brainstorming session for the northern New Mexico public. ER Project staff and the public addressed their information needs, how the public could provide meaningful comments on decisions, and how ER Project staff and the public could interact more effectively in the future.

With this information, the ER Project then formed a working group consisting of ER Project staff, DOE representatives, and interested Laboratory organizations. This working group designed an approach that consisted of informal conversations based on a standard set of questions. The working group felt that this approach, rather than conducting formal surveys, would provide the ER Project with better qualitative information and would better serve the public involvement process in the complex, multicultural environment of northern New Mexico. The working group identified a cross section of the northern New Mexico population and organizations that represented the diversity in northern New Mexico. Interviewees included elected officials, agency staff, ethnic and peace organizations, the media, educators, representatives of the business community, and other interested citizens. Approximately 42 individuals

were identified; these individuals were interviewed between June and July of 1994.

A team consisting of an experienced interviewer and a technical staff member from the ER Project conducted the interviews. Appointments were scheduled at the interviewees' choice of location and time, which necessitated travel as far south as Albuquerque and as far north as Taos. Including technical staff as part of the interviewing team enriched the information received from the interviewees and created positive feelings about the ER Project and Laboratory staff.

The interviews provided information about the Laboratory's impact on the northern New Mexico communities, assessed the interviewees' awareness and knowledge about the ER Project, identified issues that were of concern to them, and explored their ideas about how to encourage community participation in the public involvement components of the project. Most importantly, the interviews broadened the dialogue between ER Project staff and representatives of organizations or communities.

Community concerns focused on the Laboratory's profound economic and social impact on northern New Mexico. Whether supportive or antagonistic toward the Laboratory, interviewees agreed that the Laboratory's presence in northern New Mexico is of benefit to many of the surrounding communities. It is very important to the public that the Laboratory and its employees be sensitive to the indigenous people and their cultures.

Almost all interviewees addressed trust and honesty issues. The culture of secrecy that has been associated with the nuclear complex has been detrimental to any trust the neighboring communities and individuals representing them have in the Laboratory and the Department of Energy.

Health and environmental concern also rated high in the interviews. Contamination of aquifers, surface waters, and air and soil is of great concern to our neighboring communities. The interviewees voiced their concerns about Laboratory operations affecting their families' health through possible contamination of their food supplies. Many people in the communities surrounding the Laboratory have vegetable gardens and raise their own livestock or hunt deer and elk for their food supply.

In talking about these issues with the interviewees, their feedback almost unanimously showed that they

- much appreciated the personalized interview approach;
- would welcome presentations at meetings of community service organizations and local government agencies;
- trust their local community leaders and encourage the ER Project to foster closer relationships with them; and
- strongly favor one-on-one contacts with the Laboratory technical staff as a means of exchanging information.

Suggestions from the interviewees to improve public involvement activities included

- working with existing groups and identifying community and business leaders in the community. Public meetings are good but not effective in reaching the larger community. "Why not come to us instead of having us come to you?"
- emphasizing to the leaders in the community the need for their communities to participate in the Laboratory's environmental restoration and waste management activities.
- limiting public meetings. If public meetings are necessary, set a fixed time limit; involve the public in setting the agenda; establish boundaries of discussion before the meeting and request that people stick

to selected topic; value the opinions of people who attend meetings and ask people to submit questions before meetings.

designing tours that specifically target community leaders and school children. Tours would include cleanup sites (both undergoing cleanup and restored sites) and science (walking) tours, such as geological tours. Interviewees suggested that people in northern New Mexico appreciate and actively enjoy their environment. It would be a useful tool to use this appreciation to generate interest in this and other public involvement processes.

communicating scientific information. It is not easy to present to the public scientific information in understandable language. The interviewees asked that materials and presentations be in "plain language." Interesting suggestions for improvement included using local science teachers to help present scientific information, using Laboratory employees as conduits for conveying information to the public, and using the storytelling traditions of the indigenous people to communicate environmental restoration information.

As a result of the information received during the interviews, ER Project staff made an effort to visit different organizations in the northern New Mexico communities. ER Project staff visited with service organizations such as the Kiwanis and Rotary Clubs, as well as culturally diverse organizations such as Cultura del Norte and the Espaola Women's Library Club. During these visits, ER Project staff asked for volunteers to help form a committee to address issues of particular concern to the ER Project, such as site ranking, cleanup methods, and budget reductions. A number of people were very receptive to working on a committee with ER Project staff (fourteen people volunteered).

The ER Project is presently establishing a committee consisting of volunteers from the northern New Mexico community; this committee will help the ER Project make recommendations on a variety of environmental issues. These volunteers will familiarize themselves with the Laboratory, the ER Project, and its various potential release sites. The committee will have a representative voice in how these issues will be addressed.

Taking into consideration both positive and negative comments, three factors have facilitated public involvement in environmental restoration at the Laboratory. First, because the communities generally believe that the Laboratory is important to the economic well-being of northern New Mexico, they are willing to work toward solutions with the Laboratory. Second, there is considerable trust in the integrity and ability of the individuals working in the ER Project. And third, the communities believe the Laboratory has the technological ability to address cleanup issues.

Because the ER Project has changed its public involvement activities to accommodate the desires of the public, the Laboratory has gained more credibility with a far broader section of the public and not just public interest groups. In addition, ER Project staff have established many personal contacts with individuals, thereby resulting in a group of volunteers willing to spend the time and effort to work with the ER Project on a variety of environmental issues.

APPLICATION OF RISK-BASED CORRECTIVE ACTION TECHNIQUES FOR ENVIRONMENTAL RESTORATION PROJECTS AT DEPARTMENT OF ENERGY (DOE) REMEDIATION SITES

Terry A. Kuykendall

Parsons Engineering Science, Inc.

ABSTRACT

The nuclear technology community has struggled for years with the concept of "how clean is clean?", and how to approach the decontamination, decommissioning, cleanup, and release to the public of radiologically contaminated facilities and lands formerly used to support the national defense mission. Astronomical cost estimates for remediation efforts have refocused the evaluation of these programs to consider the issue of "how clean is clean enough"? Compliance to established performance-based environmental standards presents an undue burden on the national cleanup budget, since it is not practical or necessary that properties be restored to the same standard (dependant upon projected future use). An alternative to compliance with predetermined regulatory standards is the implementation and utilization of a site-specific risk-based corrective action (RBCA) process.

The concept of utilization of a risk-based approach to establishment of remediation goals has been developed primarily for RCRA sites contaminated with petrochemical contamination (e.g., ASTM Emergency Standard ES 38-94). Parsons has been instrumental in assisting a number of DOE sites in developing a basis for utilization of an analogous approach for cleanup of radiological contamination. In the event of soils and groundwater cleanup, this approach can result in progressive remediation efforts that maintain realistic health and environmental protection goals. This process can be a functional element of DOE programs involving a streamlined approach for environmental restoration (SAFER).

Risk-based decision making is used to help determine the appropriate type and level of corrective action. Based on the principles of protection of human health and the environment commensurate with actual risks (rather than strict compliance with assigned performance-based goals), and expedites corrective action in a cost-effective manner. The basis for the Parsons approach to RBCA programs integrates the framework established by ASTM, including the provisional standards for cleanup developed by the Voluntary Cleanup Task Group.

There are a number of computer-based tools and models that may be utilized to assist in defining the requirements for RBCAs at DOE sites. Computer codes such as RESRAD and GENII, modifications in hydrological and geohydrological models, and modeling computer systems such as ERMA/GIS have been utilized by Parsons and have been instrumental in preparing defensible RBCAs.

The concept of RBCA for radiologically contaminated sites could be very important in view of recent rulemaking efforts within the nuclear technology community. For example, rulemaking efforts by the Nuclear Regulatory Commission (e.g., 10 CFR 20.1400 and NUREG-1500) are being promulgated to define free release criteria for nuclear facilities and related properties. These rulemaking efforts are being conducted to provide codification of radiological criteria for site cleanup, which will allow the NRC to more efficiently carry out the functions of public health protection and environmental protection by more efficient use of resources. The intent is to allow consistent application of standards across all types of licenses and to provide a predictable basis for cleanup activities. The implementation of a uniform RBCA process to support attendant risks for site remediation would be a key step in moving forward with these goals.

BACKGROUND AND OVERVIEW

With changing congressional directives and limited funding to be allocated for environmental, safety, and health protection programs, it is more imperative that ever that governmental and industrial organizations optimize remediation and prevention budgets. In order to address the most pressing concerns, it is necessary to develop a method of ranking and/or prioritizing actions such as site remediation. A risk-based approach to site remediation is a means of ensuring that the remediation problems that are of the highest concern receive the highest priority for action.

The impetus for environmental and human health protection risk assessments may be traced to the enactment of the National Environmental Policy Act (NEPA) of 1969, which mandated the requirements for analysis of environmental impacts for major federal actions affecting the quality of the human environment. Risk analysis has developed into a major tool for identifying and quantifying hazards and the associated consequences of federal and industrial activities.

The proliferation of federal laws and regulations to protect public health and safety and to provide for the protection of the environment has generated rapid growth in risk management activities in numerous and diverse fields of applications, such as occupational safety, toxicology, industrial hygiene, nuclear safety, environmental impact assessment, engineering/reliability studies, weather prediction, epidemiology, and the social and behavioral sciences.

The science of risk analysis is a discipline that has received a great deal of attention in recent years. The body of science associated with risk has been subdivided into many interrelated (and sometimes interchangeable) components such as risk analysis, risk assessment, risk evaluation, and risk management; however, the general topics of risk analysis and management may be used to address all of the subdivisions associated with risk measurement and management. All of these concepts are integral to the development of technical bases for RBCAs.

THE ASTM STANDARD FOR RBCA

An ASTM standard has been established for petroleum release sites that can be adapted as a basis for RBCA at DOE locations. ASTM ES 38-94, entitled "Emergency Standard Guide for Risk-Based Corrective Action Applied at Petroleum Sites", promotes a three-tiered approach to risk and exposure assessment, where successive tiers require more rigorous analytical treatment and more detailed data collection and validation. This approach involves:

Tier 1 -- Qualitative risk assessment that is based on general site assessment information. The data at this level of quality should identify obvious environmental impacts (if any), potentially affected and sensitive receptors, and significant exposure pathways. Information should be sufficient to categorize sites and to determine acceptable time periods for implementation and completion of necessary corrective actions.

Tier 2 -- Requires collection and validation of more site-specific data in order to determine appropriate risk-based actions. At this higher level of analysis, the reasonable maximum impacts of the contaminants on a site are evaluated by used o site-specific characterization and monitoring data, conservative projections of expected contaminant levels after treatment and potential plume migration, and reasonable maximum exposure scenarios. This information is used to set conservative

corrective action objectives that are protective of human health and the environment.

Tier 3 -- Focuses entirely on assessment of site-specific conditions and requirements. At this level of analysis, more sophistical statistical/mathematical evaluations of transport, uptake, and fate phenomena may be utilized to generate a range of possible exposures and related risks. Site-specific risk assessment models may be developed.

The goal of the tiered approach is to achieve the appropriate level of detail and rigor of analysis that will ensure protection of human health and the environment. The advantage of this technique is that, in moving from lower to higher tiers, corrective actions can be rendered more cost-effective and efficient since the conservative assumptions of lower tiers are replaced with more accurate and realistic analyses that involve site-specific assumptions. The ASTM three-tiered approach can be adapted easily to accommodate the multitude of DOE site remediation problems, and can be evolved by each site to manage corrective actions and to facilitate the decision-making process.

BASES FOR RISK ASSESSMENT

Risk assessment is the body of technology that utilizes qualitative and quantitative analysis as methods of defining the risks associated with actions or activities, and planning for the consequences of these risks. The risk analysis can serve a variety of risk management purposes; for example, it can provide input to decision makers to:

Determine safety, environmental, and health concerns associated with specific activities and substances (e.g., hazardous waste disposal, radiological exposure, or the use of industrial chemicals); Compare new and existing technologies or determine the effectiveness of controls and mitigation techniques designed to reduce risks;

Select sites for potentially hazardous facilities and/or operations; or

Establish management priorities, such as which of several activities should be considered first for regulatory or corrective action.

As such, the risk analysis and management process can be an important factor in the routine management of operations or activities, in the establishment of criteria for abnormal or accident situations, and in the estimation of costs and related benefits for a proposed action.

METHODS OF RISK ANALYSIS

Risk analyses encompass all aspects of a safety/risk assessment, including accident scenario formulation, initiating event identification, the probabilistic risk of failures of components and systems that are intended to contain hazardous, explosive, nuclear, or chemical materials, the risk associated with fires in areas containing high explosives, and the risk to facilities from seismic events and tornados. For the formulation of RBCAs for site remediation, the predominant concerns are release, mobilization, transport, exposure, uptake, and ultimate fate of hazardous, toxic, and/or radiological contaminants.

Risk analysis/assessment is used to estimate future losses and the effectiveness of additional controls in order to provide management with information to make sound decisions regarding hazards and dangers associated with risks. Risk analysis can provide or permit:

Probability estimates of large or catastrophic accidents/events;

Summation of loss estimates (e.g., actuarial predictions) to provide a more complete risk estimate;

Cost-effective safety programs, by concentrating on high risk areas;

Optimization of the combined cost of safety programs and the cost of accidents which are present at a given level of control;

Evaluation of the effects of codes, standards, orders, directives, and regulations;

Consideration of various types of risk on a consistent basis.

The science of risk analyses encompasses analytical applications (e.g., design basis accident analysis and evaluations pertinent to applicable modeling codes). These analytical applications are to be complemented by reliability analysis and risk assessment/analysis methodologies applied to a range of release/accident conditions. Risk analyses are used in safety analyses to provide insight into those aspect of design and operational characteristics that are vulnerable to potential accident (particularly risk-dominant sequences).

Qualitative Risk Analysis

Qualitative risk analysis is used when the information available on a process/systems under consideration is inadequate to provide a numerical basis for quantitative risk calculation, or when the requirements for risk analysis are to provide an idea of the types or risks involved rather than the quantities of the related hazards. In many cases qualitative analysis is used as a precursor (the first step) to a quantitative evaluation.

If the qualitative analysis indicates that the nature of the risk is not of a type or source that would generate unacceptable accident consequences, further analysis may not be required. In this manner the qualitative risk analysis may serve as a screening method for risk management programs.

Qualitative risk analyses would be applied most often to Tier 1 RBCAs, but may apply to more simple projects at the Tier 2 level.

Quantitative Risk Analysis

Quantitative risk analysis methods are utilized when the assignment requires that the risks associated with a remedial action (or other process under scrutiny) are to be numerically specified based on information available or that must be gathered. Utilizing experienced safety analysts and sophisticated computer codes such as HAZARD-I, IRRAS, and IMPORTANCE, the knowledgeable risk analyst can reduce laborious numerical manipulations to efficient, workable tasks.

The approach to the quantification of risk is determined by the desired results of the evaluation and the information that is available. There are a wide spectrum of analytical techniques; types of basic quantitative risk analysis and projection methods include:

Gaussian Normal Projection
Subjective Risk Analysis
Log-Log Distribution of Frequency/Severity
Survey Methods
Log-Normal Distribution of Accident Data
Insurance Risk Analysis
Extreme Value Projection
Life Shortening Effects Time-Loss Analysis
Trend Analysis
Actuarial Risk Assessment

Quantitative risk analysis involves the quantification of the expected or probable loss per unit time or unit of activity and is equal to the probability of loss multiplied by the magnitude of the loss. For any operation, the risk is the sum of the individual risks for each potential

loss. Since there may be an infinite number of both probabilities and consequences for a given risk/accident scenario, an accurate quantification of risk requires consideration of the entire accident cost-frequency spectrum. In quantitative terms, risk is expressed in values ranging from zero (representing the certainty that no harm/accident will occur) to one (representing the certainty that harm/accident will occur). As an example, a risk expression of 10-6 or E-6 (as expressed in the U.S. Environmental Protection Agency IRIS database) equates to a risk of one chance in one million of harm or accident.

Quantitative risk assessment methods for complex site remediation projects might be most aptly applied at the Tier 2 or Tier 3 levels of RBCA.

Probabilistic Risk Assessment

Probabilistic risk assessment (PRA) techniques represent the most sophisticated types of hazard and risk analysis. These analysis methods have been implemented and verified by the commercial nuclear industry for complex accident scenarios involving release of nuclear materials. These techniques must meet extremely stringent requirements for the evaluation of nuclear and non-nuclear facilities compliant with U.S. Nuclear Regulatory Commission requirements. The basic PRA process involves the development of a set of possible accident sequences and the determination of their outcome. In support of this process, sets of models are developed and analyzed.

The development of sequences for the PRA generally can be divided into two sets of models: those relating to operating systems (such as waste management facilities or contamination control systems) and those relating to the containment of these systems. Models for these analyses usually consist of event trees, which depict initiating events and combinations of system successes and failures, and fault trees, which depict ways in which the system failures represented in the event tree can occur. These models are analyzed to assess the frequency of each release or accident sequence. For very complex analyses, the fault and event tree methods may be combined for both a `top-down' and `bottoms-up' analysis. The CAFTA and IRRAS computer codes typically are used to develop and evaluate event/fault tree models.

The containment models represent the events occurring after the accident but before the release of radioactive or hazardous material from containment. These models cover the physical processes induced in the containment by each accident sequence as well as the transport and deposition of materials released within containment. The analysis examines the response of the containment to these processes, including possible failure modes, and evaluates the releases of hazardous materials to the environment.

The outcome of the accident in terms of public health effects and economic losses may be assessed by the use of environmental transport and consequence models. These models use site-specific meteorological, hydrologic, topographic, and geologic data to assess the transport of hazardous materials from the site. Local demographic and health effects models are used to calculate the consequences to the surrounding population.

An integral part of the approach to PRA is uncertainty analysis. This involves not only uncertainties in the data but also uncertainties arising from modeling assumptions. The results of the risk assessments

are analyzed and interpreted to identify the plant/facility features that are the most significant contributors to risk. Numerical manipulation and prediction models such as CRYSTALBALL and APIDSS may be used to manage intricate calculations.

Throughout the analysis, it is important to use realistic assumptions and criteria. When information is lacking or controversy exists, it may be necessary to introduce conservatism or evaluate bounds. The goal for a PRA is to produce as realistic an analysis as possible.

Although PRAs typically have been conducted for nuclear safety evaluations, recent efforts have been established to apply this methodology to environmental restoration actions. A standard guide for probabilistic risk assessment is being developed by the ASTM Committee E-47 on Biological Effects and Environmental Fate. The guide will be prepared to assist risk analysts by providing an approach for developing and using probabilistic estimates of risks due to exposure to chemical and non-chemical stressors at contaminated sites. As stated in this guidance, PRAs use simulation techniques to generate probable ranges of risks and their likelihood of occurrence, providing more information to the analyst than standard point estimates of risk.

PRAs would be used most effectively in the Tier 3 level of RBCAs for complex sites involving multiple contaminants and multiple release pathways.

ENVIRONMENTAL RISK

When applying the RBCA method to a DOE site remediation project, it becomes important to assess (in an integral manner) the risks to air, land, water resources, and fish and wildlife resources. For this reason, analyses of environmental effects may be conducted in support of environmental risk analyses. Assessments of effects to the biota in the environment require information/data such as:

- Concentrations of specific radionuclides;
- Probable sources and the pathways or the movement of the radionuclides;
- Potential target species which may be harmed; and
- Toxicity/dose data for the pertinent species.

In some instances standards may be established that can provide the basis for evaluation of effects to the environment. However, for certain radionuclides, specific environmental standards may not exist. In these cases it is necessary to define evaluation criteria from various sources, such as toxicity or health physics data. The risk analyst may utilize computer codes such as GENII-S, EXREM-III, PAVAN, AIRDOS, and MESODIF to analyze the activities and pathways of radionuclides in the environment.

Human/environmental risk assessments for RBCAs at DOE sites are conducted in accordance with applicable EPA requirements and DOE Orders. Under the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), risk assessments are to be conducted based on the requirements defined in EPA/540/1-89/002, "Risk Assessment Guidance for Superfund, Volume 1, Human Health Evaluation Manual Part A," and EPA/540/1-89/001, "Risk Assessment for Superfund, Volume 2, Environmental Evaluation Manual (Interim Final)." DOE Order 5400.4 specifies that human/environmental risk assessments be conducted in accordance with the CERCLA requirements. DOE Order 5400.5 entitled "Radiation Protection of the Public and Environment" is used to establish allowable risk levels from radionuclide contaminants.

The typical approach to human health and environmental risk assessments is twofold, and requires:

Establishment of a baseline risk
Assessment of future risks based on predictive modeling.

The baseline assessment is designed to evaluate potential threats to human health and the environment. The analysis requires an understanding of the nature of chemical and radionuclide release from the site and method of transport, the potential pathways for human and wildlife exposure, and a quantification of the potential threat from the exposure. In general, there are four steps are performed to determine the baseline risks: 1) data evaluation; 2) exposure assessment; 3) toxicity assessment; and 4) risk characterization

The first step in the baseline evaluation is to collect analytical data from relevant media (air, surface water, groundwater, soil) and to evaluate its suitability for use in a risk assessment. Tentatively Identified Compounds are identified and evaluated to determine those constituents that are potential threats to human health and the environment.

The second step identifies potential human and environmental receptors and exposure points associated with the site. The potential pathways for exposure are determined. These are called exposure scenarios, that identify how the receptor becomes exposed (eating, drinking, breathing, dermal exposure to contaminants, etc.) Chemical releases from the site are estimated and environmental fate and transport are modeled as required to estimate exposure levels via air, groundwater, surface water, and soils. Chemical intakes are then estimated from the exposure scenarios. The third step involves the performance of a toxicity assessment, hazard identification, and dose-response assessment. Reference doses and slope factors are identified for systemic toxicants and carcinogens, respectively. This information is obtained from EPA approved data bases such as the IRIS or the HEAST. Toxicity values for specific constituents may also be identified in the scientific literature.

The final step compares calculated intakes to acceptable intakes for noncarcinogens, and compares calculated risks to target risks for potential carcinogens. The comparisons determine whether the site or facility presents an adverse human health or environmental risk.

Future risks are assessed by utilizing computer models which predict future chemical and radionuclide concentrations that can be evaluated through the toxicity assessment and risk characterization. Analysts may employ ground water flow and transport models such as the U.S. Geological Society approved method of characteristics (MOC) model to predict the flow and concentrations of contaminants in ground water. Models such as MODFLOW, MODPATH, QUAL2E, MT3D, SWIFT, PTC, QUICKFLOW or many others may be used to model chemical transport in streams and rivers. VADOSE may be utilized to model the subsurface unsaturated zone.

A number of models are useful for calculating radiological site contamination, doses, releases, dispersion, and effects; these models are especially useful when evaluating radioactively-contaminated DOE sites. Some of the most commonly-used models include RESRAD, SKYSHINE (and MICROSKYSHINE), PAVAN, GENII-S, PART 61, AIRDOS (and MICROAIRDOS), HOTSPOT, EXREM, and ALLDOS.

SITE CLASSIFICATION

Once the analytical portion of an RBCA has been performed, it is necessary to classify the site according to the required actions. A typical site classification scheme may involve the following four levels,

based on the calculated threat to human health, safety or sensitive environmental receptors:

Class 1 -- Immediate threat
Class 2 -- Short-term (0-2 years) threat
Class 3 -- Long-term (>2 years) threat
Class 4 -- No demonstratable long-term threat

These classes may be utilized in general for all types of human health and environmental threats, including combined and cumulative effects of radiological and hazardous contaminants.

SUMMARY

The application of RBCA techniques are becoming increasingly important to DOE environmental professionals. The complex task of estimating specific risk and cleanup levels requires the estimation of a number of input parameters, including those which are:

Media-specific (e.g., hydraulic conductivity, radionuclide content, wind speed, etc.);

Contaminant specific (e.g., decay rate, toxicity, mobility, etc.);

Receptor-specific (e.g., body weight, metabolism, ingestion rate, etc.); and

Landuse-specific (e.g., restricted use, unrestricted use, etc.).

These inputs are typically variable and uncertain; they are best represented by probability distributions. In applying a graded, tiered approach to RBCA, the risk analyst can apply uncertainty propagation techniques to quantify the uncertainty in the estimated risk, and utilize this information to prioritize risks, optimize usage of limited funding, and utilize information to make effective decisions.

SITING AN ONSITE WASTE MANAGEMENT
FACILITY AT ROCKY FLATS ENVIRONMENTAL TECHNOLOGY SITE

ABSTRACT

The Rocky Flats Environmental Technology Site (Site) has initiated a project to permit, design, construct and operate an onsite Waste Management Facility (WMF) with a capacity to receive 100,000 to 400,000 cubic yards of low-level radioactive and/or hazardous waste. The function of the WMF is to provide a repository for the remediation waste generated from Environmental Restoration risk reduction activities and Deactivating and Decommissioning activities at the Site. The WMF would potentially receive remedial waste from closure activities starting in calendar year 1996. Planned remedial actions require that a viable remediation waste management facility be operational prior to any removal actions, to eliminate additional interim waste storage concerns.

The objective of the WMF study is to select the best site and design alternative for the management of remediation waste. After viable design alternatives were developed, they were evaluated using a three-phased screening process. The first phase of the project evaluated onsite vs offsite options. The second phase evaluated onsite locations based on specific siting criteria and the third phase involved a comparison of onsite design alternatives.

This presentation focuses on the second phase of the study, the onsite selection process. In each of the first two phases, the best alternative was selected and used as a basis for the next phase. Selection criteria reflected the project objectives, siting and Corrective Action Management Unit (CAMU) criteria as well as the Interim Measure/Interim Remedial Action (IM/IRA) process. Consideration was also given to the National Environmental Policy Act (NEPA) throughout the decision process. Based on the three phases of the evaluation, the best approach was determined to be an above grade Concrete Lined Cell (CLC) designated as a CAMU and located in the eastern portion of the Protective Area near Operable Unit (OU) 4, the Solar Ponds. The CAMU cell will be designed with a geosynthetic and clay liner system which will comply with the Resource Conservation and Recovery Act (RCRA) Subtitle "C" requirements as defined in Code of Colorado Regulations (CCR) 6CCR 1007-3, Part 264 and 6 CCR 1007-2, Part 2. A leachate collection system will provide further protection between the two liners. Upon closure of the cell, an impermeable cap will be placed on the CAMU and the site will undergo post closure monitoring.

INTRODUCTION

The necessity to reduce overall risk at the Rocky Flats Environmental Technology Site (Site) dictates the need to design and construct an onsite Waste Management Facility (WMF) as a designated Corrective Action Management Unit (CAMU). The function of the WMF is to provide a repository for the remediation waste generated from Environmental

Restoration risk reduction activities and Deactivating and Decommissioning activities at the Site. The WMF will have to receive remedial waste from closure activities which are starting in 1996. Planned remedial actions require a viable remediation waste management system be operational prior to any removal actions, to eliminate additional interim waste storage concerns.

This presentation focuses on the second stage of the study, the onsite selection process. In each of the first two phases, the best alternative was selected and used as a basis for the next phase. Selection criteria reflected the project objectives, siting and Corrective Action Management Unit (CAMU) criteria as well as the Interim Measure/Interim Remedial Action (IM/IRA) process. Consideration was also given to the National Environmental Policy Act (NEPA) throughout the decision process.

SITE DESCRIPTION AND BACKGROUND

The Site is located in northern Jefferson County, Colorado approximately 16 miles northwest of Denver. Other surrounding communities include Boulder, Westminster, and Arvada, all of which are located less than 10 miles to the northwest, east, and southeast of the Site, respectively. The Site consists of approximately 6,550 acres of federal land in sections 1 through 9 and 15 of T2S, R70W, 6th Principal Meridian. Most Site structures are located within a protected central area, referred to as the Industrial Area (IA) of approximately 400 acres, and surrounded by a buffer zone of approximately 6,150 acres.

The majority of residential use within five miles of the Site is to the northeast, east and southeast. Commercial development is concentrated near residential developments north and southwest of Standley Lake as well as around Jefferson County Airport, approximately three miles northeast of the Site. Industrial land use within five miles of the Site is limited to quarrying and mining operations. Open space lands are located northeast of the Site near the City of Broomfield and in small parcels adjoining major drainages and small neighborhood parks in the surrounding communities. Irrigated and non-irrigated croplands, producing primarily wheat and barley, are located north and northeast of the Site and in scattered parcels adjacent to the eastern boundary. Future land use in the vicinity of the Site most likely includes continued urban expansion, increasing the density of residential, commercial and perhaps industrial land use in the area.

The operations at the Site consisted of fabrication of nuclear weapon components from plutonium, uranium, and non-radioactive metals (principally beryllium and stainless steel). Fabrication operations were terminated and the plant was placed in shut-down mode in 1991. These operations resulted in liquid and solid wastes containing hazardous and radioactive constituents that were managed at waste processing units across the plant. Parts made at the plant were shipped elsewhere for assembly. In addition, the plant reprocessed components after they were removed from obsolete weapons for plutonium recovery. Both radioactive and non-radioactive wastes were generated in the production process. Current waste handling practices involve onsite and offsite recycling of hazardous materials, onsite storage of hazardous and radioactive mixed wastes, and offsite disposal of Low Level Waste (solid radioactive materials) at the Nevada Test Site and Low Level Mixed-Waste (LLMW) at the Envirocare facility in Utah. However, Site operations historically included both onsite storage and disposal of hazardous waste, LLW and LLMW.

PHASE 1 - OFFSITE VS ONSITE EVALUATION

The purpose of Phase I of the project was to select the best disposal option for environmental remediation waste originating at the Site. The three options are:

Onsite disposal
Offsite disposal, or
the No Action Alternative.

This selection process is part of the decision making process for an Interim Measure/Interim Response Action (IM/IRA) to address remediation waste, and the intent is to reflect the current waste and environmental strategies and to be consistent with input from the stakeholders. Onsite disposal was selected as the best of the three options. The selection of onsite disposal was based on the following:

Projected costs for onsite disposal are significantly lower than for offsite disposal, Because of the lower cost, there would be more risk reduction activities accomplished in support of the Accelerated Site Action Project (ASAP) and the Rocky Flats Conceptual Vision (the Vision),

There would be less public exposure (human health risk) during transportation, along with less involuntary risk,

Less risk of spills in handling and transportation,

Greater capacity for onsite disposal compared to offsite disposal. An onsite facility would be more accessible and more available when needed,

Fewer schedule restrictions for an onsite facility, and

Fewer analytical requirements for an onsite facility because there is less redundancy in sampling requirements.

Ultimately, the most important difference between the onsite and offsite options is total cost and the effects of cost for reducing risk at the Site. In essence, the more it costs to dispose of a cubic yard of contaminated material, the fewer cubic yards of material the Environmental Restoration (ER) program would be able to clean up in a given time frame. This prolongs the cleanup efforts at the Site and allows contaminated materials to remain uncontrolled for much longer periods of time. In turn, this increases overall risk at the Site to human health including the offsite population, the onsite workers, and the environment.

As part of the evaluation, it was necessary to select the waste management option that could best reduce the overall risk to human health and the environment while remaining fiscally responsible. Budget restraints affect the degree of risk reduction possible. Because of lower costs, the onsite option is clearly the selection for reducing the overall risk to both the public and the environment.

With a given budget to perform work onsite, more cleanup actions can be performed more effectively, and therefore, the Site can be made safer with onsite disposal.

PHASE 2- ONSITE WASTE MANAGEMENT FACILITY SITING EVALUATION

As onsite disposal became a viable alternative for waste management at the Site, Phase 2 of the project commenced. The objective of Phase 2, the Siting Evaluation, was to: 1) identify and rank criteria to be used for WMF site selection, 2) develop a methodology for comparative analysis of the different sites and then 3) select a site or sites that would be a suitable location for a WMF within the boundaries of the Site.

This site would be a location for a WMF that would accept remediation wastes with low-level radioactive and/or hazardous constituents, but not preclude the shipment of remediation waste that can be more effectively

and economically managed offsite. The facility would be designed and constructed to meet all the applicable federal, state and local regulatory requirements.

Waste streams would include, but not be limited to:

Contaminated soil and debris collected from accelerated actions and hot spot removals,

Asphaltic materials and pondcrete (solidified sludge from the solar ponds),

Pond sludge,

Sediments from onsite ponds,

Toxic Substance Control Act (TSCA) waste such as asbestos and polychlorinated biphenyls (PCBs),

Treatment by-products from groundwater, surface water, and/or soil remediation actions,

Investigation-Derived Materials (IDM) generated during remedial investigations at the Site not suitable for disposal at the onsite sanitary landfill,

Debris from deactivation and decommissioning activities

Identification and Ranking of Siting Criteria

A number of categories of criteria were considered in developing the siting criteria. It was agreed that the criteria had to include at a minimum Applicable or Relevant and Appropriate Requirements (ARARs) as well as general guidelines that had been discussed with the various stakeholders meetings regarding a WMF at the Site. The criteria were then placed into six major categories and further divided into specific issues within each of these major categories, as outlined below:

Ability to designate the WMF as a Corrective Action Management Unit (CAMU). Key points of the CAMU Rule include:

- The CAMU should facilitate the implementation of reliable, effective , protective, and cost-effective remedies,
- Associated waste management activities shall not create unacceptable risks to humans or the environment resulting from exposures to hazardous waste or hazardous constituents,
- The CAMU should not include uncontaminated areas of the facility unless the inclusion of such areas is more protective than management of wastes at contaminated areas of the facility,
- Areas within the CAMU where remediation waste will remain in place after closure should be managed to control, minimize, or eliminate future releases to the extent necessary to protect human health and the environment,
- The CAMU should expedite the timing of remedial activity implementation when appropriate and practicable,
- When appropriate treatment technologies should be used that enhance long-term effectiveness of remedial actions by reducing the toxicity, mobility or volume of waste that will remain in place after closure of the CAMU

Ensure the Protection of the Public, per Code of Colorado Regulations (CCR) 6 CCR 1007-2 Part 2, which is the Requirements for Siting of a Hazardous Waste Disposal Site. Key points include:

- Geological and hydro-geological conditions of a site in which hazardous waste is to be disposed of should be such that reasonable assurance is provided that the wastes are isolated within the disposal area and away from pathways to the public for 1,000 years,

- Structural related issues evaluated will include slope and geo-technical stability,
- The immediate area of the site should be in an strata of minimal ground water flow,
- Geological strata combined with engineered barriers should provide a minimum permeability of 10-7 cm/sec or there should be sufficient thickness and distance between the disposal location and nearest usable aquifer to isolate any materials that are disposed of in the facility,
- Consideration should be given to the relative depth to bedrock and ground water, including seasonal fluctuations for ground water,
- The relative distance to the nearest discharge area shall include consideration of ground water flow direction and travel time

Issues that are Specific to the Site and support the Rocky Flats Conceptual Site Vision (the Vision). Key points evaluated include:

- The ability to support the Site Vision,
- The impacts from existing utilities, sewer lines, process waste lines and communication lines if the selected WMF site is with the Industrialized Area

Cost Criteria. Key points evaluated include:

- Cost of pre construction activities, including building demolition, subsurface utility line removal and rerouting, access requirements and power/facility requirements,
- Cost of engineering and construction of protective measures

Regulatory Support focusing on using State principles for onsite management of contaminated materials. Key points evaluated include:

- Minimization of the number of disposal sites and of consolidation of contaminated materials,
- Site a centralized disposal facility in an area of optimum geologic parameters preferable within or close to the Industrial Area,
- Any WMF should be located in an area having limited future land use potential and would be controlled by DOE until the interred waste no longer presents a risk to human health or the environment

Other Stakeholders concerns which included:

- General public perception and acceptance,
- Municipal or County acceptance,
- Department of Energy (DOE) Orders,
- The National Environmental Policy Act (NEPA)

Methodology for Comparative Analysis of the Onsite Locations

A basic assumption was that the entire Site, both within the buffer zone and the Industrial Area would be included in the siting evaluation. A series of maps were produced to assist in this evaluation. These maps included:

A Site Location Map showing the location of building, roads and other plant infrastructure,

A map showing hydrologic conditions including the depth to water table and the area encompassed by the 100-year floodplain,

A map showing the geological and geo-technical conditions including inferred faults traces, and areas with greater than 15% slope,

Alluvial thickness map, showing the thickness of the alluvium, and by inference potentially economic thickness of gravel,

A Ecology and NEPA map showing the location of seeps, wetlands and the Preble's Meadow Jumping Mouse (PMJM) probable habitat. PMJM is a wildlife species that is being considered for listing as a species of concern, or as a threatened and endangered species

The different elements from these maps were combined onto one map called the Adverse (for WMF siting) Conditions map. Areas highlighted on this map contained one or more conditions that would be major obstacles in siting a WMF and thus were removed from further consideration in the evaluation. In the Industrial Area, areas with minor existing buildings were kept in the study.

This initial screening of the Site reduced the number of locations being evaluated to seven, four in the buffer zone and three in the Industrial Area.

Industrial Area sites include:

Industrial Area - West (IA-W), an area on the west side of the Industrial Area,

Industrial Area - East (IA-E), an area on the east side of the Industrial Area, and

Solar Ponds - an area adjacent and east of the Solar Pond in the northeast section of the Industrial area.

The buffer zone sites are:

The New Sanitary Landfill (NSL),

An area within Operable Unit 2 (OU2),

An area in the southeast quadrant (SE Quad) of the buffer zone, and

An area in the southwest quadrant (SW Quad) of the buffer zone.

The methodology that was then applied first began by developing a relative weighting factor (%) for each of the six general categories of criteria as shown in Table I.

Table I

Next, each category was divided into specific issues. There are a total of 38 separate and distinct issues in the six categories (Table II). Each of the issues was subjectively assigned a value between 1 and 3, with a 3 being a more important issue and 1 being less important. As an example, for Category 2, Public Protection, the first issue is geological and hydro-geological conditions of a site in which hazardous waste is to be disposed of should be such that reasonable assurance is provided that the wastes are isolated within the disposal area and away from pathways to the public for 1,000 years. The second issue is structural related issues would include slope and geo-technical stability.

Table II

In this instance the first criteria was subjectively assigned a value of 3 because it was decided that issue was a more important issue then the second issue relating to slope stability which was assigned a value of 2. The next step in this methodology was to develop a matrix form with the 7 location versus the 38 criteria. The 38 criteria were then compared to the 7 sites (Table III). The sites were evaluated against the criteria and relative to one another. Each issue was assigned a score between 0 and 1. A score of 0 for any of the 38 issues would signify a fatal flaw and the site would be withdrawn from further consideration in the siting evaluation.

Table III

A weighted average was arrived at for each of the categories and the values were summed. The results of the evaluation are shown on the following table.

Overall, the Solar Ponds, the site adjacent and to the east of the Solar Ponds, ranked highest with a score of 68.5%, followed by the IA-West site (67.1%), and the NSL (65.1%) as the location to site the WMF. The Solar Ponds site was then carried on to the third phase of the evaluation.

PHASE 3 - COMPARISON OF ONSITE DESIGN OPTIONS

This third phase of the project was to select and evaluate different design options for an onsite WMF. The following design concepts were considered:

- Pyramid Design
- Butler Building
- Slab on Grade
- Hardened Concrete Vault
- Above Grade Concrete Lined Cell (CLC) with Bulk Storage
- Above Grade Concrete Lined Cell with Cargo Containers
- Above Grade Disposal Cell (landfill)
- Entombment
- No-Action

An initial concept design screen using the same criteria as was used in the siting study resulted in the following four final design alternatives selected to be carried on through the final design evaluation.

- Butler Building
- Above Grade Concrete Lined Cell (CLC) with Bulk Storage
- Above Grade Disposal Cell (landfill)
- No-Action

The final design alternative comparison used the following Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) nine criteria to select the best alternative:

- Protection of Human Health and Environment
- Compliance with ARAR's
- Long Term Effectiveness and Performance
- Reduction of Toxicity, Mobility, and Volume through Treatment
- Short Term Effectiveness
- Implementability
- Cost
- Regulatory Agency Approval
- Community acceptance

The above grade Concrete Lined Cell (CLC) was selected as the best alternative as the WMF several reasons. The primary reason is the high cost of fill material which must be imported to the site to provide the berms or side support for the waste. The use of concrete walls substantially reduces the amount of back fill material and the cost of the facility. The CLC adds another layer of protectiveness (the concrete walls and floor) to ground water from the leachate generated during operations. The CLC would be built to be compliant with RCRA Subtitle "C" standards. The above grade construction prevents ground water infiltration. The liners and leachate collection system provides the ability to detect leaks and recover contaminated leachate prior to entering the environment.

Also, this design allows for modular installation which would optimize the sizing of the cell and timing of the installation as waste is generated. This design will speed up risk reduction activities under the Site Vision because the facility can be built in sections. The first module of the 100,000 cubic yard facility would be sized for 25,000 to 33,000 cubic yards and could be installed quicker in order to handle remedial waste ready for disposition early on. Even though the design offers the benefits of a permanent facility, it still allows for retrievability. This yields the additional flexibility of being able to utilize the facility as either storage or closure as a CAMU at any time.

Even though it was one of the most versatile, protective and reliable designs, it was also the most cost effective.
The Above Grade Disposal Cell is a standard waste landfill, compliant with RCRA Subtitle "C" standards. This facility would be built above the existing grade to prevent ground water infiltration. Like CLC, the liners and leachate collection system provides the ability to detect leaks and recover contaminated leachate prior to entering the environment. This facility offered some degree of flexibility and retrievability and still remains one of the least expensive alternatives.
The Butler Building alternative was selected for the final screening because it allowed for storage of the waste until the final disposition is determined. The waste would be stored in monitored cargo containers and would be retrievable. It is believed that public acceptance would be greater for this alternative despite the tremendous cost, lack of useful life, and reduced protection to the environment.
The No-Action alternative was included in the final screening because it must go through the entire screening process as required by NEPA.

DETERMINATION OF MECHANICAL AND ISOLATION PERFORMANCE OF GRANITES
A.E. Osmanliolu
ekmece Nuclear Research And Training Center.
P.K. 1 Havaalan 34831 Istanbul
TURKEY
Tel:212.548 4050 ext. 2743
Fax: 212.548 2230
ABSTRACT
In this study, several mechanical and isolation tests are applied on granite samples in laboratory. Cylindrical granite samples, 54mm (NX core size) in diameter are prepared for mechanical tests. 50 mm in diameter samples are prepared for isolation tests. Uniaxial compressive strength, triaxial compressive strength, tensile strength and deformability of granite samples are determined under different thermal loads by using a hydraulic compressive machine. Cohesion and internal friction angle are determined. Thermal load effects on granites are shown in graphs. Thermal loads cause decreasing in mechanical strength of granites and increasing in elasticity. For isolation performance tests, radionuclide transport in granite sample are determined under different heat and pressure by using a test apparatus. Transported radionuclide amounts and activities are shown in graphs.
INTRODUCTION
The geological environment of the repository is a key element in the multi-barrier system approach to nuclear waste isolation (1). Special attention should be given to ensure long term stability and isolation of the repository. Decay heat emitted by the waste following closure of the repository, will effect the mechanical properties of surrounding rock. Small scale effects (microcracks etc.) can occur near to sources of heat in granites.
Radionuclide migrates in host rock with flowing groundwater. Connected pores in rocks have important effect on migration of radionuclide. Temperature of groundwater is increased due to the increasing pore water pressures . For these reasons, radionuclide transport is not only effected by host rock properties but also effected by main medium parameters, such as temperature and pressure (2).

MECHANICAL PROPERTIES

In this study, heat effects on mechanical strength of granites are determined in laboratory. Granite samples are prepared; F= 54 mm (in diameter) and W= 120mm (in width) for uniaxial and triaxial tests, F=54 mm, W= 54mm for tensile strength. Granite samples are heated at different temperatures (24 hours) than covered by wax to conserve their internal parameters and cooled. These samples are tested by hydraulic compression machine according to ISRM (3) suggested test methods. Cohesion and internal friction angle of granite specimen, which are determined by triaxial compressive strength and several properties are shown in Table I.

Table I

Uniaxial compressive and tensile strengths determined after different thermal loads; 20C, 200C, 300C, 400C and 500C. According to thermal loads, Uniaxial compressive strength and tensile strength of granite samples are shown in Fig. 1. Axial deformability of specimen is determined for each thermal loaded samples. Elastisity modules are shown in Fig. 2.

Fig. 1

Fig. 2

ISOLATION TESTS

A special testing equipment (Fig.1) is designed for monitoring radionuclide transport in granite samples. A stainless steel column is developed for introducing radionuclide solution to the one face of granite. Temperature of the radionuclide solution is increased by heaters. Heat is applied externally on the stainless steel column by two heaters. Heater surrounds radionuclide transfer column. Heaters are controlled by relay and switches on the control panel. Temperature is measured by a thermocouple near the contact zone of granite and radionuclide solution. Pressure values are taken by two manometers in different scales which are located on the upper lid. (2)

Upper lid is opened and cylindrical granite sample is emplaced into the bottom of column. Isolation, between the cylindrical surface of the sample and column circumference is ensured by isolation material and controlled by the bottom lid. 350 ml. radionuclide solution is poured into column. Both lids are closed tightly. Required temperature is adjusted from control panel. When contact temperature is increased to the required temperature level, sample container for transported solution is located under the discharge hole. After a constant time period, solution that passed through the granite sample is collected in sample container. Volume of this transported solution is determined. And analyzed to determine its activity by gamma spectrometry.

TEST RESULTS

Transported volume against to temperature and pressure, transported activities against to temperature and pressure are shown in Fig. 2. and Fig. 3.

COMBINING REQUIRED TRAINING PROGRAMS FOR MORE EFFICIENT TRAINING

Wilbur Bergquist
Evaluation and Training Specialist
ES&H Training Group
Los Alamos National Laboratory

ABSTRACT

Many DOE workers have similar training requirements imposed by multiple agencies. Refresher training for Treatment, Storage, and Disposal (TSD) Facility workers is one example. Both Subpart B of 40 CFR 264 & 265 (EPA's RCRA regulations) and paragraph (p) of 29 CFR 1910.120 (OSHA's HAZWOPER regulations) require annual re-training. To better serve our workers, LANL's ESH Training Group created an annual refresher program that addresses issues and topics from each of the initial training courses. This paper describes how our course for TSD Facility workers fulfills tha annual training requirements for two regulatory agencies in one eight-hour session.

INTRODUCTION

When rating the efficiency of their training, most participants are influenced both by how applicable the training is to their current job duties and by the amount of time they spend in training sessions. Time spent covering similar information in different courses is usually viewed as non-efficient training. The fact that different regulatory agencies mandate similar training for the same category of workers does not change participants' perspective that attendance at similar, but required, training is non-effective use of their training hours. An example of dual demands on participants' time is the required refresher for workers at Resource Conservation and Recovery Act (RCRA) permitted treatment, storage, and disposal (TSD) facilities. Both the Occupational Safety and Health Administration (OSHA), through 29 CFR 1910.120 (p), and the Environmental Protection Agency (EPA), through 40 CFR 264.16 & 265.16, have imposed annual refresher training for TSD facility workers.

Another case of poor use of training hours is the delivery of identical training to workers performing totally different job duties. For example, 29 CFR 1910.120 (e)(8) and (p)(7) requires annual refresher training for both environmental restoration workers and TSD facility workers. These groups of workers have very dissimilar job assignments and should have refresher training that is specific to their job duties. However, many organizations use the same HAZWOPER refresher training session for both groups of workers.

This paper describes how Los Alamos National Laboratory's (LANL) ES&H Training Group working in conjunction with the Industrial Hygiene and

Safety Group have created separate annual refresher courses that focus on the unique needs of each of these groups of hazardous waste workers.

REGULATORY BACKGROUND

OSHA Requirements

OSHA has recognized that handlers of hazardous wastes face health and safety hazards that workers in other industries do not often encounter. To provide protection for these workers, OHSA issued 29 CFR 1910.120, the HAZWOPER standard in 1989. In this standard OSHA prescribes the length, topics, and frequency of training for three different groups of hazardouswaste workers. Paragraph (e) focuses primarily on general site and occasional site workers engaged in corrective actions or clean-up operations of hazardous waste sites; paragraph (p) prescribes the training requirements for TSD facility workers; and paragraph (q) addresses the training needs for emergency responders to hazardous material releases.

A quick comparison of these three sections reveals that the degree of training required depends upon the potential to be exposed over permissible exposure levels (PELs) to hazardous materials. Paragraph (e) mandates either 40 hours or 24 hours of initial training for restoration workers depending upon how well the hazards at the work site have been characterized. The greater the risks due to unknown conditions, the greater the number of training hours required. The language in paragraph (p) recognizes that the risks at TSD facilities are better characterized, so only 24 hours of initial training is required. The number of training hours required for Paragraph (q) workers depends on the emergency responders' assigned duties. The hours of required training increase as the workers' responsibilities increase. Although all three categories of workers need annual refresher training, the standard specifies that workers covered by paragraph (e) and paragraph (p) receive 8 hours of annual refresher training.

EPA Requirements

Through the passage of the RCRA in 1976, Congress empowered the EPA to regulate the handling, treatment, and disposal of hazardous wastes. Standards for operators of hazardous waste TSD facilities are listed in 40 CFR 264 and 265. Although the EPA does not require a specific number of training hours, sections 264.16 and 265.16 requires training for personnel working at TSD facilities. Paragraph (c) in each of these sections requires that TSD facility workers receive annual refresher training.

COMPARISON OF OVERLAPPING TRAINING REQUIREMENTS

Overlaps Within 29 CFR 1910.120

Paragraph (e)(8) of the HAZWOPER standard states that workers covered by paragraph (e) shall review the topics covered in their initial 40- or 24-hour training during an annual refresher. Thus, refresher training for these workers should review the following topics:

- the health and safety hazards on the site;
- the proper use of personal protection equipment (PPE);
- safe work practices for minimizing risks;
- engineering controls appropriate to the site;
- signs and symptoms of overexposure; and
- any site specific health and safety plans (HASP), including the following topics:
  - hazard analysis of the site,
  - required PPE at the site,
  - required air monitoring,
  - medical surveillance,

- site control measures, decontamination procedures,
- emergency response plan, confined space entry procedures, and
- spill containment program, environmental sampling procedures.

The language in paragraph (p)(7) is not as prescriptive as in paragraph (e)(8). Workers covered by paragraph (p) are required to have annual refresher training that enables them to perform their duties in a safe and healthful manner. An implication of this paragraph is that the annual refresher should review the required programs being implemented by the employer for safe operations at the TSD facility. Thus, refresher training sessions for TSD facility workers should review the following topics:

the health and safety program designed to evaluate and control health and safety hazards on site;
the hazard communication program;
the medical surveillance program;
any new technology currently being used on site;
decontamination procedures;
safe material handling procedures, including drum handling; and
the site emergency response program.

There is potential training overlap on hazard recognition, administrative and engineering controls, proper PPE, and decontamination procedures in these two refresher requirements. However, the less prescriptive requirements for TSD workers allow for very site-specific refresher training sessions. There is minimal overlap between the training required for paragraph (q) workers and paragraph (e) or (p) workers. The training requirements for emergency responders are covered by paragraph (q)(6) of the HAZWOPER standard. The number of required hours for these workers depends on the duties and functions each worker performs. This section of the regulation is very specific on which topics must be addressed, and this is the only section of the HAZWOPER standard that requires an individual worker to demonstrate competency before being certified.

OVERLAPS BETWEEN HAZWOPER AND RCRA

Both OSHA, through paragraph (p) of the HAZWOPER standard, and EPA, through subpart B of 40 CFR 264 and 265, require that TSD facility workers receive annual refresher training. Although OSHA requires 8 hours of refresher training, the EPA does not have specific time requirements. Also, the EPA is not as prescriptive as OSHA on topics that must be covered during the training. The RCRA training goals specify that workers are able to respond effectively to emergencies and that they know how to handle hazardous wastes. Thus, refresher training for TSD facility workers should review the following topics:

the site emergency procedures or contingency plan;
emergency equipment available;
communication and alarm systems;
monitoring equipment;
inspection procedures;
programs designed to control health and safety hazards on site, and
safe material-handling procedures, including drum handling.

There is significant overlap between the HAZWOPER and RCRA refresher training requirements. Both require that TSD facility workers receive training in four key areas:

site-specific emergency response,

administrative and engineering controls for reducing risks due to health and safety hazards,

proper use of PPE for the hazards on site, and

procedures for safe handling of hazardous wastes.

In contrast to OSHA the EPA does not require a specific number of hours, but it does require many of the same refresher training topics. Because of this similarity of required topics, it seems appropriate to fulfill the refresher training requirements for both of these regulatory agencies in one training session. The important issue is regardless of which training topics are required, the training should be appropriate to the participants' job duties.

HAZWOPER REFRESHER COURSES AT LANL

The content for each training course is determined through a needs analysis that includes customer interviews and surveys. Based on the analysis, the ES&H training staff determined that there was enough interest and demand for separate HAZWOPER refresher courses: one course for environmental restoration workers and another one for TSD facility workers. The ES&H training staff did not create any refresher training for emergency responders because LANL has a Hazardous Materials Response Team that is responsible for emergency response training. The Industrial Hygiene and Safety Group provided the subject-matter experts (SMEs) who reviewed the course materials for content accuracy and provided suggestions on appropriate activities.

Each of these courses uses a variety of interactive training activities such as small group discussions, review games, outdoor simulations, and dress-out exercises. The following sections of this paper describe the content of each of these courses and present the similarities and differences of these two courses.

HAZWOPER REFRESHER FOR ENVIRONMENTAL RESTORATION WORKERS

Environmental restoration projects at LANL range in complexity from collecting soil samples using hand augers, to drilling exploratory bore-holes, to total removal of contaminated soils and buildings. The refresher course focuses on the hazards associated with working on thesecharacterization and remediation projects. The five modules of this course are structured around the following objectives:

to identify potential hazards and describe safe work practices that can minimize the risks associated with the hazards;

to describe the impact that any new or modified federal regulations or LANL policies will have on the workers;

to review the required components of a site-specific health and safety plan (HASP);

to review the rights and responsibilities of both the worker and the employer involved in hazardous waste operations;

to have the participants demonstrate their ability to use the information provided in a HASP by completing a simulated field exercise; and

to have participants identify the correct action or response to a given health or safety problem.

In the first module, Risk Minimization and Regulatory Update, participants view several photographs of local work sites and identify any physical, chemical, radiological, or biological hazards at the site. The participants are asked to record in their workbook a description the hazards and to propose some safe work practices that might minimize the risks. This module also provides an update of federal and state

regulations and Laboratory policies. This risk-minimization module and the fourth module (Lessons Learned) are based on current environmental restoration sites or occurrence reports.

The second module, Health and Safety Plans, reviews the required components of a HASP. This module ends with the presentation of the new HASP written for all environmental restoration projects at LANL. Due to the inefficiency of rewriting the complete plan each time a change in the scope of work occurred, the environmental restoration project staff and the Industrial Hygiene and Safety Group developed a two-part HASP. The first part is a generic HASP that addresses legal and policy issues common to all projects, and the second part is a site specific (or SSHASP) that supplements the generic HASP. The site-specific document is the one that must be modified if conditions at the site change. The heavy emphasis on the HASP makes the content of this module more applicable to paragraph (e) workers than paragraph (p) workers.

In the third module, Task-Hazard Analysis and Field Exercise, the participants conduct a simulated core-sampling exercise. This module is the heart of the refresher training sessions. To complete this field exercise, the participants need to read the SSHASP, don the proper PPE, and coordinate as a team to collect the sample. Because the needs analysis had indicated that knowing how to obtain a radiological work permit (RWP) needed reinforcing, the simulation is designed to exceed the LANL developed radiation contamination action levels that require an RWP. This simulated event should cause the field-team leader or site-safety officer to stop work and initiate the process for an RWP.

The details of the simulation are given in their workbook and in the SSHASP written for the simulation. The training focus of this module is on finding and applying the information provided in the HASP to each task being performed at the work site. To accomplish finding the information in an efficient manner, the participants are assigned to small groups that are responsible for finding and presenting the following blocks of information to the whole group:

Following the presentations by the small groups, the whole class completes the field exercise. The exercise includes having teams of workers dress out in the proper PPE, establish the work zones, collecting the samples, and perform a decontamination of personnel and equipment. Following the decontamination and doffing procedures, the module closes with a debriefing session and review the teams' performance.

In the fourth module, Lessons Learned, participants read several case studies describing an occurrence or incident that resulted in personnel injuries. The participants are asked to describe what might be the cause of the accident and propose safe work practices that could reduce the risk or eliminate the hazard. Each of the case studies appeared in the Occurrence Reporting and Processing System (ORPS) within in the last sixteen months.

The last module, Review of Selected HAZWOPER Content, provides a rapid review of most of the topics covered in the participants' initial 40- or 24-hour training. The module is essentially a Jeopardy-like review game in which the participants respond to questions on topics such as toxicology, signs and symptoms of overexposure, proper container-handling techniques, air monitoring procedures, and medical surveillance programs.

HAZWOPER REFRESHER FOR TSD FACILITY WORKERS

Although LANL has a few treatment facilities and disposal sites, most of the participants in this refresher session work at hazardous waste

storage facilities. Thus, the annual refresher for these workers focuses on hazards associated with container handling, symptoms of exposure to the more common hazardous materials in storage, hazard identification at these facilities, and proper waste handling and segregation techniques. The seven modules of this course are structured around the following objectives:

to describe the impact that any new or modified federal regulations or LANL policies will have on the workers;

to describe the changes in LANL's waste management structure;

to identify the rights and responsibilities of both the worker and the employer involved in hazardous waste operations;

to identify recurring problems of noncompliance with RCRA.

to identify the response to a given situation based on information presented during initial HAZWOPER training; and

to demonstrate the ability to recognize and correct hazardous or noncompliance situations by completing a simulated field exercise.

The first two modules, LANL Reorganization and Regulatory Update, are similar to the first module of the environmental restoration refresher course. The difference is the extent of the coverage. This additional depth is needed because LANL has undergone extensive reorganization that has effected waste handling at the Laboratory. This information is much more significant to the TSD facility workers then to the environmental restoration site workers.

In the third module, Hazard Identification and RCRA Refresher, the participants receive a review of the inspection record form (IRF) used to record the daily or weekly inspection required at RCRA-permitted facilities. The IRF has two functions. First, it creates a paper trail that documents that the TSD workers have completed the required RCRA inspections. Second, it is an administrative control that helps assure that the TSD facility is operated in a safe manner. The IRF assures that any physical, chemical, or radiological hazards are identified and corrective actions are initiated to correct the deficiency. In the fifth module, the participants use the IRF and complete a field exercise that includes an inspection of a simulated TSD facility.

The fourth module, Actions Required, addresses both the physical and chemical hazards present at TSD facilities. Like in the environmental restoration refresher, the participants identify potential hazards illustrated in several photographs. However, the scenes are different. The photographs used for this refresher show activities at LANL TSD facilities. This module also spends more time on chemical storage and incompatibility problems. The participants are givena map of a simulated TSD facility and asked to designated were they would store specific chemical and hazardous wastes at the facility. This module ends with a video on hazardous chemicals and their properties.

Module five is the field exercise. This exercise requires the participants to use the IRF and document at least twelve of the sixteen deficiencies present in a simulated TSD facility. Following the inspection, the participants work in small groups and prepare a written description of two of the deficiencies, determine what steps are necessary to correct each deficiency, and propose what PPE is needed if someone were to follow through and correct the deficiency. Depending on the time, participants can go back out to the simulated site and correct several of the simpler problems or as a class discuss what needs to be done for each of the sixteen deficiencies.

In the sixth module, Lessons Learned, participants read several case studies that describe an occurrence or incident that resulted in personnel injuries or fines. This module is expanded, compared to the one in the environmental restoration refresher, to include both OSHA and RCRA occurrences. For the OSHA incidents, the participants are asked to describe what might be the cause of the accident and propose safe work practices that could reduce the risk or eliminate the hazard. For the RCRA occurrences, the participants are asked to identify the root cause for each violation and propose corrective actions to change the conditions that resulted in the non-compliance citation.

Just like the environmental restoration refresher, the last module provides a rapid review of most of the topics covered in the participants' initial 40- or 24-hour training. The same Jeopardy-like review game covers the topics of toxicology, signs and symptoms of overexposure, proper container-handling techniques, air monitoring procedures, and medical surveillance programs.

COMPARISON OF HAZWOPER REFRESHER COURSES

Based on the needs analysis, the refresher training was made more efficient for the customer by combining the required OSHA and EPA refresher training. The critical step was ensuring that the new refresher for TSD facility workers fulfills the intent of all of the legal drivers. Because both OSHA and EPA require that the refresher include emergency response, controls for reducing risks, use of PPE, and safe handling procedures for hazardous waste containers these topics were the first ones addressed in the course design.

To the same course sequence and major topics of the existing HAZWOPER refresher course, which met the OSHA drivers, was added additional TSD- and RCRA-specific material to meet the EPA drivers. Because the daily duties of TSD facility workers are different from environmental restoration workers, the activities and contents in our courses diverged on two key topics: safe work practices and administrative and engineering controls. Because workers at TSD facilities risk exposure to chemical hazards as their daily duties involve handling containers ofhazardous materials, their refresher focuses on work practices and controls that minimize this risk. Although environmental restoration workers can encounter unknown chemical hazards, the Laboratory's experience shows that physical hazards pose a greater risk and their refresher focuses on these hazards.

This difference in hazards resulted in creating several separate activities for the refresher courses. The following tables list the similarities and differences of these two courses:

Table I

Table II

For the safe work practices portion of the refresher training, the TSD facility participants complete an activity that reviews some chemical incompatibilities and safe storage practices for various chemicals. The environmental restoration workers spend time reviewing their sit-specific HASP. The chemical segregation activity allows the participants to be in charge of a "new" TSD facility and decide where each chemical will be stored. The participants are allowed to use the DOT shipping labels, guidebooks on hazardous materials, and their neighbor to make the necessary decisions. The HASP review requires the participants to search through the HASP to answer specific job-related questions concerning PPE, action levels, decontamination procedures, and site security.

The two administrative forms reviewed in these refresher courses are the RWP and the IRF. In addition to the HASP, the RWP is required for all "hot" jobs at LANL. This permit specifies the PPE required for the job and lists any additional health or safety concerns. The IRF is LANL's form used to document the inspections required by the EPA for all RCRA-permitted TSD facilities and serves as a hazard identification tool. These daily or weekly inspections help identify any site deficiencies that may result in worker overexposure to hazardous materials or create a hazardous situation. In the TSD refresher, the participants are asked to identify all of the deficiencies at the simulated TSD facility and then describe the appropriate actions required to correct the deficiencies or minimize the risk. The participants are asked to include a list of any tools or equipment needed and propose what PPE, if any, should be used during the corrective action. These two administrative forms are part of the LANL's administrative procedures that helps assure worker health and safety.

CONCLUSIONS

Both HAZWOPER and RCRA refresher training have the same four goals:

- to remind participants of safe work practices,
- to provide the participants with an opportunity to practice job-related safety procedures,
- to review emergency response programs or procedures, and
- to update participants on any policy or regulatory changes.

LANL's HAZWOPER refresher training for TSD facility workers is more efficient this year because the training reflects the design goals identified by in the needs analysis. The first goal was to reduce demands on participants' time, which was achieved by combining refresher training required by two different agencies into one training session. The second goal was to make the training session more appropriate by making the training more job-related, which was achieved by creating separate refresher training for TSD facility workers and for environmental restoration workers. Thus the creation of these two similar, yet job-specific, refresher courses meet the intent of the OSHA HAZWOPER standard (to protect workers' health and safety) and the EPA RCRA requirements (to protect both the worker and the environment) while satisfying the customers' demands for efficient and relevant training.

ABSTRACT
Los Alamos National Laboratory has had an ongoing "interactive relationship" between the departments of industrial hygiene and occupational medicine. This requirement was recently formalized in a University of California ES&H performance measure. A close working relationship between these two departments enhances the ability to direct resources to identify and follow employees who belong in special occupational medicine surveillance programs, and to get referrals from medical when unusual examination results are found. Los Alamos has formalized the relationship between the two departments through a recently developed "interface document" that clearly defines the responsibilities and required procedures for coordination. Specific areas of mandated coordination include quarterly meetings of senior staff, joint workplace evaluation and systematic prioritization, information exchange, continuous quality improvement, individual program elements, and measures of performance. The elements of the program will be presented and the first eighteen months of implementation reviewed.
INTRODUCTION
The interface between the Occupational Medicine Group (ESH-2) and the Industrial Hygiene and Safety Group (ESH-5) (6) is an integral component of the overall Occupational Health and Safety Program for the Laboratory. ESH-2 provides a comprehensive medical program which assures protection and promotes enhancement of worker's health. Protection of worker's health includes medical surveillance and job certification when required or prudent, periodic age-dependent medical evaluations, human reliability/fitness for duty assessments, managed care/rehabilitation of work related injuries and illnesses, emergency response capability, worksite evaluations, population studies for early detection of adverse health effects and a clinic which provides support to these programs. Enhancement of worker's health is offered through medical health promotion programs (e.g., cholesterol reduction, skin cancer awareness, flu immunization, etc.), The Employee Assistance Program (e.g., personal counseling, stress management, alcohol/drug rehabilitation, etc.), and the Wellness Center (fitness programs/equipment, aerobic instruction/classes and nutrition counseling).
ESH-5 (6) works closely with Laboratory line managers to help ensure the health and safety of personnel and to ensure that employee exposure to chemical, physical, biological, and ergonomic hazards is minimized. Primary support services include the full spectrum of anticipation, recognition, evaluation, and control of occupational health hazards: consultation and field support to operating divisions; design review of new or modified facilities and operations, maintenance of Material Safety Data Sheets; review of standard operating procedures and special work permits, implementation of training programs; recommendations for personal protective equipment; toxicology support services; and evaluation of air cleaning systems.
PURPOSE
This document describes the interactions between the Occupational Medicine Program and the Industrial Hygiene and Safety Program that are used to effectively exchange occupational health and safety information. Specifically, this document describes the exchange between ESH-2 and ESH-5 (6) programs designed to meet regulatory requirements such as DOE

Orders 5480.8A (1), 5480.10 (2), 5480.4, and 5483.1A (3); DOE referenced standards and documents; and the 29 CFR Parts 1904, 1910, and 1926 (8).

SCOPE

All exchange of occupational health and safety information between ESH-2 and ESH-5 (6) is subject to this document.

REQUIREMENTS

An active interface between ESH-2 and ESH-5 is a requirement of an effective Occupational Safety and Health Program. Requirements are established in DOE 5480.10 "Contractor Industrial Hygiene Program" (2) and DOE 5480.8A (1) "Contractor Occupational Medicine Program". Additionally, this interface is required by Contract No. W-7405-ENG-36 between the University of California and the Department of Energy (DOE). This contract includes the following provision.

Using a risk-based approach, the Laboratory will develop and implement a site-wide exposure assessment and monitoring plan to characterize employee exposure to hazardous chemicals, physical agents (except ionizing radiation) and biological agents. The plan will be developed by April 1, 1995. Monitoring data from implementing the plan will be provided to the medical staff who will utilize the data in the health evaluation of employees. Baseline data will be collected during FY95. Continuous quality improvement will be based on a peer review (See Appendix A) of a random sample of employee medical charts to evaluate the interaction between the Industrial Hygiene and Medical groups.

RESPONSIBILITIES

Occupational Medicine Group (ESH-2)

ESH-2 is responsible for the following actions to maintain an effective working relationship with ESH-5.

Participating on the Occupational Medicine/Industrial Hygiene Coordinating Committee.

Participating in joint workplace health surveys with ESH-5.

Referring significant events arising from day to day occupational medicine activities to ESH-5 where these activities may have an impact on the Industrial Hygiene Program. Examples include requests for a site review to evaluate potential exposure to toxic materials, high noise levels, or ergonomic stress factors.

Participating in occupational health related information exchange with ESH-5 through effective database management and internal awareness programs.

Teaming with ESH-5 assigned IH staff on programs of mutual interest including, but not limited to, injury and illness investigations, hearing conservation, reproductive hazards , carcinogen use, respiratory protection, ergonomics, medical surveillance, and bioassays.

Conducting medical surveillance for employees identified by ESH-5 for specialty programs to include OSHA regulated chemicals. Examples include lead, beryllium, asbestos, and cadmium.

Team with ESH-5 in the evaluation, on a case by case basis, employees with chemical related illness (sensitizers - eg. formaldehyde, MDI and TDI).

Industrial Hygiene and Safety Group (ESH-5)

ESH-5 is responsible for the following actions to maintain an effective working relationship with ESH-2.

Participating on the Occupational Medicine/Industrial Hygiene Coordinating Committee.

Participating in joint workplace health surveys with ESH-2.

Referring significant events arising from day to day industrial hygiene activities to ESH-2 where these activities may have an impact on the Occupational Medicine Program. Examples include referral of suspected occupational illnesses noted during workplace inspections, reevaluation on an individual's respirator use qualifications, notification of potential exposures to hazardous agent and reporting any worksite exposures measurements in excess of OSHA/DOE permissible exposure/limits, or those levels triggering medical surveillance.

Participating in occupational health related information exchange with ESH-2 through effective database management and internal training programs.

Teaming with ESH-2 assigned medical staff on programs of mutual interest including, but not limited to, injury and illness investigations, hearing conservation, reproductive hazards, carcinogen use, respiratory protection, ergonomics, medical surveillance, and bioassays.

Identifying employees for medical surveillance for specialty programs to include OSHA regulated chemicals. Examples include lead, beryllium, asbestos, and cadmium.

Team with ESH-2 in the evaluation, on a case by case basis, of employees with chemical related illness (sensitizers, eg. formaldehyde, MDI and TDI).

RESOURCE REQUIREMENTS

Maintenance of a strong interface between ESH-2 and ESH-5 requires adequate resources for implementation of program elements common to both groups. These resource requirements will be explained in detail in future documents.

IMPLEMENTATION

ESH-2 and ESH-5 coordinate efforts in virtually all aspects of occupational health and safety. This interaction occurs on both a regularly scheduled basis and on an ad-hoc basis as issues arise. The primary interactions between the two Groups are described below.

Occupational Medicine/Industrial Hygiene Coordination

The ESH-2 and ESH-5 management meet at least once per quarter and additionally as necessary to consider and acting upon important issues related to both group's responsibilities in Occupational Health at the Laboratory and to provide for continuous quality improvement in Occupational Health programs.

The committee tracks the progress made in implementing or improving Occupational Health programs, provides management support to resolving outstanding issues, and considers the impact of new Occupational Health regulations on Laboratory operations.

The committee documents each meeting and identifies action items for follow up.

Program Implementation and Referral Activities

Both ESH-2 and ESH-5 are involved in ongoing implementation of Occupational Safety and Health program elements. These elements include, but are not limited to, the emergency management program, respiratory protection program, hearing conservation program, occupational health training programs, reproductive hazards program, carcinogen program, medical surveillance, and illness and injury prevention.

Through implementation of these program elements, referrals are made from one group to the other. For example, when industrial hygienists are conducting a workplace evaluation and note complaints of dermatitis, ESH-

2 is notified for employee examination. Alternately, when a potential noise related hearing loss is documented by a physician, the event is referred to ESH-5 for an evaluation of potential high noise exposure in the workplace. These type of interactions occur on an almost daily basis, and ESH-2 and ESH-5 work together closely until the situation is resolved. Additional examples of this day to day interaction are shown in the program elements descriptions discussed in Section 7.6.

Workplace Evaluation and Systematic Prioritization

ESH-5 has taken the lead in conducting detailed workplace evaluations to identify and prioritize potential hazards through routine surveys and the Health Hazard Assessment (HHA). Through the HHA process, workplaces are systematically evaluated and can be ranked by the degree of potential hazard through a weighting of variables such as toxicity, amount of material used, frequency and duration of use, and if controls are in-place. A graded approach can then be employed to focus follow-up actions to high hazard areas.

ESH-2 and ESH-5 use this process to systematically select areas where joint evaluations are conducted by Occupational Medical and industrial hygiene specialists. In this manner, the expertise of both groups are applied to potential high hazard areas and an opportunity for cross-training and information exchange is achieved.

Information Exchange

ESH-2 and ESH-5 use several methods to facilitate information exchange in the occupational health area. The information exchange occurs primarily through the use of automated databases and internal cross-training of personnel.

There are automated databases for health hazard assessments, personal and area air sampling, location of specific chemical inventories, confined space locations, and nonionizing radiation sources. These databases are kept current through joint efforts of the two groups and are used in daily and periodic tasks performed by personnel in both groups.

Internal information sharing is conducted through seminars where professionals from either group are assigned a topic, and members of both groups are encouraged to attend. This provides for a greater understanding of the roles, capabilities, and interactions of the two groups in the overall occupational health program. Cross-training sessions address topics such as audiometric exams, HHA's, and database use. Employee rosters and agendas for cross-training classes are maintained.

Continuous Quality Improvement

ESH-2 and ESH-5 use the Laboratory's Continuous Quality Improvement Program to address specific topics both within and between the Groups. Continuous Quality Improvement practices are applied to each group's programs using available quality assurance and quality control professionals.

Continuous Quality Improvement Committees may also be established depending on the importance and need for improvement in a given area. Any employee of either group may bring up the potential need for a Continuous Quality Improvement Committee to Laboratory Management. ESH-2 and ESH-5 both support this process and have provided personnel to serve on Continuous Quality Improvement Committees such as the Respiratory Protection Team.

Individual Program Elements

The effective interface between ESH-2 and ESH-5 is evidenced by the activities of both groups in the following program elements.

Health Hazard Assessment (HHA) Program.

ESH-5 is primarily responsible for conducting and documenting the HHA (see Section 7.3) and managing the data in the HHA database. ESH-2 is a user of the information in the HHA database to assist with specific medical surveillance programs. The ESH-2 and ESH-5 interface occurs in the following areas.

Joint participation in workplace hazard assessments.

Joint use of HHA information to conduct prioritized workplace surveys

ESH-2 uses the HHA information when conducting pre-employment physical examinations, routine medical monitoring and surveillance, and injury and illness investigations

Biosafety Program

The Laboratory Biosafety Program is described in the Environment, Safety and Health Manual, Committee Charter "Biosafety Committee". The Biosafety Committee meets twice per year to provide peer review and approval of proposed Laboratory work involving the use of infectious biological agents and recombinant DNA. Both ESH-2 and ESH-5 participate in the Biosafety Committee to coordinate the industrial hygiene and medical aspects of biosafety.

ESH-2 and ESH-5 have worked together to implement exposure control plans for certain work areas and to develop training programs related to potential exposure to bloodborne pathogens (29 CFR 1910.1030)(7).

The primary interface between the groups in the biosafety area includes the following.

Coordination of Industrial Hygiene and Occupational Medicine biosafety concerns through joint participation in the Biosafety Committee

Development and implementation of bloodborne pathogen exposure control plans

Participation in the development and periodic review of bloodborne pathogen training programs

On a case by case basis, perform joint investigations of bloodborne pathogen incidents or processes

Respiratory Protection Program

The Laboratory Respiratory Protection Program is described in AR 12-2 and the LANL Draft Respiratory Protection Program Manual. ESH-5 is primarily responsible for assisting line management in the selection, use, and evaluation of respiratory protective equipment. ESH-2 is primarily responsible for medical qualification of respiratory protection users.

The primary interface between the two groups include:

Referral of new respirator users from ESH-5 to ESH-2 when identified during workplace surveys

Referral of new respirator users from ESH-2 to ESH-5 when identified during initial or periodic medical examinations

Joint annual evaluation of the effectiveness of the Respiratory Protection Program

Annual comparison of employee listings maintained by ESH-5 for fit-testing, and listings maintained by ESH-2 for medical qualification to ensure that an accurate record is maintained of personnel in the program

ESH-2 referral to ESH-5 of individual respirator user limitations or work restrictions

Hearing Conservation Program

The Laboratory Hearing Conservation Program is described in AR 8-2. ESH-5 performs noise level measurements, hazard investigations and design review for new noise sources. ESH-2 performs medical surveillance and audiometric exams for personnel included in the Hearing Conservation Program. The primary interface between the two groups include the following.

Periodic joint evaluation of the effectiveness of the Hearing Conservation Program

Referral of events where deterioration of hearing acuity is detected through audiometric testing from ESH-2 to ESH-5 for follow-up action. ESH-5 performs a site evaluation and provides the results to ESH-2 for completion of the evaluation. Upon determination of possible workplace noise associated loss, ESH-2 and ESH-5 collaborate on the application of engineering and/or administrative controls.

ESH-5 provides noise monitoring results to ESH-2 for inclusion into the employee medical record and for administration of the audiometric testing program

Development and joint review of the Hearing Conservation Program training materials and courses

Ergonomics

Both ESH-2 and ESH-5 participate in the Laboratory Ergonomics Committee. The Committee duties are described in the Ergonomics Committee Charter. ESH-5 is responsible for workplace evaluations and control measure recommendations concerning potential ergonomics hazards.

The ESH-2 and ESH-5 interface in the ergonomics area includes the following.

Joint participation in the Laboratory Ergonomics Committee to address potential industrial hygiene and occupational medicine concerns

ESH-2 referral to ESH-5 of potential ergonomics hazards in the workplace for evaluation

On a case by case basis, joint workplace evaluations of ergonomic related injuries or illnesses

Laser Safety and Non-Ionizing Radiation

The Laboratory has established a Laser Safety Committee as described in the Environment, Safety and Health Manual Committee Charter "Laser Safety Committee". The Laboratory Laser Safety Program is described in AR 5-2. ESH-5 is responsible for evaluating laser hazard precautions and for investigating injuries related to lasers. ESH-2 is responsible for performing eye examinations related to laser use.

The Laboratory Non-Ionizing Radiation Program is described in AR5-1. ESH-2 performs medical examinations on a case by case basis.

The two groups interface in referral, investigation, and follow-up of laser and non-ionizing radiation related injuries.

Hazardous Waste Operations and Emergency Response

The Laboratory program is described in the Draft Hazardous Waste Operations and Emergency Response Program Manual. ESH-5 is primarily responsible for supporting all Industrial Hygiene Program areas related to this work including identification of hazards, air sampling, exposure assessment, personal protective equipment specification, and control measure development. ESH-2 is responsible for development of medical surveillance programs and medical support services for this work.

The groups primarily interface in the following areas.

Joint occupational health workplace evaluations of high priority operations

Joint effort to determine the appropriate level of health and safety program participation and to categorize hazardous waste worker training and medical surveillance requirements. This effort is conducted through the use of the hazardous waste or emergency response worker surveillance questionnaire. This effort is to meet requirements in 29 CFR 1910.120 (7)

On a case by case basis, perform joint oversight of contractor health and safety programs for environmental restoration and waste management activities

ESH-2 and ESH-5 work together in preplanning and prearrangement of Occupational Health services during emergencies by participating in the Emergency Management Program.

ESH-5 provides support to ESH-2 during emergencies by providing industrial hygiene support to the medical facility, information on chemical toxicity, MSDSs, and respiratory protection.

Carcinogen Program

The Laboratory Carcinogen Program is described in both Laboratory Standard (LS) 106-01.0, Chemical Hygiene Plan, and LS 106-03.0, Carcinogen Use. ESH-5's responsibilities primarily include evaluating workplace conditions and work practices, conducting exposure monitoring and sampling, evaluating the adequacy of control measures, and notifying ESH-2 of affected employees for inclusion in medical surveillance. ESH-2 responsibilities in this program are primarily to determine and implement the medical surveillance programs for carcinogen users.

The groups primarily interface in the following areas.

Joint evaluation of high hazard carcinogen use areas for potential occupational health concerns

Joint review of Standard Operating Procedures for carcinogen use areas

Joint identification of personnel to be included in the carcinogen use program and periodic comparison of personnel listings

Hazardous Materials Use

Specialty programs for specific hazardous materials use including asbestos, beryllium, lead, and cadmium have been implemented. ESH-2's responsibilities under these programs are to design and implement medical surveillance programs. ESH-5's responsibilities primarily include evaluating workplace conditions and work practices, conducting exposure monitoring and sampling, evaluating the adequacy of control measures, and notifying ESH-2 of affected employees for inclusion in medical surveillance.

The two groups primarily interface in the following areas.

Providing occupational health input for implementation or revision to hazardous materials use programs

Conducting joint surveys of high hazard work areas involving use of specified hazardous materials

Conducting periodic review of hazardous materials use programs to ensure compliance with industrial hygiene and medical requirements

Coordination in the maintenance of lists of employees who are qualified to work with specified hazardous materials

Personal and Area Workplace Sampling Program

SH-5 conducts personal and area sampling to characterize individual employee exposure to chemical, physical, and biological agents. This information is maintained on a database and, along with the HHA, can be accessed by ESH-2 prior to performing medical examinations for individual employees.

ESH-2 and ESH-5 interface in the following areas.

ESH-2 and ESH-5 both use personal and area sampling data on-line to coordinate occupational health requirements

ESH-5 coordinates with ESH-2 to maintain personal and area sampling data in a format useable by both groups

ESH-5 provides copies of memos concerning personal sampling information to ESH-2 and provides interpretation of personal sampling data as requested by ESH-2. (Provisions for privacy protection are in place and followed)

Chemical Inventory and Toxicology

ESH-5 has implemented an extensive database management program for occupational health data concerning potentially hazardous chemicals and physical agents. ESH-2 maintains databases for medical surveillance programs and employee health status monitoring. Most data is either personal computer based or operates on the ESH Division Office (DO) VAX in the Oracle environment and can be used by both groups. Due to the confidential nature of most ESH-2 medical data, it is not accessible by ESH-5.

The databases jointly used and accessible by both groups include the following.

Chemical Inventory. The Automated Chemical Inventory System (ACIS) database tracks the location, using groups, and quantities of chemicals throughout the Laboratory. This database is available on-line to both groups through the ESH-DO VAX.

HHA. The HHA is available to both groups on the ESH-DO VAX for information concerning individual workplaces, including hazards present, employees, hazard control measures, and chemical use.

Sampling and Monitoring. A database of all air sampling, noise, etc. conducted by ESH-5 is maintained on the ESH-DO VAX. This information is used by ESH-2 physicians prior to conducting physical examinations.

Confined Space Locations. ESH-5 maintains a database of confined space locations at the Laboratory on the ESH-DO VAX. This information is available on-line to ESH-2 personnel.

Non-ionizing Radiation Sources. ESH-5 maintains a database of non-ionizing radiation source information by location on the ESH-DO VAX. This information is available to ESH-2 personnel.

Asbestos Inventory. ESH-5 maintains a database of asbestos-containing materials by location on personal computer. This information is not currently accessible by ESH-2 personnel on-line, however customized hard-copy reports can be generated upon request.

Pregnancy Consultation

Employee procedures for reporting pregnancies or receiving consultation regarding contemplated pregnancies are outlined in AR 2-1. ESH-2 is responsible for initial coordination with the employee and recommending temporary work restrictions if necessary. ESH-5 is responsible for conducting workplace evaluations for potential reproductive hazards.

The primary interface between ESH-2 and ESH-5 include the following.

ESH-2 referral of cases to ESH-5 for workplace evaluations

Joint ESH-2 and ESH-5 workplace evaluation of selected work areas for potential workplace reproductive hazards

Occupational Injury or Illness Reporting and Investigation

The Laboratory program is described in AR 1-1, Accident and Occurrence Reporting. For occupational illness or injury, ESH-2 is responsible for initial documentation and reporting. ESH-5 is responsible for determining the need for additional investigation and reporting.

The two groups primarily interface in the following areas.

Referral from ESH-2 to ESH-5 of all reported injuries and illnesses

Joint investigation of priority injuries or illnesses with medical and industrial hygiene implications

Joint implementation of preventive measures when lessons learned from an injury or illness affect both medical and industrial hygiene programs

Control Measures

The Laboratory has a program to implement adequate control measures for potentially hazardous work. Controls are selected that will eliminate or reduce the hazard to manageable levels using the following hierarchy.

Substitution

Engineering Controls

Safe Work Practices or Procedures

Administrative Controls

Personal Protective Equipment

ESH-5 maintains the lead role in recommending and evaluating the effectiveness of control measures for industrial hygiene hazards. ESH-5 interfaces with ESH-2 concerning implementation of control measures that may impact individual employee health status. This occurs most frequently when implementing the use of respiratory protection and for administrative controls such as job rotation.

MEASURES OF PERFORMANCE

The quality of the interface between the Occupational Medicine Group and the Industrial Hygiene and Safety Group in itself is a measure of performance of the overall Environment, Safety and Health Program at the Laboratory according to contract provisions. The following indicators may be used to measure the quality of this interaction.

Trend and analysis of occupational illnesses and injuries at the Laboratory

Workplace inspections conducted jointly by the Occupational Medicine and Industrial Hygiene and Safety Group

Results of external audits related to the interaction between the Occupational Medicine and Industrial Hygiene and Safety Groups

Interface activities for special medical surveillance programs such as hearing conservation and beryllium.

Focus on highest, more common accident types: strains/sprains; repeative trauma; and contusions/lacerations.

ABSTRACT

The Department of Energy (DOE)/Nevada Environmental Restoration Project is comprised of several subprojects which include many dissimilar activities ranging from remediating radioactively contaminated soils on Alaska's western coast, to decontamination and decommissioning activities at the Nevada Test Site. In order to include all these activities in the same health and safety program, the Environmental Restoration Division of the DOE Nevada Operations Office has developed a tiered approach to its health and safety plans. There is an "umbrella" health and safety plan that provides background details of the program and procedures, which is then integrated with site-specific health and safety plans that cover details such as site hazards, history, and personal protective equipment. Working together, these two plans provide the necessary framework to do work safely.

The site-specific health and safety plan contains all information required by 29 CFR 1910.120, "Hazardous Waste Operations and Emergency Response," in abbreviated form. This "user friendly" format is computerized and is completed by checking boxes, filling in blanks, and making brief statements. The site-specific plan is deliberately designed to exclude details that have no relevance to specific information about an individual location. The site-specific health and safety plan format is deliberately simple and is not easily adaptable to complex operations. Therefore, multiple, task-specific, site-specific health and safety plan forms may need to be compiled to address individual activities for complex operations. However, similar activities at different sites may be grouped under a single, site-specific health and safety plan if the hazards and protective measures are closely related.

This integrated approach has been applied to both large and small federal sites; treatment, storage, and disposal facilities; and commercial hazardous waste operations with equal success. The articulated health and safety plan is a cost-effective solution to the drivers of environmental restoration activities associated with multiple regulatory requirements, complex combinations of large- and small-scope operations, and diverse organizations.

INTRODUCTION

The DOE/Nevada Environmental Restoration Project's Health and Safety Program must integrate numerous regulatory and operational requirements to support a diverse environmental restoration program without reducing the efficiency of operations with overly burdensome requirements. Traditional approaches to health and safety plans were evaluated and subsequently rejected because of the enormity of a task involving a multitude of sites, located from Alaska to Nevada with more than five separate contractor organizations, and because of the urgency to increase efficiency through the streamlining of plan production, review, and dissemination. The product of this effort is the subject of this discussion.

OVERVIEW OF THE DOE/NEVADA ENVIRONMENTAL RESTORATION PROJECT

DOE/Nevada Environmental Restoration Project activities encompass characterization and remediation of inactive sites associated with DOE nuclear testing programs. Sites under this project typically have areas of low-level radioactive or chemical contamination (or both) and are found at the Nevada Test Site, Tonopah Test Range, and Nellis Air Force Range as well as remote locations in Alaska, northern and central Nevada, Colorado, New Mexico, and Mississippi. Many organizations are involved with the DOE/Nevada Environmental Restoration Project, including federal and state agencies in both operational and regulatory roles and multiple contractor organizations. These organizations must all work together with the DOE/Nevada Environmental Restoration Project to accomplish it's goals and objectives. Under these circumstances, it is frequently difficult to ensure efficient, effective communication between the various participants of the Project, and considerable effort has been expended simply to assure all entities, including workers, are kept informed of site hazards and controls.

Most of the activities conducted by the DOE/Nevada Environmental Restoration Project are hazardous waste activities as defined by the Occupational Safety and Health Administration (OSHA) in Title 29 of the Code of Federal Regulations, Part 1910, Section 120 (29CFR1910.120), "Hazardous Waste Operations and Emergency Response" (HAZWOPER), and have been adopted by the Department of Energy in DOE Order 5480.4, Environmental Protection, Safety, and Health Protection Standards. This section of 29 CFR 1910.120 (b) requires a safety and health program for hazardous waste operations, and paragraph 1910.120 (b)(4)(i) requires that a site-specific health and safety plan be produced as well. These requirements were reviewed by the Project in 1992, and the preferred approach was to produce two integrated documents: the DOE/Nevada Environmental Restoration Project Health and Safety Plan and site-specific health and safety plans.

Additional standards are also addressed by the use of this site-specific health and safety plan approach. Hazard communication (29 CFR 1910.1200), construction industry specifics (29CFR1926), and a variety of other standards and requirements such as specific contaminant controls (29 CFR 1910.1000, et al.) and elements of environmental protection (40 CFR) are built into each plan. The site-specific health and safety plans also draw on the requirements and procedures of the DOE Radiological Control Manual, and 10 CFR 835, "Radiological Protection."

The DOE/Nevada Environmental Restoration Project's varied project locations, objectives, contractors, and tasks create a challenge for effective health and safety planning and control. An additional complication arises when the mix of personnel includes those with backgrounds in the hazardous waste industry, radiological hazards only, environmental sciences, and government agencies because of the specialized terms and ideas that often cause confusion when addressed outside those particular fields. As with any communications difficulty, this confusion is assumed to affect planning effectiveness, document peer review efficiency, and possibly actual worker safety due to misunderstood instructions during project operations.

A decision was made early in the development of the DOE/Nevada Environmental Restoration Project Health and Safety Plan to use the document as a standard with a common set of definitions and concepts. To assure clarity, specific definitions of terms were provided. In some cases, such as Occupational Safety and Health Administration (OSHA)

construction standard terms in Title 29 of the Code of Federal Regulations, Part 1926 (29 CFR 1926), a "cross-index" was provided to equivalent terms used by the hazardous waste industry in its Hazardous Waste Operations and Emergency Response standard. Similarly, terms common to both the radiological health and hazardous waste fields, but having different meanings, are provided in a common dictionary.

ENVIRONMENTAL RESTORATION HEALTH AND SAFETY PLAN

Traditional health and safety plans are typically cumbersome documents designed to include all aspects of a health and safety program. The solution of this problem was to develop a brief plan in a standard format, focussed entirely on the particular job at hand.

DOCUMENT PRECEDENCE

The DOE/Nevada Environmental Restoration Project's Health and Safety Program's main objective is to protect workers conducting field operations. To accomplish this and encompass the Project's widely varied activities, a programmatic or "umbrella" health and safety plan is in place that prescribes the minimum procedures to be followed while doing work. Individual subprojects, sites, and/or tasks require site-specific health and safety plans to identify the particular features, hazards, communication methods, and protective measures to be employed at that location. Together, the programmatic health and safety plan and the site-specific health and safety plan compose the health and safety program for a subproject, site, or group of tasks. Figure 1, "DOE/Nevada Environmental Restoration Project Health and Safety Document Hierarchy," shows the relationship of the various components which document the DOE/Nevada Environmental Restoration Project's Health and Safety Program.

Fig. 1

Occasionally, a "full" health and safety plan, rather than the site-specific health and safety plan will be developed for an activity. This all-encompassing plan is the traditional health and safety plan approach mentioned earlier and contains extensive details of training, medical monitoring, and site control in much greater depth than is found in the "fill-in-the-blank" format usually used in the DOE/Nevada Environmental Restoration Project Health and Safety Plan. This traditional format may be required when extensive public scrutiny of the project might be involved or when it is requested by participating organizations, usually when such a plan will be more easily understood during plan review and approval.

CONTENTS OF THE DOE/NEVADA ENVIRONMENTAL RESTORATION PROJECT HEALTH AND SAFETY PLAN

The DOE/Nevada Environmental Restoration Project Health and Safety Plan is the governing document under which all operations are conducted. It describes the entire health and safety program, including such vital ingredients as health and safety responsibilities, hazards assessment, hazard control program, personal protective equipment, and site control. Each of these areas is addressed in the plan so that the requirements are clearly delineated and apply to all Project sites. The following sections are addressed in the plan:

Responsibilities - contains the requirements for each functional area from project manager to site supervisor to oversight organizations for the safety of site workers and describes the relationships between each of the roles. General responsibilities that apply to all personnel are also included.

Hazard Assessment - describes when a hazard assessment is to be done and what must be included/considered/addressed.

Hazard Control Program - includes discussions and descriptions of acceptable and/or required procedures related to general practices such as working with the "buddy system" and how to handle site visitors. This section also contains procedures related to common hazards/mitigation measures that may be encountered while performing work on the DOE/Nevada Environmental Restoration Project. These hazards include ionizing radiation, contracting heat and cold illness, hearing conservation, working in confined spaces, engineering and work practice controls, handling drums and containers, excavating, operating aircraft, and dealing with ordnance materials and other physical hazards as well as lockout/tagout procedures and sanitation, illumination, asbestos, and ergonomics issues.

Personal Protective Equipment - includes discussions on the selection and use of proper personal protective equipment, definitions of levels of protection, hazards assessment, and training.

Site Monitoring - involves topics such as airborne contaminant and personnel monitoring, records keeping, and notification.

Employee Training - discusses general training issues including tailgate safety briefings, material safety data sheets, and health and safety plans. Specific training requirements such as radiation safety, hazardous waste operations and emergency response, supervisor's course, first aid and CPR, requirements for site-specific training, and instructor qualifications are also listed.

Medical Surveillance - includes requirements for physical examinations, record keeping, and injury and illness treatment.

Emergency Procedures - includes general emergency procedures, i.e., responses to worker injury or fire, and notification and documentation requirements.

Site Characterization and Analysis - outlines the requirements for site health and safety evaluations, general site information to be gathered, initial site entry procedures, and hazard communication.

CONTENTS OF SITE-SPECIFIC PLANS

Each site-specific health and safety plan incorporates the applicable requirements from the programmatic health and safety plan and delineates how the requirements will be accomplished for that location's scope of work. General project information is included such as a brief site history, investigative objective/activity description, and a notation about whether the site is regulated under 29 CFR 1910.120. Other sections contained in the site-specific plans include:

Material characteristics

Facility descriptions

Confined space descriptions

Investigation-derived waste handling

Hazard analysis Site control procedures (personal protection requirements, surveillance equipment, monitoring requirements)

Site setup

Decontamination procedures

Potential exposure action levels

Emergency procedures and communications

Exposure symptoms and required actions

Address and specific directions to the nearest hospital (and an alternate, if available)

Personnel information
Accident/injury/near miss checklist, and emergency notification requirements
Contact and phone numbers

Also included in the plan is a section that requires the signature of each site worker acknowledging his/her understanding of the contents of the site-specific health and safety plan.

Site-specific health and safety plans are usually prepared by the organization with primary responsibility for completion of the work to be performed and are reviewed by all participating organizations, which assures complete concurrence and understanding of all participants. The time required for this process varies, but is typically a one- to four-week process, depending on the number of reviewing organizations and complexity of the tasks involved.

A computerized program has been developed to accelerate the production of site-specific health and safety plans. This approach has helped to standardize their format, thereby making them more useable to the employee in the field. After a brief adjustment period, field technicians have become accustomed to the site-specific health and safety plan format and can find and interpret information quickly in the printed document. This Microsoft Windows-based application is designed to fit any platform running Microsoft Windows with compatible functionality and design. As part of the Windows approach, on-line help screens are available on all form fields to help the user in completion of the site-specific health and safety plan. However, given the variety of contractor and government organizations expected to produce these plans under the DOE/Nevada Environmental Restoration Project, a word processor version was also developed. Either format is allowed by the DOE/Nevada Environmental Restoration Project Health and Safety Plan, and while the same basic information must be included, other formats are acceptable as well. This flexibility has allowed the health and safety program to focus on content, rather than form, with a concurrent increase in worker acceptance and understanding.

APPLICATION TO VARIOUS PROJECTS AND SITES

The DOE/Nevada Environmental Restoration Project Health and Safety Plan has been successfully applied to many different operations, i.e., the location of the Salmon test, an underground experiment performed under the Plowshares Program, a program evaluating the peaceful uses of nuclear explosives. Activities on this site included threatened and endangered species surveys; surface water, groundwater, sediment sampling; and biological sampling. Initial evaluation of the project seemed to dictate the use of a "full" health and safety plan, a traditional health and safety plan containing all background information in addition to site-specific information. However, by grouping tasks on location and type, it became apparent the site-specific health and safety plan approach would satisfy site requirements by using multiple "short form" style health and safety plans. Each task plan essentially became a chapter discussing the hazards and protective measures appropriate to that task and was then assembled into a complete site-specific health and safety plan for that location. This approach proved very effective given that each sampling team or personnel from each specific discipline activity could refer to a single, brief document rather than search through a large document for information specific to their tasks.

ASSOCIATED PROGRAMS

Several programs complement the health and safety plans. An integral part of the DOE/Nevada Environmental Restoration Project's Health and Safety Program is the Tailgate Safety Briefing. This briefing serves to reinforce information covered in the site-specific health and safety plan specific to that shift's activities and is conducted at the beginning of each shift or whenever new employees arrive at the job site once work commences. The briefing includes possible contaminants and exposure symptoms, personal protective equipment requirements, hazards, decontamination procedures, and emergency information. Each person entering the site, including visitors, must acknowledge attendance by signing a Tailgate Safety Briefing form.

Examples of other programs that complement the health and safety plans are the Radiological Work Permits and Permit Required Confined Space entry programs. These programs require specific training, documentation, and procedures which are not duplicated in the site-specific health and safety plan or the DOE/Nevada Environmental Restoration Project Health and Safety Plan. Each of these programs is referenced, and a brief description of the key features and requirements of the program is presented. This feature avoids the problems of document size and document control by incorporating these other programs by reference.

USE IN OTHER ENVIRONMENTS

The original basis of the "short form" approach to site-specific health and safety plans grew out of a need to produce such a plan to meet OSHA requirements for environmental emergency response operations. A large, unwieldy site-specific health and safety plan would be impractical to produce in the very short response time required, but the alternative, no plan at all, was both unwise and failed to meet OSHA requirements. The development of a concise, "check box" approach was the solution to this dilemma. The early versions of this approach were used in many rapid-response situations such as chemical spills on federal or state lands with great success.

An additional benefit of this approach was the reduced cost of preparation, which was appealing in the competitive commercial environment in which it was first developed and applied. Commercial hazardous waste operations typically regard the letter of the law as a necessary evil, therefore viewing such cost-savings as reduced health and safety plan production time as a boon to operations' profitability. Within this setting, however, is the possibility of an OSHA audit. A necessary component of completing an audit without incurring a citation is a health and safety plan which meets OSHA requirements. Meeting this requirement effectively dictates a health and safety plan and plan production process which is cost-effective in terms of production time and effort. The site-specific health and safety plan approach used by the DOE/Nevada Environmental Restoration Project provides this effectiveness.

SUMMARY

The format of the health and safety program outlined here provides efficiency in the process from project inception to close-out. The programmatic part of the health and safety plan had only to be developed once and revised annually. It reduces redundancies in documentation and does not repeat information found in other requirements documents, but serves to reference all the requirements in one place. This helps to ensure all requirements are being met in the most efficient manner. Each site-specific health and safety plan contains only the information needed to accomplish the scope of work covered by the document. The

format lends itself to quick production and review, and the workers on a site can easily read and understand the hazards and mitigating measures for the functions they are performing.
The DOE/Nevada Environmental Restoration Project articulated approach has been applied to large and small federal sites; treatment, storage, or disposal facilities; and commercial hazardous waste operations with equal success. The articulated health and safety plan approach is a cost-effective solution to the drivers of environmental restoration activities associated with multiple regulatory requirements, complex combinations of large- and small-scope operations, and diverse organizations.

31-5
PREVENTING ERGONOMICS INJURIES DURING REMEDIAL INVESTIGATIONS

Lisa Nelowet
Jacobs Engineering Group Inc.

ABSTRACT
Health and Safety Plans for Remedial Investigations (RI) at hazardous waste sites often focus on chemical hazards and overlook physical hazards. The ergonomic hazards contributing to Carpal Tunnel Syndrome (CTS) and other musculoskeletal disorders (MSDs) are some of the most commonly overlooked physical hazards. A recent case of severe CTS developed while working on a remedial investigation site, was evaluated to determine which CTS risk factors were implicated. From that point, CTS risk factors routinely encountered on RI sites were identified through a series of RI site visits. CTS risk factors identified include the following: decontaminating sample spoons, lowering and raising pumps into wells, a variety of high strength gripping activities, surging wells with pipe and surge blocks, lowering and raising bailers into wells, using hand tools which force the hand into an unnatural position, subjecting the hand to cold, and wearing chemical protective gloves which hinder the motion of the wrist. RI activities examined include soil gas surveys, borehole soil sampling, well development, soil, water or sediment sampling and related RI activities. From this review of RI activities, it appears that CTS is a likely hazard on RI sites. Further work is required to examine the actual occurrence of CTS in RI workers, both reported and unreported cases.

HEALTH AND SAFETY HAZARDS FOR REMEDIAL INVESTIGATIONS

Remedial investigations (RI), as required by the Environmental Protection Agency in the Comprehensive Environmental Response, Compensation, and Liability Act, serve as mechanisms for collecting data for site and waste characterization and for conducting treatability testing as necessary. The field component of the RI may include a wide variety of activities, each presenting their own unique occupational safety hazards.

Field Activities During Remedial Investigations

The investigation team may implement any of a number of sampling methods during a remedial investigation. Site characterization efforts may include soil gas surveys, borehole drilling, well development, containerized materials sampling, and soil, water or sediment sampling.

Hazards of Activities During Remedial Investigations

Field activities during RI present chemical, radiological, biological and physical hazards. Field workers risk exposure to the chemical wastes they are investigating, as well as other chemicals used or stored onsite. Onsite safety staff use direct reading instruments and personnel air

sampling to gauge the degree of airborne chemical hazards. Local exhaust ventilation, remote sampling devices and other engineering controls are integrated with safe work practices and personal protective equipment to protect workers from chemical exposures. Similarly, controls are required by federal law and the locally-implemented Radiation Control Manuals to keep exposures to radiation and radiological contamination As Low As Reasonably Achievable (ALARA). Biohazards may be present in hazardous wastes such as hospital or research facility wastes. More commonly biohazards derive from the natural environment and may include disease-causing organisms (pathogens), and dangerous plants, insects, and other animals. Perhaps the most ubiquitous hazard at a hazardous waste site is presented by physical dangers. Safety issues such as electrical safety, lockout/tagout of hazardous energy sources, the use of fall protection, slipping and tripping hazards, working in confined spaces, use of heavy equipment, and a number of other physical safety issues manifest during an RI. While chemical, radiological and biological hazards are generally addressed in Health and Safety Plans and site-specific worker training, physical hazards are often addressed insufficiently. The ergonomic factors contributing to Carpal Tunnel Syndrome (CTS) and other repetitive strain injuries are some of the most commonly overlooked physical hazards.

CTS FACTORS-GENERAL

Repetitive movement, excessive wrist force or improper wrist position of the hand or fingers cause the tendons to slide against the walls of the carpal tunnel. The carpal tunnel is the channel in the wrist through which the median nerve and several finger flexor tendons run. As the tendons slide against the walls of the carpal tunnel, they may become irritated, causing then to become inflamed and swollen. With no room to expand, the swollen tendons press against the median nerve, causing pain. In OSHA's draft ergonomics standard, OSHA describes five signal risk factors, that is workplace risk factors whose presence is a signal that there is an increased likelihood of work-related MSD's. Those five risk signal risk factors include:

Performance of the same motion or pattern every few seconds for more than (2) hours at a time.

A fixed or awkward work posture (for example, overhead work, twisted or bent back, bent wrist, kneeling, stooping, or squatting) for more than a total of (2) hours.

Use of vibrating or impact tools or equipment for more than a total of (2) hours.

Forceful hand exertions for more than a total of (2) hours.

Unassisted frequent or forceful manual lifting.

Activities which require the hand to perform repetitive bending, twisting or pounding operations may create high risk of CTS. Subjecting the hand to cold, or using gloves which hinder motion or enforce an awkward wrist position may also increase risk. Risks are presented by objects which are difficult to grasp, or when gloves make it difficult to grasp an object. Additionally, powered hand tools may produce high levels of vibration. Poorly designed and bulky gloves can reduce hand strength up to 30%. Finger pinching is more stressful than hand gripping. It takes four to five times as much muscle strength and tendon force to pinch an object than it does to grip it.

REMEDIAL INVESTIGATION CTS RISK FACTORS

Table I summarizes the relationship between remedial investigation activities and CTS risk factors. CTS risk factors exist in most common RI activities including soil gas surveys, borehole soil sampling, well development and groundwater sampling, and sampling of containerized materials, soil, surface water or sediment. In some cases the stressing activity may be limited to a brief interval during the workshift. Some CTS risk factors appear in a variety of RI activities. For example, subjecting the hand to cold in outdoor work on many locations. Wearing chemical protective gloves may hinder the motion of the wrist and fingers, and increases the amount of force required for grasping. Inadequately designed hand tools, used for a number of different activities, may force the wrist into unnatural positions.

Table I

Soil Gas Surveys

Repetitive wrist twisting and excessive wrist force is indicated by the number of actions requiring unscrewing and screwing parts together during a soil gas survey. A single soil gas sample may involve screwing the tip adaptor to the soil gas rod, screwing the hammer cap to the soil gas rod, unscrewing then replacing the hammer cap to screw in a second rod once the first rod has been hammered down, unscrewing the hammer cap to screw on a sample port, then reversing the entire process. The entire process may take as little as 30 minutes, and 6-14 locations may be sampled in a single workshift.

Borehole Soil Sampling

Photograph One shows a commonly utilized sampling apparatus, the split spoon. Repetitive twisting and pounding, as well as excessive wrist force may be associated with use of this sampling apparatus to obtain subsurface soil samples. Subsurface soil sampling with a drill rig generally involves hand screwing the sampling apparatus to the drill rod either by hand or using a pipe wrench, drilling to the desired depth, unscrewing the sampling apparatus, and disassembling the sampling apparatus to obtain the soil sample. This process is repeated for each sample. Decontamination of sample spoons includes unscrewing the end cap or boot, cleaning and reassembling the spoon.

Well Development and Groundwater Sampling

Surging for well development often entails the use of pipe and a surge block, as shown in Photograph Two. When surging is performed by hand, repetitive wrist bending and significant wrist force may be involved. This approach involves the assembly of threaded lightweight piping such as polyvinyl chloride pipe. The pipe is often assembled in five foot sections with total lengths commonly ranging from 20 to 50 feet. A surge block is screwed onto the end of the pipe. The pipe is lowered by hand down the well and then raised and lowered along the screened interval of the well for 10 to 15 minutes at a time. After the surging is completed, the pipe is unscrewed and decontaminated.

Sampling of monitoring wells often involves lowering either a teflon bailer or a pump into the well. Equipment is lowered by line with a hand over hand motion requiring repetitive twisting and bending at the wrist. Photograph Three shows the use of a bailer for groundwater sampling.

Sampling: Containerized Materials, Soil, Surface Water or Sediment

Handling any sample generally involves screwing and unscrewing lids on sample jars, and labeling sample jars. Wearing chemical protective gloves can increase the amount of force required in the hand and fingers to perform these tasks.

While sampling containerized materials appears to involve minimal CTS risk. Removing and replacing bung tops on drums involves forceful finger pinching when a bung wrench is not used. A scenario such as sampling dozens of bung top drums in a workshift might present increased risk. Surface and near-surface soil sampling may include using a pick axe, shovel or scoop. Using a hand auger, as shown in Photograph Four requires repetitive twisting of the wrist. Posthole diggers may also be used. While surface water sampling does not appear to involve any significant CTS risk factors, sediment sampling may. Sediment sampling often involves lowering a sampling device by hand to the sediment to obtain a sample. Whether the sampler is lowered on a rigid pole or flexible line, repetitive wrist bending may be required.

CASE STUDY OF CARPAL TUNNEL SYNDROME (CTS) INJURED WORKER

"Joe" is the pseudonym used here for a worker who developed carpal tunnel syndrome (CTS) apparently while performing field work during an RI. This case is interesting in that many of the CTS risk factors inherent in RI work were all present in this case. Table I specifies that "Joe's" work activities would have subjected his hand and wrist to repetitive twisting, bending and pounding, excessive force, and improper positions. His long workshifts in a very cold environment also could contribute significantly to his injury. Furthermore, wearing both chemical protective gloves and gloves for warmth may have hindered the motion of his wrist and increased his required grasping torque in the performance of his tasks.

Medical History

Shortly after "Joe" was sent to a new field assignment, he noticed that his hands were becoming numb. This gradually worsened and began to keep him up at night with throbbing pain. He had noted much muscle tenderness in association with this discomfort. Upon completing his approximately one month field assignment, he returned home and saw a physician who felt that he had bilateral carpal tunnel syndrome. At this time, "Joe" complained of loss of grip strength and significant loss in coordination. He had difficulty writing, which resulted in severe tingling and burning of the hands. He was subsequently diagnosed with moderate to severe CTS which required surgery on both wrists.

Fig. 1

Fig. 2

Fig. 3

Fig. 4

Work History

"Joe" is a field technician who participates in a wide range of field labor activities during environmental investigations and remediations. This section details "Joe's" work activities during his one month work assignment. Shifts during "Joe's" field assignment were generally twelve to seventeen hours per day. Activities included decontamination of equipment, monitoring well development and groundwater sampling. Equipment decontamination included cleaning bailers, sample pumps and sample spoons. Each spoon assembly weighs approximately 20 pounds. "Joe" was involved in equipment decontamination for at least one to two hours each morning over the course of seven days.

For approximately seven hours each day for an estimated two weeks, "Joe" was involved with another team member in well development. This activity involves surging the well with pipe and surge blocks and then lowering a pump into the well. The pump, lowered into the well by hand, weighed

approximately 10 to 12 pounds, plus the weight of the line. Pumps were lowered from 15 to 50 feet into a well.
Finally, "Joe" participated in groundwater sampling. Sampling of monitoring wells involved lowering either a 1 3/4 " by 36" teflon bailer or a pump into the well.

CONCLUSIONS

From this review of RI activities, it appears that CTS is a likely hazard on RI sites. Further work is required to examine the actual occurrence of CTS in RI workers, both reported and unreported cases. As a corrective action, "Joe's" employer now includes a review of likely ergonomics hazards for pending field activities. Likely ergonomics hazards and controls are described in the site-specific health and safety plan, and discussed at the site orientation training.

ABSTRACT

This study's objective is to assess means for controlling water infiltration through waste disposal unit covers in humid regions. Experimental work is being performed in large-scale lysimeters 21.34 m x 13.72 m x 3.05 m (75 ft 45 ft 10 ft) at Beltsville, Maryland. Results of the assessment are applicable to disposal of low-level radioactive waste (LLW), uranium mill tailings, hazardous waste, and sanitary landfills.

Three kinds of waste disposal unit covers or barriers to water infiltration are being investigated: 1) resistive layer barrier, 2)conductive layer barrier, and 3) bioengineering management. The resistive layer barrier consists of compacted earthen material (e.g., clay). The conductive layer barrier consists of a conductive layer in conjunction with a capillary break. As long as unsaturated flow conditions are maintained, the conductive layer will wick water around the capillary break. Below-grade layered covers such as 1) and 2) will fail if there is appreciable subsidence of the cover, and remedial action for this kind of failure will be difficult. A surface cover, called bioengineering management, is meant to overcome this problem. The bioengineering management surface barrier is easily repairable if damaged by subsidence; therefore, it could be the system of choice under active subsidence conditions. The bioengineering management procedure also has been shown to be effective in dewatering saturated trenches and could be used for remedial action efforts. After cessation of subsidence, that procedure could be replaced by a resistive layer barrier or, perhaps even better, by a resistive layer barrier/conductive layer barrier system. The latter system would then give long-term effective protection against water entry into waste without institutional care.

As mentioned in the preceding paragraph, a bioengineering management cover might well be the cover of choice during the active subsidence phase of a waste disposal unit. Some maintenance is required during that period. Final closure, using geological materials, could follow cessation of subsidence. No further significant maintenance would then be required. If the geological material used is merely a clay barrier to water infiltration, the cover will be "sensitive" to imperfect construction or degradation by penetrating roots. The roots will die and decay, causing markedly increased permeability of the clay with the passage of time. A system using a conductive layer under the clay layer as a water-scavenging system will, in comparison, be "robust." Roots will still degrade the clay layer but will not degrade the scavenging layer. A roothole through the conductive layer will be analogous to a hole through a wick. It will do no significant damage. The combination of a resistive layer with a conductive (scavenging) layer underneath is thus less dependent on perfect construction techniques and will be resistant to damage by root invasion. In the absence of subsidence such a system should function effectively for millennia.

Another very useful application of the resistive layer barrier/conductive layer barrier system would be to protect an earth-mounded concrete bunker disposal unit. In that case, the barrier system would shield the concrete from exposure to flowing water. The resulting stagnant alkaline film of water would tend to protect the concrete from degradation over a long time period. Similarly, a resistive layer barrier/conductive layer barrier system could be used to protect high-level waste. If high-level waste were disposed of in fractured rock, this system could be used to divert possible fracture flow water around the waste.

INTRODUCTION

Infiltration of water into waste is the foremost problem associated with near-surface disposal of low-level radioactive waste (LLW). Up to this time, disposal unit covers have generally been constructed from soil materials. In humid areas, these soil or clay covers have generally proved less than satisfactory; often, the cover itself has served as the principal pathway for water entry into the waste (1). Water infiltrating

to buried wastes, contacting the wastes, then exiting the area can reasonably be expected to be the most important of radionuclide transport agents. Some radionuclides, such as tritium (present as tritiated water), and those present in anionic form or neutral complexes, will essentially move with the flow of water; others, present as cations, will move much more slowly, but all will move to a greater or lesser degree. Clearly then, it is advantageous to reduce water infiltration to buried waste to as low a level as reasonably achievable. It is the purpose of our work to examine and demonstrate various approaches for achieving that goal.

Three kinds of waste disposal unit covers or barriers are being investigated in this work:

1) Resistive Layer Barrier
2) Conductive Layer Barrier
3) Bioengineering Management

The resistive layer barrier is the well-known compacted clay layer and depends on compaction of permeable porous materials to obtain low flow rates. Flow through porous media is described by Darcy's law (2). Investigations on flow through such layers have gone on for over 100 years, so further progress in this area can be expected to be slow.

The conductive layer barrier (1) is a special case of the capillary barrier (3). Use is made of the capillary barrier phenomenon not only to increase the moisture content above an interface, but to divert water away from and around the waste. During such diversion, water is at all times at negative capillary potential or under tension.

This system consists of a porous medium underlaid by a capillary break (rock layer). Infiltration barriers such as a conductive layer barrier or a clay layer barrier (or a combination thereof) must fail if subjected to substantial shearing caused by waste subsidence. Reestablishment of a layered system after subsidence failure is a difficult undertaking and is exacerbated by the increasing complexity of the layered system. The failure potential of in-ground layered systems during the subsidence period argues for development of an easily repairable surface barrier for use during that period. To that end, a procedure called "bioengineering management" was developed (4). The bioengineering management technique utilizes a combination of engineered enhanced run-off and moisture-stressed vegetation growing in an overdraft condition to control deep water percolation through disposal unit covers. An artist's conceptual drawing is shown in Fig. 3, referenced in (5).

EXPERIMENTAL AND DEMONSTRATION

In this section we will discuss experiments being conducted in large-scale lysimeters at a humid region site in Beltsville, Maryland (see Fig. 4), referenced in (5).

Bioengineering Management

In bioengineering management the necessary run-off is provided by features installed at or above the soil surface rather than within the profile. The procedure, described by Schulz et al. (4), was designated bioengineering management. Its principal advantage is that subsidence can easily be managed by relatively simple, inexpensive maintenance of the above-ground features rather than by difficult reconstruction of below-ground layers. It should be noted that, after a length of time sufficient so that the organics have decayed and the waste containers have completely failed, subsidence will cease and a layered system could be then installed which could last over geological time periods.

In essence, the bioengineering management technique utilizes a combination of engineered, enhanced run-off and stressed vegetation in an overdraft condition to control deep water percolation through disposal unit covers. To describe it further: if a waste burial site is selected so that incoming subsurface flow is negligible, then precipitation is the sole source of input water. In a simplified model, that water has three possible fates: 1) evapotranspiration, 2) run-off, and 3) deep percolation. Evapotranspiration has a definite limit, governed by energy input. Ideally, deep percolation should be zero, leaving only the run-off component available for unlimited manipulation. Positive control of run-off becomes difficult with the use of compacted porous media trench caps as the sole barrier to water infiltration. The compacted material tends to become more permeable with the passage of time, due to fractures caused by waste subsidence and from the inexorable process of root growth, followed by death and decay of the roots, thus creating water channels. Evapotranspiration cannot then use all of the infiltrating water, and water percolates downward to the waste. As stated before, evapotranspiration has a theoretical maximum dictated by solar energy input to the system; only run-off remains available for nearly unlimited management. This run-off can be surface or subsurface, as long as it occurs before water reaches the waste.

Surface run-off can be managed to as high as 100% by means of a perfect, leak-proof roof, which is expensive and hard to guarantee. Alternatively, adequate but not total run-off can be engineered rather inexpensively by using an impermeable ground cover over part of the surface to achieve high and controlled levels of run-off. Vegetation planted between areas of impermeable cover will extend over the cover to intercept incoming solar energy to evaporate water. Roots will extend under the cover in all directions to obtain water.

Such a system can be visualized by imagining a supermarket parking lot, where trees are planted in islands, surrounded by concrete curbs, within an extensive paved area. In this case, the trees are maintained in a drought environment due to the small soil surface available for infiltration of precipitation. The paving, along with the curbing around the trees, causes run-off of most precipitation. Aboveground, the tree's branches and leaves extend over the parking lot and intercept incident solar energy. Beneath the surface, the roots, in a drought state, explore outward under the paving for any available water. Utilizing this concept, it should be possible, by combining engineered run-off with vegetation, to maintain the soil profile in a potential overdraft condition on a yearly basis.

Initial investigations of the bioengineering management technique were carried out in lysimeters at Maxey Flats, Kentucky. Results obtained in seasonal 1984-1985 and 1985-1986 were reported by O'Donnell et al. (6). In that work, a fescue grass crop was used with an engineered cover of stainless steel. Following seasonal 1985-1986 the grass cover was removed, a new stainless steel engineered cover was constructed, and Pfitzer junipers were planted in the lysimeters. After the junipers were established, percolation data were again collected in 1988 and reported by Schulz et al. (7). The woody junipers were excellent in preventing deep percolation of water in the lysimeter.

The encouraging initial results obtained in the Maxey Flats lysimeter experiment led to the establishment of a large-scale field demonstration at Beltsville, Maryland (Fig.4), referenced in (5). Figure 5, referenced

in (5), is a photograph of lysimeter 1, bioengineering management, taken in December, 1994, eight years after planting of the Pfitzer junipers. Alternating panels of aluminum and fiberglass were used as the hard cover. These plots, or lysimeters, are 21.3 m (70 ft) long by 12.7 m (45) ft wide, and the bottoms are 3.05 m (10 ft) below grade. Figure 6, referenced in (5), shows a side view of construction details of lysimeters 1 and 2 (bioengineering management). The only difference between the two was the initial water level in the lysimeters. The water level was 90 cm above the bottom of lysimeter 1 and 190 cm above the bottom of lysimeter 2. The water level in the lysimeters simulates the water table in a flooded disposal cell. In addition to the two bioengineered lysimeters, two reference lysimeters (3 and 4) were initially constructed. They were similar to the former, except that they were merely planted with fescue grass. No hard cover was present, but surface slopes were similar to the two bioengineered lysimeters (i.e., a slope of 1:5). Performance data for the reference lysimeters are given in Fig. 7, referenced in (5).

The water level in the two reference plots or trenches (lysimeters 3 and 4) rose until it was near the surface. At that time, water was pumped from the lysimeters to keep them from running over. The graphs of the water tables (i.e., water levels) in the bioengineered plots (lysimeters 1 and 2) show an entirely different story, as evidenced in Fig. 8, referenced in (5). In both cases, the water table was eliminated. It appears that the bioengineering approach could prevent water infiltration to a disposal unit. It also could be used for a remedial action in dewatering existing problem sites such as Maxey Flats.

On February 4, 1988, lysimeter 4 was pumped out to prevent overflow. It was then discontinued as a reference lysimeter and converted to a rock-surfaced, resistive-layer barrier plot. Lysimeters 1 and 2 (bioengineered) and lysimeter 3 have been continued. A summary of run-off, evapotranspiration, and pumping from those three lysimeters is given in Fig. 1.

Fig. 1

Figure 1 shows that there was very little run-off from the grass-covered plot. Most of the precipitation was disposed of, via evapotranspiration, by the fescue crop, but this was not adequate to prevent the rise of the water table. Table I gives the run-off, evapotranspiration, and deep percolation in the bioengineered plots during the past eight years. There was no deep percolation during this period. Until seasonal 1993-1994 the evapotranspiration had been rising annually, probably as a result of the greater vegetative canopy intercepting a greater percentage of the precipitation. In 1988, 1989, 1990, 1991, and 1992 the run-off percentages were 80, 74, 70, 67 and 63, respectively. In 1993, the run-off decreased to 61% of the precipitation. In 1994 the run-off remained the same as in 1993 (8). In 1995 the run-off decreased to 58% of the precipitation. During 1989, the water table was completely eliminated in both plots (Fig. 8), referenced in (5).

Table I

In addition to rainfall, run-off, and evapotranspiration measurements discussed above, neutron-probe soil-moisture measurements have been made continuously to monitor soil moisture changes in all six lysimeters depicted in Fig. 4, referenced in (5). The neutron probe measurements will indicate whether there is a gain or loss of moisture from the soil profile or, perhaps, steady-state situation, where there is little or no

net gain or loss of soil moisture during a year. A steady-state situation with relatively constant-moisture "dry" soil above waste would be highly desirable with a bioengineered cover. There would then be a large safety margin to protect the waste from infiltrating water.

Neutron probe apparatus, as supplied by the manufacturer, is calibrated against moisture measurements in sand. Such calibration is of unknown accuracy when applied to soil measurements. For this reason, the probe was calibrated using the same soil as in the lysimeters. Six hundred and twenty-eight kilograms (1400 lbs) of soil were placed in a weighing lysimeter, and measurements were made over a seven year period. Calibration data obtained using the weighing lysimeter are given in Table II, referenced in (5). The resulting curves, depicting the factory calibration and the weighing lysimeter calibration, are given in Fig. 10, referenced in (5). It is evident that use of the factory calibration on sand would result in a very large error in soil moisture determination.

Results of some neutron probe measurements are shown in Fig. 2 for bioengineered lysimeters 1 and 2. The data are plotted as volumetric moisture content, as a function of soil depth, on specific dates. Only ten widely spaced measurement dates are shown, for clarity. From inspection of the figure it is seen that, at the start of the experiment in July, 1987, the moisture content of the soil increased with depth until the water table was reached, then became constant. By July, 1989, the water table had been eliminated from both lysimeters, and the soil profiles were drying out. However, the soil moisture content, although much lower in the soil profile than in July, 1987, still increased with depth. This same relationship was still evident in October, 1995, although the soil profile had become still drier.

Fig. 2

Figure 12, referenced in (5), shows the moisture content of the soil profiles in lysimeters 1 and 2 at the end of each seasonal year. Following the complete removal of the water tables during the 1987-1989 period, the soil profiles were dried out further during the ensuing years. However, an unanticipated result turned up in lysimeter 1 at the end of seasonal 1993-1994. The moisture content of the soil profile increased slightly. To shed light on that result, the moisture content in the soil profiles at four depths were plotted monthly along with monthly rainfall data (Fig. 3). Here we see seasonal cyclical variations in moisture content in the soil profiles, with peak moisture concentrations occurring in the early spring, following periods of significant rainfall and minimal evapotranspiration. That cycling is both obvious and expected. What was totally unanticipated was the increase in the moisture peaks in lysimter 1 in each of the 3 seasonal years leading to 1994-1995. The increasing amplitudes of the moisture curves did not appear to be a result of rainfall variations, nor were they present in lysimeter 2. The aforementioned trend did not continue during the past year, seasonal 1994-1995.

The results to date indicate that bioengineered closure, as described in this experiment, would maintain the cover over buried waste in a "dry" steady-state condition. This would not only prevent water from percolating down to the waste, but would do so with a large safety factor.

Resistive Layer Barrier

As previously mentioned, on February 4, 1988, lysimeter 4 was pumped out, discontinued as a reference lysimeter, and converted to a rock-surfaced,

resistive-layer barrier plot. The primary reason for constructing that particular cover is the likelihood of such covers being used for uranium mill tailings. An end view of that plot or lysimeter is shown in Fig. 14, referenced in (5). This lysimeter was completed in the fall of 1988, and data collection (measuring performance) is underway. The most important information to be gained here will be the relative weighing of the advantages and disadvantages of rock surface vs. a vegetated surface.
In addition to the UMTRA or rock-surfaced, resistive-layer barrier plot, a vegetated resistive layer barrier plot was constructed. The primary purpose of this plot is for comparative measurements. Essentially, this plot is similar to the rock-surfaced plot except that topsoil replaces the rock layer, and the plot is planted with fescue grass. A diagram of this plot is given in Fig. 15, referenced in (5).
Fig. 3
In Fig. 1, the fate of precipitation in the UMTRA and grass-covered, clay-layer lysimeters is given. There was more than twice as much run-off from the rock-covered plot was as from the grass-covered plot. The data show no deep percolation through the clay layers through seasonal 1993-1994 in either lysimeter and there is little indication as to how much safety margin has been offered. In seasonal 1994-1995, 0.10 cm (0.04 in) passed through the cover in Lysimter 4. Nor is it known how consistently such near-perfect clay barriers would be installed in a routine operation. That remains a problem for future consideration.
Another concern is the possible drying out of clay barriers. If this were to happen, the clay layer would not be as efficient a barrier for preventing radon escape as planned in the UMTRA application. In addition, drying out of the clay layer could lead to cracking, leading to subsequent leakage prior to resealing by wetting. Figure 4 gives the volumetric moisture content of clay in the rock-covered (lysimeter 4) and the grass-covered (lysimeter 6) plots. In no case did the clay layer dry out significantly. On the contrary, in the UMTRA or rock-covered plot, which was devoid of vegetation, there was a slight increase in moisture content with time, suggesting that some leakage of water through the clay layer would occur in the future. That first leakage occurred during the past year, seasonal 1994-1995. Lysimeter 6 has a clay layer and a grass cover. In this case, no increase in moisture content has been observed. On the contrary, to date the moisture content of the clay layer seems to be in a rather steady state, taken over the 7 year period of measurement.
Conductive Layer Barrier
If we consider the case of water flowing downhill in an unsaturated porous medium, we have the case shown in Fig. 17, referenced in (5). The "holes" shown in the diagram could be a rock layer, affording a capillary break or capillary discontinuity (Fig. 18), referenced in (5). Under appropriate conditions, water everywhere in these cross-sections will be under tension, and there will be no leakage. This might then serve as an excellent means of protecting waste by conducting water around the waste. Figure 17, referenced in (5), simulates a conducting porous medium, such as a fine sandy loam soil, lying smoothly on top of a rock layer.
Problems with water flow under saturated conditions could certainly arise where a less than smooth surface ends up being constructed as depicted in Fig. 19, referenced in (5). That is, what happens if imperfections are constructed so that "pockets" of soil extend down into the rock layer? Figure 19 represents that case. Again, there will be no leakage, provided

conditions are such that the water in all parts of the conductive layer remains under tension.

Fig. 4

The big question is, can conditions required to maintain the necessary soil water tension be practically maintained while using this procedure to effectively protect waste disposal units? To answer this question the apparatus schematically depicted in Fig. 20, referenced in (5), was constructed, i.e., a "soil beam." Several miniature soil beams (Fig. 21), referenced in (5), were constructed for use in the laboratory so that a variety of candidate conductive-layer materials could be quickly evaluated.

A number of materials were evaluated using the miniature soil beams. It was quickly established that it would be necessary to construct a resistive layer barrier above the conductive layer barrier to have a practical system. The standard was set that the resistive layer barrier have an easily achievable conductivity of not greater than 10-6 cm/sec. On this basis it was found that material such as fine sandy loam could provide an effective conductive layer barrier, that is, conduct around the waste 100% of water percolating through the resistive layer. However, the measurements showed that such materials would not provide the desired (factor of 10) safety margin.

Further investigations turned up a material, diatomaceous earth, that would fit these requirements. Measurements of tension vs. distance of flow are shown in Fig. 22, referenced in (5).

The results of this experiment in the 137 cm (4.5 ft) long beam suggest that, as long as the flow rate is no greater than 4.2 10-4 cm/sec, the soil water will remain under tension regardless of the soil beam length. These results show that with the use of diatomaceous earth for the conductive layer and following the easily achievable standard set above for the resistive layer, it should be possible to construct a barrier that would allow no water leakage to a waste disposal unit. However, before final selection of the diatomaceous earth as the conductive layer material, we believed it to be prudent to conduct tests in a large-scale soil beam. The large beam, shown in Fig. 23, referenced in (5), has a soil beam length of 6.4 m (21 ft). As shown in Fig. 24, referenced in (5), a matric potential of about -15 to -20 cm of water is maintained over the entire 6.4 m length of the beam when the flow rate does not exceed 3.1 10-4 cm/sec.

The studies carried out in the large soil beam closely confirmed the data obtained in the miniature beam. Accordingly, diatomaceous earth was used as the conductive layer material in the demonstration lysimeter (lysimeter 5). It has been estimated that purchasing and shipping the diatomaceous earth to a job site any place in the United States will add about $0.50 per ft3 of disposed waste. This is over the cost of using locally obtained soil, and based on waste being 3.05 m (10 ft) deep.

After the time-consuming task of selecting the conductive layer material was accomplished, a resistive layer barrier over a conductive layer barrier was constructed in lysimeter 5. It was completed in January, 1990. A local clay from Beltsville, Maryland, the Christiana Clay, was selected as the resistive layer barrier. Testing has shown this material more than meets specifications. A cross-section of the cover system is shown in Fig. 25, referenced in (5).

Performance of this cover is shown in Figs. 1 and 4 (lysimeter 5). Until seasonal 1993-1994 the cover system was 100% effective in preventing

water movement downward through the cover. In seasonal 1993-1994, 0.13 cm (0.05 in) of water passed through the cover to the pan shown in Fig. 25, referenced in (5). In seasonal 1994-1995, 0.18 cm (0.07 in) passed through the cover. Although that amount is an extremely small percentage of the total rainfall, in theory no water should have percolated through the cover to pan. It is possible that the cover system was compromised by the instrumentation installed to measure performance.

Further Studies of Conductive-Layer Materials

For the Beltsville study, diatomaceous earth was selected for the conductive-layer material, based both on performance and cost considerations. Based on these two considerations only, diatomaceous earth would still be the material of choice, particularly since it has a much lower bulk density than sand and is therefore less expensive to ship. However, the engineering properties of sand are better known, thus sand may be more attractive to some installers. Therefore, we have been conducting further studies with various sands. Results of studies of the unsaturated flow characteristics of four different sands are given in Fig. 26, referenced in (5). All these sands exhibit unsaturated flow rates that are about twice that of the diatomaceous earth at any given negative matric potential. The particle size distribution of the four sands is given in Table III, referenced in (5). The mortar sand, for example, had the narrowest particle size range, and the foundry sand had the widest particle size distribution, although the particle size distribution did not have an important effect on the flow rates reported in Fig. 26. The Nevada dune sand and the Kelso dune sands are from large eolian deposits in the Nevada and California deserts, respectively. The Kelso deposit has been mined commercially. This work on the unsaturated flow characteristics of various materials is ongoing. Hydraulic properties will be studied over a larger range of matric potentials, further deposits will be located and investigated, and these investigations will be described in a future report.

APPLICATION

The three procedures described in the Introduction may be used singularly or in combination to protect disposal units from percolating water. The principles apply equally to above-ground or below-ground disposal. For example, a combination of covers 1. and 2., described in the Introduction, could be ideal for a stabilized, shallow land burial facility, whether it is above or below ground; e.g., the subsurface disposal could be in below-ground vaults, and the above-ground disposal units could be earth-mounded concrete bunkers. A combination of a resistive layer over a conductive layer in a concrete bunker or above-ground application is shown in Fig. 27, referenced in (5). The resistive (clay) layer is the primary barrier. The small amount of water passing through the clay layer will be diverted around the concrete bunker by the conductive layer. This cover over the concrete bunker can, in theory, be 100% effective, shielding the bunker from exposure to flowing water. This would result in a film of stagnant alkaline water at the gravel/concrete interface. The presence of this high pH, stagnant water would tend to protect the concrete from degradation over a long period.

The bioengineering concept could be advantageous for either a tumulus or shallow land burial unit that would be likely to exhibit subsidence. If desired, and after subsidence has ceased, a combination of covers 1. and 2. could be constructed with geological materials to give extremely long-

term isolation without further maintenance. Another possible application of a combination of covers 1. and 2. described in the Introduction is shown in Fig. 28, referenced in (5). Here, high-level waste is emplaced in a tunnel excavated in rock. If a fracture were present in the rock, and fracture flow occurred, the combination of a resistive layer and a conductive layer could provide excellent isolation of the waste from flowing water. Figure 29, referenced in (5), depicts an application where only very low flow rates need be protected against (essentially, dropwise fracture flow). Here, the system could be simplified so that only a conductive layer with a capillary break is necessary.

ACKNOWLEDGMENTS

Funding for this project was provided by the Waste Management Branch, Division of Regulatory Applications, Office of Nuclear Regulatory Research. Dr. Edward O'Donnell is the Project Manager, Dr. Sher Bahadur is Chief of the Waste Management Branch, and Dr. Bill M. Morris is Director of the Division of Regulatory Applications.

The authors wish to express their thanks to Lester M. Fujii for his contribution to this study. Furthermore, we are indebted to the support provided this project by the University of Maryland's Experiment Station, Beltsville Unit staff, notably Peter Godwin.

ABSTRACT

The Los Alamos National Laboratory (LANL) low level radioactive waste (LLRW) disposal facility at Area G is currently completing a draft of the site Performance Assessment (PA) as required per DOE orders. The site is located on a narrow mesa top of volcanic tuff where possible mechanisms of subsurface transport include vapor movement with vapor-liquid phase coupling, transport in fractures, and other as yet unresolved subsurface dynamics. The large depth to the water table (~250m) combined with uncertain hydrogeologic data below 100m and the complex stratigraphy of layered volcanic flows and ash provide for a challenging analysis. Results from previous field studies have estimated a range in recharge rate up to 1 cm/yr. Recent estimates of unsaturated hydraulic conductivity for each stratigraphic layer under a unit gradient assumption show a wide range in recharge rate of 10-4 to 1 cm/yr depending upon location. Numerical computations show that a single net infiltration rate at the mesa surface does not match the moisture profile in each stratigraphic layer simultaneously, suggesting local source or sink terms possibly due to surface connected porous regions. The best fit to field data at deeper stratigraphic layers occurs for a net infiltration of about 0.1 cm/yr. Surface moisture data and vertical moisture profiles suggest a wide range in infiltration at the near surface. Transients are hypothesized to play an important role in fracture infiltration and evaporation, but are seen in analyses to dampen rapidly within the mesa tuff matrix to a steady state condition.

A recent detailed analysis evaluated liquid phase vertical moisture flux, based on moisture profiles in several boreholes and van Genuchten fits to the hydraulic properties for each of the stratigraphic units. Results show a near surface infiltration region averages 8m deep, below which is a dry, low moisture content, and low flux region, where liquid phase recharge averages to zero. Analysis shows this low flux region is dominated by vapor movement. Field data from tritium diffusion studies, from pressure fluctuation attenuation studies, and from comparisons of in-situ and core sample permeabilities indicate that the vapor diffusion is enhanced above that expected in the matrix and is presumably due to enhanced flow through the fractures. Below this dry region within the mesa, near the interface of the vitrified and devitrified tuff units and also coincident with the elevation of the adjacent canyon floor, is a moisture spike which analyses show corresponds to a moisture source. This may indicate a narrow region with unique hydrologic properties, or horizontal moisture transport from the canyons. However, the likely physical explanation is seasonal transient infiltration through surface-connected fractures. This anomalous region is being investigated in current field studies, because it is critical in understanding the moisture flux which continues to deeper regions through the unsaturated zone.

INTRODUCTION

The Los Alamos National Laboratory (LANL) low-level radioactive waste (LLRW) disposal facility at Area G has completed a preliminary draft of the site Performance Assessment (PA) (1) as required per USDOE orders.

The final draft PA becomes the technical basis for authorization and management of disposal operations at the active disposal site.

The Area G disposal facility is located on the top of a narrow finger-like mesa composed of volcanic tuff (Bandelier Tuff), deposited in stratigraphic layers of ash and solidified volcanic flows. Waste disposed at Area G is placed into pits excavated in the volcanic tuff, crushed in place, and backfilled with the native crushed tuff to about 30% waste package and 70% tuff by volume. These disposal operations are evolving to minimize future disposal volume, and to assure stability of emplaced waste.

The unresolved subsurface dynamics of the mesa top site location and the adjacent canyons with the large depth to the water table (~250m) provide for a challenging analysis. Uncertain hydrogeologic data below 100m have led to preliminary analyses focusing on the near surface hydrology in the mesa-canyon system. Preliminary review by the USDOE Peer Review Panel indicated that the proposed subsurface transport conceptual model (2) was not fully integrated with the numerical models (3) used to evaluate the site, especially in defining the transition from significant transient events to the steady state analysis and in defining the possible role of vapor transport. This report provides additional data review and analyses to address these issues.

DATA REVIEW

Area G site hydrology was summarized (4) as of 1987, based primarily on field studies by Bendix (5). Several boreholes and core samples were used to characterize moisture verses depth and detailed hydrologic parameters. Moisture profiles by in-situ neutron probe measurements were seen to be independent of time below depths of about 2m. This was confirmed in recent measurements in a borehole into the crushed tuff backfill of an active Area G disposal unit (6). These results suggest transients in moisture content play a negligible role at depth.

A recent review of the site geohydrologic data (7) including recent permeability work has been completed as part of the Area G PA work. The layered stratigraphy within and beneath the disposal site mesa is illustrated in Fig. 1. Interpretation of the site geohydrologic data (2) identified several field observations which may be important in subsurface transport and postulated that transient infiltration into and long-term dryingfrom fractures play a significant role.

Fig. 1

In-situ air permeability measured by a borehole packer-isolation method was seen to be 4 to 20 times greater than the permeability of recovered core samples (4,5). Similar results were obtained recently comparing core sample air permeability in borehole (G-5) (8) to in-situ permeability measured in the same borehole (9). Attenuation with depth of atmospheric pressure oscillations (10) is consistent with permeabilities much larger than that measured on intact core samples. Subsurface diffusion of a tritium plume at Area G has been compared with numerical results to determine an in-situ diffusion coefficient (11).

Attributing the migration to vapor diffusion (liquid phase transport is negligible under the field conditions as will be discussed) gives a vapor diffusion coefficient which is more than one order of magnitude larger than that expected in the volcanic tuff matrix. These results indicate that fractures in the mesa top stratigraphic layers play a major role in determining the air permeability and effective vapor diffusion in the mesa.

ANALYSES

Unsaturated hydraulic conductivity and water characteristic curves were determined from van Genuchten fits (12) to matric potential data and from saturated conductivity data for several core samples in each of the near surface stratigraphic units at Area G disposal facility (13,14). Detailed comparisons of unsaturated conductivities predicted in this manner with values measured by the unsaturated flow apparatus (UFA) centrifuge method (15) show good agreement in only about half the cases and indicate a large variability and uncertainty in the transport characterization (16,17).

The stratigraphic unit averages of van Genuchten fits were summarized for the Area G PA work (7) (Fig. 2) over a range in moisture content up to 25% where the fits are accurately approximated by a straight line on a log scale. Assuming unit hydraulic gradients in the field, these curves correspond to recharge rates of 10-4 to 1. cm/yr in the range of in-situ moisture content from about 1% to about 10%. If there are no local source or sink terms, then the recharge or flux through the strata must be constant, which would result in higher moisture contents in Units 1b and in the Cerro Toledo (see Fig. 1, results labeled T-CT in Fig. 2, and labeled C in Fig. 3). This trend is consistent with field observations, but an accurate match of moisture content to field observations in each unit simultaneously is not possible as shown in the following.

Fig. 2

Fig. 3

This issue is examined in a comparison between numerical results and field data shown in Fig. 3. Steady state moisture contents are computed for several values of net infiltration at the mesa top, shown along a vertical line through the center of the mesa in a 2-D model with accurate stratigraphic cross-sections. The range of field data is shown as the darkened area. The canyon floors adjacent to the mesa coincide closely with the interface between Units 1b and 1a at Area G. The best agreement with field data occurs for downward vertical flux values of 0 to 0.001 cm/yr in the top two units, about 0.1 cm/yr through Units 1b and 1a, and as much as 1 cm/yr in the Otowi. Recent simulations show the higher moisture contents in the Otowi can be matched with lower flux values (0.1 cm/yr) when hydraulic properties of deeper strata (subject to large uncertainty) are included in the numerical model.

The steady saturation profile calculated for any single infiltration rate does not match all the in-situ saturation data gathered at the site. Saturations within the mesa top (Units 2b and 2a) are extremely low in field data. Saturations below the base of the mesa (Unit 1b and below) are higher. Several factors which may contribute to this discrepancy include: 1) infiltration from canyons or from deep surface-connected fractures resulting in higher saturations below the base of the mesa, 2) evaporation from the mesa sides and from fractures resulting in very low saturations within the mesa top, 3) uncertainty and heterogeneity in the hydrologic transport parameters.

For preliminary PA modeling work through all of the stratigraphic units, a rate of 0.1 cm/yr was chosen as the best 'fit' because there is no detailed knowledge of local source or sink terms to supply to the numerical effort. However, the comparison summarized in Fig. 3 suggests a complex situation with local (elevation dependent) source and sink terms to the recharge rate.

The source and sink terms in the underlying strata were examined in detail in a recent study (18). The vertical flux and the vertical component of its divergence, interpreted as a local source or sink term, were evaluated directly from vertical moisture profiles using the stratigraphic unit-averaged van Genuchten fits to determine the hydraulic transport parameters for matric potential and for unsaturated hydraulic conductivity, and thus the vertical flux as a function of local moisture content. Results are discussed in detail for data from a dozen boreholes at Area G (18), for example, as shown for one 'typical' hole in Fig. 4.
Fig. 4
Figure 4A (top) shows the moisture profile in a borehole located near the center of the mesa top disposal facility. The inferred vertical flux and an effective source term to the local recharge rate labeled 'source' in Fig. 4B (middle), evaluated as the difference in vertical flux between adjacent points, show nearly zero flux or source throughout the range in depth from 7m to 25m. Near the surface there is a net downward flux (negative value of flux) of about 1 cm/yr, but there is also a net sink (negative source term) in this region, presumably corresponding to an evaporative loss to the surface or surface-connected fractures. At ~30m depth there is an apparent source of moisture with vertical moisture movement and evaporation (net sink) away from that source location. Similar results are seen in all the boreholes at this depth, however, quantitatively, there is a large variability with location (18).
The near surface infiltration region also has a large variability with location dependent upon the local disposal operations (18). Modeling of deep percolation from the disposal pits is sensitive to assumed rooting depths, leaf area index, and other parameters which govern the detailed surface water balance (19). The large variability in surface flux is consistent with the broad range measured in surface soil moisture content (20).
The source term indicated by the vertical difference in moisture flux can also be normalized per unit depth which allows the source to be expressed as an inverse time scale. This time scale can be interpreted as a characteristic time over which the moisture flux (labeled St-inv in Fig. 4C) is changing locally due to liquid phase movement, or, the time scale over which the moisture content (labeled St-inv*vol%) is changing if the entire vertical component of the divergence of flux is interpreted as a time dependent effect.
In Fig. 4C (bottom) the source term time scale for the moisture content (St-inv*vol%) is seen to be at least one year at all locations, and 100-1000 years over most of the 'low fluxregion' identified from Fig. 4B. In the near surface infiltration region, the observed characteristic time scale of 6-10 years implies deep penetration only once every several years, consistent with predictions by detailed surface water balance modeling studies (19). Interestingly, the apparent source at the ~30m horizon has the minimum characteristic source time scale of about 1-3 years, consistent with significant infiltration once every few years. The short times near depth 30m may be an artifact of the unresolved stratigraphic hydrologic properties near the 1b-1a interface or may indicate a significant local source. Field studies are currently underway to resolve the matric properties within this region, which should allow a determination as to whether the apparent source term is real.
If the apparent source of moisture proves to be real, it may indicate moisture influx by horizontal transport from the adjacent canyons or from

another fast flow path. A possible explanation is that this elevation is the bottom of a network of surface-connected fractures which allow transient infiltration during intense and infrequent storm events. The magnitude of the source term as a characteristic time scale of about 1-3 years is consistent with significant recharge once every few years.

DISCUSSION

Transients

Field studies (4,5) and analyses (18) indicate that transients in moisture content within the Bandelier Tuff matrix are dampened over short distances of 1-2m. Transients are expected to play a negligible role in moisture flux through the mesa tuff matrix compared to steady state flux. Transients can be significant if fast paths exist, e.g., near elements of surface-connected macro-porosity which can include surface-connected fractures, horizontal strata of high permeability (as proposed may occur at the surge beds between Units 2a and 2b) or other possible 'macro-pores'. An example of this may be the moist horizon observed near the vitrified-devitrified interface at ~30m depth. These transients average to an effective steady state moisture flux and moisture source term for long time scale numerical simulations.

Vapor Phase Flow

Vapor phase movement may be enhanced by diffusion due to barometric pumping or temperature fluctuations especially in strata of high permeability, however, the net convective movement of air through the tuff matrix is negligible. Evidence suggests convective movement through surface-connected features is significant and may influence the matrix flow. As such, diffusion of vapor phase contaminants is related to empirically determined effective diffusion coefficients which include possible barometric pumping effects.

Moisture profiles are expected to be driven by vapor diffusive movement when the moisture content falls below a specific value, which is about 2-5% for the hydrologic properties of the Bandelier Tuff under Area G. Here, in the low flux, dry region of the mesa interior, vapor phase loss through evaporation to surface connected fractures may contribute as a local sink term to drying regions below the moisture content expected to support liquid phase movement. It may be possible to model this as a sink term in the liquid phase matrix transport equations. To model transient dynamics between the fractures and the matrix, more sophisticated source/sink terms need to be considered such as that afforded by a dual porosity, dual permeability numerical model which can account for rapid fracture flow following infiltration events and evaporation along fractures during dry periods.

Upward and Horizontal Migration

Analysis of upward vertical moisture or contaminant flux from the disposal units to the surface is on-going. Preliminary results suggest near surface moisture profiles relax rapidly enough that long-term upward contaminant transport is negligible, leading to less surface contamination than the small amount attributed to translocation by biotic species as analyzed previously (1).

A preliminary parametric evaluation of horizontal moisture flux from the disposal unit to the mesa edges shows small contaminant concentrations can reach the mesa edge on the time scale of a thousand years. Numerical simulations currently in progress in accurate 2-D mesa geometry yield similar results and show radionuclide concentrations in the adjacent canyons comparable to that eventually reaching the ground water

compliance point. Contamination at the mesa edge is assumed to be carried to the adjacent canyon floor by run-off and will be input to the off-site receptor dosimetry model and to a surface contamination source term for subsequent unsaturated transport to the deep aquifer under the saturation conditions existing beneath the canyon. The net contribution to canyon receptor dose and to deep ground water contamination via this canyon contamination route is expected to be demonstrated to be small compared to the direct path beneath the mesa site.

Canyon Recharge

Recharge under the canyons adjacent to the mesa top disposal facility is likely to be much larger than that predicted within the mesa. Borehole data at nearby canyon locations shows volumetric moisture content values greater than 10% and profiles which do not vary greatly with depth in the Otowi layer. Assuming unit gradient conditions, valid under the reasonable assumptions that $Q/z \sim 0$, and $hm/z \sim 0$ (where Q is volumetric water content and hm is matric potential expressed as a head) then the recharge rate is evaluated from the Kunsat curve (Fig. 2) and corresponds with (1 to ~30) cm/yr over the observed moisture range in the Otowi from 10% to 22%. This large recharge rate may mix with the low recharge rate under the mesa at some depth, dependent upon the complex 3-D stratigraphy and stratigraphic properties. This is the subject of on-going investigation.

Toward a Conceptual Model

In this iteration of continuing analyses, the conceptual model which emerges considers first the unperturbed system and then the result of disposal operations. Transient events and vapor-liquid phase coupling can be modeled using local sources (increased local infiltration) and sinks (net evaporation from fractures or surge beds) or using more sophisticated dual porosity, dual permeability models.

Vertical contaminant flux through the unsaturated zone may be complicated by moisture source and sink terms for elevations equal to and above the adjacent canyon floors. The physical nature of these terms is uncertain, however, a picture consistent with data in the upper most strata assumes that infiltration and drying from the fractures in the mesa contribute to near surface (0-10m) moisture profiles and deeper (10-25m) drying relative to that expected for a constant vertical moisture flux. At the elevation of the adjacent canyons there is evidence of a moisture source which implies moisture migration from canyon alluvial aquifers with possible 2-D and 3-D effects, or deep infiltration through open fractures. The evidence is ambiguous and intended to be resolved in on-going field studies.

Disposal operations have been projected to increase the net moisture flux to the aquifer by over 200% of the unperturbed flux (1,3), through effectively increasing the moisture content and thus the hydraulic conductivity of the region beneath the disposal units and thus beneath the mesa as a whole. This perturbation is very sensitive to the assumed ground cover and rooting depth on the disposal unit post-closure covers (19). The effect of disposal operations on moisture flux and therefore contaminant migration from the site is therefore likely to be significant, emphasizing that operations should be conducted to minimize the perturbations to a geologic system which is naturally well suited to minimize contaminant migration and maximize waste isolation.

Unsaturated transport from the disposal site through each of the strata to the main aquifer is being approximated using conservative estimates

for the unknown transport properties in the deeper strata. The net result in concentrations and transit time to the aquifer is being revised from that determined in the original steady state analysis (1,3) to include transport through the deeper basalt layers and 3-D geometry effects.

CONCLUSIONS

As more data and analyses accumulate, the best estimate of the mean recharge rate in the upper stratigraphic layers within the mesa decreases while the variation between locations remains large. Our present best estimate is that the mesa interior is dominated by vapor phase movement and supports negligible liquid phase movement at least down to an elevation near the adjacent canyon floors. This holds under undisturbed conditions but is uncertain under the disturbance of disposal operations. A moisture source is apparent in analyses of the moisture profile peak observed near the depth of the interface between the vitrified and the devitrified tuff, also near the elevation of the adjacent canyon floors. Surface connected fractures to this depth could explain this source although the analysis method is inconclusive, subject to data uncertainties requiring additional field work for verification. At greater depths below the mesa the recharge rate is less well determined but results are consistent with a downward flux of 1 mm/yr or less directly beneath the mesa. Beneath the adjacent canyons the recharge rate is higher and remains to be quantified in near future studies. Preliminary results showed little mixing of infiltration originating beneath the canyon and mesa in the case of horizontal stratigraphy. Recent model results show different behavior with mixing sensitive to the imposed dip of some units. The extent of mixing between canyon and mesa infiltration in more realistic 3-D geometry is currently under evaluation. The implications for PA modeling is the subject of on-going work.

32-3
U.S. NUCLEAR REGULATORY COMMISSION STAFF TECHNICAL POSITION ON EFFLUENT DISPOSAL AT LICENSED URANIUM RECOVERY FACILITIES
Latif Hamdan

Chris McKenney

Division of Waste Management
Office of Nuclear Material Safety and Safeguards
U. S. Nuclear Regulatory Commission

ABSTRACT

NRC-licensed uranium recovery operations, including conventional mills and in situ leach (ISL) facilities, generate liquid waste (i.e., effluent) that requires proper disposal. This paper discusses a Staff Technical Position (STP) that was issued by NRC's Division of Waste Management in April 1995, which provides the technical and regulatory basis for review and evaluation of proposals for effluent disposal at NRC-licensed uranium recovery sites. The STP is primarily intended to guide NRC staff reviews of site-specific proposals for disposal of liquid waste at conventional mills and ISL facilities; but the STP can also be used by licensees for the preparation of such proposals.

According to the STP, disposal of liquid waste at licensed uranium recovery facilities should comply with the design standards and other provisions for ground water protection in Appendix A to 10 CFR Part 40; the dose limits and other regulations in Subparts K and D, 10 CFR Part 20, as applicable depending on the proposed disposal procedure; and NRC's decommissioning requirements. In addition, the STP points out that in accordance with the provisions of Part 20, compliance with the dose limits in Part 20 does not relieve licensees from complying with the other applicable Federal, State, and local environmental and health protection regulations governing any other toxic or hazardous properties of materials that may be disposed under Part 20, Subpart K.

Specific regulatory requirements and guidance on compliance with the NRC regulations at particular sites are outlined for four known effluent disposal methods practiced at uranium recovery facilities. These are: on-site evaporation, on-site land application including on-site irrigation, release in surface waters, and injection in deep wells.

BACKGROUND

NRC-licensed uranium recovery facilities, including conventional mills and in situ leach (ISL) facilities, generate liquid waste (i.e., effluent) that requires proper disposal. At conventional mills, effluent may include liquid wastes discharged from mills, tailings liquor, and contaminated water recovered from ground-water corrective action programs and tailings dewatering activities.

At ISL facilities, effluent is generated from four liquid waste streams: Two involving the host aquifer and the other two originating from above ground operations. Liquid waste streams involving the host aquifer include production bleed and ground-water sweep. Production bleed is ground water extracted from the aquifer during the uranium recovery operation, in excess of injected water, in order to maintain a net ground-water inflow into the recovery zone and minimize or eliminate the migration of lixiviant and dissolved uranium outside the recovery zone. Ground-water sweep is ground water extracted primarily to restore ground-water quality in the recovery zone, after the ore extraction is stopped. Liquid waste streams originating from above ground operations include wastewater from yellowcake processing and reject brine from reverse osmosis treatment of contaminated water.

Evaporation has generally been used for management of liquid waste at licensed conventional mills and mill tailings disposal sites. This

practice involves discharging liquid waste in one or more on-site lined evaporation ponds where the water is lost to the atmosphere by surface evaporation and other evaporation enhancement systems, and the remaining sludge is placed in a licensed tailings disposal facility. At ISL facilities, management of liquid waste has generally involved such disposal practices as release in surface waters, on-site land applications including on-site irrigation, and injection in deep wells.

PURPOSE AND APPLICABILITY

The NRC Staff Technical Position (STP) on effluent disposal provides guidance and discusses the technical and regulatory basis for review and evaluation of proposals for disposal of liquid waste at licensed uranium recovery facilities.

The STP is primarily intended to guide NRC staff reviews of proposals for effluent disposal at conventional mill and ISL sites. The STP can also be used by NRC licensees and applicants for preparation of proposals for effluent disposal at particular sites.

The STP is applicable to both licensed and new facilities.

APPLICABLE REGULATIONS AND STANDARDS

In general, applications and proposals for effluent disposal at licensed uranium recovery facilities must comply with the regulations in Appendix A to 10 CFR Part 40; Subparts K and D, 10 CFR Part 20, as applicable depending on the proposed disposal procedure; and the applicable decommissioning requirements.

Applicable Regulations in Appendix A to 10 CFR Part 40

The applicable regulations in Appendix A to 10 CFR Part 40 (Appendix A) a, mainly include design standards for construction, maintenance, and operation of surface impoundments that are used for disposal of liquid waste or waste containing free liquids (Criteria 5A(1) through 5A(5)); installation of liners (Criterion 5E); and seepage control (Criterion 5F). Appendix A also includes other generally applicable provisions for ground-water protection, including site-specific standards for radioactive and non-radioactive hazardous constituents (Criteria 5B, 5C, and 13); corrective action programs (Criterion 5D); monitoring requirements (Criterion 7); and closure requirements (Criterion 6). Furthermore, Criterion 8 of Appendix A requires that byproduct materials be managed so as to conform to the applicable provisions under the U.S. Environmental Protection Agency's (EPA) National Pollutant Discharge Elimination System (NPDES) regulations, in 40 CFR Part 440, "Ore Mining and Dressing Point Source Category: Effluent Limitations Guidelines and New Source Performance Standards, Subpart C, Uranium, Radium, and Vanadium Ores Subcategory," as codified on January 1, 1983. A detailed discussion of the EPA NPDES regulations is outside the scope of this paper; but a summary of those NPDES regulations that are applicable to effluent disposal from licensed NRC facilities, including those pertaining to conventional mills and ISL facilities, is provided in an appendix to this paper.

Applicable Regulations in 10 CFR Part 20

Byproduct material disposal under Part 20b requires compliance with the applicable regulations in 10 CFR Part 20, Subpart K (Waste Disposal) and Subpart D (Radiation Dose Limits for Individual Members of the Public). Subpart K offers provisions for byproduct material disposal by "release in effluents"(20.2001), or other disposal methods proposed by the licensee (20.2002). Among other requirements, the provisions in 20.2001 and 20.2002 require compliance with the radiation dose limits for

individual members of the public in 20.1301, and a demonstration of compliance with these limits as provided in 20.1302.

The dose limits in 20.1301 include the total effective dose equivalent to individual members of the public (1 mSv/year), as well as the dose in any unrestricted area from external sources in any one hour (0.02 mSv in any one hour) (20.1301 (a) and (b)). In addition, the regulations allow a licensee to apply for Commission authorization in advance to operate up to an annual dose limit for an individual member of the public (5 mSv), which the Commission may generally authorize on a temporary basis or under special circumstances involving existing facilities (those designed prior to January, 1994), subject to the requirements in 20.1301 (1), (2), and (3). The regulations also require (in 20.1301 (d)) that licensees who are subject to the provisions of EPA's generally applicable environmental standards in 40 CFR Part 190 shall comply with these standards. In some cases, the Commission may impose additional restrictions on radiation levels and on the total quantity of radionuclides that may be released in effluents in order to restrict the collective dose at a particular site (20.1301 (e)).

In order to demonstrate compliance with the dose limits for individual members of the public in 20.1301, licensees and applicants must do so according to the provisions of 20.1302, which require that licensees:

a) demonstrate compliance with the dose limits for individual members of the public by conducting surveys of radiation levels in unrestricted and controlled areas and radioactive materials in effluents released to unrestricted and controlled areas; and,

b) show compliance with the annual dose limit by demonstrating, by measurement or calculation, that the total effective dose equivalent to the individual likely to receive the highest dose from the licensed operation does not exceed the annual dose limit; OR, by demonstrating that the annual average concentrations of released radioactive materials do not exceed the effluent concentration values (for water) provided in Table II of Appendix B to 20.1001-20.2401 and that the dose from external sources to a continuously exposed individual would not exceed the established standard (0.02 mSv/hour and 0.5 mSv in a year).

The provisions of 20.1302 also allow licensees, upon approval by the Commission, to adjust the effluent concentration values in Table II of Appendix B to 20.1001-20.2401 for members of the public to take account of the actual characteristics of effluent that will be released (20.1302 (c)).

The provisions of 20.2007 explicitly state that compliance with the dose limits in NRC regulations does not relieve licensees from complying with the other applicable Federal, State, and local environmental and health protection regulations governing any other toxic or hazardous properties of materials that may be disposed of under Subpart K.

In addition to the above requirements, licensees and applicants considering disposal of licensed materials under the provisions of either 20.2001 or 20.2002 are further required to comply with NRC's regulatory provisions for decommissioning of licensed facilities, prior to facility closure and license termination. These provisions include the interim cleanup criteria presently in use, and those specified in the final rule when the final rule is promulgated (the proposed radiological criteria for decommissioning are provided in the proposed rule in 10 CFR Part 20, Subpart E: 20.1401 through 20.1405, FR Vol 59, No. 161, page 43228, dated August 22, 1994).

APPLICABLE REGULATIONS BY DISPOSAL METHOD AND PROPOSAL REVIEW AND EVALUATION CRITERIA

In general, licensees of uranium recovery facilities are required to submit proposals for disposal of liquid waste, and obtain NRC's approval of the proposed procedures. Proposals will be approved on a site-specific basis by NRC staff based on demonstrated compliance with all of the applicable regulations.

The applicable regulations and proposal review and evaluation criteria are discussed in the following paragraphs for four disposal procedures that have been in practice at licensed uranium recovery facilities. These include: on-site evaporation; release in surface waters; on-site land applications; and injection in deep wells.

On-Site Evaporation

In accordance with the provisions of Appendix A, proposals for on-site evaporation systems must demonstrate that the proposed disposal facility is designed, operated, and closed in a manner that prevents migration of waste from the evaporation systems to a subsurface soil, ground water, or surface water. In addition, applicants must demonstrate that site-specific ground-water protection standards and monitoring requirements are adequately established to detect any migration of contaminants to the ground water and to implement corrective action to restore ground-water quality if and when necessary as required by the regulations.

Specifically, evaporation pond systems will be approved if they comply with the regulatory requirements in Appendix A. These mainly include the design provisions for surface impoundments (Criteria 5A(1) through 5A(5)); installation of liners (Criterion 5E); and seepage control (Criterion 5F). In addition, evaporation ponds must also meet other generally applicable provisions for ground-water protection, including site-specific standards for radioactive and non-radioactive hazardous constituents (Criteria 5B, 5C, and 13); corrective action programs (Criterion 5D); monitoring requirements (Criterion 7); and closure requirements (Criterion 6). The closure requirements in Criterion 6 would not apply to evaporation pond sites if the evaporation impoundments are dismantled after evaporation is stopped, and the remaining sludge and other contaminated materials are transferred to a licensed tailings impoundment for long-term disposal. However, compliance with the applicable decommissioning regulations would still be required.

Release in Surface Waters

Proposals for effluent release in surface waters must demonstrate compliance with the provisions of 20.2001 and 20.2007, as well as the effluent limitations in 40 CFR Part 440, as applicable based on site-specific conditions, pursuant to Criterion 8 of Appendix A to 10 CFR Part 40.

Specifically, release in surface waters must meet the regulatory provisions in 20.2001 (a)(3), which require compliance with the dose limits for individual members of the public in 20.1301. Licensees and applicants will need to demonstrate compliance with these limits in accordance with the provisions of 20.1302. The provisions in both 20.1301 and 20.1302 have already been discussed (see Applicable Regulations above). It should be noted that pursuant to the provisions of 20.2007, compliance with the dose limits under 20.1301 and 20.1302 will not relieve the licensees and applicants from complying with other applicable Federal, State, and local environmental and health protection regulations

governing any other toxic or hazardous properties of materials disposed of under Subpart K.

Compliance with Criterion 8 of Appendix A to 10 CFR Part 40 requires conformance to the EPA's NPDES provisions in 40 CFR Part 440, as applicable (see appendix). Licensees must obtain NPDES permits issued by the EPA or a permitting state, and demonstrate compliance with the effluent limitations in 40 CFR Part 440, Subpart C, as they apply to their particular sites.

The effluent limitations in 40 CFR 440 that are applicable to existing NRC-licensed facilities are provided in Tables I and II (in the appendix). The concentrations of pollutants discharged from existing mills, including conventional mine-mill facilities and process wastewater from existing ISL facilities, shall not exceed the BPT-based effluent limitations for "mill discharge" in Table I. At ISL facilities, process wastewater that must comply with the effluent limitations in Table I includes liquid waste generated from yellowcake processing, reject brine from reverse osmosis treatment of wastewater, and production bleed from the host aquifer.

Table I

The concentrations of pollutants discharged in mine drainage, from conventional mines and mines using ISL methods, shall not exceed the BAT-based effluent limitations for "mine drainage" in Table II. At ISL facilities, mine drainage that must comply with the effluent limitations in Table II includes groundwater sweep, or ground water extracted to restore water quality in the host aquifer after uranium and pregnant liquor extraction is stopped.

Table II

It is noted that the effluent limitations in Tables I and II are identical for Zn, Ra226 (dissolved and total concentration). However, the effluent limitations in Tables I and II are different in the following respects: 1) Table I provides effluent limitations for TSS, As, NH3, and pH for which there is no corresponding values in Table II; 2) the effluent limitation for COD in Table I is different from that in Table II; and 3) only Table II provides an effluent limitation for uranium. Therefore, ISL licensees proposing to dispose byproduct material by release in surface waters under 40 CFR Part 440 may need to satisfy different effluent limitations, depending on whether the effluent discharged is characterized as a "mill discharge" or a "mine drainage". Consequently, licensed ISL facilities that involve commingling of process wastewater and groundwater sweep wastewater in an interim common storage facility (i.e., storage reservoir) before the wastewater is released in surface waters have two alternative options to satisfy the regulations. Under the first option, a licensee would monitor the incoming wastewater by source and meet the corresponding effluent limitations separately for "process wastewater" and "mine drainage" at their respective points of discharge into the interim storage facility. If both input streams are within the appropriate effluent release limits, the licensee would be free to release the wastewater from the storage facility. In the second option, a licensee would not monitor the input streams, and would release the liquid waste under 10 CFR Part 20, Subpart K and meet the dose limits and other applicable requirements in 20.2001, before releasing the commingled wastewater in surface waters.

Licensees and applicants disposing effluent by release in surface waters are further required to comply with NRC's regulatory provisions for

decommissioning, prior to facility closure and license termination (decommissioning requirements have already been discussed under Applicable Regulations and Standards).

Land Applications

Proposals for disposal of liquid waste by on-site land applications, including irrigation, will be approved under the provisions of 20.2002. Licensees must in this case provide a description of the waste, including its physical and chemical properties that are important to risk evaluation; the proposed manner and conditions of waste disposal; an analysis and evaluation of pertinent information on the nature of the environment; information on the nature and location of other potentially affected facilities; and analyses and procedures to ensure that doses are maintained As Low As Reasonably Achievable (ALARA) and within the dose limits in Part 20 (i.e., 20.1301).

Proposals must analyze and assess projected concentrations of radioactive contaminants in the soil; projected impacts on ground-water and surface water quality, and on land uses including particularly crops and vegetation; and projected exposures and health risks that may be associated with radioactive constituents reaching the food chain to verify that the projected doses and risks conforming to the risk levels permitted under Part 20. It is expected that proposals include provisions for periodic soil surveys that include contaminant monitoring to verify that the contaminant levels in the soil do not exceed those projected, and a remediation plan that can be implemented in the event that the projected levels are exceeded.

In addition to the radiation dose, it may also be necessary in some cases to conduct analyses to assess the chemical toxicity of radioactive and non-radioactive constituents in order to evaluate the health risks associated with land applications involving irrigation at particular sites, in compliance with other applicable Federal, State, and local environmental and health protection regulations that must also be satisfied pursuant to 20.2007. Staff will work with appropriate Federal and State agencies if necessary to review site-specific chemical toxicity evaluations, and to verify that any necessary permits for this purpose are secured as warranted by the applicable regulations.

In the absence of compliance monitoring wells in the uppermost aquifer in the area used for effluent disposal or for installation of land application systems including temporary surface storage facilities, proposals must demonstrate that contaminants will not be returned to the ground water and cause exceedence of any site-specific ground-water protection standards that are established pursuant to Appendix A of 10 CFR Part 40.

Licensees and applicants disposing effluent by on-site land applications are further required to comply with NRC's regulatory provisions for decommissioning, prior to facility closure and license termination (decommissioning requirements have already been discussed under Applicable Regulations and Standards).

Deep-Well Injection

Proposals for disposal of liquid waste by injection in deep wells must meet the regulatory provisions in 20.2002. Specifically, proposals must in this case include a description of the waste, including its physical and chemical properties that are important to risk evaluation; the proposed manner and conditions of waste disposal; an analysis and evaluation of pertinent information on the nature of the environment;

information on the nature and location of other potentially affected facilities; and analyses and procedures to ensure that doses are ALARA, and within the dose limits in Part 20 (i.e., 20.1301).

Proposals must also demonstrate that the injection zone is confined, that it is not a drinking water source, and that the injected contaminants will not cause exceedence of any established site-specific ground-water protection standards in the uppermost aquifer or result in any cross contamination that would adversely impact another zone that is a source of drinking water. If necessary and warranted by site conditions, proposals may include provisions for periodic ground-water monitoring in the vicinity of the injection well to verify that drinking water zones are free from cross contamination, and a remediation plan that can be implemented in the event that unacceptable levels of contamination are detected.

In addition, pursuant to the provisions of 20.2007, proposals for disposal by injection in deep wells must also meet any other applicable Federal, State, and local government regulations pertaining to deep well injection, and obtain any necessary permits for this purpose. In particular, proposals must satisfy the EPA's regulatory provisions relevant to the injection of radioactive waste under the Underground Injection Control (UIC) Program (i.e., 40 CFR Parts 144, 145 and 146), and obtain necessary permits from the EPA and/or States authorized by EPA to enforce these provisions. In general, proposals that satisfy the EPA regulations under the UIC program will be approved by NRC staff.

Licensees and applicants disposing effluent by injection in deep wells are further required to comply with NRC's regulatory provisions for decommissioning, prior to facility closure and license termination (decommissioning requirements have already been discussed under Applicable Regulations and Standards).

ISSUES

The NRC staff has received many comments on the STP from the uranium industry. The primary issues raised by the industry to date are:

1) The soil cleanup requirement in the proposed rule for decommissioning of licensed facilities is too stringent and cannot possibly be met by the licensees disposing effluent by land application/irrigation.

2) According to the industry, the sludge in the radium settling ponds may no longer be considered as an 11e.(2) byproduct material if the groundwater sweep is considered as a mine drainage and not an 11e.(2) byproduct material; therefore, licensees may not be able to continue the practice of sludge disposal in tailings impoundments.

These issues are not considered germane to the STP because the STP only interprets and provides guidance on implementation of the applicable regulations, and is not a rulemaking instrument. Nevertheless, these are important issues and the staff will make necessary revisions to the STP as warranted after the issues have been satisfactorily resolved.

APPENDIX

A Summary of Effluent Limitations and Standards Applicable to NRC Licensed Facilities in 40 CFR Part 440: "Ore Mining and Dressing Point Source Category,Subpart C, Uranium, Radium and Vanadium Ores Subcategory"

The U.S. Environmental Protection Agency's (EPA) regulations in 40 CFR 440 that are applicable to NRC licensed uranium recovery facilities are provided in 40 CFR 440.30, 440.32, and 440.33. Since the NRC does not regulate conventional mining, the effluent limitations in 40 CFR 440 pertaining exclusively to conventional mines, including the new source performance standards, in 440.34, are not applicable to NRC licensed facilities and will not be discussed in this summary.

Effluent limitations in 40 CFR Part 440 that are applicable to NRC-licensed facilities are reproduced in Tables I and II. The effluent limitations in Table I, representing the degree of effluent reduction attainable by the application of the best practicable control technology available (BPT), are applicable to the concentrations of pollutants discharged from existing mills, including conventional mill-mine facilities and mines using in situ leach (ISL) methods. The effluent limitations in Table II, representing the degree of effluent reduction attainable by the application of the best available technology technologically achievable (BAT), are applicable to pollutants in mine drainage from existing mines, including conventional mines and mines using ISL methods.

Treatment technology for specific sites will be approved by the EPA based on the regulatory provisions in 40 CFR Part 125: Criteria and Standards for the National Pollutant Discharge Elimination System; Subpart A: Criteria and Standards for Imposing Technology Based Treatment Requirements Under Sections 301 (b) and 402 of the Act (i.e. Clean Water Act) (40 CFR Part 125, 125.1 through 125.3).

The definition of ISL methods in 40 CFR Part 440 indicates that in situ mine and mill process wastewater does not include discharges from wells from within or surrounding the in situ mines used to restore aquifers after all actual mining activity (i.e., extraction of ore or pregnant liquor from the in situ process) has been completed (40 CFR Part 440, Subpart L, and 47 FR 54604). NRC's Office of the General Counsel has interpreted the EPA regulations such that the effluent limitations in Table I would apply to wastewater discharge from conventional mills and process wastewater discharge from ISL facilities; and that the limitations in Table II would apply to mine drainage from conventional mines (unregulated by NRC) and to groundwater sweep discharged from ISL facilities as a result of aquifer cleanup activities after ore and pregnant liquor extraction is stopped.

Therefore, effluent discharge from existing mills, including process wastewater discharge from existing ISL facilities, shall not exceed the BPT-based effluent limitations provided for "mill discharge" in Table I. Groundwater sweep from existing ISL facilities, shall not exceed the BAT-based effluent limitations for "mine drainage" provided in Table II.

HLW DISPOSAL IN DEEP SULFUR-FILLED BOREHOLES: START OF R&D*

Alexei V. Byalko
L.D. Landau Institute for Theoretical Physics
117940, Kosygin St., 2
Moscow, Russia

ABSTRACT

According to a new concept for high level nuclear waste (HLW) disposal which was recently suggested 1) and discussed 2), great number of small (of about 0.2---0.3 m in diameter) capsules with HLW are loaded in

sequences into the mouth of deep (about 4 km), narrow (less than 1 m in diameter) sulfur-filled borehole. The capsules sink downward melting sulfur by their rad-heat and after about a year will reach the borehole bottom where they accumulate - initially as a column of adjusted capsules. Being relatively cold (120C) during the loading process the capsules near the borehole bottom will undergo slow heating up to temperatures about 400C, causing thermal and chemical destruction of the borehole walls along the column of accumulation. At these temperatures sulfur reacts mainly with oxidized iron Fe(II) of rocks forming stable pyrite and troilite. Then capsules should form an ensemble (hot magma droplet) of diameter about a few meters and of temperature exceeding the rocks melting temperature (1600C). Due to its higher than rock average density such ensemble will sink down up to the moment (30-100 years) when its decreasing radioactivity becomes insufficient to melt rocks thus forming a deposition at depth 5 to 8 km.

The experimental and computer research of related processes was going in the directions:

1) Study of sulfur-granite interactions in the temperature range 120 to 550C (Natalia A. Kosyakova, Institute of Experimental Mineralogy, Russian Academy of Sciences [RAS], Chernogolovka). First results are: liquid sulfur penetrates through granite micro-crackings and slowly interacts with surface of grains. At moderate temperatures water-permeability of sulfurized granite decreases. Durability of obtained materials is under further investigation.

2) Study of dynamic melting around a single model capsule (Barrikad V. Zamyshliayev, Vladimir M. Chernyshev, Viktor S. Osolovsky, Central physical-technical institute, Sergiev Posad) and around groups of capsules heated by microwaves (Andrei V. Vityazev A.V., Julius I. Zetzer, Igor B. Monastyrsky Georgy A. Ovsyannikov, Institute for Dynamics of Geospheres RAS, Moscow). The nontrivial equilibrium form of heat evolving and simultaneously sinking ensemble was found in experiments with microwave heating. Computer modelling is intended to confirm this dynamic equilibrium and to find its possible modifications in real media.

3) Study of thermally induced stresses developing during rocks heating and then cooling after solidification of rock melt. (Yuri A. Paveshenko, Institute of Applied Mathematics RAS, Moscow). In a long-term run these stresses can in principle cause multiple cracks in fresh rocks which could lead to water convection driven by the radioactive heat source.

THE "NEWDEEDS" CONCEPT AND RELATED PROBLEMS

The idea of the "NEWDEEDS" (NuclEar Waste DEEp Disposal in Sulfur filled boreholes) concept (1,2) is to transport high-active nuclear waste to great depths through a narrow channel bored in rocks and filled with sulfur. It is a development of a known (3,4) idea of HLW self-burial but starting from initial deep horizon reached by borehole thus providing higher safety (patents (5,6), the first variant reported in 1991 (7)). The theoretical results show a principal possibility for its practical implementation. The disposal depth leads to high isolation from the environment. The estimates show reasonable economic efficiency of the proposed method due to a possibility of multiple use of the borehole. The diameter of the borehole in rocks (granites) can be made as small as 0.4---0.5 m in its main cross-section and near the bottom. The next operation is a filling of the borehole with natural sulfur. This operation is a problem for technology, but no principal difficulties can be seen on the way of its realization. Then loading of nuclear waste

starts: a consequence of hermetically-sealed capsules with HLW sink down in sulfur filled borehole, melting sulfur by the heat release of waste, it is possible by a series of rather small capsules with the diameter less than 0.2 m. If the time interval between consequent capsules is less than 1 day, then each capsule is moving in a thermal channel of previous capsules, the theory of such consequent loading was given in (1). The peculiarity of this loading process is based on a fact that the sulfur heat conductivity is more than 10 times lower than that of rocks. The temperature of the hole walls remains low during loading, it never exceeds the sulfur melting temperature 113---120C (depending on pressure).

Capsules accumulate near the borehole bottom causing a local temperature increase, which in its turn causes the thermal and mineral instability of the surrounding rocks. The criterion of the borehole thermal instability obtained in (1), shows that it occurs about a year after the start of accumulation when temperature near the bottom increases up to 300-400C. Somewhere in the same temperature region the mineralogical interactions of sulfur with granite also leads to sharp decrease of the rock durability.

The loss of stability due to the thermal expansion and sulfur erosion of the walls leads to deformation of the hole. Then the whole heavy column of the accumulated waste (a several hundred meters) subsides to the bottom of the hole. There the ensemble of capsules is formed (a hot droplet or heavy magma chamber). Its temperature will be growing to those of softening of granites (about 1600C). By that moment the whole sulfur in this droplet is to be spent already for chemical reactions, the basic products of which are solid, water insoluble pyrite and pyrrhotite. Since the densities of both pyrite and encapsulated waste are higher than that of granite, a hot droplet will separate from the sulfur column and start melting rocks in a self-burial regime. The theory of sinking of a hot sphere was given in (8), however the equilibrium form of a liquid hot moving body was unclear.

After some cooling of the droplet due to decay of the most active isotopes with the half-time 30 years a solid water-non-soluble matrix will form around the disposal, it should preserve a leakage of radionuclides into underground waters. However some cracking of this solid matrix is possible during its cooling, this process was unclear in details.

RESEARCH DIRECTIONS

On account of great responsibility for radioactive and ecology safety it appears to be necessary to carry out some laboratory simulations of main stages of the suggested method of HLW disposal without actual use of radioactive isotopes. Four intercrossing directions were suggested for further theoretical and experimental research:

1) calculations of thermodynamical equilibrium in the sulfur-rock system and comparing its results with the experimental rock samples undergoing thermal contact with sulfur;
2) a study of electrically heated capsules sinking in sulfur;
3) a study of collective motion simulated by microwave heating of liquid droplet in a microwave transparent media;
4) a study of solidification in the trace of a hot droplet.

Here some results of these studies will be briefly reported.

MINERALOGICAL STUDIES

We found no scientific literature on mineralogical experiments on granite rock interactions with sulfur. Such a contact is also not observed in natural environment. Preliminary theoretical results for thermodynamical equilibrium in the granite rock-sulfur system are included in the book (1). The intermediate mineral compositions are determined by temperature and the overall sulfur concentration among a vast variety of possible minerals and chemical compounds in the system of sulfur, water and iron oxides. Other natural minerals (oxides that constitute granite rocks) apart from iron II and III oxides and water were found not to interact with sulfur, they produce only secondary influence on the final equilibrium phases. Actually in the temperature region 100-600C 12 stable regions on the phase diagram for the system FeO+S and 24 stable regions on the phase diagram for the element system Fe-S-H-O were found theoretically.

The mineral distribution in the cross-section of the initial mineral sample (granite) after a fixed exposition with hot sulfur is determined by simultaneous processes of heat conductivity and diffusion along natural cracks. It corresponds to a cross-section of the phase diagram known from thermodynamic calculations, thus it could give a principal possibility to compare experimental and theoretical results. These results also will give a possibility to predict the final mineral composition along the sulfur filled borehole and column with radioactive waste. Study of simultaneous processes of heat transfer (the rock heat conductivity is known) and diffusion (the diffusivity along cracks is unknown and nearly impossible to evaluate theoretically) should give estimates of the time scale for the mineral processes involved. These results are urgently need to be incorporated in the computer program modelling the HLW disposal behavior during loading, initial heating and future development.

The set of experiments was started in the Institute of Experimental Mineralogy RAS by Natalia A. Kosyakova. Its results will be published elsewhere and here are reported as a principal summary.

The samples for further analysis were obtained with a rock in sulfur exposition from 8 to 24 hours for fixed temperature in the range 120 to 500C. We made two types of mineralogical experiments. 1) Closed in vacuum quartz containers with a rock sample covered with melted sulfur were heated in stove and fast cooled after the exposition period. 2) To emulate a situation in real borehole we drilled a cylindrical hole in granite rock samples, filled it with sulfur and use a thin electric heater inside the hole with the open air contact and external cooling. The maximum reached temperature in the second type experiment was 160C. Then both type samples were cut and their surface analyzed optically and by electronic microanalyzers (the installations CAMEBAX and LINK) which generally give possibility to obtain a detailed mineral analysis along the samples with high space resolution.

The results of our mineralogical experiments occur to be in a sense unpredictable. First of all, we found that the liquid sulfur permeability in granite is very high. An exposition of a few hours in closed containers leads to full penetration and nearly homogeneous distribution of sulfur along samples of about a centimeter in size. In samples of the second experiment type we observed a visual sulfur gradient of a few millimeter deep from the hole, it was also statistically confirmed by the instrumental analysis. However, results given by electronic microanalyzers are rather difficult for simple mineralogical

interpretation. We found practically no exact mineral compositions with sulfur, moreover, the sulfur content was highly variable along the sample with fluctuations about the order of magnitude. Our preliminary conclusion is that the liquid sulfur penetration into solid granite is very effective along the micro cracks in between granite grains. Sulfur fills all the empty micro spacings in granite but only slow chemically interacts on surfaces of mineral grains.

First experiments to establish the durability of obtained sulfur exposed granite materials show that their strength is nearly unchanged for temperatures lower 160C and is drastically reduced at temperatures somewhere in the interval 300-400C. Moreover, we found even some increase of sample durability at low temperatures, but this conclusion is yet not statistically significant due to small number of tests.

EXPERIMENTS IN SULFUR WITH ELECTRICAL HEATING

Theoretical calculations for the processes going when hot capsules melt sulfur and move in the melt prove to be rather difficult since viscosity of sulfur strongly and unusually depends on temperature (after melting point it has a minimum, then sharply increases up to the maximum which is more than two orders higher than the minimum value, then slowly decreases). The other reason to determine the sinking rate experimentally is a complex convective structure in the upper part of hot capsule, especially in the case when small water impurities are residual in sulfur.

The sulfur melting experiments were fulfilled by Barrikad V. ZAMYSHLIAYEV, Vladimir M. CHERNYSHEV, Viktor S. OSOLOVSKY in Central physical-technical institute, Sergiev Posad (9). The general scheme of this experiment is rather simple. A metal sphere of diameter about 10 cm with an electric heater inside is placed on the surface of sulfur in a cement tube imitating the borehole. Two variants of initial sulfur constitution were tested: a)melted and then solidificated sulfur and b)dispersed sulfur with small content of water in spacings. These two variants correspond to the possibly different methods of the borehole filling with sulfur. This study was intended also to determine the proper method of the borehole filling. The tube and capsule radii and the thermal power are chosen to be close to real parameters of borehole and high level waste.

When the capsule heating is on, it begin to sink in sulfur inside the cement tube. Its position was measured by microwave detector and temperature measurements. This experiments gave velocities of capsules in dependences on the applied thermal power. The results generally confirmed the theoretical evaluation. The sinking velocity in melted and solidificated sulfur for a single sphere of 100 mm in diameter and the thermal power of 60 W proves to be about 1 mm/min that corresponds to 0.5 km per year. It means that sinking of a chain of consequent capsules of even lower power can reach an average velocity of a few kilometers per year.

Heating of the same capsule in dispersed sulfur with water remnants in spacings leads to reaching a final depth of about the sphere radius. The observed water convection in a cavity formed over the sphere was a main source of the heat removal. However, application of the additional air pressure inside of about 1.2 atm (extra) prevent the water boiling and lead to continuation of the sinking process with velocity close to the case of solid sulfur.

MICROWAVE HEATING EXPERIMENTS

A set of experiments in transparent solid-liquids with model microwave heating results the structure of convective flows (10). In the experiments with microwave heating paraffin was uses as a model solid-liquid media. The microwave installation of Institute for Dynamics of Geospheres with videotape recording gave possibility to obtain convective patterns around a hot droplet which models a magma chamber with HLW heating. Since current positions of capsule models (which absorb radiation) are changeable, a moving mechanical support with back regulating connection was designed and constructed. The process was recorded into videocassets for further investigation.

The second experiment with liquid heaters absorbing microwave radiation was intended to obtain experimentally a fraction of capsules remaining in the solidificated column. Its result was rather impressive. It was found that liquid heat evolving bodies in the process of sinking have no tendency of self separation or fractionating. Moreover, it was found that the equilibrium form of such hot moving droplets is not a tailed sphere with partial dispersion as it was supposed before experiments, but a dynamic stable saucer-like body.

The computer modelling of heated liquid body which melts down is under development (Yuri A. Paveshenko, Institute of Applied Mathematics RAS, Moscow). The other purpose of this calculations is to establish the distribution if thermal stresses around a cooling trace of a HLW self burial. In a long-term run these stresses can in principle cause multiple cracks in fresh rocks which could lead to water convection driven by the radioactive heat source. However at such depths due to heightened temperature and pressure the reverse process of cracks closing becomes also active.

The possible additional output of these experiments and computer modelling can be also valuable for study of natural geophysical processes such as magma ascending and gravitational separation of minerals.

CONCLUSION

The final goal of the current stage is to implement the obtained experimental results into a computer program with changeable interactive input and graphical output. The program should model all stages of the disposal development and predict the final underground fields of temperature and mineral depositions. In their turn, they can reveal in the first approximation the final radioactivity distribution.

This research was made possible in part by Grant M47000/47300 from the International Science Foundation and support of Ministry of Science.

U-234/U-238 FRACTIONATION IN VADOSE ZONE PORE WATERS OF THE APACHE LEAP TUFF

E. L. Hardin
R. L. Bassett
The University of Arizona

M. T. Murrell
Los Alamos National Laboratory

ABSTRACT
Decay of U-238 in the natural environment leads to production of U-234 (t1/2 = 2.48 x105yr). In a closed system of sufficient age the U-234/U-238 activity ratio (AR) approaches unity, but is > 1 in typical groundwater. The isotopes exhibit equivalent kinetic behavior in natural chemical reactions, so fractionation must result from the energy released by alpha-decay. The AR was analyzed in surface waters, near-surface fracture waters, perched waters, and vadose zone pore waters from the Apache Leap Tuff. This tuff has features that are similar to Yucca Mountain tuffs and amenable to investigation. Novel methods were used for sampling vadose zone pore waters from preserved drill cores. The AR for all surface, fracture, and near-surface pore water samples was in the range 1.4 to 2.1. A deeper transition in pore water AR from 2 to 5 correlated with trends in saturated matrix hydraulic conductivity and magnetic susceptibility, delimiting the penetration of oxidative weathering into the vadose zone. From C-14 apparent ages (1) it is evident that this multiple transition does not reflect the former high stand of a perched water table. A lumped parameter model was used to evaluate the relative contributions from selective leaching and direct recoil mechanisms to perched water fractionation at Apache Leap, integrating mass balance, radioactive decay, sorption, isotopic exchange, and direct recoil effects. The strategy was to identify a set of model parameters describing the total U concentration and AR for perched waters from different sampling locations without direct recoil, then recompute the ratios with direct recoil. The results showed that leaching selectivity is probably much greater than the observed mobile phase AR,

and that within the likely range of effective partitioning behavior the contribution from direct recoil to observed activity ratios is probably < 1.

INTRODUCTION

This study was motivated by the observation of elevated U-234 activity in perched waters in tuffs at Yucca Mountain, Apache Leap, and elsewhere. The general objectives were to investigate the spatial distribution of pore water fractionation, evaluate alternative conceptual models for fractionation, and identify implications for transport of natural U. Methods were developed to sample vadose zone pore waters for U isotopics, and applied at the Apache Leap Research Site (ALRS) to investigate U-234 fractionation throughout the vadose zone.

Davidson (1) described sampling pore waters from preserved tuff cores by core squeezing using the method and the equipment of Peters et al. (2). In the Apache Leap Tuff welding increases with depth, and this method was effectively limited to the uppermost 30 m of the section because of low water yield. Using the chemical separation and isotopic analysis methods described by Goldstein et al. (3) the U concentration and U-234/U-238 activity ratio (AR) of squeezed pore waters were compared with other waters from Apache Leap including surface waters, fracture waters from shallow borings, and perched waters (Table I, Fig. 1). A mixing plot shows that U leaching near the surface is different from the process that produces fractionation in deeper waters (Fig. 2).

Table I

Fig. 1

Fig. 2

PORE WATER SAMPLING BY FLUSHING OF PRESERVED CORES

A method was developed to inject Milli-Q water through tuff cores at a pressure of 15bars. Cores were preserved in Protec-Core packaging from the time of drilling. Leachates from 3 to 5 cores were composited yielding a total U mass of as little as ~1 ng. Accordingly, control and measurement of contamination were critical. A tracer was used to quantify leakage of confining fluid into the sample, and contamination from this source was concluded to be negligible. A blank of ~60 pg U was estimated for a typical isotopic measurement, which is less than the ~180 pg U blank estimated for core squeezing.

Using the flushing method for more densely welded samples, the AR was analyzed for pore waters from as deep as 100 m. A total of 35 cores were leached and 7 composites analyzed isotopically. Activity ratios from flushing are indistinguishable from ratios for squeezed pore waters (Table I) indicating that both methods sampled the same phase. The observed AR is a lower bound on actual pore water composition since the sample may acquire less fractionated U from the solid phase. As a byproduct of this method the matrix saturated hydraulic conductivity (Ksat) was measured.

The flushed pore water isotopics show that a transition occurs between 20 and 30 m depth in the DSB (Table I, Fig. 3) where the AR increases from 2 to ~5. Using equivalent U concentrations derived for the flushed pore water samples, a mixing plot (Fig. 2) shows that these new data are intermediate between near-surface waters and perched water.

Fig. 3

FRACTIONATION MECHANISMS

Selective leaching of U-234 from recoil-damaged sites apparently occurs in surface soils and near-surface fracture zones, given the short

residence time and the relation between total U and the AR for these waters (Fig. 2). A wide range of concentration was observed in squeezed near-surface pore waters, all with AR~2 (Table I).

The three perched water samples analyzed had similar C-14 ages (~3,000 yr) but samples from the tunnel discharge and Oak Flat borehole had 3 times more U (Table I). This is probably because the perched water table at Oak Flat lies within the near-surface porous tuff layer which is thicker there. At the ALRS the perched water table lies deeper within the formation where hydraulic conductivity is dominated by fractures. In the tunnel discharge (which probably recharges in Oak Flat) the AR is also moderately high (Table I). Where similar AR's occur over a wide concentration range the fractionation is generally attributable to selective leaching.

As pointed out by Petit et al. (4) congruently dissolving mineral phases that contain U-238 tend to dilute the excess U-234 derived from selective leaching, limiting fractionation. They argued that this always occurs given the U abundance and etching rates of rock-forming minerals. Attributing the observed perched water fractionation at the ALRS to selective leaching could imply unrealistic rates of congruent dissolution for U bearing minerals (e.g. <10-13 m/yr). Petit et al. proposed an auto-oxidative leaching mechanism instead, in which primary U-238 existing as U(4+) decays down to U-234(6+) and fractionation occurs because U(6+) is more soluble.

If sampled near-surface fracture waters represent recharge, then a selective leaching model for perched water at the ALRS requires a highly fractionated leaching "end member." The needed selectivity is directly related to the intensity of isotopic exchange with an adsorbed phase. Secondary minerals are present which tend to be good adsorbents but such partitioning could produce conditions favoring direct recoil, in which U-238 at or near the liquid:solid interface decays and the a-recoil leads to U-234 accumulation in the mobile phase. Recoil from U-238 adsorbed to secondary oxides has been suggested as the fractionation mechanism for perched waters from tuffs on the Nevada Test Site (Zielinski and Rosholt, 1978).

In the vadose zone at the ALRS, pore water residence time controlled by matrix Ksat might be a determinant of the direct recoil effect. Contrary evidence may be found in the C-14 apparent ages reported by Davidson (1) which ranged from 1,000 yr in the upper part of the tuff section to 3,000 yr in the perched zone, suggesting that residence time does not vary enough to account for the observed AR transition (Fig. 3). Alternatively, increased fractionation with depth could be caused by increased leaching selectivity at the depth to which weathering has penetrated and the rock is substantially oxidized, in accordance with the auto-oxidative leaching mechanism. Mechanisms for fractionation in vadose zone pore waters at the ALRS are the subject of ongoing investigation.

The AR transition at the ALRS correlates (within a depth range of < 10 m) with steeply decreasing Ksat and with a transition in magnetic susceptibility caused by oxidative weathering (6). At the nearby Oak Flat borehole, similar transitions in hydraulic properties and magnetic susceptibility occur at the modern perched water table. Vadose zone pore water AR's are less than the perched water AR, suggesting decay from a former high stand of perched water table roughly 105 yr ago. However, this possibility is contradicted by the C-14 apparent ages reported by Davidson (1), so it is evident that fractionation in deep vadose zone

pore waters developed independently of the perched water table elevation at Apache Leap.

The remainder of this paper evaluates the relative contributions from direct recoil and selective leaching in the perched zone at Apache Leap. This requires a model that integrates mass balance, radioactive decay, sorption, isotopic exchange, and direct recoil. The strategy was to describe the fractionation and total U in DSB and tunnel perched waters using selective leaching only, and then to use these parameters in the same model with direct recoil added.

STEADY STATE MODEL FOR FRACTIONATION IN THE PERCHED ZONE AT THE ALRS

Matrix hydraulic conductivity at the ALRS declines sharply with depth so that below a depth of 20 to 30 m recharge must move through fractures. Davidson (1) showed that perched water at the ALRS has low chloride similar to surface water, whereas the pore waters sampled had significantly more chloride which was likely leached. Thus surface waters move downward through fractures without acquiring much solute from vadose pore waters. Recharging waters from the surface are relatively unfractionated (AR~2) so it may be inferred that fractionation in the perched water (AR~6.2) occurs mostly in the perched zone. This is the rationale for a lumped parameter approach to modeling perched water fractionation.

The model is based on a system of equations (Fig. 4) solved using a Runge-Kutta method with adaptive step size (7). Initial conditions correspond to chemical and isotopic equilibrium of both the mobile and adsorbent phases with the combination of inflow and leaching. Radioactive decay begins at t=0, and time stepping to 1 My brings the system reasonably close to steady state U-234 concentrations in the mobile and adsorbent phases depending on the rate of isotopic exchange. Perched water residence time of 3,000 yr is based on the C-14 apparent age. Recharge with 100 ppt U and AR=2 similar to near-surface fracture waters is the inflow to the model.

Fig. 4

Preliminary data from selective extraction of Mn from pulverized tuff show that as much as half the whole rock Mn exists as MnO_2 (depending on the extent of oxidative weathering) containing about 50 ppm U (Fig. 5). Assuming typical values for MnO_2 abundance and pore water U concentration the whole-rock U partition coefficient is about K=100mL/g. The effective value for isotopic exchange is probably smaller because of desorption hysteresis and because part of the MnO_2 phase is inaccessible. The effective K for direct recoil is probably smaller still since this involves only U adsorbed within a few nanometers of fluid-filled pores in communication with the mobile phase.

Fig. 5

Leaching rates can be estimated under the assumption of a chemical steady state, from total U concentrations (Table I) and residence time from C-14 apparent age (3,000 yr). For the deep slant borehole (DSB) at the ALRS the corresponding leaching rate is 0.033 ppt/yr, and for the tunnel discharge it is 0.167 ppt/yr. This does not constrain the leaching selectivity, defined as the AR of leached U.

A key parameter for which few constraints are available is k, the rate constant controlling isotopic exchange. Whole rock U and Th analyses by fusion and ICP/MS show that the Th/U ratio changes little through the tuff section, therefore the rate constant must be large enough to permit sorption of leached U. If $k<10^{-14}$ sec-1 then more than a few percent of

the whole rock U would be lost over 1 My, given realistic leaching rates. Constraint on k was also derived by running the model with the initial condition of zero adsorbed U, showing that a k value of 3x10-14 sec-1 is sufficient for sorption equilibrium within a fraction of the age of the tuff (Fig. 6). If k exceeds this then significant isotopic equilibration occurs in <1My which is unrealistic given the observed fractionation.
Fig. 6
Calculations plotted in Fig. 7 show the relation between mobile phase AR, leaching selectivity, and partitioning. Strong partitioning causes dilution of the mobile phase AR even for very selective leaching, because of isotopic exchange and radioactive decay. The same values for the rate constant and leaching selectivity were used for both perched waters, but the leaching rates differed. The curves in Fig. 7 are based on concentrations of 200 and 600 ppt for the DSB and tunnel waters, respectively, with recharge having 100 ppt and AR=2. By assuming a value for leaching selectivity it is possible to pick K values for each perched water type (LAR~12 is about the smallest value that works for both). The difference between these K values reflects model mass balance requirements. The tunnel discharge K value is larger than the DSB value, which may mean that the effective adsorbent abundance is greater where there is more flow through the tuff matrix. Another application for the model could be to estimate K values from independent data, assume a selectivity, and compute values of the rate constant k for different waters.
Fig. 7
Adding direct recoil (Fig. 8) confirms that the incremental fractionation is important for larger values of K. Within the likely range of effective partitioning behavior the contribution from direct recoil to observed activity ratios is probably < 1, under the model assumptions.
Fig. 8
CONCLUSIONS
Fractionation in perched waters from the Apache Leap Tuff is attributable to selective leaching, with a minor contribution from direct recoil. Fractionation in surface and near-surface waters from the ALRS (AR~2) is attributable to less selective leaching from weathered rock. Activity ratios up to 5 were found in deep vadose pore waters and perched waters, however, the AR transition correlated with a trend in magnetic susceptibility representing the penetration of oxidative weathering. From apparent C-14 ages (1) it is evident that this multiple transition does not reflect a former high stand of the perched water table.
Using a mechanistic model it was shown that leaching selectivity is probably much greater than the observed mobile phase AR. Assuming a minimum value for selectivity consistent with the observed AR, the model permits estimation of the in situ partition coefficient. Model assumptions include a hydraulic steady state, first-order isotopic exchange kinetics, and chemical equilibrium with respect to U-238. Fractionation encountered in perched water at Yucca Mountain (AR~7.5, J. Stuckless, personal communication) is probably not limited to perched zones but exists in vadose zone pore waters as well. Fractionation can be interpreted in terms of conditions that promote or inhibit retardation of natural U. These results in conjunction with the C-14 data of Davidson (1) show that rapid recharge pathways through the vadose zone can be identified from the isotopic character of pore waters.

ABSTRACT

The United States Department of Energy has used subsidence craters from underground nuclear detonations in Yucca Flat on the Nevada Test Site for disposal of low-level radioactive waste since the late 1960s. Two adjoining craters in the Area 3 Radioactive Waste Management Site were filled primarily with bulk radioactive waste and temporarily capped with a minimum of 30 cm of native alluvium in 1987. Effects of the subsurface detonation on the hydrologic properties of the alluvium near a subsidence crater, the effect on the soil moisture regime, and the migration of chemical constituents and radionuclides from the waste were examined in this study. Two angle boreholes were cored and drilled to provide samples for analysis and comparison. One passed under a subsidence crater used for waste disposal while the other passed through undisturbed alluvium. In situ water content and water potential measurements on core samples

from the two boreholes were similar. Water potential gradients were steepest near the surface and decreased with depth and indicated evaporative conditions in the zone penetrated by the boreholes. Stable isotope ratios for soil pore water were consistent with evaporative conditions. Chemical analyses of samples for waste constituents showed no evidence of migration of metals into the alluvium below the waste. Similar results were found for the gamma emitters 241Am, 60Co and 137Cs. Tritium concentrations, however, were found to be somewhat elevated. Estimates of tritium diffusion from the detonation cavity indicated that the waste was the probable source of the tritium observed in the borehole samples.

INTRODUCTION

The thick vadose zones found in alluvial valleys of deserts in the western United States have characteristics favorable for shallow burial of solidified radioactive waste. The great depth to the water table and the arid climate in these regions combine to inhibit transport of radionuclides to groundwater below the waste. Shallow disposal in alluvium usually requires excavation of pits or trenches in the alluvium to receive the waste. However, in Yucca Flat on the Nevada Test Site in southern Nevada hundreds of subsidence craters remain as a result of the nuclear weapons testing program. An early proposal for disposal of radioactive waste in deep, dry alluvial deposits of Yucca Flat considered use of a crater formed by the near-surface detonation of a nuclear device as a waste cell (1).

Four subsidence craters in the Area 3 Radioactive Waste Management Site (RWMS) in Yucca Flat either have been or are now being used for disposal of low-level radioactive waste. Tests that led to the formation of the craters in the Area 3 RWMS were conducted hundreds of meters below the ground surface in shafts bored vertically into the alluvium. Upon detonation of the nuclear device, pressures and temperatures increased forming a cavity in the alluvium. When the gas pressure dissipated to a point at which it could no longer support the overburden, the roof of the cavity collapsed and the void region propagated upward to the surface forming a saucer-like subsidence crater on the surface (2). The region through which the void propagates is referred to as the chimney. An important consideration in the use of craters for waste disposal is whether the ability of the climate and geologic formation to isolate the waste from the water table is compromised by the presence of the chimney. Although hundreds of nuclear tests have been conducted in the vadose zone, little is known about the properties of chimneys (3). The little that is known relates to the size distribution of rubble formed in competent rock such as welded tuffs and granodiorite and cannot be extrapolated to alluvium or friable tuffs (3). Some measurements of saturated hydraulic conductivity have been made on core taken from near the surface of subsidence craters in alluvium (4). Values of hydraulic conductivity were similar to those found in an undisturbed area (5). Although hydraulic properties of chimneys in alluvium may not be different from undisturbed alluvium, studies of a crater in Yucca Flat (4) have demonstrated that craters capture precipitation and may capture runoff. Ponded conditions develop which enhance infiltration through the surface of the crater. The magnitude of the enchanced infiltration depends not only on the precipitation but also on the size of the catchment area outside the crater boundary. This increased infiltration could potentially result in recharge to the water table. Tyler et al.

(1992) (4) estimated that the infiltration rate through the bottom of a crater in Yucca Flat was approximately 0.6 m yr -1.

In the present study hydrologic properties of the alluvium in the vicinity of a subsidence crater were compared with those from an undisturbed area to determine if these properties were affected by formation of the crater. The effect of the presence of the crater and its use for waste disposal on the soil moisture status was examined, and sampling was conducted to determine if migration of chemical constituents and radionuclides from the waste had occurred. Two angle boreholes were cored and drilled to provide samples for analysis and comparison. The first borehole passed under a subsidence crater used for waste disposal whereas the other passed through undisturbed alluvium adjacent to the crater.

SITE DESCRIPTION

The RWMS is located at an elevation of approximately 1220 m in an alluvium-filled basin typical of the Basin and Range Physiographic Province. Alluvium beneath the RWMS is chiefly sand-sized clasts derived primarily from Tertiary volcanic rocks and Paleozoic carbonate rocks. Estimates of the thickness of the alluvium range from 370 to 460 m, with the uppermost aquifer being encountered at a depth of 490 m. Characterization of physical properties conducted in an area within a few kilometers of the study site suggest that undisturbed alluvium beneath the Area 3 RWMS has no flow-impeding layers or preferential flow paths. Air temperatures in Yucca Flat are typical of the upper Mohave Desert with large diurnal and seasonal variations. Precipitation is minimal and also highly variable with an annual mean of 15.9 cm and a standard deviation of 7.9 cm. Evaporation from an open water surface was estimated to be approximately 1800 mm/yr for a site in Yucca Flat (R. H. French, unpublished data). The small ratio of precipitation to evaporation implies that the moisture distribution in the upper part of the alluvium is strongly influenced by evapotranspiration.

A waste cell with approximately 228,000 m3 capacity was formed at the Area 3 RWMS by excavating alluvium between two adjacent subsidence craters, U3ax and U3bl, as shown in Fig. 1. Prior to excavation, U3ax was 19m deep and 138 m in diameter and U3bl was 14 m deep and 122 m in diameter. Both craters were formed from underground nuclear tests conducted in 1962. Disposal in U3ax, the deeper crater, began in the late 1960s. Disposal in U3bl began in 1984, as the level in U3ax reached that of U3bl. Waste forms consist primarily of contaminated soil and scrap metal with some construction debris, equipment, and containerized waste. Small quantities of oil, fuel, and ethylene glycol remaining in machinery and tanks were the only liquid wastes possibly placed in U3ax or U3bl. The radioactive constituents were estimated to be approximately 1200 curies with 85 percent of the activity being due to tritium. The next largest contributor was 60Co which accounted for only 1.6 percent of the total curie content. Most of the curie content was disposed during the years 1976 to 1981. The only known hazardous constituents were lead and cadmium. A temporary cover of native alluvium was placed over the waste in December of 1987. The cover is from 0.3 to as much as 4 m thick.

Fig. 1

METHODS

Two 45o angle boreholes were cored and drilled to a vertical depth of 50m to provide samples for analysis and comparison (Fig. 1). The first borehole passed under one of the subsidence craters used for waste

disposal (U3bl) shown in Fig. 2 whereas the other passed through undisturbed alluvium. The craters U3ah and U3at shown in Fig. 1 are currently being used for the disposal of low-level bulk radioactive waste.

Fig. 2

A casing advance under-reaming system was used to drill the boreholes. Air was the only drilling fluid used in this system to minimize the disturbance to the alluvium samples. The method used to obtain representative core samples was to drive a sample tube containing segmented polycarbonate liners 8.9 cm in diameter. Multiple core segments were collected from each 0.8 m core run. Measurements of the ambient water potential were made on the core samples using a water activity meter. Stable isotope concentrations were determined by mass spectroscopy following toluene distillation. The following analyses were conducted on drill cuttings samples. Lead and cadmium concentrations were determined by atomic absorption spectroscopy. Activities of 241Am, 60Co and 137Cs were determined by gamma spectroscopy. Tritium concentrations were determined using liquid scintillation.

RESULTS

The following results are presented as profiles in vertical depth from the surface. Water content profiles indicated that water contents are generally low with a mean value of 0.11 m3 m-3 and exhibit no trend with depth. The water content profile under the cell was indistinguishable from that in undisturbed alluvium. Water potentials increased with depth from -6 MPa near the surface to approximately -1 MPa at 50 m depth. Once again, the profile under the cell was indistinguishable from that in undisturbed alluvium. Analyses of drill cuttings samples from the borehole under the cell did not reveal the presence of lead or cadmium. Analyses of these samples for 241Am, 60Co and 137Cs showed that these radionuclides were not present in concentrations exceeding background. Tritium, however, was found in detectable concentrations under the cell. Profiles of tritium concentrations in soil water with depth for both boreholes are shown in Fig. 3.

Fig. 3

DISCUSSION

The similarity of the water content and water potential profiles for the two boreholes suggests that the presence of the crater has not altered the soil moisture regime at this site. A comparison of isotopic compositions of pore water from the boreholes showed that the isotopic composition of pore water from the borehole under the cell is indistinguishable from that in undisturbed alluvium. This indicates that processes affecting the correlation between dD and d18O are similar in both locations. The compositions diverged from the global meteoric water line in a manner indicative of a soil moisture regime strongly influenced by evaporation.

Movement of water in soil occurs as the result of a gradient in total potential. Here the total potential is taken to be the sum of the matric and gravitational potentials. These potential profiles for the borehole under the cell are shown in Fig. 4. The osmotic component of the water potential for the alluvium was estimated from the chloride concentrations to be less than -0.001 MPa in the near surface and zero below a depth of 10 m. Water potentials are thus taken to be equivalent to matric potentials. For the total potential, a negatively sloped line indicates that flow is upward, a positively sloped line that flow is downward and a

vertical line represents the static condition. Figure 4 shows that the zone below 35 m, where cores were taken from under the cell, is nearly static. The slope of a best fit line through the total potential data from a depth of 39 m to 49 m indicates a slightly negative gradient in this region. Thus, the flux of liquid water under the cell is negligible. This indication of a negligible flux is supported by the lack of metals or waste-related radionuclides in the samples taken from below the cell.
Fig. 4
Tritium concentrations in undisturbed alluvium (Fig. 3) are low and decrease quickly with depth to levels near or below the detection limit of 350 pCi/l. Samples with concentrations less than the detection limit are plotted at the limit. The concentrations of tritium found in the borehole under the cell generally increase with depth to nearly 10,000 pCi/l at the deepest point sampled. These concentrations are two orders of magnitude greater than expected from atmospheric deposition of tritium but 1/100 of the Nuclear Regulatory Commission's concentration limit of 1 x 106 pCi/l for effluent released to an unrestricted area.
These samples represent not only tritium concentration with increasing depth but also with increasing proximity to the chimney below the center of the waste cell as shown in Fig. 2. The only potential sources of tritium that could conceivably account for the concentrations found in the samples are the waste placed in the crater and the cavity located 160 m below the crater. The activity of the waste has been estimated to be 1200 Ci, 85 percent of which is attributable to tritium. The other potential source is the tritium remaining in the cavity following the test. The migration of tritium in dry soil was examined by Smiles et al. (1995) (6). Their diffusion model predicts that the movement of tritium from a source in dry alluvium will be limited to a distance of less than 100 m. This result implies that the elevated tritium concentrations under the cell are due to the migration of tritium from the waste. The evidence of negligible liquid flux under the cell provided by the water potential profile and the lack of metals or radionuclides other than tritium suggests that tritium migration from the cell is primarily due to diffusion.
The similarities in water content, water potential and stable isotope ratios between undisturbed alluvium and alluvium below the cell and the absence of waste constituents below the cell demonstrate that for this crater no enhanced recharge has occurred. The implications are that nuclear subsidence craters with minimal catchment area outside the crater boundary can provide a means for shallow burial of low-level bulk radioactive waste that will effectively isolate the waste from the groundwater below.

ABSTRACT
The Republic of Korea has ten operating nuclear plants and six under construction and another seven planned. Spent fuel and low level radwaste has been accumulating at the nuclear plants since the start of operation of the first plant in 1978. This study looked at several options for spent fuel storage and different disposal facility with proposed operating dates and radwaste processing options to provide guidance in the planning and policy making with regards to storage and disposal in the future.
This paper will describe the study parameters, various scenarios under consideration, different away from reactor spent fuel storage design concepts, and different operating dates spread over several years. Postponing the operating date for the disposal facility greatly increased the storage needs.
Many key factors involved in the study and had different influences on the outcome of the study, including the options recommended to help formulate future policies for the back end of the fuel cycle.

INTRODUCTION

Electricity from nuclear power began in the Republic of Korea with the commercial operation of Kori Unit 1 in 1978. The plant owned and operated by the Korea Electric Power Company (KEPCO) was the first of the ten operating nuclear plants in Korea. Six more plants are under construction and seven more are planned for operation by June 2006. The plants are

listed in Fig. 1. The two types of plants in use and planned are either pressurized light water reactors (PWRs) or heavy water moderated reactors (PHWRs).

Fig. 1

There are no disposal sites for either spent fuel or low/intermediate level radwaste, and all radioactive wastes are temporarily stored at the nuclear plants. Because the spent fuel pools at the older existing nuclear units are getting full, a need for updating the plan and schedule for the safe management of spent fuel was needed. The Nuclear Environment Management Center (NEMAC) of the Korea Atomic Energy Research Institute (KAERI) authorized Sargent & Lundy in the fall of 1994 to jointly study several options for spent fuel storage and different spent fuel disposal facility operating dates along with low and intermediate level radwaste processing options. The purpose of the study was to study the most appropriate option for the Government with regards to storage and disposal in the future.

The focus of this particular study was to develop feasible scenarios for long-term management of both spent fuel and radwaste, focusing on the once-through or direct disposal of spent fuel, and the effects of volume reduction on disposal of low and intermediate level radwaste (LLW/ILW). Reprocessing was excluded as a spent fuel option for this study.

The period of time for the study covered from the year 2002 when a central spent fuel storage facility, an away from reactor (AFR) facility is assumed to be operational, until 2080. As stated earlier, the planned nuclear plants and those already under construction would be in operation by the year 2006. Figure 1 lists the existing and future plants until 2006. For purposes of the study, nuclear plants of the "Advanced" types, APWR and APHWR, were assumed to be placed in service starting in 2007. Between 2007 and 2030, the last year of new nuclear plants, 19 APWRs of 1000 MWe would be installed and five 700 MWe and three 1000 MWe APHWRs. The operating life of the conventional nuclear plants was assumed as 30 years and for advanced plants as 40 years. The last of the advanced plants would be taken out of service in 2070. The spent fuel would be stored onsite for five years and all of the fuel would be shipped to the repository by 2080. Electric generating capacity from nuclear plants increases from 8,616 MWe at the end of 1995 to a peak capacity of 32,300 MWe in 2026.

To temporarily solve the shortage of AR storage, KEPCO the sole national electric utility in Korea, exerted a great effort. For example, Wolsung Unit 1 a PHWR operating since 1983, has already installed some dry storage casks for spent fuel storage. KEPCO may also tranship some spent fuel from one unit to another and from one plant to another.

SPENT FUEL DIRECT DISPOSAL OPTIONS

Several countries with operating nuclear plants are planning on direct disposal of spent fuel. When reviewing direct disposal of spent fuel in a geologic repository, several scenarios were brought into consideration; different operating dates for a high-level waste repository for intact fuel assemblies, fuel rod consolidation prior to storage and disposal, and disposal of the PWR spent fuel assemblies separately from PHWR spent fuel with a different operating date for disposal for the two types of reactor spent fuel.

Each scenario for direct disposal of spent fuel includes some spent fuel storage. Storage includes the use of the spent fuel pools at each nuclear plant and a planned central facility to provide away from reactor (AFR)

spent fuel storage from several nuclear plants. The length of time for storage at the AFR and the amount of spent fuel stored will be dependent on the operational date of the disposal facility. The amount of time that spent fuel is stored prior to disposal, can change the economics of the fuel cycle. The design of the repository may be changed, if the spent fuel has been stored 40-50 years versus 10-15 years because of the reduced decay heat and lower radiation levels of the older fuel. However, the structural integrity of the fuel elements may be less with a longer storage time.

The longer storage scenario allows for more time to collect funds for the cost of the repository, but it increases the cost for storage of the spent fuel. The longer storage allows for more research and development to determine optimal disposal facility design and allows more time for other countries to obtain experience with their high-level waste repositories, which could benefit Korea.

Three different scenarios were selected for further study along with two different subscenarios. Variations in the economic parameters used for the scenarios was also considered for the discount rate, ie., cost of money minus inflation. Three discount rates, 2%, 5% and 8.5% were used for each of the three scenarios. The basis for these discount rates is discussed later.

The three direct disposal scenarios are based upon the timing of the start of operation of the waste repository:

Scenario 1 Early Introduction in 2030
Scenario 2 Intermediate Introduction in 2050
Scenario 3 Late Introduction in 2070

As discussed earlier, the basis for the earliest date for operation of the repository (2030) was selected as probable earliest date that a repository could be operational in Korea. While it might be possible to have a repository operating earlier, there are so many variables that could delay the start of the facility, 2030 appears to be a practical date that could be met.

The late introduction date for the repository was selected as 2070. The input information for the study projected the last advanced nuclear units being added in 2030. With a lifetime of 40 years for the advanced design reactors, the last reactors would be retired in 2070.

The intermediate introduction date was selected as 2050, a date halfway between the early and late introduction dates. By using three dates, the economics for the range of different operating dates was made. The three dates are also within the range of dates planned by other countries for their high-level waste repositories. Some countries plan to be earlier than 2030 and some later than 2070.

Two of the reasons to operate the repository early are regulatory and public opinion. Nuclear regulatory officials in the U.S. have always believed that nuclear waste, either high or low level, should be placed in a repository as soon as possible, as it is considered the safer option than storage. From a political standpoint, many anti-nuclear advocates have used the argument that the nuclear industry does not have a solution for disposal of high level waste, and therefore should not construct (or operate) any more nuclear plants until the nuclear industry has a place to dispose of the waste. Others feel that the disposal facility is needed sooner rather than later, not to put the burden of disposing the waste to future generations of people. However, spent fuel and low/intermediate level waste has been stored safely for 25 to 30 years.

INTERIM STORAGE

Interim storage is required to some extent with all nuclear fuel cycle back end options, reprocessing or direct spent fuel disposal. The flow diagram for interim storage in the back end of the fuel cycle is shown in Fig. 2. Earlier studies by KAERI, selected that the spent fuel capacity for the first AFR would be 3,000 metric tonnes equivalent (MTU), and that it would be a wet pool type. Subsequent AFR's would be of the dry type.

Fig. 2

The size of the subsequent AFR's was not predetermined. Early in the study, it was thought that there may be some cost advantages to add AFR capacity in the same size as the first AFR, reducing the engineering and construction costs. However, with the amount of spent fuel being generated in the future, It came to the point where an AFR had to be added every couple of years. The final choice for AFR capacity, was to make the second AFR twice as large, 6,000 MTU and the third and subsequent AFR's with 12,000 MTU capacity. The flow chart to show the dates for AFR additions and a projected second AFR site, is shown in Fig. 3. The number of AFRs increases if the repository startup date is later. The early operating date for the repository would require only one AFR site with study parameters chosen for the AFR site. Later dates would require a second AFR site to be selected and developed.

Fig. 3

In the U.S. some nuclear plants have reached the limit of the fuel pool capacity with re-racking and have turned to the use of dry concrete casks for additional spent fuel storage capacity. Because the many nuclear plants are owned by many different electric utilities, the central AFR for storage has not been contemplated. A big advantage to using the dry concrete casks for the individual nuclear plants is that several different dry cask designs are pre-licensed for use. This is very cost effective for the U.S. utilities versus the cost required to license an AFR. Also the different timing for the need for more spent fuel storage makes it difficult for a utility to construct an AFR. U.S. utilities have been promised by law that a monitored retrievable storage (MRS) facility operated by the Department of Energy would be available in 1998. At this point in time utilities are not expecting the MRS for quite a few more years. In Korea, with one electric utility and less transportation problems, a central AFR is feasible.

This study focused on the different scenarios for direct disposal of spent fuel. However, the cost for constructing additional spent fuel storage by expansion of the original AFR in steps to accommodate more spent fuel, was an important step to the economic evaluation. The costs for spent fuel AFR storage varied by the type of storage method chosen, but only one dry type storage cost estimate was used in the economic study for disposal costs. The timing of the storage cost varied with the date of operation of the spent fuel repository, and that became a factor in the economics.

Some countries are using wet storage for central AFRs, with dry storage being used in some. Future plans for some countries show consideration for dry systems. In the U.S., commercial nuclear reactor plants are using dry cask storage of three different type designs. Two other dry storage designs are the air cooled metal or concrete cask which may store 20 to 40 fuel assemblies and the modular dry vault storage systems. The dry storage concept is usually based upon natural convection cooling without forced air. The building design for the modular vault could be designed

for either natural for forced air depending on the heat removal requirements.

LOW AND INTERMEDIATE-LEVEL WASTE MANAGEMENT OPTIONS

The low and intermediate-level waste management portion of the study reviewed the projected LLW/ILW quantities of existing and future nuclear plants and reviewed volume reduction technology. Waste quantities for the future decommissioning of nuclear power plants (NPPs) is a significant amount and was included in the projected amount of waste. Waste generated by the storage of spent fuel is negligible as compared to the normal operations waste quantities and that of decommissioning.

Volume reduction of LLW/ILW is recommended for the NPPs to reduce the cost of developing and operating an LLW/ILW repository. Every NPP does not require all of the possible volume reduction systems. Some major systems such as incinerators should be located initially at two NPPS and supercompaction could be located at one facility. The economic evaluation of volume reduction was very beneficial in reducing disposal costs and, to a lesser extent, transportation costs. It was recommended that volume reduction equipment be purchased and installed as soon as possible, to also reduce the cost of building and operating storage facilities at the NPPs.

SUMMARY

The economic analysis considered the sensitivity of the discount rate for money in Korea of 2%, 5%, and 8.5%. These discount rates had been used for other studies in Korea and were selected to provide a range of rates to show the effect of the discount rate on overall economics for selecting the direct disposal scenario. The total cost estimate for the HLW repository was estimated at $11,000,000,000 in 1994 dollars. This cost estimate was based primarily on cost estimates published in Swedish technical reports. American reports were also reviewed as to their cost estimates. Because no country has constructed or operated an HLW repository, the actual cost could vary due to many factors. As another sensitivity factor to selecting the scenariooptimum disposal operating date, the economic analysis varied the estimated cost of the repository by $5.0 billion. That made the range of repository costs used in the study $6 - $16 billion.

With both sets of sensitivities considered, the economic analysis slightly favored an operating date of 2070 over the 2050 date. The non cost factors favored an earlier operating date rather than a later date, by a wider margin than the economic difference. Therefore, the recommended scenario for the HLW repository for direct spent fuel disposal, was with an operating date in 2050.

The recommended scenario for spent fuel management was to provide away from reactor centralized spent fuel storage facilities until a high-level waste (HLW) repository can begin operation in 2050.

Considerable R&D activities are required prior to the development of an HLW repository and some items should be started in the next few years.

A NEW GLASS VAULT INTERIM STORAGE AT LA HAGUE AND ITS ADAPTATION TO MULTIPURPOSE STORAGE FACILITIES

C. Bonnet
SGN

ABSTRACT

The La Hague reprocessing plants, UP2 and UP3, were equipped with vitrification facilities, R7 and T7 respectively, in which fission products are vitrified for final disposal. Each of these facilities has an interim buffer storage capacity designed for cooling and transport of vitrified residues.

While awaiting geological disposal, French requirements also demand new interim storage capacity in addition to the existing capacity. An installation was also needed to rehandle the stored glass packages, load them into transport casks and ship them to Cogema's clients.

To meet these requirements, a modular interim storage facility called "Entreposage Verres Sud Est" was constructed as an extension of the T7 facility. With an initial capacity of about 4,000 packages (corresponding to approximately 5500 tU reprocessed) and a first module containing two vaults, it can be extended gradually by adding modules of three identical vaults. The facility's main characteristics is its use of cooling by natural convection associated with an innovative storage pit design which enables the removal of up to 24 kw per pit. The facility has its own installation for receiving and rehandling packages by shuttle, with a flow of about 1000 packages per year.

Based on this technology, as well as that used at the CASCAD Cadarache Facility, where exotic fuel from CEA research reactors is stored before reprocessing or final disposal in 50 years, SNG has developed the "Advanced Cascad System" for long term storage of HLW or Spent Fuel.

THE NEW GLASS VAULT INTERIM STORAGE FACILITY

The first module of the new glass vault interim storage consists of two buildings. The first building contains all of the shared equipment and auxiliary system such as utilities, the electrical system, access functions and shuttle reception air-lock. The second primarily contains two interim storage vaults, each with its stack and air intake, and a common handling bay for operations of the transfer crane and the package transfer casks. (see Fig. 1). The bay and the air intake can continue to be used as capacity extensions are added.

Fig. 1

The primary functions performed at the installation called "Entreposage Verres Sud Est" (EVSE-Glass Canister Storage in the Southeast Facility) are:

- package reception in a shuttle,
- package transfer from the shuttle to the interim storage wells,
- package cooling by natural draft ventilation,
- package transfer from the wells to the shuttle,
- package containment in the wells,
- shuttle inspection and shipment.

Package Transfers by Shuttle

The packages enter and leave the facility in a shielded shuttle transported by a flat-bed vehicle. The facility equipped with an enclosure at the loading station, enables the packages to pass between the shuttle and the transfer casks. The enclosure has seven openings corresponding to the seven cavities of the shuttle (See Fig. 2).

Fig. 2

Loading the Storage Facility by Cask and Transfer Crane

The vaults are loaded by a transfer cask carried by a transfer crane. The transfer casks, whose weight is limited to 60 t, is a cylindrical containment consisting of:

concentric and contiguous elements which form the radiological shielding,

a removable upper portion, accommodating a camera and other equipment,

a rotary floor mounted on a ball ring and receiving the packaging and plug support systems,

high reliability electro-mechanical tongs, consisting of five high-strength stainless steel fingers, designed to grab the packages and plugs, operating satisfactorily at 400C.

The transfer crane with a capacity of 700 kN, is of the twin-beam box girder type. Placed on the slab of the storage facility, it has the following components:

a springer with travel and guide rollers,

a perpendicular steering trolley supporting the cask,

drive system for the different travel and lifting functions,

The wells and loading/unloading openings are served in automatic mode. Accordingly distances are measured by laser. Data transmission, including images from the casks onboard camera, is also performed by laser.

During loading operations, the transfer cask is used to handle the biologically shielded plug of the storage wells and to lower the packages inside.

Cooling by Natural Draft

The desire to guarantee optimal safety, and to achieve intrinsically safe cooling of the storage facility, guaranteeing a glass temperature under 510C in all circumstances, led to the selection of a natural draft cooling system.

The design of the EVSE facility from its outset took into account disturbances connected with weather conditions at La Hague (storms, rain and fog, frost, snow and drifts) to ensure that no succession of plausible events could cause the complete shutdown of the cooling system.

The selected design helps to avoid the following causes of failure:

mechanical, since there is no equipment,

electrical, since no power supply is needed,

control, since there need be no control system,

utilities since there are no fluids,

of human origin, since no human action is necessary.

In interest of compactness, packages are stacked 12 high in the wells at short 85 cm intervals. Each vault contains 18 rows of 10 wells.

To remove the heat dissipated in each well (up to 24 kw/well) by natural convection, the following design was implemented. A liner around each well forms a double jacket, and the cooling air circulates in the annular space thus formed. Fresh air, previously filtered through electrostatic filters, enters at the bottom of the vaults at the lower end of the wells, and travels upward in the annular space around the wells. The driving force is provided by passage of air in the double jackets and in the 35 m high stack, designed to withstand earthquake as well as the most violent winds.

A thermally insulated containment supplemented with air circulation protects the structural concrete from exit air temperatures over a range of 140C.

Wind tunnel tests were performed on a mock up, optimizing the shape of the stacks to create the best negative pressure caused by the wind at the top of the stack. The tests also took into account the effect of the site's environment within a 500 m radius. These tests showed that the winds in general, particularly those from dominant sectors, assist the

natural draft by producing temperatures in the vaults that are lower than those obtained without wind.

During the commissioning tests, thermal tests were carried out with heat releases up to 240Kw (10 loaded wells). The results of these tests were in good accordance with detailed calculations performed by qualified computer codes such as TRIO and FLUENT demonstrating a good understanding of all the mechanisms involved and a sufficient safety margin.

ADAPTATION TO MULTIPURPOSE STORAGE FACILITIES

Based on the above EVSE system as well as on the experience gained by SGN in the construction of interim storage facilities for fuels, high level, medium level and low level wastes, SGN has developed the Advanced CASCAD System to offer its clients solutions tailored to their needs. The proposed facilities may be specific to a given type of product (fuel elements or waste) or designed for the interim storage of different types of waste in a single facility (1,2.)

Such is the case for design of the facility to be constructed by the Dutch company COVRA (Centrale Organisatie Voor Radioactief Afval) to store:

- spent fuel
- vitrified reprocessing waste
- cemented hulls and end-pieces, cemented technological waste and bituminized waste from fuel reprocessing
- miscellaneous waste from research reactors and nuclear facilities.

SGN is currently designing this facility with main following characteristics:

The two first types of waste will be stored in 3 vaults, in vertical pits cooled by natural convection, using the technology implemented for the EVSE facility.

The two last types, packaged in cemented containers or stainless steel drums, will be stored in 3 bunkers similar to those implemented at La Hague for such waste.

Storing such various types of products in a same facility presents advantages from a cost standpoint since only one unloading and canistering unit with its associated auxiliary functions (power supply, ventilation, utilities) is needed for all the modules.

CONCLUSIONS

The new EVSE facility commissioned at La Hague for the interim storage of glass canisters presents innovative features such an increased storage density and cooling by natural convection of high heat generating products. Therefore, this facility offers very high technical and economical performance while maintaining high safety standards.

ENCAPSULATION PLANT FOR SPENT FUEL IN SWEDEN

Tommy Hedman
Stig Pettersson
Jan Vogt
Svensk Krnbrnslehantering AB
Box 5864

S-102 40 Stockholm, Sweden
ABSTRACT
Sweden currently has a system in operation that will manage all types of radioactive waste in the country for a long period ahead. The system comprises a final repository for short lived operational waste (SFR), a central interim storage facility for spent nuclear fuel (CLAB) and a transportation system. The remaining system components now being planned are an encapsulation plant and a deep repository for final disposal of spent fuel and other types of long lived waste. The Swedish program for the encapsulation plant and the deep repository is well advanced. According to current plans, the encapsulation plant will be built as an extension to the CLAB facility. The co-location of the two facilities will enable the use of existing infrastructure and staff at CLAB. The fuel handling system of the encapsulation plant can also be directly connected to the storage pools for spent fuel in CLAB.
The spent fuel will be encapsulated in a copper canister containing an insert. The copper canister development work has been going on for more than 10 years and in 1995 full size demonstration canisters were fabricated successfully. The Basic Design for the encapsulation plant is scheduled for completion in 1996. The licensing application is programmed for submission to the Swedish authorities in early 1998. The construction work is expected to start at the end of the century. The first commissioning of the facility would then start in 2005 and delivery of canisters to the deep repository is planned for 2008. The design capacity of the plant is one canister per working day, corresponding to an annual output of approximately 210 canisters. One BWR/PWR canister will contain approximately 2,2/1,8 tons of uranium respectively. The Swedish nuclear program is expected to generate approximately 8 000 tons of uranium and about 75 percent is BWR fuel. The total investment cost for the plant is estimated to be in the order of 1 700 MSEK (260 MUSD).
THE SWEDISH WASTE MANAGEMENT SYSTEM
The Swedish nuclear power utilities are responsible for the safe management and disposal of spent nuclear fuel and other radioactive waste from the 12 Swedish nuclear power stations. In order to fulfil this responsibility, the utilities have jointly created SKB, the Swedish Nuclear Fuel and Waste Management Co, with the task to plan, build, and operate the necessary waste management facilities and systems. SKB has developed a system that ensures the safe handling of all kinds of radioactive waste from the Swedish nuclear power plants for the foreseeable future. The keystones of this system are:

- A transport system which has been in operation since 1983;
- A central interim storage for spent nuclear fuel and core components, CLAB, in operation since 1985;
- A final repository for low and intermediate level, short-lived waste, SFR, in operation since 1988.

The remaining parts of the system, now being planned are:

- An encapsulation plant for spent nuclear fuel;
- A deep repository for encapsulated spent fuel and other long-lived radioactive wastes.

The Transportation System
As all the nuclear power plants, SFR and CLAB are located on the coast and have their own harbours, SKB has developed a sea transportation system. This has many advantages, such as a high load capacity and low interference with other traffic. The system comprises a purpose built

ship, the M/S Sigyn, 10 transport casks for spent fuel, 2 casks for spent core components, 27 transport containers, type IP II, for transporta tion of low and intermediate level waste and 5 terminal vehicles. The terminal vehicles are used for the land transport from the reactor site to the harbour and from the harbour to CLAB or SFR.

Central Interim Storage for Spent Fuel (CLAB)

CLAB is located at the Oskarshamn nuclear power plant on the east coast of Sweden. Operation started in 1985, and at the end of 1995 more than 700 casks containing some 2300 tonnes of fuel had been received. Also, approximately 70 casks with activated core components, eg control rods, had also been received. The arrangement of CLAB is shown in Fig. 1.

Fig. 1

The main complex above ground is the receiving building, where the fuel transport casks are unloaded. The unloading is performed under water. The CLAB storage section is located in a rock cavern, the roof of which is 25-30 metres below ground level.

The present capacity of CLAB, approximately 5 000 tonnes of uranium, covers the requirements until 2004. The Swedish nuclear program is expected to generate approximately 8 000 tonnes of which approximately 75 percent is BWR fuel and 25 percent PWR fuel. CLAB must therefore be expanded by adding storage pools in a new rock cavern close to the existing one. According to the current plan, the construction of the second cavern will start in 1999. The spent fuel will remain in CLAB for approximately 30-40 years to decay before encapsulation.

Final Repository for Radioactive Waste, SFR

The operation of SFR started in April, 1988. It is a repository for low and intermediate level waste, built in the bedrock under the Baltic Sea, close to the Forsmark nuclear power plant. 60 m of rock cover the repository caverns under the sea bed. The first stage, which is in operation, include buildings on ground level, tunnels, operating buildings and disposal caverns for about 60 000 m3 of waste. A second stage is planned to be built and commissioned after year 2000. Until the end of 1995, a total of approximately 18 000 m3 of waste has been disposed of at SFR.

THE DISPOSAL CANISTER FOR SPENT FUEL

Development Work

The spent fuel is planned to be encapsulated in a disposal copper canister with an insert. The canister development work has lasted for more than 10 years and full size demonstration canisters have been fabricated during 1995. The development work with electron beam welding (EBW) of the canister copper lid is done in co-operation with TWI (formally The Welding Institute), Cambridge, England. A preliminary design of a disposal canister with an BWR insert for 12 fuel assembles is shown in Fig. 2. A canister with a PWR insert for 4 fuel assemblies will have the same outer dimensions.

Test welding of full size lids on copper canisters with reduced length was carried out during 1994/95. Figure 3 shows the machining of the inner surface of one of the full size canisters.

The Lid Welding Pilot Plant

A crucial function in the encapsulation plant is the welding of the lid to the copper canister. This will be done remotely with high accuracy, and in such a way that the weld can be checked afterwards by non-destructive testing (NDT). The welding method preferred at present is EBW at reduced atmospheric pressure. A full size pilot plant is planned which

will be used for testing of EBW and NDT equipment for the copper canister lid weld. The experience gained will be used in the continued design work of the encapsulation plant. The welding in the pilot plant is planned to start early 1998 and the results from the pilot plant will be used to support the licensing case.
Fig. 2
Fig. 3
THE ENCAPSULATION PLANT
General
A feasibility study for the Encapsulation Plant was performed in 1993/94 by four different European companies. In June 1994, BNFL plc, (via its subsidiary BNFL Engineering Ltd) England, was selected as the main consultant for the Conceptual and Basic Design of the encapsulation process. In parallel, ABB Atom, Sweden, was selected as consultant for service and auxiliary systems and service areas of the encapsulation plant. ABB Atom was also selected for the Conceptual and Basic Design work for the extension of the storage capacity of CLAB. The coordination between BNFL and ABB Atom and the plant layout work is done by SKB.
The Basic Design of the encapsulation plant will be completed in 1996 and will be the base for the Preliminary Safety Report. The licensing application is programmed for submission to the Swedish authorities in early 1998. The construction work for the encapsulation plant is expected to start at the end of the century. The commissioning operations of the facility would then start in 2005. Delivery of disposal canisters to the final deep repository is planned for 2008. The design capacity of the plant is one canister per working day, corresponding to an annual output of approximately 210 canisters. Core components and reactor internals will also be conditioned in the encapsulation plant. These activities are planned to start approximately year 2020, after evaluation of the first operation stage of the spent fuel encapsulation and disposal operation.
Fig. 4
Plant Layout
The encapsulation plant is planned to be built adjacent to the existing CLAB receiving building. The main functions and the principal arrangement of the plant are shown in Fig. 4. In addition to the handling and process equipment necessary for these operations, auxiliary, service and control systems as well as different workshops and staff facilities are required. Great advantage can be achieved by utilizing the existing corresponding systems and functions in CLAB.
The encapsulation plant consists of a main building connected to CLAB and the existing fuel elevator. The new handling pool in the encapsulation building is parallel to the receiving pools in CLAB. The handling cell and the different process stations are arranged to permit flexibility in the plant layout for future modifications of the plant. During the construction and commissioning the encapsulation plant will be separated from CLAB and will have its own site entrance. Later, during active operation, the encapsulation plant will be fully incorporated with CLAB operation.
The location as an extension to CLAB provides possibilities to extend several existing functions into the encapsulation plant. These functions include the fuel elevator, cooling systems, water purification systems, draining and fire fighting systems as well as electrical power supply. The local control room in the encapsulation plant is staffed only during the daytime shift. The central control room in CLAB is planned to be used

for supervision and limited operation of the encapsulation plant outside the daytime shift. The CLAB central computer may also be used for recording of all relevant data from the encapsulation process. The layout of the encapsulation plant is shown in Fig. 5. The dimensions of the building is approximately 80 m x 70 m x 25 m (LxWxH).

THE ENCAPSULATION PROCESS

The following will present a more detailed description of the functions and work foreseen in the different parts of the plant. The location of the different parts are marked in Fig. 5.

Transfer Channel, Handling and Connection Pools

The storage canisters with fuel (or core components) are transferred from CLAB into the new pool in the encapsulation plant using the existing fuel elevator system, which is already prepared for this extended function. In the pool, checking of each fuel assembly will be done. The checking before placement in the disposal canister will include a gamma measurement. This measurement may also be utilized for the determination of the residual power and safeguards verification of the fuel assemblies. The results of these measurements are compared with expected values and transferred to a computer for confirmation and final selection of fuel assemblies with regard to the maximum allowed decay heat, which is approximately 1.5-2.0 kW, per canister. The selected assemblies are placed in a transfer canister with 12 BWR or 4 PWR loading positions. The transfer canister is moved to the ramp elevator leading to the handling cell.

Fig. 5

Handling Cell

The transfer canister, in the ramp elevator cage, is moved up the ramp and is stopped at a position above the water level and below the handling cell. In this position the transfer canister is allowed to drain. The canister is then lifted out of the cage with an in-cell crane and is transferred to one of the two drying stations in the cell. The fuel is dried for approximately 12 hours by means of hot recirculating air in a closed system with a HEPA filter.

A disposal canister, placed in a sleeve and shielded frame, is docked from the transfer area below the cell. The steel lid of the insert is removed and temporarily stored in the cell in such a way that it is protected from surface contamination. After drying the fuel assemblies are lifted, from the transfer canister, one by one and placed into the disposal canister insert. The fuel assemblies may also be identified to ascertain the final canister contents.

The steel lid is temporary placed back onto the insert prior to undocking. The lid provides shielding and tightness during the transfer from the cell. The shielded frame is also provided with a shielded gate on top. The canister is then ready to be transferred to the next process station for inerting and final lidding of the insert.

Transfer Vehicle and Transfer Area

The disposal canisters are transferred between the different process stations in shielded transfer vehicles. A vehicle consists of a transporter and a shielded frame, which allows docking of the canister in its sleeve to the handling cell and the process stations in a way that provides radiation shielding and prevents contamination of the transfer area. The vehicles are remotely operated and bring the canisters to the different positions in the transfer area. The vehicles can also be brought to the active workshop for maintenance.

The transporter is currently planned to be of air cushion type, which offers flexibility in movement and position adjustment. The shielded frame has a lifting feature which lifts the canister in its sleeve into the docking port of the different stations. The shield is telescopic with an outer and an inner cylinder.

Inerting and Lidding Station

Operations in the inerting and lidding station are performed in order to change the atmosphere in the canister insert and to finally seal the steel lid. The station has a vacuum chamber with equipment for handling and bolting the steel lid and is connected to systems for vacuum and inerting with argon or helium gas.

The filled canister with the steel lid temporary fitted arrives below the station on the transfer vehicle and is docked to the chamber. The steel lid is lifted to permit the exchange of the air with the inert gas. After gas filling, the steel lid is placed back on the insert and is bolted tight.

The seal between the lid and the insert provide gas tightness during the subsequent welding of the copper lid.

Welding Station

The transfer vehicle brings the filled canister to the welding station where the canister is docked to the vacuum chamber from below in such a way that vacuum conditions can be achieved at the welding area at the top of the canister.

The vacuum chamber contains equipment for cleaning the weld surface and for welding. The copper lid is posted into the chamber before the canister is docked and positioned.

The canister is rotated during the welding process. The EBW equipment is fixed on an adjustable mount so that the beam can track the joint between the lid and the cylinder during welding.

The welding starts with a gun conditioning and testing using a copper target situated directly above the canister. This enables the welding parameters to be adjusted immediately before welding of the canister. The copper lid welding is then completed following a pre-set procedure.

NDT and Machining Station

In this station the copper lid weld is machined and checked with non-destructive testing (NDT). The station is provided with equipment for machining of the welded zone and for ultrasonic and radiographic testing. There is also equipment for machining for repair of failed welds. The canister arrives from the welding station in the shielded frame and is docked to the station from below.

Canisters with failed welds are either rewelded immediately or put aside and stored for later rewelding and repair. Canisters rejected after repeated rewelding can be cut open in the NDT and machining station. The fuel will then be removed in the handling cell after opening of the insert. The insert can be reused but the copper canister will probably have to be scrapped.

Monitoring and Decontamination Station

From the NDT and machining station the canister is brought to the export port of the transfer area. There it is lifted up from the shielded frame by a shielded handling machine belonging to the buffer store. This machine transfers the canister and lowers it into the monitoring and decontamination station. The canister surface is checked with remote smear testing and if contaminated the canister is cleaned with high

pressure water. Smear test samples are brought from the station remotely through a shielded opening and measured locally at the operator platform. The clean canister is transferred from the station to the canister buffer store by the shielded handling machine.

Buffer Store

The buffer store serves as a buffer for filled canisters prior to transport to the repository. The canisters are stored under a shielding floor with shielding plugs over the storage positions. Thick walls protect the surrounding area from radiation. Cooling is provided using air on a once-through basis. The shielded handling machine place the canister into an empty storage position after first lifting the shield plug. Before leaving the position the machine replaces the plug. When a canister is to leave the store the machine moves it into the cask entrance area where it is lowered down into a transport cask.

Core Components

The conditioning of core components in concrete moulds will have a route similar of that of the disposal canisters. The storage canisters with core components are dried in the handling cell and then placed in a mould in a shielded frame similar to the ones used for canisters. The main outer dimensions of the concrete mould could be 1.2 m x 1.2 m x 4.8 m and with a wall thickness of 200 mm. The lidding of the mould and the eventual filling of the void with grout will be done in separate lidding and grouting stations. The monitoring and decontamination and the buffer store with the shielded handling machine, are planned for use for both canisters and moulds.

Transport Cask Loading

The buffer store handling machine is used for transferring canisters and moulds into the transport cask. A special docking position and port in the storage area is provided for this operation. Below the position a transport cask is positioned for receipt of a canister.

The Dispatch Hall

The dispatch hall is divided into a large area for transport and temporary storing of goods, connections to the buffer store and a transport cask maintenance area. A passage from the hall leads to the active workshop. The hall has an air lock for entering and dispatching goods. The dispatch hall has equipment for lifting transport casks and containers and for handling the empty canisters and moulds. The empty canister will be tilted vertically and placed in a sleeve, checked and prepared for positioning into the shielded frame. There are also general areas for storing empty canisters and moulds. Items to be transported are transport containers for empty copper canisters, casks for filled canisters, containers for empty moulds and transport cask for filled moulds. Copper lids for canisters and EBW copper test targets are also handled in the hall.

The transport procedure for filled canisters starts with a transport cask in the dispatch hall air lock. After removing the shock absorbers, the cask is raised to a vertical position and lifted into a bogie with a surrounding platform. The platform enables the bolts of the lid to be removed. The bogie is moved into a shielded export area where a filled canister is lowered directly into the cask with the buffer store shielded handling machine. The cask lid is positioned, the cask withdrawn from the loading bay and the lid is tightened.

SUMMARY

The plans and design of the encapsulation plant are well advanced. According to current time schedule, the commissioning will start in 2005 and the first copper canister delivery to the deep repository will be in 2008. The production target for the encapsulation plant is one canister per working day corresponding to an annual output of about 210 canisters or encapsulation of approximately 400 tonnes of uranium per year. The Swedish nuclear program is expected to generate approximately 8 000 tonnes. The total investment cost for the encapsulation plant is estimated to be 1 700 MSEK (approximately 260 MUSD).

STORAGE, EMPLACEMENT AND DISPOSAL OF RADIOACTIVE WASTE IN THE U.K.

C. S. Mogg
A. M. McCall
UK Nirex Ltd

ABSTRACT

This paper describes the current treatment and storage approach for the management of low level and intermediate level radioactive waste in the UK. The current Nirex conceptual design for a deep waste repository incorporating vaults at a depth of 650m below ordnance datum is described.

The emplacement of the waste within underground vaults is discussed together with the envisaged vault construction methods.

Finally, the principle of the Nirex disposal concept is included together with an indication of the current status of the plans for a deep waste repository in the U.K.

Nirex have been investigating a site near Sellafield in west Cumbria and a public inquiry into planning application for a Rock Characterization Facility has just concluded and Nirex anticipate that a decision on this phase of their proposed development will be made in 1997.

INTRODUCTION

During the latter part of this century significant resources have been devoted to the safe storage and disposal of the UK's radioactive wastes. Of prime consideration is the length of time for which the waste should be isolated from man's environment, a time-frame considerably longer than any for which human society must usually plan. Sea Disposal was used for some LLW, between 1950 and 1982, but the bulk of these wastes have been, and continue to be, disposed of at BNFL's Drigg site in West Cumbria and a similar but smaller facility at UKAEA's Dounreay site in the NE of Scotland. Most radioactive wastes continue to be stored at the sites at which they arise.

A solution which tackles the required isolation of the waste, long term, is to bury the waste underground where the rock provides a suitable host environment. An underground excavation or 'repository' created in a suitable host rock must be engineered for the safe, efficient and cost-effective emplacement of radioactive waste and its ultimate disposal. This paper discusses the current arrangements in the UK for the storage of solid, intermediate level and low level wastes and the technology being applied for its final emplacement and ultimate disposal in a deep waste repository.

RADIOACTIVE WASTE IN THE U.K.

Radioactive waste represents 0.04% by volume of the total waste generated in the United Kingdom. Of a total annual radioactive waste generation of approximately 46,000m3, 44,000m3 is low level, 2000m3 is intermediate

level and 30m3 is high level. This compares with 4,500,000m3 of solid and liquid toxic waste generated annually (1).

CURRENT ARRANGEMENTS FOR LOW LEVEL WASTE PACKAGING AND DISPOSAL

Low level waste (LLW) has a small radioactive content and requires few special precautions to be taken by those handling it. LLW is typically made up of paper, packaging materials, plastic sheeting, protective clothing, scrap metal and building rubble. It originates from a variety of sources, principally reprocessing activities at BNFL Sellafield nuclear power stations, hospitals, research establishments and other industry.

LLW has been safely disposed of at the Drigg disposal facility in Cumbria since 1959. This 110 hectare site is owned and operated by BNFL and located 6 km south of Sellafield. Since it began operations, Drigg has received in excess of 750,000 cubic meters of waste.

Since the late 1980's disposal of LLW at Drigg has been within a purpose built, reinforced concrete lined surface vault designed to accept containerized waste in a form that will extend the useful life of the site well into the 21st Century. The waste is placed within the vault in steel containers that are stacked in an orderly manner resulting in good utilization of the space available. Once the vault has been filled an impermeable layer is placed over the waste and the vault is capped and landscaped to blend with the surrounding environment.

CURRENT ARRANGEMENTS FOR INTERMEDIATE LEVEL WASTE PACKAGING AND STORAGE

The volumes of intermediate level waste (ILW) are considerably less than those for LLW, but the increased activity associated with this waste makes ILW more complex to handle and dispose. Typically, ILW comprises irradiated fuel cladding, reactor components, chemical process residues, ion exchange resins and filters. Currently, no final disposal route exists for ILW pending the availability of the deep waste repository. The ILW already in existence is stored in a form that makes it readily accessible for future deep disposal.

One of the ways this is achieved is by conditioning the waste into a manageable and consistent solid waste form by encapsulation within a cement grout matrix in stainless steel drums. Solid ILW is placed inside a purpose-designed 500 liter drum and liquid grout infill added to encapsulate the waste. Following initial curing, the contents of the drum are capped by the addition of a further wet grout mix. After capping, the drum is lidded, decontaminated and monitored prior to storage within an engineered facility.

Liquid waste is encapsulated in a similar fashion, the main difference being that the grout is added to the drum contents dry rather than wet. Drums for liquid wastes incorporate 'in-drum' mixing features to allow the contents to be mixed with the dry grout powders. These drums are subsequently capped, cleaned, monitored and stored in the same way as for the solid wastes.

In addition to conditioning and storage of ILW in 500 liter drums, other standard containers are also in use. Waste is currently being placed in these containers with a view to interim storage and ultimate disposal within a deep repository, and these contain the de-commissioning wastes and items unsuitable for the 500 liter drums.

There are a number of such engineered stores throughout the UK but the Government continues to favor a policy of deep disposal rather than indefinite storage of ILW.

GOVERNMENT POLICY

In the UK, the impetus for site-specific work on radioactive waste disposal dates from the late 1970s. It sprang from a report of the Royal Commission on Environmental Pollution (2) examining Nuclear Power and the Environment. To underpin new investment in a nuclear power generation programme, the Commission saw it as essential to demonstrate safe "permanent disposal" for long-lived radioactive wastes. That statement is as true today as it was then, and, viewed from any angle, safe disposal of the inheritance of wastes from past, present and future nuclear operations is essential.

In May 1994, the Department of the Environment announced a Review of Radioactive Waste Management Policy and the subsequent White Paper published in 1995 (3) re-affirmed that the UK government continued to favor deep geological disposal for intermediate level radioactive wastes.

UK NIREX LTD

Nirex, founded in July 1982, is the company in the United Kingdom responsible for providing and managing new national disposal facilities for solid ILW and some LLW. Since 1987, Government Policy has been that ILW generally should go deep underground, and that the same facility could be extended to take LLW, as a cost effective alternative to developing a "green-field" site.

The principle of deep disposal of smoothwall radioactive wastes is recognized internationally and is reflected in the radioactive waste policies of many countries . Several countries including the UK are already disposing of radioactive wastes in near surface or excavated facilities. Most of these countries are now considering developing a deep repository.

Nirex has no responsibility for high level waste disposal.

REPOSITORY DESIGN - EMPLACEMENT CONCEPTS

The bulk of the LLW generated from the UK Nuclear Industry will continue to be disposed of at Drigg. The current planning basis for waste to be disposed of in an underground repository is a range of 200,000m3 to 275,000m3 of radioactive waste. This includes 15,000m3 of LLW containing long-lived radioisotopes, making this waste unsuitable for disposal at Drigg.

Since 1987 Nirex has concentrated on identifying suitable locations for a deep disposal facility in the United Kingdom for intermediate and low level wastes. In March, 1989, the company announced its intention of undertaking detailed geological investigations, including the sinking of boreholes, at Sellafield in Cumbria, North West England and at Dounreay in Caithness, Scotland. The investigation established that both sites have the potential to meet the demanding safety requirements for a deep repository, but, in July 1991, Nirex announced that it was to concentrate further investigations at a site adjacent to BNFL at Sellafield.

The current Nirex design concept is based on drift tunnel access running underground to a depth of about 650m below ordnance datum from near BNFL's Sellafield works, where approximately 65% of the waste for deep disposal orginates.

There are numerous types and configurations of underground spaces that could be used for emplacement of radioactive waste, however the current Nirex preferred concept is to emplace the waste in cavern vaults deep underground. This concept design is under constant review.

Fig. 1

LLW Vaults

The cross sections of the vaults will be influenced by the size and configuration of the waste packages in order to make maximum use of the available space within the excavation profile. LLW packages are typically standard ISO freight containers with nominal dimensions 2.4m(w)x2.2m(h)x 4m(l) and can be stacked up to 6 high. At the Deep Waste Repository, Nirex propose to adopt a similar philosophy to that at Drigg of local manual control for LLW emplacement equipment. Packages arriving at the underground facilities from the drift transport system will be off-loaded using an overhead crane and temporarily parked in a buffer store area adjacent to the emplacement vault. A heavy duty forklift truck will be used to collect the packages from the buffer area and transfer them into the vault. This form of handling allows the maximum use to be made of the vault excavation cross section as illustrated in Fig. 2. A single vault is currently envisaged to accommodate the total planned LLW capacity. Some self-shielded ILW may also be emplaced alongside the LLW where appropriate.

ILW Vaults

Higher radiation levels for the unshielded ILW packages preclude local manual intervention in the waste emplacement operation. Once the waste is removed from the heavily shielded containers in which it is transported to the repository, unshielded package handling must be carried out via remote control. Inlet facilities enable remote removal of the waste from the transport containers for onward transfer to the vault. Handling of waste within the vault is by overhead crane enabling remote, accurate placement of packages to be achieved. The majority of the unshielded ILW for disposal is in the form of 500 liter drums, these are handled using a stillage which contains four of these drums, this lends itself to efficient overhead handling and is currently handled in this manner during storage. Since an open crown space is required above the waste stack to accommodate the crane structure, unshielded ILW emplacement by this technique will lead to less efficient utilization of the excavated vault cross section compared to the LLW vault (Fig. 2). Approximately 6 vaults will accommodate the planned ILW capacity over the 50 year operational period.

Fig. 2

Characteristics of the Host Rock

The geotechnical setting within which the repository is to be excavated has a major influence on the excavated dimensions and orientation of the vaults. The rock mass quality and structure, the intact rock quality, discontinuity geometry, in situ stress, rock behavior characteristics, and hydraulic conditions are just some of the factors which must be considered. Hence the design process has a significant interface with the Nirex site investigation program.

Vaults appear to be the most popular form of underground excavation with countries such as Sweden, (Forsmark) Finland (Louiisa), and the USA (WIPP) having such excavations as part of their nuclear waste repositories.

Construction

The general design of a layout incorporating vaults is relatively simple and practicable with uncomplicated waste, ventilation, drainage, spoil removal and backfilling routes, together with easy accommodation of services and ancillary facilities. This assumes that the host rock has no features that preclude such a layout. A general principle to be adopted in the construction of vaults is to establish as quickly as possible a

connection between the access roadways (pilot headings). These pilot headings provides an extra free face for blasting and can also be used to prove the geology ahead of the main excavation. Having established a ventilation circuit, and a means of spoil clearance, the connection can be enlarged to the required dimensions of the vault by a series of benches worked progressively along the length of the vault.

Vaults can be constructed with either conventional drill and blast techniques but peripheral damage to the excavation profile would need to be controlled by the use of appropriate techniques, such as smoothwall blasting.

The nature of the project demands a different approach from that usually applied in underground mining, although many of its functions are similar. The development of vaults to ensure structural integrity would necessarily be to a standard that took into account the restrictions on access once the emplacement of waste had begun. Also the layout of the repository will have to reflect the need to excavate and furnish new vaults at the same time as waste is emplaced in constructed areas. Prime consideration is given to the ventilation circuits for both emplacement and construction areas and the ability to isolate these as necessary.

ALTERNATIVE VAULT CONCEPTS

At this stage of repository development Nirex has progressed design to the concept stage only and must keep an open mind to the design of emplacement systems for a deep repository. The following alternative emplacement systems have been considered by other waste disposal agencies in other countries.

Silos

An alternative emplacement arrangement for unshielded ILW is the use of a silo and a shielded package handling machine similar in principle to that used in the Encapsulated Product Stores at Sellafield. A feature of the silo design is the shielded 'cap' over which the emplacement machine operates. The cap supports an array of shield plugs which are removed by the emplacement machine to enable access to the silo. The shield plug is removed from the top of the channel, the waste emplaced in the silo and the plug replaced. The major benefit of the shielded emplacement machine and the shielded plug cap arrangement is in the unhindered man access afforded by the nature of the operation. Silo dimensions are influenced by a number of factors including package integrity, materials handling, backfill placement and ventilation. To date silos have been incorporated in the underground repositories in Sweden (Forsmark) and in Finland (Okiluto).

They can have distinct advantages over vault options should the area of suitable host rock be limited due to adverse geological and geotechnical features. The geotechnical issues relating to silos will be similar to that for the vaults. Silos can be accommodated in a smaller plan 'footprint' but may be influenced by changes in vertical stratigraphy.

Silos can be constructed by conventional drill and blast 'blind' shaft sinking technology with spoil removal via the top of the silo. The diameter and depth of the silo would not be constrained by the method of construction. Alternatively, if a series of silos are being constructed, then the provision of an additional access at the base of the silo for spoil removal would allow the use of raise boring equipment. This involves the drilling of a pilot hole which would be reamed to the required diameter.

Boreholes

Another potential emplacement option involves the adoption of large boreholes drilled in modules which afford similar construction advantages as the silo option. The construction of these boreholes would be by large diameter drilling techniques using raise boring techniques.

THE NIREX DISPOSAL CONCEPT

Nirex, in common with other disposal agencies internationally, has developed a concept of deep geological disposal for radioactive wastes which uses a multi-barrier containment system. It is implicit in the requirements that Nirex should provide a disposal system that does not rely on monitoring or intervention to ensure safety once the repository has been filled and closed.

The concept makes use of both engineered and natural barriers, working in conjunction to achieve the necessary degree of long-term waste isolation and containment.

A physical barrier within the repository will be provided by the steel and concrete packaging within which the radioactive material is immobilized. The long-term containment properties of the engineered system in respect of radionuclides dissolved in groundwater will stem from the establishment of uniform chemical conditions and high sorption capacity across the repository. This will be achieved by surrounding waste packages with the required amount of a cement-based backfill, Nirex Reference Vault Backfill (NRVB) which has been developed and patented by Nirex to meet the needs of the long term safety case.

The multi-barrier containment system is illustrated in Fig. 3.

Fig. 3

NIREX ACTIVITIES

The engineered repository system combines nuclear technology for the conditioning, handling and care of radioactive waste packages and mining technology in terms of providing underground openings for the emplacement and ultimate disposal of these wastes.

The final repository design and configuration will be dependent upon a number of inter-linked parameters, the most important being an understanding of the geological environment.

In 1992 Nirex stated its intention to undertake underground laboratory work in the first stages of repository development. The purpose of that work would be to complement investigations conducted from the surface and so develop a fuller understanding of the surrounding geology and hydrogeology. That understanding would then provide a basis for refining analysis of long-term safety and geotechnical information that would be required for subsequent detailed design and construction of a repository.

Based upon the results obtained from the continuing programme of regional borehole drilling, a planning application for an underground Rock Characterization Facility (RCF) was submitted in July 1994.

The purpose of the RCF is to provide:

a) rock characterization information to permit firmer assessment of long-term safety.

b) information needed to decide the detailed location, design and orientation of a repository.

c) geotechnical data to inform decisions on repository construction methods.

A public inquiry into the planning application for the RCF has just been concluded and Nirex anticipate that a decision on the outcome will be made in 1997.

The UK Government continues to favor a policy of deep disposal rather than indefinite storage for ILW and considers it appropriate that Nirex should continue with its programme to identify a suitable site. It has decided that once a suitable site has been found, it should be constructed as soon as reasonably practicable. The precise timetable will depend on the granting of planning consent and compliance with regulatory requirements including the establishment of a sound safety case.

CONCLUSION

Through continued site investigation, scientific and engineering programmes and ongoing design development, Nirex will increase its understanding to ensure the most appropriate repository system is developed for operation.

FAST FLUX TEST FACILITY SPENT FUEL OFFLOAD TO DRY CASK STORAGE

S. W. Hiller
D. L. Nielsen
P. L. Scott
Westinghouse Hanford Company

ABSTRACT

The United States Department of Energy owned, Westinghouse Hanford Company operated, Fast Flux Test Facility (FFTF) is one of many facilities located on the Hanford Site in southeastern Washington State. The FFTF is a 400 MWt liquid metal-cooled research reactor which began operation in 1980. In December, 1993, the Department of Energy ordered Westinghouse Hanford Company to initiate the transition of FFTF to permanent shutdown. Accordingly, Westinghouse Hanford Company prepared and implemented the FFTF Transition Project Plan which delineates the progression of activities required to place the reactor facility into a long-term, low maintenance, industrially safe shutdown configuration pending final decontamination and decommissioning. The primary objective of the Plan is to provide the logic/approach and project baseline for the transition in a cost effective and quality manner while ensuring safety, security, and environmental compliance.

One of the challenging activities of the FFTF Transition Project is to offload the inventory of highly radioactive spent reactor fuel assemblies to above-ground dry storage casks. This paper will present an overview of the FFTF fuel offload, including a description of the interim dry cask storage system and the processes required to transfer the fuel assemblies

from sodium pool storage to dry cask storage. Additionally, the paper will discuss pertinent design philosophies and key regulatory criteria that are applicable to the FFTF dry cask storage system. The design features that were implemented to address the concern of fuel cladding degradation, will also be addressed.

INTRODUCTION

The FFTF is the largest, most modern, liquid metal-cooled test reactor in the world. Originally constructed to support the U.S. Liquid Metal Fast Breeder Reactor Program, the FFTF supported various missions from 1980 to 1992, including both national and international breeder reactor programs, production of medical and industrial isotopes, material testing for the fusion and space programs, and providing customized neutron environments to meet a variety of customer's needs. In December, 1993, the FFTF was ordered to shut down when the Department of Energy concluded there was no possibility of financial viability and the reactor was no longer needed to support its missions. The FFTF Transition Project Plan (1) was developed which delineates the activities required to place the reactor facility into a long-term, low maintenance, industrially safe shutdown configuration for long term surveillance and maintenance prior to final decommissioning. Approximately seven years are currently estimated to complete the transition of the FFTF to this shutdown state. The major activities to accomplish this task include: reactor defueling, fuel offload to dry cask storage, Sodium Storage Facility construction, sodium drain from the plant systems, and auxiliary plant systems shut down.

Fuel offload from sodium pool storage to dry cask storage, the subject of this paper, forms a significant portion of the overall integrated FFTF Transition Project. This activity includes implementation of the new hardware and facility modifications that are required to transfer the fuel to dry storage casks. The FFTF dry storage system hardware includes the Interim Storage Cask and the Core Component Container packages, which are combined to store up to seven fuel assemblies each. After loading with fuel, the Interim Storage Cask and Core Component Container packages will be placed within the newly constructed Interim Storage Area, which is adjacent to the reactor complex. Approximately 55 Interim Storage Casks and Core Component Containers will be required to store the 371 component inventory of FFTF fuel. The facility modifications required to load irradiated fuel into the Interim Storage Casks and Core Component Containers consist of: 1) installation of ion exchange columns in the existing sodium removal/fuel washing system to substantially reduce radioactive liquid waste by recycling the wash water, 2) design and fabrication of 15 new tools and 13 major new components for remote handling operations, and 3) installation of new fuel handling equipment interface capabilities for the Interim Examination and Maintenance Cell, a remotely operated shielded hot cell, and the Cask Loading Station, a below grade dry cask transfer station.

Following completion of the facility modifications and hardware acquisition, an extensive Acceptance Testing Program was initiated on June 21, 1995 to demonstrate the ability to safely transfer irradiated fuel to the Core Component Container and Interim Storage Cask for dry storage using the new, existing, and modified equipment and facility stations. The initial phase of the Acceptance Testing was performed with "mock" assemblies to verify equipment interfaces. The mock assemblies conformed dimensionally to a fuel assembly but were not irradiated nor did they contain fuel. The "cold" testing phase performed all operations

required to receive, load, handle, transfer, and unload both an Interim Storage Cask and Core Component Container using the new interfacing equipment and several new operating procedures developed for the fuel offload process. This phase was also used to provide hands-on training for the hot cell operators prior to proceeding with remote fuel operations. Approval to proceed to "hot" testing with irradiated fuel was granted after acceptable completion of the cold testing phase. The function of the hot testing was to perform shielding verification tests on all new components and to conduct final operating procedure validations in preparation for unrestricted operations. The hot phase of the testing program was successfully completed on January 22, 1996 with the transfer of the first loaded storage cask to the Interim Storage Area. Unrestricted fuel offload activities are expected to begin in early-February to retrieve the remaining fuel that currently resides in liquid sodium pool storage and to transfer these fuel assemblies to the dry cask storage system. Offload of the fuel to the Interim Storage Area is expected to be complete in approximately three years.

FFTF DRY CASK STORAGE SYSTEM

The requirements considered when developing the FFTF dry cask storage system included: capability to implement the storage system within the time-frame required by the FFTF Transition Project schedule, consistency with the requirements established for commercial nuclear spent fuel storage as specified in 10CFR72 (2), ability to demonstrate a safe storage configuration, capability to interface with the facility's existing equipment, flexibility to relocate the storage system to a central Hanford storage complex at a future date, and retrievability of the fuel at any time during its storage life.

Following the DOE shutdown order, it was critical that the dry storage system be provided in a short time-frame to support the aggressive FFTF Transition Project schedule. Until the fuel is removed from sodium pool storage and transferred to the dry storage system, drain of the two sodium-filled fuel storage vessels, shut down of the associated auxiliary systems, fuel offload processes and equipment, and ramp down of the related staff cannot occur. The cost of supporting the sodium pool storage, fuel offload systems, and the associated personnel is on the order of $20 million per year. Consequently, any delay to the fuel offload would have high economic impact. Approximately 55 Interim Storage Casks and Core Component Containers will be required at an estimated cost of $15-20 million to offload the inventory of FFTF fuel. One year of additional storage and maintenance of the necessary support systems and personnel would off-set the cask procurement costs. In addition to the avoidance of the schedule delay costs, dry cask storage also provides a more economic and low maintenance configuration for interim storage of up to fifty years.

The schedule and economic needs for the FFTF shutdown, combined with the existing fuel handling equipment compatibility, resulted in the development of a vertical top-loading Interim Storage Cask that is smaller in size than a typical commercial dry storage cask. The smaller cask size eliminated the need for extensive and time consuming facility modifications. The contract for design, analysis, and fabrication of the Interim Storage Casks was awarded to a vendor that could demonstrate previous Nuclear Regulatory Commission licensing experience for either a transportation or a storage cask. In addition to the requirements of 10CFR72, the design specification also required the vendor to provide a

storage cask to meet the facility- and fuel-specific interface and retrievability requirements. Additional design criteria were imposed to allow for future on-site relocation of the Interim Storage Casks to a central Hanford storage complex. While the Interim Storage Cask can be relocated at Hanford due to the administrative limitations that can be imposed and controlled on-site, the cask does not meet the requirements for licensed shipping casks and cannot be used for off-site transport. Although the Interim Storage Cask is smaller than a typical commercial dry storage cask, the storage system's design basis functional requirements are the same. The primary functions of the dry storage system are; passive removal of decay heat, criticality control, shielding, and confinement. The cask confinement boundary is required to prevent the release of radioactive material, to provide a benign storage atmosphere via an inert gas blanket (helium), and to control the in-leakage of air and moisture to limit any fuel cladding degradation or fuel oxidation reactions such that the condition of the fuel assemblies is preserved for the duration of the storage life. There are similarities between the FFTF fuel and commercial fuel, and additional conservatisms that were incorporated into the FFTF dry storage system, that allow the application of the commercial dry storage concept to the FFTF fuel. The similarities that exist are that both commercial and FFTF fuel are oxide fuel forms and extensive irradiation histories are available for each. Very conservative operating controls were imposed on FFTF fuel during all phases of fabrication, reactor operation, storage, and subsequent handling. During reactor operations, avery sensitive tag gas monitoring system was used to detect cladding breaches and the reactor was shut down whenever an unacceptable breach occurred. The monitoring system was capable of identifying the breached assembly with 100% accuracy. Historically, only four significant cladding breaches occurred during the reactor's operation. These breached assemblies will be disassembled in the Interim Maintenance and Examination Cell and the failed pins identified and encapsulated prior to dry storage.

In addition to the irradiation history of the fuel assemblies, the strict operating controls imposed to maintain fuel cladding integrity, and the cask confinement boundary, a very conservative decision was also made to containerize the FFTF fuel within the Core Component Container. Commercial dry storage does not typically require this boundary, in addition to the cask, unless there are gross cladding defects in the fuel. As a result of this decision, the functions of the Core Component Container are to provide a sealed confinement boundary, packaged handling capability, and long-term geometry control for the stored fuel. The added barrier provided by the container was determined to be desirable for the FFTF fuel for two reasons. First, there is no long term data that is directly applicable to document the FFTF fuel cladding condition following extended time in dry storage. Application of acceptable commercial dry storage data was not considered to be conservative due to the inherent differences between the FFTF fuel assemblies and commercial fuel. Some differences between the fuel assembly types are: 1) the cladding is constructed of different materials (FFTF fuel cladding is stainless steel versus zircalloy for commercial fuel), 2) materials testing was a primary function of FFTF and there are three different cladding materials, 3) the reactor environments were different, 4) the FFTF fuel sustained higher burn-ups than commercial fuel, and 5) the FFTF reactor coolant and fuel storage environment is liquid-metal sodium

versus water for commercial fuel. Secondly, a concern was raised regarding the need for data to support the absence of cladding degradation during extended dry storage. This concern arose due to observations of cladding degradation during post-irradiation examination of a small number of non-FFTF fuel pins at other facilities. This phenomena is known as "hot cell rot" and is thought to be a complex stress-corrosion cracking and fuel oxidation process involving reaction of sodium, fuel, oxygen, moisture, and cesium fission product with the stainless steel fuel cladding. Similar cladding degradation has never been observed during post irradiation examination of FFTF fuel in the Interim Examination and Maintenance Cell. Additionally, the limited data associated with these observations indicate that extended storage in hot cells and air may have contributed to the cladding degradation. Since "hot cell rot" is currently defined as a corrosion process, which requires oxygen and moisture to occur, it is considered unlikely that significant cladding degradation will occur in the environment of the FFTF dry storage system. However, the concern could not be firmly refuted due to the lack of actual data for long-term storage of the FFTF fuel in this manner. Consequently, additional conservatism was implemented into the FFTF dry storage system design.

The Core Component Container (Fig. 1) was designed by Westinghouse Hanford Company. Specific features were incorporated into the design to address the cladding degradation concerns described above. The container has a bolted closure with a metallic seal and separate closed bottom support tubes for each fuel assembly. The support tubes are fabricated from stainless steel and inconel to ensure corrosion resistant storage. The Core Component Container is unshielded, provides seven storage locations, and is designed for remote grappling and dry transfer capability. Its storage tubes and supports provide the geometry to ensure criticality control during handling and storage of the fuel, even in the unlikely case of full water moderation. Although not expected, if the accident condition occurs whereby the fuel cladding degrades, the Core Component Container will provide for safe and controlled retrievability of the fuel. Additionally, for retrieval of the Core Component Container after extended storage, it is required that the actual condition of the storage atmosphere within the Interim Storage Cask cavity be assessed prior to removing the cask's closure bolts. The Interim Storage Cask closure is designed with a penetration port with a quick disconnect fitting that is used to perform this sampling. If the storage atmosphere sample results are acceptable, then operations can proceed normally with Core Component Container retrieval via a shielded transfer cask. If the atmosphere sample results are not acceptable, then appropriate measures must be used to protect personnel and the operations area from potential contamination.

Fig. 1

The Interim Storage Cask (Fig. 2) was designed by General Atomics and Sierra Nuclear Corporation. The contract to design, analyze, fabricate, and test the prototype design was placed in September 1993. The first Interim Storage Cask was delivered in June 1995 after successful completion of performance testing. The Interim Storage Cask design is required to meet the requirements of 10CFR72, without licensing, and consists of a passively ventilated concrete and steel shielded cask with a stainless steel confinement boundary. Maximum weight of the cask, with the 2,268 kilogram (5,000 pound) Core Component Container payload, is

52,000 kilograms (114,200 pounds). The outside diameter of the cask is 216 centimeters (85 inches) and the overall length is 462 centimeters (182 inches). The internal cavity is 53 centimeters (21 inches) in diameter and 373 centimeters (147 inches) in length to accommodate the Core Component Container. The Interim Storage Cask provides a secondary leak-tight boundary for a defense-in-depth approach to confinement of the spent fuel. Coupled with maintaining the inert atmosphere, the cask eliminates the introduction of oxygen and moisture in-leakage that could accelerate spent fuel assembly degradation over the interim storage lifetime. The Interim Storage Cask is designed with a bolted closure which has redundant metal seals. The cavity penetration port in the closure has redundant covers which are independently seal welded after inerting the cask with helium following loading. The confinement capability of the loaded Interim Storage Cask is ensured by helium leak testing both closure seals after assembly and dye penetrant testing both seal welds of the penetration port cover plates. The confinement capability for the liner is assured by a combination of inspection techniques. During fabrication, each confinement weld requires radiographic or ultrasonic inspection and a complete helium leak test. The maximum permissible leakage rate for the Interim Storage Cask confinement boundary is "leaktight" as defined in the American National Standard for Leakage Tests on Packages of Shipment of Radioactive Material, ANSI N14.5 (3). At this leakage rate of 1 x 10-7 scc/sec, oxygen and moisture are prevented from entering the cask. As such, there is no known mechanism for accelerated corrosion of the spent fuel. In addition to the confinement boundary, the Interim Storage Cask also provides the necessary passive decay heat removal, shielding, and structural integrity for safe dry storage of the spent fuel. An impact limiter is located at the bottom of the internal cavity of the cask to protect the spent fuel if an inadvertent drop of the Core Component Container was to occur during loading or unloading. The FFTF fuel to be stored in the Interim Storage Casks has decayed since cessation of reactor operation in April 1992 and a substantial reduction in heat load and fission gases has occurred. As of August 1995, the highest decay heat assembly was 329 watts and the average decay heat per assembly of the fuel inventory was 81 watts. By November 1996, all assemblies will be below the 250 watt decay heat limit imposed for dry storage. The maximum fuel clad temperature predicted for storage of 250 watt assemblies is less than 390C (736F) during the hottest summer day. Even for the accident case, where no credit is taken for the passive ventilation system of the cask, there are no storage system components that exceed any normal condition limit. Based on these results, a high margin of safety for passive heat removal is demonstrated and there are no safety requirements to monitor the ventilation ducts. However, surveillances will be performed to ensure that the ventilation ducts remain open, in order to maintain storage temperatures as low as possible. These conclusions, which were based on the analytical temperature predictions, were confirmed by performance testing that was conducted prior to loading the Interim Storage Cask with fuel. The FFTF fuel cladding temperature limit for storage is 482C (900F). This limit was based on preventing stress rupture of the clad for the duration of the storage life (50 years) based on the most limiting type of fuel clad material. An irradiation history of < 150,000 MWD/MTHM (Pu taken as 29.3% of the heavy metal) followed by a decay period of four years was used to

conservatively bound the majority of the FFTF fuel. This source term also forms the basis for the radiological release calculations. For all design basis accident conditions, the storage system analyses demonstrate there will be no releases. To further demonstrate the margin of safety associated with dry storage, two radiological release accidents were analyzed. These cases are the "beyond design basis" and "hypothetical" radiological release events. The beyond design basis release accident assumed administrative handling limits were violated and this resulted in a cask drop accident beyond the currently analyzed height of 2.44 meters (8 feet). The beyond design basis release resulting from this accident consisted of 100% of the radioactive gas from all the fuel pins and other fission products resulting from exposure of 1% of the fuel material. No credit was taken for either the Interim Storage Cask or Core Component Container in mitigating the event even though such an impact would not be expected to produce a major escape path. The resulting dose consequence determined for off-site and on-site was 4 millirem and 4.5 rem, respectively, well within allowable limits. An additional non-mechanistic or hypothetical accident release was also analyzed. This case was similar to the beyond design basis case above except that it also assumed a higher source term is present and a crushing/shearing of the fuel stored within the cask occurs whereby 100% of the radioactive gas is released and 5% of the fuel is crushed and exposed. Again, neither the Interim Storage Cask or the Core Component Container were assumed to prevent or restrict the release. The hypothetical analysis resulted in a site boundary dose of 160 millirem. Accordingly, it was concluded that the FFTF fuel storage is not a public health and safety hazard, even under the most extremely unlikely hypothetical event.

Fig. 2

The Interim Storage Cask was designed to provide the radiation shielding required for handling operations and above ground storage such that the dose rate at the cask surface is less than 2 millirem/hour and the dose rate at the Interim Storage Area fence perimeter, located 23 meters (75 feet) from the stored casks, is less than 0.05 millirem/hour. Extensive radiation surveys were conducted during the Fuel Offload Acceptance Test which demonstrated the effectiveness of the cask shielding. The total collective dose measured throughout the fuel loading sequence was determined to be 15 person-millirem. This collective dose is considered higher than what will be experienced during normal handling and loading operations because the testing required numerous surveys of transient interfaces and a larger number of personnel observed the activities than will be present during a routine evolution. The total collective dose from the loading and handling of the remaining fuel inventory is not expected to exceed one person-rem.

FFTF FUEL OFFLOAD PROCESS OVERVIEW

In addition to the Core Component Container and Interim Storage Cask, there are several stations and pieces of equipment that perform vital functions of the fuel offload process. These components are best described by their respective functions in the spent fuel offload sequence. This sequence transfers the spent fuel, one assembly at a time, from its initial location in sodium pool storage to its final dry storage configuration. In the final storage configuration, the fuel will be located inside a sealed Core Component Container, which is inside a sealed Interim Storage Cask, which is located in the Interim Storage Area.

The offload sequence starts with removal of a single fuel assembly from its sodium pool storage location and transfer to the Interim Examination and Maintenance Cell using the existing reactor refueling machines. In the argon inerted hot cell, the sodium-wetted fuel assembly is placed into the sodium removal chamber. In this chamber, the sodium removal process is conducted. This process is comprised of injecting moist argon gas into the chamber to react the residual sodium in a controlled manner. Following the moist gas phase, the assembly is rinsed several times to ensure the requisite cleanliness is achieved. Final cleanliness is determined by the conductivity of the final rinse water (i.e., < 20 microsiemens/cm) and visual examination of the assembly. Cleanliness is required prior to long-term dry storage of the spent fuel due to the corrosive and reactive nature of any residual sodium. Additionally, after each assembly has been washed, it is dried prior to placing it into a clean Core Component Container.

When the Core Component Container is loaded with spent fuel assemblies, the cover is installed which mates to the container body crushing a metallic o-ring between them. The argon atmosphere of the hot cell is used as the inserting gas for the Core Component Container. As such, limitations are imposed on cell atmosphere impurities to limit both oxygen and moisture to a nominal 100 ppm. The Core Component Container cover is installed with 12 bolts which are torqued to 21 kilogram-meters (150 foot-pounds) using the hot cell manipulators. After the cover is installed, a pressure decay leak test is performed to ensure proper seal installation and the Core Component Container is transferred into the Solid Waste Cask.

The Solid Waste Cask is an existing transfer cask that is used in conjunction with the facility cranes and an electric rail transporter to provide the necessary shielding and sealed atmosphere to transfer the Core Component Container from the hot cell, located in containment, to the Cask Loading Station, which is located in the Reactor Service Building. The Solid Waste Cask was previously used to transfer non-fuel irradiated components to a waste burial cask. Several upgrades have been completed to provide safe handling of the spent fuel in the Core Component Containers. These upgrades included a new and more reliable control system and the addition of seals, an argon purge system, and a grapple locking device to be used during rail transport to the Cask Loading Station. The Cask Loading Station has also been modified to accommodate dry fuel transfers of the Core Component Container. These modifications consisted of upgrading the structure to meet seismic qualification, providing sealed interfaces with testable connections, providing shielded adapter plates for the Core Component Container transfers, and providing specific interfaces to position the Interim Storage Cask for remote dry loading. At the Cask Loading Station, the Solid Waste Cask uses an electric driven hoist to lower the Core Component Container into the Interim Storage Cask and ungrapple it. Once the unloaded hoist is raised back into the Solid Waste Cask, the shielded closure valves for both the transfer cask and the Cask Loading Station are closed, which allows the Solid Waste Cask to be safely removed. (See Fig. 3)

Fig. 3

After removal of the Solid Waste Cask from the Cask Loading Station, the closure is remotely installed into the Interim Storage Cask. The first step is to attach a lift rod to the 30.5 centimeter (12 inch) thick, 815

kilogram (1800 pound), bolted cask closure and to place it on top of the Cask Loading Station moveable shield valve. Then, additional shielding is installed over the lift rod and closure assembly. Once the proper shielding is assembled, the closure is lifted slightly via the overhead crane which is attached to the lift rod. Once the closure is suspended, the shielded closure valve is opened and the closure is slowly lowered into the Interim Storage Cask. When complete set-down is confirmed, as indicated by the lift rod travel, the shielding equipment is removed and the closure is secured to the Interim Storage Cask by torquing the sixteen closure bolts to 207 kilogram-meters (1500 foot-pounds). This torque is required to crush the redundant metallic seals and to provide the design basis pre-load for both storage and on-site transport. After torquing the bolts, three evacuations and back-fills are performed to inert the cask cavity with high purity helium gas. After inserting, mass spectrometer leak testing is performed to verify the redundant metallic seals of the closure and plug seal on the interseal leak test port are functioning to provide a leak rate of less than 1 x 10-7 scc/sec.
The use of redundant metallic seals in the closure with an interseal leak test port and a removable fitting provides the capability to perform a functional test of the Interim Storage Cask seals. Continuous monitoring of the cask seals is not currently planned due to the expected short duration of fuel storage at the Interim Storage Area prior to consolidation with the other Hanford fuel inventories. Failure of multiple seals or degradation of the fuel is not likely to occur during this short time frame. The number of seal failures that would have to occur to provide a leakage path to the fuel include; failure of the inner and outer metallic seals of the Interim Storage Cask, failure of the Core Component Container metallic seal, and failure of the fuel cladding. Additionally, analysis of the seal performance for normal and accident conditions, including cask drop and tip-over accidents, does not result in seal failure. Therefore, after the cask seals have been certified as "leak-tight" and the pressure is verified within specification, redundant plates are seal welded over the penetration port quick-disconnect fitting. The Interim Storage Cask is then removed from the Cask Loading Station using a spreader bar to vertically lift the cask and transfer it to the transporter. During the transfer operation, shielding and contamination surveys are performed to verify dose rates are within specification and that there is no contamination prior to removal of the cask from the Reactor Service Building. The cask is placed on a doubledrop-deck trailer in a vertical orientation and is secured using an engineered tie-down system. The Interim Storage Cask is transported approximately 183 meters (600 feet) to the Interim Storage Area using a tractor. At the Interim Storage Area, the cask is unloaded from the transporter using a mobile crane and a weather protection cover and tamper indicating devices are installed. (See Fig. 4)
Fig. 4
The sequence described above will be repeated until all FFTF spent fuel assemblies have been offloaded from sodium pool storage to long-term low maintenance dry cask storage. Approximately three years will be required for this evolution. The final configuration will consist of an array of Interim Storage Casks located in the Interim Storage Area. Over the 50 year design life of the dry storage system, surveillances will be performed on the general storage area to monitor for security, perimeter fence dose rates, vegetation growth, build-up of dirt or debris,

condition of the perimeter fence, and adequate lighting levels. Surveillances of the Interim Storage Casks will also be performed to assess inventory control, to clean areas around ventilation screens to ensure storage temperatures remain as low as possible, to perform visual inspections on the general condition of the casks, to perform upkeep of the concrete shielding surfaces of the casks, to perform routine radiological surveys of cask surface dose rates, and to verify the absence of contamination on cask surfaces. These surveillances will be conducted to ensure that the storage conditions remain within acceptable limits.

CONCLUSION

The FFTF dry cask system will provide safe, cost-efficient, and low-maintenance storage and retrievability for the highly radioactive spent fuel in a manner consistent with the standards implemented by the commercial nuclear sector.

STAKEHOLDER TRAINING IN NEGOTIATION AND CONFLICT RESOLUTION: A KEY TO SUCCESSFUL PUBLIC INVOLVEMENT

Todd A. Bryan
Colorado Center for Environmental Management

ABSTRACT

We have seen many advances in the development of collaborative decision-making processes and techniques. The goal of each of these efforts has been to provide stakeholders with meaningful opportunities to become involved in public decision-making. But something is still lacking. Public involvement professionals often report significant conflict. Public managers are often reluctant to bring stakeholders together because of conflict and may conclude that collaborative decision-making simply does not work where it is needed most.

The primary reason collaborative decision-making projects fail is because stakeholders become bound up in conflict. Creating opportunities for stakeholder involvement, then, is only one part of effective public decision-making. Providing facilitation and mediation assistance is another. But mediators and facilitators can only do so much to help stakeholders identify and resolve differences. Another key is through the development of collaboration and conflict resolution skills that begin to create a unique "culture" within the stakeholder group. The parts work together to break down barriers and build agreement: Public decision-

making processes provide opportunities for stakeholders to work together. Facilitators and mediators help guide the process. And collaboration and conflict resolution skills give stakeholders the necessary tools and understanding.

INTRODUCTION

This purpose of this paper is to suggest a strategy for improving the effectiveness of public involvement in industry and government decision-making by training stakeholders in negotiation and conflict resolution skills. As decision-making power becomes more balanced through public involvement processes, industry and agency officials and other stakeholders will have to negotiate solutions and agreements that satisfy mutual interests. Most of us mistake the process of arguing and debating (I win/you lose) with the process of negotiating (we both win).

Negotiation and conflict resolution are critical parts of the public involvement process yet nowhere are we taught these vital skills. As a result, many public involvement processes limp towards unsatisfying compromises or they fail completely due to unresolved conflict.

The public involvement process serves as a "road map" from a starting point to a destination. The process itself is filled with opportunities for stakeholders to work together to resolve differences and reach agreement. Negotiation and conflict resolution skills are a set of tools that stakeholders take with them on the trip and use them, like they would a Swiss Army knife, to solve problems.

THE CONTEXT FOR STAKEHOLDER TRAINING

Public involvement has existed as a recognized discipline since the 1960's, although James Creighton (1) dates the modern era of public involvement to the 1970's. In the environmental field, public involvement can be traced to early legislation and regulations, such as the National Environmental Policy Act (NEPA), which created opportunities for the public to comment on proposals and projects that required environmental impact statements. Since that time public participation has evolved into a multi-disciplinary field that combines the traditional fields of public relations and communication, organizational development and psychology, environmental and public policy, and alternative dispute resolution. In fact, most public involvement practitioners come from one of these disciplines.

One could argue that public involvement has grown over the years as a result of the publics' interest in becoming more involved. In some ways the field has followed the ladder of citizen participation first described by Arnstein (1969)(2) and later adapted by Chess et.al. (1988)(3). Arnstein's ladder shows a progression of involvement from the bottom up:

- Delegation of Decisions
- Negotiation and Consensus
- Meaningful Consultation and Advice
- Pro Forma Consultation
- Informing the Public of Actions
- Acting Alone

In the "old days" industries and agencies simply did what they wanted when they wanted. For years that behavior was accepted by the general public and we stayed on the first rung of the ladder. NEPA was an attempt to change this pattern. With NEPA came public hearings and public comment periods and, for a time, people accepted this new rung on the ladder. Many had high hopes that their concerns would finally be considered.

Attempts to involve citizens through public hearings, presentations and public comment still work in some areas, but have dwindled over time due to growing dissatisfaction with this modest level of citizen input. Why? In part, it is because the public process created expectations on the part of stakeholders that their comments would either be integrated into the project or would actually cause the project to be scrapped. When neither occurred, stakeholders became disillusioned. These processes did a pretty good job of informing citizens of pending actions or policies, when they were done objectively, but did a poor job of actually involving citizens in important decisions. In most cases, the important decisions had already been made. As this became apparent to stakeholders, the bloom came off the rose.

Citizen dissatisfaction with public comment processes led to pressure on some industries and government agencies to take the next step. That pressure came in part from law suits to block or delay projects and in part from recognized dissatisfaction with the public comment processes themselves. Industries and agencies that have taken the next step up the ladder have done so voluntary since, in most cases, there is no regulatory obligation to go beyond the public comment process.

The next steps on the ladder involve some form of direct dialogue or conversation with stakeholders. Citizen advisory boards, policy dialogue committees, regulatory negotiations and other stakeholder forums place industry and agency officials in situations where they must work cooperatively with stakeholders to accomplish their goals. If they cannot work together, the process will likely fail. Expectations among stakeholders are very high and there is significant pressure to succeed. If they cannot work together, the process will likely fail. Agency and industry officials may feel "burned" by unreasonable stakeholders. Stakeholders may feel that industry and agency people were never serious about sharing decision-making power. Both sides may feel that they were "suckered" into a decision-making process that was bound to fail.

THE CASE FOR STAKEHOLDER TRAINING

To help avoid this potential pitfall, public involvement specialists have turned to facilitators and mediators. Facilitators and mediators, while trained in slightly different ways, help guide the decision-making process without interfering with or influencing substantive decisions. To put it another way, facilitators and mediators act as third-party neutrals and help stakeholders negotiate decisions that satisfy mutual interests (for our purposes, negotiation is defined as the process of resolving differences, solving problems and reaching agreement). Most facilitators and mediators receive some training in negotiation principles and skills and work within the group decision-making process to get stakeholders to negotiate with each other instead of arguing and debating.

Facilitators and mediators are extremely beneficial in helping parties negotiate. However, facilitators and mediators are limited in what they can achieve when stakeholders insist on arguing and debating. The process is at best inefficient and more likely is like "herding cats". Even when stakeholders are civil, they may be disposed towards strong positions that lead to win/lose outcomes, stalemates and compromises. When agreements are reached through argument and debate they seldom maximize joint gains.

When we are locked in a debate we are not trying to solve a problem, we are trying to win an argument. It is only when we stop trying to convince

the other party of our position and begin to take their interests, and our own, and structure an agreement that all parties can live with that we are finally solving a problem.

The distinction between debating and negotiating is important in public involvement because of the diversity of legitimate public interests at stake and the need to integrate a broad spectrum of public interests into a decision. Moreover, it is almost impossible to win a debate if winning means convincing the other party of the correctness of our position. The chances of doing that are almost none. Yet we persist.

Public involvement processes that create meaningful opportunities for stakeholders to influence decisions is only part of the solution. The other is the development of collaborative problem solving skills through training in negotiation and conflict resolution. The two work hand-in-hand: The public involvement process provides opportunities to negotiate. Negotiation skills better enable stakeholders to communicate in ways that resolve differences, build agreement and maintain positive working relationships.

BASIC NEGOTIATION AND CONFLICT RESOLUTION PRINCIPLES

Negotiation and conflict resolution skills are not the miracle cure for the ills of public decision-making. They are, however, a step in the right direction. As a science, negotiation has existed for a relatively short time. While researchers and practitioners have written about collective bargaining for many years, modern teachings on negotiation date back to the 1970's. The most popular and still most widely accepted publication on negotiation is the book Getting to Yes by Roger Fisher and William Ury of the Program on Negotiation at Harvard University (4). Fisher was one of the pioneers of the modern field of interest-based negotiation. Interested-based negotiation is the process of focusing on underlying interests as the basis for exploring options that lead to agreement. Interest-based negotiating is described in more detail below. According to Fisher and Ury (1981)(4), there are five main principles behind the concept of interest-based negotiation. They are:

- Separate Human Issues from Substantive Issues
- Focus on Underlying Interests Instead of Hard-line Positions
- Search for Objective Criteria and Fair Standards
- Determine Your Best Alternative To a Negotiated Agreement
- Invent Options for Mutual Gain
- Look for Solutions that Satisfy Multiple Interests

Separate Human Issues from Substantive Issues

Fisher and Ury recognize that parties attempting to solve substantive problems often get caught up in conflicts dealing with emotions, beliefs, values, perceptions, trust, power and relationships. These "human" issues often prevent the parties from solving the substantive problem. The conventional approach to dealing with human issues is to subtly negate them or discount their importance. Instead of directly addressing the fears of neighbors over the cleanup of a local site, for example, the Agency will say, in so many words, "Just be rational. Trust us. We'll take care of it."

Fisher and Ury advise us to separate human issues from the substantive issues and to address the human issues first. In fact, unless the human issues are addressed to the satisfaction of stakeholders, they simply won't go away. Human issues that keep surfacing in environmental decision-making arenas are usually those dealing with emotions, values, trust, perceptions and past relationships. Such issues emerge first as

emotions and need to be dealt with on that level. The four primary emotions that people experience are fear, anger, joy and sadness. Psychologists believe that our other emotional experiences are combinations of or variations on the four primary emotions. In environmental debates two of the four emotions usually emerge, fear and anger, but are expressed as only one of the four, anger.

How do we separate human issues from substantive issues? To do this we must deal directly with the emotions that are preventing substantive problem solving. First, negotiators need to be aware that emotions are present. This is somewhat difficult because most of us are "programmed" to deny or down-play emotions, especially in professional situations. Second, negotiators must recognize the emotion by stating its existence to the party in a non-threatening way. Simply saying "You seem very angry about this..." or "I can tell you're very upset..." lets the party know that the negotiator is aware of the emotion without judging it or them. This acknowledgment will allow the party to let go of some of the tension.

The third step requires "actively" listening to the party's concerns. Active listening requires the listener to carefully paraphrase the speakers words until the speaker feels that the listener understands his or her concerns. At the end of the process of active listening the speaker should be able to say, simply, "Yes, those are my concerns." At the point of understanding much of the emotion will have drained from the dialogue. The speaker will feel that someone is listening, perhaps for the first time. Note that the listener has not attacked the speaker's position nor has he/she agreed with it. It is simply understood.

Focus on Underlying Interests Instead of Hard-line Positions

The second step in negotiation is to focus on identifying and satisfying interests instead of positions. Your position is one way, your chosen way, of satisfying your interests. Your interests are your underlying needs. Why do we focus on interests instead of positions? Because it is easier to satisfy underlying interests than to reconcile divergent positions. If we negotiate over positions, our negotiations become a test of will and power. If we negotiate over interests, we are more likely to find integrative solutions to our problems.

Let's use an example from CCEM's TRIP (Technology/Regulatory Integration Project) Implementation Manual to illustrate. Two opposing positions regarding the cleanup of a contaminated site might be to 1) clean the site to pristine conditions and 2) clean only the hotspots and seal the rest of the site. A stakeholder debate over these positions would be very difficult to resolve. We can do one or the other but not both. How might focusing on interests be any easier? Looking at the underlying interests that support these positions, we might find that stakeholders taking the first position care mainly about 1) reducing health risks to zero or almost zero, 2) restoring the ecological integrity of the site, and 3) holding the agency accountable for its past actions. Stakeholders taking the second position care mainly about 1) reducing costs, 2) lowering health risks to acceptable standards, and 3) avoiding further disturbance to the site.

Negotiators now have an initial list of interests that they can address. Negotiators could discover additional interests by probing more deeply into the reasons behind the interests stated. For example, why is avoiding further disturbance to the siteimportant? Perhaps to preserve existing wildlife habitat. Or, why is reducing health risks to zero or

almost zero important? Perhaps to assure stakeholders of minimum health risk, or to protect vulnerable populations that live near-by.
Negotiators could then develop what we call a "Joint Problem Statement" for this particular issue:

How can we... reduce health risks to zero or near zero
protect vulnerable populations
restore the ecological integrity of the site
hold the agency accountable for its past actions
while also... reducing costs
lowering health risks to acceptable standards
avoiding further disturbance to the site
preserving existing wildlife habitat?

The illustration leaves us with a set of interests - some common, some opposing and some simply different - that we must try to satisfy by negotiating. Will it be easy? No. But it will be a lot easier than knocking heads over opposing positions.

Search for Objective Criteria and Fair Standards for Resolving Differences

Objective criteria and fair standards are used in negotiations to establish impartial and unbiased methods for avoiding and settling data conflicts and generating information that will be used to make decisions. Objective criteria and fair standards are also used in negotiations to determine the value of an item independent of the resources that might be available to acquire it.

There are hundreds of examples of how objective criteria and fair standards are applied to negotiation situations. Salaries are based on comparable pay in the field. Home prices are based on comparable sales, replacement costs or rental income. Used car prices are based on the "Blue Book." Risk assessments are based on a standard model. Objective criteria are usually based on some quantitative assessment or accepted practice that is widely recognized by the public or a particular profession. Fair standards, on the other hand, may be quantitative, but are more likely based on what reasonable people believe is fair. When decisions are made without being "anchored" to some impartial and recognized objective criteria or fair standard, those decisions seem arbitrary or biased to outsiders.

Environmental decisions frequently run into problems with objective criteria and fair standards. We refer to these problems as data conflicts. For example, many complex public decisions involve planning and engineering studies and environmental impact assessments. These studies, designed and carried out by one of the party's experts, generate data that are then analyzed, interpreted for the public and used to make or justify a decision. The supporters of the project believe the studies. The opponents of the project do not. Did the studies use objective criteria and fair standards that were acceptable to all stakeholders? Probably not. They may have used scientifically defensible methods to conduct the studies, but if other affected parties were not part of the study design team, the studies may be perceived as biased. What usually happens in a data conflict is that both sides hire experts that support their positions and then become even more locked into those positions. Negotiators need to avoid data conflict traps by insisting on and finding objective criteria and fair standards that are supported by all stakeholders before a study is conducted.

Understand Your Best Alternative To a Negotiated Agreement

The principle of Best Alternative to a Negotiated Agreement (BATNA) was developed by Fisher and Ury to better explain the power and decision-making dynamics in a negotiation. Literally your BATNA is what you will do if you don't reach agreement in a negotiation. Or, put another way, what will occur if you can't reach agreement. If, as a negotiator, your BATNA is poor, if it is worse than a proposed negotiated solution and you can't improve it, it is wise to accept the negotiated solution. If your BATNA is good, if it is better than the best negotiated solution you can obtain, it is wise to walk away and pursue your BATNA.

Your BATNA must be a real alternative or it must be an alternative that you can reasonably count on. If your best alternative to getting the raise you want is to take another job, you are much better off having a firm job and salary offer from another employer. If the negotiation over the raise doesn't produce the results you desire, you will have some place to go. And, you will be able to compare your current employer's counter-offer with your new offer.

BATNA's can also be used to explain why certain public interest groups participate in collaborative decision-making processes while others decline. Often parties that won't participate believe their alternatives (BATNAs) are better than any agreement they could reach by negotiating. This is partly because many believe that negotiating means compromising and they are not willing to compromise. Many environmental organizations are reluctant to enter negotiations and feel that court action, or the threat of court action, is a strong BATNA. Fisher and Ury believe we should enter negotiations with a clear understanding of our BATNA's and walk away only when our BATNA is clearly better than the proposed agreement. If we want stakeholders to participate, we need to make them aware that a negotiated solution can be better than their BATNA. Or we can help them understand that their BATNA may not be that great.

Look for Solutions that Satisfy Multiple Interests

Interest-based negotiation requires stakeholders to seek solutions that are good for all. In order to do this, parties must have opportunities to get together for the explicit purpose of solving a joint problem. They must identify common and divergent interests behind their respective positions and make proposals that satisfy those interests. To aid this process, facilitators and mediators often ask stakeholders to suggest solutions that they believe everyone can support. Fisher and Ury call this Inventing Options for Mutual Gain.

Inventing options for mutual gain requires parties to be creative. However, creativity is risky. There is a tendency in any creative endeavor to immediately judge ideas that are new or unconventional. Judgment, however, has the effect of stifling most creativity. After all, how many of us want to look bad for suggesting a dumb idea? So we suggest ideas that we know will be accepted by the group and we end up with status quo solutions or no solution at all.

To better assure creative problem solving we must separate the inventing of options (brainstorming) from judging and selecting among them. Negotiators need to establish a simple ground rule: No judging or evaluating options until the inventing is complete. A second ground rule is often necessary when dealing with public officials and others who may worry about being attributed with an idea expressed during a brainstorming session: No attributing any ideas to specific individuals. Such an individual may have a creative solution in mind that integrates many interests but may be reluctant to express the idea for fear of

having it taken the wrong way. These rules protect all parties from outside attacks while providing the freedom necessary to be creative. Smart negotiators offer proposed solutions that they believe satisfy mutual interests. Proposals are then improved by all negotiators. Negotiated decisions, therefore, tend to maximize joint gains or, to put it in perspective, maximize public benefits. Debaters, on the other hand, minimize and discredit the arguments and positions of their "opponents" and sometimes even attack them personally. When they win, they seldom integrate the legitimate public interests of others. We tend to get one-sided victories that fail to maximize public benefit. While one-sided victories are sometimes the only way to solve problems, in most cases there are realistic ways to maximize public benefits that are lost because we don't know how to negotiate.

ADDITIONAL TRAINING CONCEPTS

In addition to the basic negotiation and conflict resolution principles and skills discussed above, an effective training program would address the following:

- Building trust
- Conflict resolution styles
- Improving listening skills
- Creating incentives to negotiate
- The role of power
- Dealing with difficult people
- The Solomon trap
- Escalation traps
- What stakeholders really want
- Responding to conflict
- Raising conflict
- Analyzing conflict
- Group dynamics

TRAINING METHODOLOGY

Training workshops are usually between one and three days in length and are most effective when done with 18 to 24 participants. The workshops combine the theory of interest-based negotiation and conflict resolution with principles and skills that participants can immediately apply in their work. Skills are developed and practiced through interactive negotiation exercises where participants play specific roles in a dispute or problem-solving situation. Participants are given a set of instructions that contain a common description of the problem and a context for the dispute. They are also given confidential roles that they must play throughout the negotiation. The roles create a tension between typical positional and confrontational strategies and interest-based negotiation skills. Like learning to ski, participants develop and practice the skills under relatively easy conditions (on a gentle slope) and then must maintain the skills as the conditions become more complex and contentious (the slope gets steeper and steeper).

Participants typically begin with positional and confrontational strategies, and only respond when others start to probe for underlying interests or make sincere attempts to understand other perspectives or seek joint gains. The dilemma negotiators face is whether to be the first to use the interest-based approach. If no one risks going first, no one will follow.

Following the training exercises, participants are debriefed about both the substantive outcome of their negotiation and the negotiation process

itself. The debriefing provides rich opportunities for participants to talk about negotiation and conflict resolution strategies and skills, group dynamics, power relationships and other issues. Often, the discussions shed new light on communication patterns that produce conflict.

INTEGRATING TRAINING INTO THE PUBLIC INVOLVEMENT PROCESS

Training can be integrated into the public involvement process at any time but is perhaps best at the early stages of development. Early training will help stakeholders address and resolve difficult issues before they become contentious. Once conflict appears, it is usually more difficult to get stakeholders to focus on alternative techniques. Ideally, training should be part of the initial orientation for the project, however, it could be brought in later, once group members feel more comfortable with the public involvement process, with each other and with the convening agency. Finally, training could be introduced at a point when the stakeholder group reaches an impasse over an important issue or decision. It is less likely that training will be accepted at this point, but it is still worth a try.

There are three factors that may serve as barriers to training and must be considered when determining how to integrate training into the public involvement process. First, negotiation and conflict resolution training may be perceived by some stakeholders as a method of controlling or influencing the outcome of a decision, or inducing stakeholders to compromise their hard-fought positions. Stakeholders who value their confrontational styles or who do not trust the decision-making body may resist such training. When this barrier occurs, it may be better not to push the training too early in the process.

Second, some stakeholders may question whether the training is necessary. Stakeholders who believe they are good negotiators may feel that they don't need additional skills. This is often the case with senior level professionals. Our experience is quite the opposite. Supposed "good" negotiators are often those individuals who are the most competitive in their styles and who are capable of making and defending strong arguments. They are usually not very good at collaborating to achieve joint gains. In addition, agency representatives who serve as stakeholders often believe that the training is intended for "all those unruly types" and not for them. This attitude fuels the notion that the training is designed to control the angry and unruly elements.

Finally, negotiation training may be seen by some as a way to "arm the enemy." "Why would we want to help the other side? " they would ask. "Let them fend for themselves." This attitude shows a clear misunderstanding of interest-based negotiation where the purpose is to help everyone do better.

Training in interest-based negotiation and conflict resolution was originally tested and is gaining in popularity in union/labor negotiations where their is a history of conflict over wages and benefits. The purpose of training in the union/labor arena is two-fold: to break down communication barriers that prevent negotiators from working together and to provide new skills for solving problems collaboratively.

CONCLUSION

Facilitators and mediators now fill the role of helping stakeholders negotiate tough decisions. They help parties separate human issues from substantive issues, focus on interests instead of positions, search for

objective criteria and fair standards, invent options for mutual gain and remind parties of the consequences of indecision. Facilitators, in short, help stakeholders move from arguing and debating issues to identifying and solving joint problems. But facilitators must struggle against the tendency of stakeholders to be argumentative and positional. Since we are not taught interest-based negotiation skills anyplace in our lives, few of us really know how to use them to solve complex problems.

Through TRIP, we have learned that stakeholders can become more effective participants when they are able to use interest-based negotiation skills. We recommend as part of any public involvement process that stakeholders be trained in these skills. CCEM recognizes that effective environmental decision-making requires opportunities and resources for stakeholders to work together and the skills necessary to solve problems once they are together. Most stakeholder processes provide opportunities and resources but fail to address skills. We tend to assume that people know how to solve problems collaboratively even though both history and current events tell us that just the opposite is true. Moreover, we would never consider providing someone with the opportunity and resources to swim, ski, drive a car or fly an airplane without also providing the skills. Why should solving important environmental problems be any different?

EXPLAINING RADIOACTIVE WASTE TO YOUNGSTERS

Andrej Stritar
Radko Isteni
Joef Stefan Institute
Jamova 39
Ljubljana, Slovenia

ABSTRACT

Following the strong public opposition after the announcement of the results of possible site selections for the final low and intermediate waste repository in Slovenia in 1993, the Agency for Radwaste Management has completely revised its public information strategy. The information and education programs, that should lead to greater public acceptance, are described. At present the bulletin, leaflets, booklet, permanent exhibition and lectures in the Nuclear Training Centre are applied. Special emphasis is given to information program oriented towards young generation, age 13-15 years.

INTRODUCTION

On May 27, 1993 the Agency for Radwaste Management of Slovenia has organized the press conference to present the results of the third phase of site selection for the low and intermediate level (L/ILW) surface radioactive waste repository. During the presentation five potential

sites in Slovenia were announced. Only few hours later reporters of the national television went to the village Kalievci, one of the potential repository sites, to get the first impression directly from the inhabitants. People from the village had expressed strong negative opinion by kidnapping the media crew. The crew was released only when the local inhabitants received a written statement of the representative of the government that within their community there will be no repository construction without their permission.

Reaction of the residents of Kalievci and also appearance of NIMBY (Not In My Back Yard) syndrome in such aggressive form has not surprised only the Agency for Radwaste Management but also the politicians and representatives of the media themselves. It was obvious that the public relations strategy of the Agency must be revised and renewed.

Radioactive waste in Slovenia originates from medical and industrial applications of radioactivity, from research and from the operation of the Krko plant, which is the main contributor. The construction of that Westinghouse plant took place in late seventies when the acceptance of nuclear power in Slovenia was not problematic. The general public was informed about the construction and about the economic benefits of the plant but there was no systematic public information and education program on the technology and its implications. Disposal of radioactive waste was not considered a problem and was not given any priority in comparison with completion and operation of the plant. Siting of the repository for low and medium level waste was postponed into the period of plant operation when it became obvious that the on-site storage capacity (about 11000 drums of low and intermediate level waste) will be reached in a foreseeable time. The siting process finally started without any previous education or information program and reached the phase when the potential sites were made public exactly in the period of fierce opposition to anything nuclear. The above described public reaction was understandable and at given time unavoidable. The whole process of site selection without the serious public information work was wrong and had to be changed. Therefore Agency for Radwaste Management under the new leadership has developed a new information strategy and started with its implementation. Nuclear Training Centre plays an important role in it.

PUBLIC RELATIONS STRATEGY

The first step in creating revised and renewed public relations strategy was the analysis of past experience. The analyses have shown that the communication activities in the past were insufficient. Since the dialogue was not established, the media and the public have little confidence in the information coming from the institutions working in the field of peaceful use of nuclear energy.

The Agency has also studied the strategies of foreign Agencies for radwaste management in overcoming the NIMBY phenomenon. On the basis of this analysis the communication strategy of the Agency for radwaste management was prepared. Three important aspects were included: communications, education and negotiations. In the first phase communication activities are used to attain a higher level of quality in addressing the issue; the communication activities are targeted at the general public. The educational activities are a logical and more focused sequence of the informing activities. For this reason the Agency is preparing various educational programs that consist of diverse activities. Negotiations are a necessary part of the communication strategy as the final decision should be made by the local community.

Communication activities concerning the issue of the waste encompass various tasks. First, there is the need to overcome the rejection of dialogue on this sensitive issue and second, to seek dialogue with the general public which is of key importance in any decision making process concerning radioactive waste.

Therefore the plan of PR (public relations) activities has the following basic objectives:

To establish a well qualified team for successful and highly professional work in the field of communication and crisis communication management;

To prepare different written materials that can be used for information and educational purposes;

To organize educational and information activities.

INFORMATION

At the present there is a great interest on nuclear issues in the public. The information on radioactive waste management comes from various sources. Often the information is distorted or misguided, many times resulting in negative atmosphere about radwaste management activities. In last years the Agency has given more attention to the public information through the media. Several articles on radioactive waste management have been prepared and published in most popular Slovenian newspapers. In one year thirteen articles, seven reports, four press releases, three interviews and two statements have been published. It should be mentioned that before 1994 there were no such contributions. Through these activities many contacts with journalists were made that will facilitate further communication activities.

Agency's Bulletin has been published recently. The first number of Bulletin gives answers to the most frequently asked questions on radwaste management. Present and future Agency's activities are also briefly described. Special care is dedicated to the clear and simple language so that no special technical background is necessary to understand the subject.

INFORMATION AND EDUCATIONAL ACTIVITIES AT NUCLEAR TRAINING CENTRE

Part of the information and education activities of the Agency for Radwaste Management has been taken over by the Nuclear Training Centre, which is part of the "Joef Stefan" Institute. Several activities related to the Radioactive Waste have been prepared. It has been decided to concentrate on youngsters as the main target group and to prepare an information program consisting of lectures, radwaste exhibition, visit to the interim radwaste storage, at-a-glance information leaflets, radwaste booklet and video tapes.

The information and education program consists of the following activities and information materials:

The Lecture Radioactivity and Radioactive Waste

The lecture informs the students about the following subjects:

1) Radioactivity and Radiation,
2) What Is Radioactive Waste?
3) Radioactive Waste in Slovenia.

The lecture set consists of 30 viewgraphs and lasts approximately 45 minutes. There are additional 10 slides available for more detailed explanation of typical questions. We always encourage the discussion. Typical visiting group at the Centre consists of about 50 students, but we can accommodate also up to 100 visitors. The lecture can be presented also elsewhere in the country. Since September 1995 there were 16 groups

attending the lecture comprising altogether 890 students with 57 teachers.

In addition to this particular lecture about the Radioactive Waste Management only, we are offering also another lecture about the Nuclear Power in general. Radwaste management is also covered in the narrower extent. This lecture was attended by approximately 6000 students in the year 1995, which represents roughly 10% of total population of that age (13-15 years).

Radwaste Exhibition

A set of 16 panels explaining radwaste is added to the existing permanent exhibition Electricity from nuclear energy. The panels explain the origin of low, intermediate and high level waste, technology of waste disposal and examples from different countries. There are also a normal and compacted radwaste barrels and a mockup of the surface repository displayed. The visit to the exhibition usually follows the lecture, therefore it represents repeated and supplement information. Yearly about 6000 visitors see the exhibition.

Visit to the Interim Low and Intermediate Level Waste Storage at the Reactor Centre

The Nuclear Training Centre is part of the Reactor Centre in Podgorica near capital Ljubljana, which includes an interim waste storage facility intended for the waste originating from research, medical and industrial use of radioactivity in Slovenia outside the Nuclear Power Plant. During the visit the storage is shown only from the outside. On special request of smaller groups it is possible to see also the interior.

The lecture, the visit to the exhibition and the visit to the storage facility are typically merged during a single visit of student groups to our training centre. Every year students from around 100 schools come to the Nuclear Training Centre.

At-a-glance Information Leaflets

In the Nuclear Training Centre a set of four at-a-glance information leaflets has been prepared for the Agency for Radwaste Management describing the following topics:

1) Radioactivity and Radiation
2) Radioactive Waste
3) Disposal of Low Level and Intermediate Level Radioactive Waste
4) Disposal of High Level Radioactive Waste

The fifth leaflet, Radwaste Storage in Slovenia, is in preparation now. The purpose of the leaflets is to provide the reader with a lasting correct information for later reference. The leaflets have been designed in a style appealing to youngsters (see Fig. 1). They are widely distributed to anyone interested in the subject in Slovenia.

Fig. 1

Booklet about Radioactive Waste

The booklet is conceived as an information source to the readers who are willing to spend more time than just glancing through the leaflets. It describes the nuclear fuel cycle, radioactivity, sources of radioactive waste and radioactive waste disposal on about 40 pages. The booklet is in print now and will be distributed to anyone interested in the subject, primarily to the schools.

Video Tapes

Because Slovenia is rather small country it is, for the time being, too expensive to produce our own video tape material. Therefore we have

translated three video tapes about the Swedish radioactive waste management system to Slovenian language. In the future we intend to bring closer to our public some similar material from other countries and to produce some own material. The French video is being translated now.

Journalist's Guide to Radwaste

Speaking about technical matters is often confusing or hardly understandable for non-technical people. Therefore we are preparing the version of the booklet about Radwaste which is written by a journalist. We expect this to be more understandable for the wider public.

FAQ about Radwaste

Another material, that is in preparation, is a set of Frequently Asked Questions about Radwaste. Most of them are being asked by our visitors. We hope, that this will provide fast and easy answer to interested public.

Future Plans

The final objective of all public information activities is to obtain the acceptance of wider and local public for the radioactive waste repository. Keeping that in mind we are trying to produce material that is easily understandable and can be easily distributed. All available technical means should be used, especially newly emerging ones. So in the near future we intend to prepare information about radioactive waste for the World Wide Web, a part of the Internet system. An extensive material about nuclear energy in general has already been prepared and is available on http://www2.ijs.si/~icjt/kakoje/ (in Slovenian Language). Another media, very popular especially among the young generation, is a hypertext computer presentation on a CD ROM. We intend to publish some material about the Radwaste in a user friendly computerized way.

PUBLIC OPINION

Influence of our activities is hard to measure exactly. Immediate response during and after the visit is positive. The opinion of the general public is measured every year by a wider polling performed by the Faculty of Social Sciences in Slovenia. Some positive shift in the attitude towards nuclear energy in general can be observed from their answers. It is shown on Fig. 2, that number of those in favor of further operation of NPP is increasing.

Fig. 2

CONCLUSIONS

The problem of acceptance of radioactive waste disposal facility by the general public is becoming one of the key problems of nuclear energy everywhere in the democratic world. Recent examples in different western countries (Switzerland, USA) are not encouraging. It is also obvious there is no perfect general solution, that would work everywhere in the world. In Slovenia we are carefully studying other experiences and trying to find our own way to solve the problem. Next several years special care will be devoted primarily to the information and education of the people in order to make them understand the facts about radwaste. Only after a certain level of public confidence will be achieved, the further steps towards the final disposal will be taken.

AN INDEPENDENT TECHNICAL REVIEW OF THE PROPOSED NEW DOUBLE-SHELL TANKS AT HANFORD

Glenn Paulson
Paulson and Cooper, Inc.
PO Box 1541
Jackson Hole, WY

ABSTRACT

This paper describes the approach used by an independent Technical Team created to advise the Dollars and Sense Committee of the Hanford Advisory Board regarding the need for new Double-Shell Tanks at Hanford, and presents the Team's conclusions and recommendations. The process used led to rapid acceptance of a dramatic re-direction of the new tank proposal by internal and external parties.

The Technical Team produced a safety-driven analysis based on a "worst case" budget scenario to ensure that minimum required facilities were available for waste management and operated with a manageable level of risk in the 200 West Area and 200 East Area tank farms, and that major activities of waste processing (e.g., evaporation, storage and waste volume reduction) will have the storage needed for the next several years. The risks of the various feasible options for waste management were balanced against cost constraints and the necessity to move forward with the remediation mission. These considerations guided the Team in developing its recommendations to the Hanford Advisory Board regarding the project. By design, the Team investigated only technical issues, but recognized that the Board had the ability and the obligation to combine technical insights with other important and valid considerations and values as it developed its own recommendations to DOE regarding the proposed new tanks and other features of the Tank Waste Remediation System.

The Technical Team focused its recommendations on waste storage needs from 1995-2004, the time period covered in the Draft EIS on Safe Interim Storage and the time period of current importance to the new TWRS program. After 2004, the waste treatment division at Hanford is scheduled to begin to retrieve and treat solids from Single-Shell Tanks; when this treatment cycle begins, the need for large volume, long-term storage capability will be reduced as treatment proceeds. Evaluation of treatment processes and systems and the need for (operational, short-term) storage specifically required by these treatment processes were far beyond the Team's assignment. However, if the start of treatment is delayed beyond 2004, then retrieval of SST solids must also be delayed--and this would have significant implications for the long term storage capability needed at that time. It is important to keep firmly in mind that tank needs after 2004 are determined by treatment facility configuration, retrieval and treatment rates.

The Team was limited by too few risk assessments as well as the level and frequency of change of the data provided to it regarding waste volume projections and tank waste classification. This was understandable; the situation during the Team's review period was a fluid one, indeed. Despite these limitations, the Team arrived at seven recommendations, focusing on the three areas of primary concern: 1) tanks, 2) the Cross Site Transfer System (CSTS), and 3) risk analyses. The Hanford Advisory Board unanimously adopted these recommendations, which were complex and technically sophisticated, for formal transmittal to DOE. The process

used by the Team ensured that the recommendations (and the reasoning were understood by the Board, other stakeholders, DOE and its contractor. The full paper presents the technical substance of the analysis and recommendations, as well as additional information on how the Team worked with stakeholders both without and within the DOE system.

INTRODUCTION

The Assignment

In late September 1994, Dr. Thomas Engel from the University of Washington asked the author on behalf of the Dollars and Sense Committee (DSC) of the Hanford Advisory Board (HAB) to organize a Technical Team to review issues, assumptions and alternatives surrounding the Multi-Function Waste Tank Facility (MWTF) being proposed by the Tank Waste Remediation System (TWRS) at Hanford. The original goal of the Technical Team review was to "enable DSC and HAB to understand and examine the assumptions and key policy decisions behind the decision to proceed with a project to construct six new Double-Shell Tanks, and understand the costs and alternatives so that the Board may offer timely advice and principles/values regarding policy choices." The Technical Team, led by Dr. Paulson, then Research Professor at the Illinois Institute of Technology, and assembled under the auspices of the firm of Paulson and Cooper, Inc., included Professor Frank Parker of Vanderbilt University and Dr. Michael Kavanaugh, a Principal of ENVIRON. This Team was able to address issues of policy, history, engineering (including design integrity, waste volume inventory and projections, and facilities required), alternatives, cost, and risk. In addition to the technical experts, the project was supported by Ms. Susan Sink, a technical writer and researcher, who reviewed and summarized documents and helped prepare drafts of this final report to speed the Technical Team members' review process. Logistical and research support in the Tri-Cities was provided by Ms. Jennifer Plemmons of Pasco, WA.

Re-scoping of Assignment

The details of the review assignment soon changed dramatically, as a result of the "Double-Shell Tank Inventory and Available Space" report of December 28, 1994, and the February 1995 recommendation from Westinghouse Hanford to DOE's Richland office is that no new tanks be built. However, the thrust behind the basic DSC/HAB request to "examine the assumptions and key policy decisions behind the [project] decision" was still valid. The Technical Team therefore examined in detail the assumptions and key policy decisions that led to the new recommendation (not to build tanks). Any decision on whether or when to build additional tanks is impacted by many considerations, including the risks, benefits, costs, uncertainties and impacts in future years of a decision not to build tanks soon. An evaluation of all these impacts was beyond the scope of the review. It was, however, possible to examine the potential consequences associated with various courses of actions until the Single-Shell and watch list tanks (not mutually exclusive) are stabilized. The review was limited in time, scope, and dollars, and could thus not be guided by long-term, integrated technical efficiency, but it nevertheless provided for a "No Regrets" outcome which meets near-term and mid-term safety needs and does not preclude additional action related to storage and treatment in the years beyond 2004. Just as important, the Team's review provided what the Hanford Advisory Board needed to know when it needed to know it--to provide focused, results-oriented to advice to DOE. In the present uncertain climate, while one must be sure that actions taken now do not

foreclose future options, strategic planning within limited time horizons may be the wisest course, both for DOE and its stakeholders, especially its formal site-specific advisory boards.

A Word on the Process

Extensive documents were obtained from DOE and its contractors, all of whom were extremely cooperative. The author, who led the Team, participated in selected meetings of the DSC and the HAB during this research period. With the help of DOE, the DSC/HAB, and its own contacts, the Team made aggressive efforts to reach other stakeholder groups not represented on the HAB, internal and external critics of the new tank proposal, retired "old timers" who had worked at the tank farms years and even decades ago, and others who might be able to contribute technical or other relevant information. While informal, this process was thorough.

In February, 1995, after completing its review of all relevant documents, the full Team spent several days at Hanford, holding a series of meetings with those identified above. The Team's visit was publicized by the Board and DOE; in addition, the Team established a local contact office for two months before the visit. These meetings could be classed as informal public hearings, in a sense; members of the HAB participated as observers much of the time, and appropriate DOE, Westinghouse, federal and state agency figures were also present. Several private citizens ("old timers") joined the Team's meetings as well, some of whom had traveled considerable distances at their own expense. The meetings, while informal, were vigorous in their discussions and debates. Before leaving the Tri-Cites, the Team met in private to develop its analysis, recommendations, and conclusions, and to begin drafting its report.

A draft of the Technical Team's report was provided in late February to several anonymous expert reviewers selected by the Team, and shortly after that a revised version was made generally available to interested individuals and agencies in the Pacific Northwest and at DOE headquarters. The DSC was fully briefed on the findings and recommendations in the revised draft report at its regular March meeting, and the final draft of the Executive Summary was provided to the full HAB in advance of its April meeting. Additional comments from agency and other reviewers were received in April, and the final report of the Team was submitted to the HAB in advance of its regularly scheduled May meeting, where a full discussion of it was held.

Project Areas Addressed by the Report

The Team evaluated in depth both the initial proposal in the August 1994 "Safe Interim Storage Draft EIS" and the revised February, 1995 proposal. The Team early on decided that the decision to build tanks or not build tanks cannot be considered in isolation from the other elements of the initial proposal (particularly the CSTS). The Team also assessed possible impacts of the new proposal for no tanks on the safety of tank farm operations in the medium term (until the start of pre-treatment and treatment, scheduled for 2004). The Technical Team considered the issues of projected increase/decrease in waste volumes, relationship of new tank construction to operational plans at Hanford, cost, as well as material selection, design, and other features of the proposed tanks.

Background Assumptions

The Technical Team based its recommendations on several key assumptions associated with the original proposal (six tanks) and the changed proposal (no tanks). The key were:

1) technical issues associated with the new proposed action regarding tanks (no new tanks)
2) tank waste storage needs until pre-treatment begins
3) risks and probable consequences of new proposed action
4) relationship between current waste volume projections and the new proposed action
5) relationship between compatibility of waste types and the new proposed action
6) availability of contingency plans and other waste management issues

It was the aim of the Technical Team to determine if the new proposed action was sound and whether or not new tanks are needed. Further, the Team identified what types (capacity and function) of tanks might be needed, resulting from an assessment of the consequences of the new proposal given current information on waste type, integrity of both existing tanks and the CSTS, and waste volume projections.

DESCRIPTION OF INITIAL APPROACH

The Safe Interim Storage Draft Environmental Impact Statement (DEIS) considering new tanks at Hanford and completed in August 1994 assessed the three major components: 1) six new double-shell tanks (DSTs), 2) the Cross-Site Transfer System (CSTS), and 3) the Initial Tank Retrieval System.

A full description of the proposed new tanks facility can be found in the DEIS and was the official preferred alternative by the Department of Ecology and USDOE Richland Operations Office through December 1994. The rationale behind this recommendation focused on the need for additional storage space to passively mitigate tanks 101-SY and 103-SY through dilution.

SUBSEQUENT APPROACH

Tanks

Based on the revisions to the Waste Volume Projections, the decision to actively mitigate tank 101-SY (and if necessary tank 103-SY) with mixer pumps, and driven by the then-current budget situation, TWRS in February 1995 recommended that no new DSTs be built. The new recommendation reflected a shift in the Waste Volume Projections, and clearly included assuming a higher level of risk and uncertainty than was associated with the original plans for 200 West Area. This risk had not been quantitatively assessed at the time, although one report offered a "high/medium/low" scale for evaluating risk of certain components of the new projections. The possible consequences of failure of any of the assumptions included in the Waste Volume Projection January 1995 revisions are assessed in section V of this paper.

The recommendation not to construct tanks was based on the following major assumptions connected with Waste Volume Projection revisions and associated Path Forward paper:

- Continued and maximized use of the East Area Evaporator
- Significantly reduced future waste generation from site generators
- Revised estimates of the "porosity" of incoming waste (increasing volume which will be treated by the Evaporator)
- Timely construction of the new CSTS
- Minimal waste produced by the planned sludge washing demonstration
- Active mitigation through mixer pumps for 101-SY and 103-SY (if needed)
- Consolidation of compatible wastes now found in several tanks into fewer tanks

With revised waste volume projections based on these assumptions, the waste volume would exceed the projected capacity in 1999 (by 0.22 million gallons), and by 1.22 million gallons by the year 2001. The proposed solution for storage of excess waste was to use evaporator support tanks for spare space and store additional waste in 102-SY, the current staging tank for all waste which must be moved from 200 West to 200 East. The Path Forward document of February 1995 predicted 0.5 million gallons will be stored in 102-SY as other space becomes unavailable. However, only TRU-compatible waste can currently be stored in this tank. The proposal is also dependent on the operability of the current and new CSTS to transfer wastes in 102-SY, and the successful resolution of TRU-compatibility issues for 102-SY.

Cross-Site Transfer System (CSTS)

The new proposed action strongly recommended, in fact requires, the construction of a new Cross-Site Transfer System. The volume projections which justify not building any new tanks require the use of the existing CSTS through 1998. The January 1995 proposal recommended construction of the new CSTS as developed originally and described in the DEIS, without considering modifications based on the fact that it will no longer serve the six originally proposed new tanks. The CSTS proposed consists of 2 lines routed over approximately 6.5 miles, parallel to the existing system except for the stretch just before it enters the East Area. The routing had apparently not been re-evaluated following the decision not to build new DSTs.

Initial Tank Retrieval System (ITRS)

The ITRS was no longer needed for tank 101-SY and 103-SY, since passive mitigation by dilution has been dropped as a solution to the hydrogen gas build-up situation. Thus, the ITRS no longer fell within the scope of the Team's assessment of the project.

NEW CONSIDERATIONS RAISED BY JANUARY, 1995 CHANGE IN APPROACH

The new approach, to drop plans to construct tanks in either the 200 East area or 200 West Area, was based on a set of major assumptions which may or may not hold true. The decision not to build tanks is based on all the assumptions holding true. In the view of the Technical Team, it was not reasonable to base such a major decision on a conclusion that all assumptions will hold true; a fuller understanding of risks involved is essential for sound decision-making. Key issues which needed to be considered as a result of the new proposed option include: risk analyses; accuracy and consequences of errors in waste volume projections; the interim approach to addressing leaking SSTs in West Area which may result due to incompatibility or failure of the CSTS; and the impact of the decision to actively mitigate 101-SY and 103-SY.

Critique of Risk Assessment in the "Path Forward" Decision Paper

In the Path Forward decision paper, only the risks inherent to the new path chosen were presented. Even this risk evaluation had problems for independent validation in that only safety, financial and programmatic risks were evaluated and then only in terms of "High/Medium/Low," with no definition of the numerical meaning of the terms. Even the "comments" were plagued by vague terms instead of quantifiable terms, and there were some important contradictions in the reports, raising a question as to whether predictions for cross-site transfer capability were reasonable, the failure of which would result in a serious waste storage shortfall. With no probabilities of the events given, with no estimates of the consequences given, and without the same information for plausible

alternatives and the costs for the alternatives (and with no sensitivity analysis), it was impossible to judge which alternative is best or even if any is satisfactory. The recommendation to proceed without any new tanks is a case in point. According to the data given to the Team in February 1995, in the year 1999, even with positive outcomes on all the waste reduction assumptions, there would be a shortfall of tank space requiring use of the Evaporator support tanks (with its impact on Evaporator operations), and in the year 2000, the use of space in tank 241-102-SY will be required to meet the shortfall, though preliminary indications already had cast doubt on the viability of this plan unless special actions are taken regarding 102-SY.

Additionally, the viability of the existing pipelines between 200W and 200E is required until the new CSTS lines are in place, projected at that time to be no earlier than 1998. There were no relative probabilities given for each of the actions required to make this plan succeed. In the Team's view, this was not a technically sound way to make decisions on complex matters of such importance.

All risk analyses start with incomplete information, but with sensitivity analysis one is able to determine what information is most critical and obtain that. There is certainly more risk information available than what was presented. For example, when we probed, we learned that a formal risk analysis had calculated a 70% likelihood of failure of the first mixer pump during its lifetime. Similarly, in a rough fashion one could calculate the likelihood of the remaining two cross-site transfer lines staying in operation until a replacement system is in place; we calculated this to be only 40%.

Issues Related to Available Tank Storage Capacity and the Waste Volume Projections

The five key issues regarding available tank storage at Hanford were, in the Technical Team's opinion, 1) waste volume projections; 2) waste compatibility; 3) areas of production; 4) waste transfer capabilities; and 5) evaporator effectiveness. These issues are explored in depth in this order.

The Technical Team was provided significant information that established the estimated waste volume projections from 1994 to 2004. The most recent projection reviewed indicated that in the year 2000, the current capacity of the DSTs (given the estimated capacity for the 28 DSTs is 31.28 million gallons) will be exceeded; a shortfall of available storage space will occur. The Team intended to generate a similar summary for the total volume of waste combining the existing inventory with waste volume projections. Unfortunately, the categories in the February 1995 document were different than those that can be extracted from other relevant reports, and we were not able to carry out this task in a manner acceptable to the Team within the schedule we had to finish our review.

The accuracy of the revised waste volume projections are absolutely critical for a decision to not proceed with construction of any new DSTs. The Team did not believe that the assumptions used in the most recent volume projections were documented clearly enough. While minor inaccuracies in projected generation and treatment would not affect the final recommendations of the Team, the possible failure of the other major assumptions to contribute to waste volume reduction (compatibility, transfer, evaporation, etc.) should be revisited and evaluated as part of development of a contingency plan and associated risk analyses. Just as important is the need for DOE and Westinghouse to monitor waste volumes

actually produced month by month. If the projections are exceeded--that is, if more wastes are produced than are currently foreseen--timely re-adjustments to the entire waste storage system will be called for, perhaps on very short notice indeed.

The second key issue regarding the management of the liquid and salt waste in the Hanford Tank Farm is compatibility of waste. A major issue is the compatibility of waste in SSTs in 200 West Area with the staging tank 102-SY. The best estimate we received from a staff member at DOE was that as much as 1/3 of the current liquid waste in West Area (or roughly 1.2 million gallons) might be incompatible with the staging tank. If this proves to be an accurate estimate, it greatly affects the scenarios developed as part of our final report.

Additional wastes will continue to be produced from various facilities in 200 East Area and 200 West Area over the time period considered. Documents the Technical Team reviewed gave waste generation figures only after evaporation, figuring all the waste "generated" as slurry or "solid" waste stored in 200 East. These figures do not demonstrate how much waste will need to move through 200 West Area, particularly through 102-SY (which accepted only TRU-compatible waste) or provide estimates of generated waste which will need to be stored in 200 West Area if the old CSTS is not operational. Therefore, these projections are based on two assumptions which involve considerable risk. Rev. 20 gave a figure of 13.01 million gallons for waste generated through 2004 without evaporation. By the time the new CSTS was expected to go on-line, in 1998, 6.68 million gallons of waste will be generated. If even a small portion of this waste is generated in the 200 West Area and not transferred for evaporation and/or storage, there will be a serious shortage of tank space in 200 West Area.

It appeared to us that sufficient capacity exists in the DSTs in the 200 East Area (25 tanks are located there, and only 4 are on the Watchlist). There is sufficient capacity in the remaining 21 tanks, particularly if certain wastes are consolidated, to accommodate waste generated even in unevaporated form over the near term.

Current and future waste transfer capability, both within each area and especially between the 200 West area (where storage capacity is low) to the 200 East area (where it is greater) is a very significant issue for both now and later. The Team did not evaluate in-depth the plumbing and pumping details of how waste moves within the 200 West and 200 East Areas, or from facilities to the 200 Area. However, it was unclear to us whether sufficient flexibility exists to move wastes in emergency situations, or if the existing transport system from other areas of the Hanford Site to the Tank Farm are sufficiently reliable to ensure low risk of waste releases. The Team concentrated on the risks associated with assumptions regarding the operability of the CSTS, although it recognized the importance of other transfer capabilities. Apparently appropriate above-ground emergency transfer lines exist to accommodate emergencies (leaks) within each Tank Farm, but there is no equivalent contingency to move waste between 200 East and 200 West Areas. The reliability of the waste volume projections, therefore, are primarily dependent on the existence of a functioning CSTS to maintain evaporation projections.

The Evaporator in the 200 East Area is the only operating evaporator system in the entire Tank Farm. The old Evaporator in the 200 West Area has not been operational for more than 10 years, and it would not be

justified to renovate it to treat the limited amount of liquid waste inventory in 200 West Area. Clearly, the continued operation of the East Area Evaporator and its capacity for further reducing the total volume of waste is an essential component of both the current and the long-term waste management strategy at the Hanford Tank Farm. The reported reduction of waste through evaporation in calendar year 1994 was 5.2 million gallons. Both campaigns were slightly below the reduction rate projected. For example, DOE staff reported that campaign 94-1 was projected to reduce 2.9 million gallons by 2.5 million gallons (85%). Actually, it reduced the waste by 2.4 million gallons, resulting in an unanticipated excess of 100,000 gallons. If more recent waste volume projections predict higher rates of evaporation, as we believe is the case given a further reduction in specific gravity (even when the initially proposed predicted factor was not met), the actual performance may fall even farther behind the predictions, significantly affecting the accuracy of the waste volume projections. Again, the capability of the Evaporator to reduce waste inventory is affected by other factors, including the operability of the CSTS in the near and long term, waste compatibility, and compatibility of sludge and slurry with storage space in East Area that is available.

The Team reviewed with great care the then-current waste volume projections, a subject of great importance of course, but fraught with too many details to cover in this brief paper. In short, it was impossible to determine how much waste was to be produced by each of the site generators. And even aggressive use of the Evaporator cannot be expected to reduce the waste generated to 0.

A key assumption in the 1994 projections is that the DST inventory specified in 1994 would remain constant until the year 2004. This volume was based on the inventory as of October 1994, and has been reduced through operation of the Evaporator. It was unclear to the Team why this number should remain constant over the 10-year planning period. A similar point can be made regarding the concentrated waste. Does this mean, for example, that the concentrated waste volume remains constant from the year 1996 beyond? Presumably the volume of concentrated waste should increase (while supernate waste decreases) as liquid waste is treated at the Evaporator and the resultant waste is transferred for storage in East Area tanks.

In the planning horizon of 1995-2004, at least two different projections were completed. One predicted waste tank shortfall capacity will occur in the year 2000. This shortfall could be exacerbated by the incompatibility of wastes. This analysis suggests that the Hanford Tank Farm is operating at, or close to, its capacity. If no additional tank capacity is installed in either 200 West or 200 East Areas, the uncertainties regarding the waste projections, particularly with respect to waste generation in the West Area which must be transferred to the East Area for treatment, indicate a significant storage shortfall could occur even before 2000. Specifically, if the new wastes are not evaporated, the cumulative volume of these waste would amount to approximately 1.1 to 1.4 million gallons per year. Given the current space available for storage of waste in West Area of 300,000 gallons to 1 million gallons (if successful transfer of the contents of 102-SY could be made), and the ability to store only TRU-compatible waste in the available tank in West Area, even a small amount of waste generated and not transferred to the

Evaporator could cause a shortfall in the West Area in the very near term.

Emergency Interim Report to Leakers Not Addressed

In its final report, the Team stressed the need for contingency plans to provide for failure of interim stabilization efforts for the remaining tanks which are not yet stabilized, and presented a series of Hobson's choices; space does not allow this important subject to be presented in depth here. But all of these unpleasant alternatives pointed to the urgency of getting the proposed new CSTS built and operational and with adequate redundancy.

Impact of Decision Associated with Active Mitigation of 101-SY

The need for any new DSTs in 200 East Area was eliminated by the decision to actively mitigate 101-SY (and if necessary, 103-SY) using mixer pumps. The primary rationale for constructing new tanks in 200 East Area was to accommodate the additional waste produced by a dilution ratio of 3:1 for both 101-SY and 103-SY, which would require transfer from West Area to provide storage space before evaporation and for storage of "solid" waste following evaporation of the dilute waste. Since there has apparently never been any additional perceived need for new tanks in 200 East Area either to accommodate additional waste generation or Evaporator operations or to address incompatibility and Watchlist issues in the East Area, the decision to actively mitigate 101-SY and 103-SY is sufficient reason to eliminate construction of the proposed storage DSTs in East Area in the near term. This decision assumes some risk, particularly related to the continued success of the mixer pump. If the currently installed mixer pump fails, a back-up pump exists. It is in light of this contingency that the Team believed the associated risk for the near term is not great enough to require additional back-up in 200 East Area. However, if the mixer pump fails or fails to be a successful solution for mitigating hydrogen build-up in Tank 101-SY and/or 103-SY, the issue of needs for new tanks and alternative mitigation methods will need to be revisited immediately. In any case, the question of whether or not to build additional tanks in 200 East Area will need to be revisited for the time frame beyond 2004, to assess storage needs related to process and treatment operations scheduled to begin at that time.

The decision to actively mitigate 101-SY and 103-SY does not in itself eliminate the perceived need for new DSTs in 200 West Area. The Waste Volume Projections and associated assumptions regarding leaking SSTs in the West Area and operability of the CSTS need to be evaluated before conclusions can be made regarding the need for new tanks in the West Area.

SCENARIOS GENERATED BY THE TECHNICAL TEAM

Given the information and set of assumptions on which the reductions in waste volume were accomplished, in conjunction with the existent compatibility issues, the Technical Team produced a series of decision flow diagrams to assess possible risks and outcomes to inform conclusions regarding the need for tanks in West Area. The scenarios were based on the following basic assumptions: a) all SSTs in West Area are assumed either to be currently leaking or to begin leaking at a rate of 1-2 additional tanks per year, b) waste storage space must be made available for these leaking wastes to provide a RCRA compliant storage alternative, c) whenever a CSTS is available for transport of SST wastes (either the current system or the new system), a staging tank (or tanks) of sufficient size and compatibility to accommodate transfer to the

Evaporator in East Area must be available, and d) no adequate emergency contingency plan exists for managing wastes if they are unable to be stored in the only available tank space (102-SY, currently at 300,000 gallons). A complete discussion of each scenario can be found in our complete report, which is available for the cost of printing, handling and shipping from our office, PO Box 1541, Jackson Hole, WY 83001.

RECOMMENDATIONS

The Team's recommendations were meant to help the DSC/HAB focus DOE effort on high priority items which will lead to a more robust and lower cost system capable of addressing all safety issues with minimal construction costs over the term of the next decade (through the expected pre-treatment/treatment date of 2004). They anticipate the risks as outlined in the series of scenarios developed, and generally reflected the budget constraints being imposed on the program. The recommendations fell into three basic categories: A) decisions regarding tanks, B) the Cross-Site Transfer System, and C) emergency contingency plan and risk analyses to guide operations and address leaking tanks in the near-term

Tanks

1) Evaluate, as a top TWRS priority, the possibility of a 102-SY clean-out to render this tank fully useable for storage and transfer of all types of wastes, not just TRU-compatible wastes.

2) As a second priority, evaluate the option of building smaller transfer tank (or tanks) to move SST liquid waste if 102-SY cannot be cleaned out.

3) Accept the DOE view that no additional immediate action regarding tank construction be taken for the 200 East Area.

Cross-Site Transfer System

4) Pursue and complete the fastest possible review and decision-making for the proposed new CSTS. Without pre-judging the final, broad-based decision on this new system, from a purely technical perspective the Team believed its analysis strongly justifies accelerated construction of the new CSTS.

Contingency and Risk Analyses

5) Develop a contingency plan to address the possibility that the current CSTS will not be operable in the 1995-1998 time frame (or until the new CSTS is operable).

6) Prepare more quantitative risk analyses for each element of the system, and to make these analyses available to interested and affected parties.

7) Carefully evaluate the new waste volume projections, and just as important, monitor on a frequent on-going basis, whether the predictions of the most recent projections are borne out in the months and years ahead, so that timely re-adjustments can be made to the operation of the entire Hanford waste storage complex.

THE AFTERMATH

As of today, not only did the HAB accept all seven recommendations as presented, but several other positive things have happened. Testing of the existing CSTS showed that to the surprise of many, including the author, the remaining lines are still functional, and the existing CSTS has been used to drain much of the pumpable volume of tank 102-SY from the 200 West to the 200 East area for evaporation. Important as part of the effort to decrease the total stored volume of wastes at Hanford, this step also frees up 102-SY for both routine and emergency uses. The compatibility of wastes with the sludge in 102-SY is also being further assessed; the more types of SST wastes that can be shown to be compatible

with the residual contents of 102-SY, the more effectively 102-SY can be used for its highest and best use, as the critical staging point to move wastes from the West to the East area.

The regulatory agencies quickly concurred in the use of the existing CSTS, which is definitely not up to current requirements, for the foreseeable future, in return for which DOE has increased the priority for the new CSTS. The schedule for the new CSTS has been accelerated, the draft EIS has been revised when published as the Final EIS to call for only the new CSTS and no new tanks.

The effect of the rest of the Team's recommendations is harder to determine at this point, at least to an outsider. Certainly the importance of waste minimization, contingency planning, better risk analyses, etc., was clearly seen by the Hanford Advisory Board as well as DOE and its contractors when the Team's report was published. One can only hope that these other recommendations have, as appropriate, been adopted and internalized by those responsible for the Hanford tanks and their contents.

ABSTRACT

The US Department of Energy (DOE) is attempting to clean up hundreds of thousands of acres of contaminated land at federal energy facilities throughout the country, mostly in the West. Currently, the technologies do not exist, or are not fully developed, to do the job. As technologies are developed, they are often met with resistance from public and tribal stakeholders who don't trust DOE and don't fully understand the technologies and their environmental impacts. The problem is compounded by broad "cultural" differences such as tribal/government and public relations, an exclusive operating mode within DOE and a vast gulf in technical expertise. DOE's Office of Technology Development is trying to overcome these barriers through the Technology/Regulatory Integration Project or TRIP. TRIP is a systematic process for involving diverse stakeholders in complex scientific and technology decisions. TRIP may serve as an effective decision-making model for the 21 st Century.

INTRODUCTION

The purpose of this paper is to describe a model environmental decision-making process developed by the Colorado Center for Environmental Management (CCEM) known as the Technology/Regulatory Integration Project

or TRIP. TRIP is a comprehensive process designed to effectively integrate stakeholders into the technology and regulatory decision-making stream. CCEM has recently published a TRIP Implementation Manual and accompanying training program aimed at helping project managers, principal investigators and public involvement specialists integrate public and stakeholder needs for involvement with technology design, development and deployment. TRIP is funded by the Office of Technology Development of the US Department of Energy (DOE).

THE ENVIRONMENTAL CLEANUP PROBLEM

The Western Governor's Association (WGA) project to Develop On-site Innovative Technologies (DOIT) estimated in 1994 that federally owned and managed lands contributed to over 50% of the nation's environmental contamination and cleanup problem. According to WGA, the Department of Energy (DOE) manages approximately 4,000 sites encompassing thousands of acres contaminated with both radioactive substances and hazardous wastes. By its own accounts, DOE must clean up 137 contaminated energy facilities in 33 states and one territory spread over a total of 3,300 square miles. DOE faces the task of remediating nearly 10,000 individual hot spots. Contamination problems at other federal facilities are even more extensive. WGA estimates that the Department of Defense (DOD) has 18,795 contaminated sites and 1,800 installations included in its Installation Restoration Program. The Department of Interior (DOI) lists 422 sites on the Federal Facilities Hazardous Waste Compliance Docket. The total number of abandon mine sites on federal lands is unknown but may run as high as 500,000. The cost to clean up federal sites alone is almost $400 billion based on 1992 figures while the nation's total cost for environmental cleanup is nearly $700 billion.

Environmental cleanups on public lands have been hampered by many factors and these factors have differed to some extent at each site. Common themes do exist however: Stakeholder acceptance, technology advancements, and regulatory approvals are some of the barriers commonly put forward to explain the problem.

Stakeholder Acceptance

Barriers are erected when people who may be affected by an action to cleanup the environment are not adequately involved in making decisions. When people feel left out of a decision that could, from their perspective, have a significant impact on their health, livelihood or quality of life, they will likely resist not only the decision but the process, the institution and people making the decision.

When we think of stakeholders in the environmental cleanup arena we tend to think of angry citizens groups or neighbors whose health or property may be affected by the cleanup process. But a stakeholder can be any party affected or potentially affected by a decision or anyone who has a "stake" in the outcome. Stakeholders can be citizens, public interest organizations, labor organizations, technology developers, government regulators, plant workers, tribal governments, public officials, production industries and environmental consultants.

Technology Advancements

Environmental cleanup problems are currently much larger than the technologies we have to solve them. Many of the needed technologies don't yet exist or have not been approved for commercial use. The publics' repeated mandate to move quickly to clean up federal energy and defense sites and the environmental remediation industries' lack of the technology to do the job are in sharp contrast.

Regulatory Approval

DOE and other government agencies recognize that new technologies are critical to the cleanup of federal energy, defense and mining sites throughout the US. Yet one of DOE's most significant problems in nurturing new technologies is the time it takes to navigate the regulatory process. These time constraints, it is thought, act as a deterrent to the development, demonstration, approval and commercialization of new technologies. How? DOE believes the prime factor is the lack of interstate and interagency cooperation in the permitting process. State and federal regulatory agencies are required to test and approve new technologies before they can be used in the cleanup process. These agencies are reluctant to approve new technologies and are, for the most part, unwilling to accept regulatory approvals from other states and other agencies.

TRIP PRINCIPLES

The TRIP process is designed to help overcome the stakeholder, technology and regulatory barriers described above in part by integrating the key people who represent those barriers, in a systemic way, into the decision-making stream. The TRIP process, when implemented carefully, results in ownership among the parties holding decision-making and "blocking" power. Ownership breaks down barriers. TRIP considers a good decision-making process one that meets the expectations of stakeholders while satisfying the needs of site managers, regulators and technology developers.

TRIP provides six key principles for guiding effective stakeholder involvement projects and programs. The principles are not specific steps in a stakeholder process, but are designed to give guidance in the development of necessary components of a stakeholder plan. The TRIP principles are:

- Bring the right stakeholders to the table
- Develop a decision-making process that effectively integrates stakeholders
- Develop an effective information and data collection program
- Develop a communication and responsiveness program for all publics
- Jointly frame the technology/regulatory problem
- Develop an action plan that integrates technology, regulatory and stakeholder interests

Bring the Right Stakeholders to the Table

Basically, stakeholders are those who are potentially affected in some way by the decision or action being considered. Any interested party could potentially be a stakeholder and all stakeholders, whether they represent primary or secondary issues, should have access to a fair and open decision-making process. One of the most important challenges of effective stakeholder involvement, however, is to actively recruit the right stakeholders. The right stakeholders are those who can best represent the issues and interests at stake, those most affected by the decision or action under consideration and those who have the clear authority to make decisions for the organizations or groups they represent.

Develop a Decision-making Process that Effectively Integrates Stakeholders

This principle has two inter-related parts. The first has to do with empowering stakeholders or giving them the power to influence decisions

that affect them. The second has to do with requiring stakeholders to be accountable and responsible for their actions.

Empowering stakeholders means providing them with opportunities to influence decision-making in ways that meet their expectations. If stakeholders expect to be kept informed of decisions or actions and expect that they will have access to information when they ask for it, they will feel empowered if you meet those expectations.

The second part of the principle has to do with requiring stakeholders to be accountable and responsible for their actions. This goal is more difficult to achieve because most stakeholders, like each of us, will initially see the problem from only one perspective - their own and will likely resist attempts by others to see the problem from other perspectives. Overcoming this barrier is critical to the TRIP process and without it the process will not move forward.

The best way to get accountability and responsibility from stakeholders is to enlist their help in designing a stakeholder involvement process that meets their needs. If the process is reasonable and fair, and has been substantially designed via a partnership, they are more likely to be accountable for their actions and responsible to others and the process.

Develop an Effective Information and Data Collection Program

Decision-making processes often break down because of conflicts over information and data. The classic environmental battle is between two experts who disagree over the data, the interpretation of the data, the data collection process and even the assumptions made in designing the study. Conflicts over information and data occur all the time:

- How much of the contaminant is present?
- What is the risk to human health and the environment?
- What is an acceptable risk?
- How much of it should we clean up?
- What technologies should we use?

These are all questions that are pertinent to the clean up process and require extensive data and information. At every step in the decision-making process there is a need for information and at every step there is the potential for conflict.

TRIP reduces data conflicts by emphasizing joint studies and other procedures that decide on fair and impartial data collection methods before data is collected. TRIP also focuses on integrating risk assessment, management and communication into the stakeholder process, providing stakeholders with independent technical support to verify existing data, providing educational and training opportunities, making information and data collection accessible and presenting information in ways that meet stakeholder needs.

Develop a Communication and Responsiveness Program for all Publics

Many public involvement projects recognize and focus on a core stakeholder group but fail to keep the larger stakeholder group - those who are represented by the people at the table - involved in the process. The larger stakeholder group could be the citizens of a community or tribe, an industry group, plant employees, members of the environmental organization etc. It is not possible to involve all of these people directly in the TRIP process so it is necessary to select people who will represent them. Their involvement is just as critical as the immediate stakeholder group.

A communication program should run parallel to and compliment the stakeholder decision-making process. The communication program should be

easy to access and allow opportunities for people to keep abreast of current happenings by reading objective and relevant material, viewing presentations and videos, attending important events, touring sites and providing feedback.

Jointly Frame the Technology/Regulatory Problem

This TRIP principle requires us to describe the problem we are facing in an integrative way rather than in an "us and them" way. The problem then becomes our problem instead of my problem and your problem. An integrative problem, also called a Joint Problem Statement, requires stakeholders to look at the problem as a set of common and divergent interests, their own and others, instead of hard-line and opposing positions and to take responsibility for the whole problem instead of a single piece. The Joint Problem Statement encourages ownership of both the TRIP process and the problem itself.

The Joint Problem Statement integrates stakeholder interests into a description of the problem that all stakeholders can support and presents it as a question or series of questions. The question is essentially an equation that the stakeholders will try to solve:

How can we satisfy ABC while also satisfying XYZ?

A, B and C are the interests and concerns of the agency and X, Y and Z are the interests and concerns of the stakeholder group. Together they are the array of stakeholder interests and concerns that make up the overall problem.

Develop an Action Plan that Integrates Technology, Regulatory and Stakeholder Interests

An action plan evolves from the Joint Problem Statement. It lays out a plan to answer the question(s) posed by the Joint Problem Statement(s) and integrates the information and data collection program and communication program into the plan. The action plan should be developed, insofar as possible, by the stakeholders and project manager with the help of a facilitator.

The action plan should contain goals, objectives, strategies and tasks, and may also contain more specific Joint Problem Statements that result in goals, objectives, strategies and tasks for specific programs or more detailed problems. For example, the group may choose the Joint Problem Statement that asks:

"How can we bring new technologies on line quickly while assuring that they are adequately tested and approved by state regulators and accepted by the general public?"

Stakeholders now have a problem that they can tackle together. An information and data collection program could emerge from this statement that would integrate stakeholders concerns for trust and accountability with concerns for efficiency, objectivity and truth.

APPLYING THE TRIP PRINCIPLES: DESIGNING THE STAKEHOLDER PROCESS

Successful stakeholder involvement requires considerable planning and preparation. However, because no two stakeholder processes are alike and because the process is shaped, to a large extent, by the stakeholders themselves, the planning and preparation necessary to make the process successful also requires considerable flexibility. In this section we will discuss the design phase. There are six design steps that are consistent with the TRIP principles:

- Define and scope the problem
- Identify and select the right stakeholders
- Design the decision-making process

- Develop an effective data collection program
- Develop an interactive communication program
- Develop a preliminary joint problem statement

Define and Scope the Problem

It is important to define the overall problem in a way that is acceptable to all stakeholders. An acceptable problem definition is one that integrates the perspectives of all stakeholders. Their are two main sub-steps in the definition and scoping process:

- Define and clarify agency and project missions.
- Identify the contamination, technology, regulatory and stakeholder issues and concerns that make up the problem.

Your agency and project missions needs to be examined in the context of the organization and it needs to be understood and accepted by your stakeholders. The mission statements are important because they build credibility for the agency and project and announce your purpose to others. Also, you are mandated to carry out your mission. How you accomplish your mission, however, may be determined through a stakeholder partnership.

Begin by defining the contamination, technology, regulatory and stakeholder issues and concerns that you want the stakeholder group to address. You are preparing stakeholders to tackle the problem and the first step in this process is to define the problem as clearly and concisely as possible using terms and language that are widely understood. Describe the problem first in terms of issues and second as a statement of your concerns about those issues for your agency and for stakeholders.

Stakeholder Identification and Selection

This section describes a three-step approach for identifying and selecting the right stakeholders:

- Identify and select an initial group of stakeholders who represent, in the broadest context, the issues at stake.
- Using the initial group, select a more comprehensive working stakeholder group based on the TRIP principles.

This two-step procedure adds an additional layer of objectivity to the process and better assures that a comprehensive group is selected. The initial stakeholder group should represent all of the issues and concerns you are addressing in the TRIP process and should also be representative of the communities or regions where the project will occur. The comprehensive group should close any gaps that might exist. The most credible stakeholder groups are those with the most comprehensive and representative participation and those that are easily accessible to observers and new members.

Design the Decision-Making Process

Now that you have established a process for selecting stakeholders, let's go back to the problem you are dealing with and establish a process for making decisions. Remember that the decision-making process must integrate the interests of stakeholders. There are four sub-steps to this process:

- Establish a timeline for critical decisions.
- Determine acceptable decision points and decision rules.
- Integrate the timeline with decision points and rules.
- Determine an effective meeting forum.

As you begin designing the decision-making process, remember that your stakeholders may want to modify the process to fit their needs. That's

O.K. In fact, from the standpoint of establishing ownership, it's better if they change it.

The timeline should clearly illustrate the sequence of events that need to take place and the points along the way where decisions and advice are needed. Decision rules let everyone know just how decisions will be made. The most effective decision rule is consensus. A decision in a consensus-based process is triggered when a stakeholder, or the facilitator, asks for a proposal that satisfies mutual interests. When a proposal is introduced the group must try to reach consensus on it by offering improvements until everyone can agree.

Some meeting forums are unknowingly adversarial and actually invite conflict. Others allow and even encourage stakeholders to work together. Your challenge is to create the right forum and atmosphere for constructive dialogue and problem-solving. Forums that tend to invite conflict are those that pit stakeholders against each other in an attempt to win-over a decision-making body. Experience with TRIP has shown that stakeholders are most comfortable with a more traditional forum wherein individuals meet at a neutral location that is comfortable and accessible and where they have the time and energy to talk through important issues.

Develop an Effective Data Collection Program

The quality of information and data is critical to the TRIP process. Environmental decisions hinge on scientific information. Stakeholders need such information to make informed decisions and recommendations. Yet the process for gathering, interpreting and disseminating information is often so contentious that decision-making bogs down. There are five sub-steps in the data collection process:

- Determine stakeholder information needs.
- Identify existing information.
- Identify missing information.
- Identify potential data conflicts.
- Determine a process for collecting and disseminating information.

Stakeholders should rightfully have access to all information that is available to decision-makers and scientists except for information that requires security clearance. They should have access to information even when it may be obvious that the information is too complex to understand or too burdensome to manage. Moreover, stakeholders should not have to invoke sunshine laws to obtain information. Existing information should be identified and catalogued for easy reference and gathered at a location accessible to the public. You should identify all sources of information that exist, even if some of it is in raw form and not easily readable.

What gaps do you see in your data? As you consider the project, what information and data needs do you have that are not currently addressed by objective studies? More importantly, what will stakeholders likely say are the gaps in your data?

What about potential data conflicts? Any time you can reasonably anticipate that people will disagree about a scientific study or body of technical information, you may be entering a data conflict trap. Data conflicts occur when parties have different perceptions of the problem, different methods for addressing the problem or different ideas about what constitutes an acceptable solution to the problem.

As a general rule stakeholders and agency representatives should be thoroughly involved in determining a fair and objective process for

collecting and disseminating information and should be comfortable with the process before any of the information is collected.

Develop an Interactive Communication Program

Stakeholder process managers sometimes forget about the broad public and instead focus almost entirely on their core stakeholder group. It is important to remember that your core stakeholders only represent the broader public - your real stakeholders. You must establish one-way and two-way strategies for communicating both with the broader public and your core stakeholder group. There are two sub-steps in the process.

- Determine an interactive stakeholder communication process
- Determine an interactive public communication process

Your core stakeholder group will attend most meetings and will be kept informed through attendance. Nevertheless, you should have a process for keeping them up to date about decisions and actions that result from meetings and from agency decisions. The best way to keep stakeholders informed is through carefully kept minutes and flip-chart notes.

You will also need a process for communicating with stakeholders about decisions and actions taken by the agency outside of stakeholder meetings. A regular newsletter is the most common tool for such communication and can be easily developed in-house. Two-way communication with the general public is much more difficult and will depend on the nature and complexity of the problem and the magnitude of the stakeholder population. To start, you will need to define the "public" as that population that is broadly represented by the people at the table. Once you have identified these populations, your task will be to develop an effective one- and two-way communication program that will reach them. The most effective programs combine various forms of media to pass information along, monitor broad stakeholder satisfaction and receive input.

A final note on communication. Communicating with the public is no longer a public relations process. The public is too sophisticated to buy into the slick PR approach designed to make the company, agency or project look good. In fact, that approach is part of the problem. The way we communicate with the public should result in improved public relationships.

Develop a Preliminary Joint Problem Statement

The foundation of the TRIP process is the integration of technology, regulatory and stakeholders issues and concerns. In Section 3.5 we discussed the TRIP principle of framing the problem in a way that requires stakeholders to address it in an integrative way. We then called this new problem the Joint Problem Statement.

It is useful to list all of the issues and concerns in the statement, no matter how cumbersome it seems, and then go back and simplify it until it is clear and concise without losing its meaning. Also, use verbs to describe the interests and concerns so they fit directly into the sentence structure. Consider the following example:

How can we...	preserve historic structures and scenic views
	maintain wildlife habitat
	protect water quality and aquatic life
	assure adequate monitoring
	avoid public health risks and
	maintain property values...
while also...	reducing costs
	meeting project deadlines

avoiding duplicative efforts
complying with regulations and standards
reducing risks to workers and the public and
avoiding dueling expert conflicts?

The Joint Problem Statement is now in a form that can be revised and refined by stakeholders until it meets their needs. You can return to the statement at anytime to review your progress, determine whether you are addressing the real problem, and maintain your focus when you get lost.

Develop an Action Plan to Address the Problem

The Action Plan should primarily describe the step-by-step process you will go through to address the Joint Problem Statement. It should also include your timeline, information and data collection program and communication program. The Action Plan should contain the following:

- Project mission
- Goals and objectives for accomplishing the mission
- Tasks to be completed along the way
- Milestones for completing the tasks.
- Results

The TRIP Action Plan is not much different from typical action plans developed for technology or cleanup projects. Its main differences are that 1) stakeholders are involved in developing and refining the Plan, 2) stakeholder issues and concerns are integrated into the Plan and 3) stakeholders are involved to some extent in carrying out the Plan.

Now that you have integrated stakeholder issues and concerns into the Joint Problem Statement described above, you should be able to turn the Joint Problem Statement into a new project mission. Instead of wording the Joint Problem Statement as a question, it can be reframed as your project mission. As an example, let's reframe a Joint Problem Statement and turn it into a project mission. In section 3 we used the following example to illustrate the structure of a Joint Problem Statement:

"How can we bring new technologies on line quickly while assuring that they are adequately tested and approved by state regulators and accepted by the general public?"

Reframed, the project's mission would be to:

"Bring new technologies on line quickly while assuring that they are adequately tested and approved by state regulators and accepted by the general public."

The Action Plan is developed to accomplish the project mission. The value of framing your Joint Problem Statement as the project mission is that it reinforces both the integration of stakeholders in the Action Plan and the logical sequence of steps from the Statement to the Plan. The rest of the Action Plan flows from the project mission. As long as the mission truly reflects the Joint Problem Statement and the Statement is a true stakeholder collaboration, the Action Plan will meet the TRIP requirements.

CONCLUSION

In Section 4 we discussed the TRIP process from the perspective of one who is designing a stakeholder involvement project. The emphasis was on the design phase - knowing the terrain and planning a general path. We also discussed the need to anticipate and remain flexible to the changes that stakeholders will make as they become more involved.

For purposes of this paper we will conclude with the design phase. The next phase, Managing the TRIP Process, addresses the process from the perspective of one who is ready to convene stakeholders or is already

immersed in the daily management of a TRIP stakeholder project. The next phase requires TRIP process managers to revisit all of the steps in the design phase, along with stakeholders, to develop a process and plan that substantially meets their expectations.

LESSONS LEARNED FROM 17 PUBLIC MEETINGS ON THE FOREIGN RESEARCH REACTOR SPENT NUCLEAR FUEL DRAFT ENVIRONMENTAL IMPACT STATEMENT

Charles R. Head
Patrick J. Wells
U.S. Department of Energy
Office of Spent Fuel Management

Paula W. Austin
Ronya J. McMillen
Science Applications International Corporation

ABSTRACT

The Department of Energy (DOE) and Department of State conducted 17 public meetings during May-June 1995 as part of the public comment process on the Draft Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel. The purpose of the proposed policy is to promote U.S. nuclear weapons nonproliferation policy objectives, specifically by seeking to reduce, and ultimately eliminate, highly enriched uranium from civilian commerce. One of the management alternatives in the Draft EIS is for the United States to accept and manage spent nuclear fuel from foreign research reactors (only spent fuel containing uranium enriched in the United States). Spent fuel would be stored and/or chemically separated at a DOE spent fuel management site.

To implement the alternative of U.S. acceptance, the Draft EIS identified and evaluated five candidate DOE sites and ten candidate ports of entry. Spent fuel would arrive into a port by sea and be unloaded for shipment to a DOE site by rail or truck.

In preparing the Draft EIS and preparing for the public comment process, DOE and Department of State set out to communicate the global and national issues behind the proposed policy and communicate the results of the impact analyses for the various alternatives. The 17 public meetings were held at candidate site and port locations and in Washington, D.C. DOE used an informal, interactive format for the meetings.

This paper will discuss the results of the meetings and effectiveness of DOE's meeting strategy. Over 900 individuals attended the 17 public meetings, with individual meeting attendance ranging from 2 to 250. There was an overwhelming difference, depending on location, in the public reaction and effectiveness of the interactive meeting format. Port communities, which were not generally familiar with DOE issues, focused on port-specific issues. The informal, interactive meeting format worked well in all locations except for the West Coast, where the attendees were highly organized in opposition and preferred a more traditional recorded hearing approach.

INTRODUCTION

In April 1995, the Department of Energy (DOE) and the Department of State released for public comment the Draft Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel. The proposed action is for the U.S.

to adopt a policy to manage spent nuclear fuel from foreign research reactors. Only spent nuclear fuel containing uranium enriched in the United States would be covered. The purpose of the proposed policy is to promote U.S. nuclear weapons nonproliferation policy objectives, specifically by seeking to reduce, and ultimately eliminate, highly enriched uranium from civilian commerce.

Several management alternatives to implement the proposed policy were analyzed, including U.S. acceptance of the spent fuel for management at one or more DOE sites, management of the spent fuel at overseas facilities (under certain conditions), and a combination of alternatives. For alternatives involving U.S. acceptance of the spent fuel, the Draft EIS identified five candidate DOE management sites and ten candidate ports of entry. These sites and ports are identified on the map in Fig. 1. Environmental impacts were analyzed for the shipment of the spent fuel by sea, entry and unloading at each candidate port of entry, transportation (truck and rail) to each of the five candidate DOE sites (representative routes), and the interim storage and/or chemical separation at candidate DOE sites. In addition to analyzing the environmental impacts of the various alternatives, the Draft EIS analyzed the policy implications of implementing or not implementing the proposed policy, including implications to U.S. nuclear weapons nonproliferation policies and objectives. Thus, the Draft EIS dealt with issues ranging from worldwide and national policy issues to community-specific issues.

Fig. 1

STRATEGY FOR CONDUCTING THE PUBLIC MEETINGS

The Message

In preparing for the public comment process, DOE and Department of State set out to communicate the global and national issues behind the proposed policy and communicate the results of the impact analyses for the various alternatives. As will be discussed later, local concerns became the major factor in many of the public comments at certain port communities. Informational materials were developed to complement the Draft EIS (summary document, fact sheets, video, poster exhibits). The materials attempted to communicate the full range of considerations in the Draft EIS in an easy-to-read manner. Again, the broader global and national issues were emphasized, along with general statements of potential impacts, which were found to be low.

Meeting Format

Unlike the traditional public hearing process, where commentors present time-limited oral testimony recorded by a transcriber, DOE and Department of State experimented with a more informal approach in order to encourage open dialogue, questions and answers, and one-on-one interactions. Meetings started with a one-hour "open house" where people could, at their own leisure, peruse the exhibits and materials and have one-on-one discussions with project personnel. A display area was also provided for informational materials of other groups. Following the open house session, the meeting session started with a 15-20 minute presentation by a DOE representative and then opened up to dialogue and questions and answers. A third-party facilitator was used to help keep the dialogue flowing, assure fairness, and record on flip-charts key comments and questions. As discussed later, this format worked well under some conditions but not in others.

Advertising and Information Dissemination

In addition to the required Federal Register Notice to announce public meetings, DOE and Department of State utilized additional means to advertise the meetings at the local level. An official DOE/Department of State announcement was published in local newspapers at all site and port locations at least one week before the meeting date and the day prior to the meeting. A seven-minute video was provided to local cable-access stations to run several times during the week prior to the meeting. Public service announcements were provided to NPR radio stations and TV networks. A distribution list of State officials and port authorities was used to mail out the Draft EIS in advance. In all advertisements, a 1-800 number was provided for the public to request copies of the Draft EIS or Summary.

Locations of Public Meetings

Initially, 16 public meeting were planned -- five site locales, ten port locales, and Washington, D.C. The idea was to get as close to the community as possible. A second Tacoma area meeting was added at the request of local officials in Tacoma (the first meeting was in Seatac, which was between Seattle and Tacoma). Figure 1 shows the meeting locations.

RESULTS OF PUBLIC MEETINGS

Over 900 individuals attended the 17 public meetings, with individual meeting attendance ranging from 2 to 250. The most heavily attended meetings, with about 70% of the total attendance, were at the West Coast port communities. Table I shows the approximate head count (not all attendees chose to register) at each meeting.

Table I

There was an overwhelming difference, depending on location, in the level of organized opposition and effectiveness of the interactive meeting format. The level of advertising and organization by opposing activist groups and local and Congressional officials played a major role in the attendance and demeanor of the meetings. A general observation was that the West Coast port locations were the heaviest attended (through organized activism), the most focused on local fears, and the least interested in interactive dialogue with DOE and Department of State. Although some East Coast locations showed lack of support of spent fuel shipments through their ports, the interactive format worked well and people seemed satisfied with the dialogue and question and answer sessions.

Issues Raised

The issues raised at the meetings differed depending on whether they were site or port locations. Site meetings received low attendance (2-20) and the issues focused primarily on existing problems at sites, funding issues, storage vs. chemical separation technologies, concerns about de facto storage, and nonproliferation issues.

DOE's experience at the port communities was new (other than during scoping meetings, which involved a lesser number of candidate ports). These communities were not familiar with DOE issues (with the exception of a few) and were, for the most part, opposed to shipments of spent fuel through their ports. Although many supported a proposed policy, in general, they did not want nuclear waste in their communities. In addition to the many statements of direct opposition to spent fuel shipments, comments and questions at the port meetings focused primarily on port-specific issues, such as:

- Port selection process

- Risks of accidents at port or on land
- Health risks from exposure to spent fuel
- Risks of terrorism or sabotage
- Local emergency response capability
- Local traffic conditions and routing
- Funding for training and equipment

Format of Meetings

With the exception of the West Coast port meetings, the informal, interactive meeting format worked well. The open house session could have been shorter (people tended to only spend five to ten minutes at the exhibits, then waited in the meeting room). However, people did peruse the exhibits and pick up the information materials. It also helped to provide a more comfortable and informal setting for the public. Written comment forms were also available for those who wanted to write their comments that night. With few exceptions, the meeting sessions lasted for two-to-three hours, until there were no more questions. In most cases, the atmosphere was friendly and the dialogue was productive. Many of the East/Gulf Coast and site meeting attendees commented positively about the interactive format. One observation that can be made was that the East/Gulf Coast and site meetings were small enough (2 to 60) to accommodate an interactive session. Such was not the case for two of the four West Coast meetings.

At the four West Coast meetings (Concord, Portland, Seatac, and Tacoma), the majority of public attendees were members of highly organized activist groups or were there as a result of widespread local press and organized activity. Attendees were largely unified in opposition to use of their port and wanted to present their statements for the record. There was little interest in interactive dialogue with the DOE officials at the meeting. DOE was flexible in changing the meeting format to accommodate those that wanted to read statements. Attendees at three of the meetings also objected to the fact that DOE did not have a court reporter to transcribe the statements for the official record. (DOE was accepting written comments from individuals for the record; and the meeting notetakers' notes from each public meeting would also be included in the Final EIS.) The second meeting in Tacoma was recorded on tape and transcribed for the record.

Advertising and Information Dissemination

The amount of advertising was often raised as an issue at the public meetings. Many people said they did not know of the meetings "until the last minute." Many said the newspaper ad was too small and did not provide enough information. Although the advertising was consistent in all locations, it was difficult to judge its effectiveness in that attendance varied so widely.

However, one case-study example on the effectiveness of ads is the meeting held at Tacoma. A full-page, provocative ad was published by a local activist group (picture of a baby with a radiation symbol on its forehead). The Tacoma meeting had 250 attendees, with 200 turned away at the door (because of fire codes). Obviously, the petition drives and media attention, combined with the ad, had a greater impact on attracting people's attention than DOE's level of advertising.

Many people commented that they did not know about the Draft EIS or how to get it. They commented that sending copies of the Draft EIS and Summary to the Public Readings Rooms was not sufficient.

Meeting Location

Because most meetings were held in the communities most affected, meeting location was not an issue except for the Tacoma port area. The first meeting was held in Seatac, which is half-way between Tacoma and Seattle. Many in the Tacoma area argued that the location was one-half hour away from the affected community and posed hardships on those wishing to attend. In response to overwhelming Congressional and local community requests, DOE added a second meeting in Tacoma proper.

KEY LESSONS LEARNED

Based on DOE's and Department of State's experience with these public meetings, several key lessons were learned that could be applied to future meetings of a similar nature. These include:

When setting the meeting format, recognize that the public in some areas, possibly those with more organized activist communities, may prefer a traditional meeting style where the public's statements are read into the record. Government agencies conducting such meetings would have to determine whether it is better to simply accede to such local preferences (which would generally give opposition groups a highly visible medium through which to make their case), or to make extremely clear in the meeting announcements the format that would be used for the meetings.

Location, Location, Location! Make sure the meeting facility is within the community most affected.

Utilize local libraries and other local services to the maximum extent possible to disseminate information. Multiple copies of Draft EIS Summaries should have been sent to each local library in the affected communities. Fliers would have been useful for distribution to schools, libraries, civic centers, malls, and other local places well in advance. (In Tacoma, activist groups distributed 3,000 of their own fliers, which contributed largely to the high number of attendees.) The announcement section of major and local community newspapers would have reached more people than an advertisement (unless the ad was large enough to stand out).

Recognize that no matter how far-reaching and global an issue may be, communities are most interested in how the issue affects them personally. Be prepared to address local issues.

NCPP ROCKY FLATS COMPETENCE PROGRAM - A CASE HISTORY

Keith Biddle
Rocky Flats Environmental Technology Site
National Conversion Pilot Project
Golden, CO 80402-4085

ABSTRACT

The National Conversion Pilot Project (NCPP) in unique. The Project involves reuse in three ways; shutdown facilities, scrap materials and displaced workers. This is being done on a Department of Energy (DOE) site and will culminate in the award of a manufacturing license for a private company to operate refurbished facilities.

The Competence Program of the NCPP has responded to both the regulatory demands of the DOE and the needs of business.

The Competence Program has three major phases: 1) links to pre-NCPP history of potential employees, employee selection and Base Competence

Verification, 2) Additional Skilling & 3) Pursuit of Excellence. Phases 2) & 3) are collectively referred to as Competence Enhancement.
This topic will interest those involved in privatization, training or cultural change.

CASE HISTORY - THE NCPP IDEA

In 1993 Dr. Dennis Floyd, Vice President of Manufacturing Sciences Corporation (MSC), had the idea for "three-way" reuse of resources at the DOE's Rocky Flats Environmental Technology Site (RFETS) in Colorado. Firstly, to clean and refurbish machines and buildings previously used to form beryllium, depleted uranium and stainless steel. Secondly, to recycle ex-weapons component beryllium, depleted uranium and contaminated steel into commercial products. Thirdly, to reemploy ex-weapons plant workers. This idea eventually became what is now known as the National Conversion Pilot Project (NCPP).

MSC has a business association with British Nuclear Fuels plc (BNFL) in the United Kingdom. One of BNFL's plants in England, at Springfields near Preston, had been implementing some major, business-driven change programs since 1989. These programs were increasingly people-focused, rather than technology-focused. In particular, a competence program designed to cope with an uncertain business future, called the Additional Skilling Project, which involved a form of multi-craft work, caught Dennis Floyd's attention. This was because the Additional Skilling Project had already dealt with the difficult cultural and competence gap issues then facing the NCPP at the RFETS.

To test if American workers would have support for the BNFL Springfields type of approach, Dr. Keith Biddle, the BNFL Additional Skilling Project Manager, met with the leadership of the local United Steelworker's Union at RFETS in November 1993. He explained in detail how the system worked at Springfields and how the outcome affected the workers. The response of the Union leaders was positive; the main reason for that was the participatory and fit-for-purpose theme.

The NCPP commenced in April of 1994 with Stage I - Feasibility and Planning awarded to MSC. Stage II - Cleanup and Refurbishment began in October 1944 also awarded to MSC, and will take until late 1997 to complete. Stage III - Manufacturing Operations will follow after a competitive bid process.

WHAT WAS NEW ABOUT THE NCPP COMPETENCE PROGRAM?

Answer: a fresh approach to competence on a DOE site. The NCPP treats safety and technical competence as seriously as all good organizations. Also, the NCPP approach of competence needs analysis, structured training delivery, competence assessment and auditable evidence of competence is paralleled in the best organizations. What is different for the NCPP at Rocky Flats is the extra features of the Competence Program. These are a combination of: a) a team competence approach, b) business-led ("flexible working") training perspective, c) emphasis on "cultural" competence as well as safety-technical competence, d) competence activities are an integral part of the Project's master work and e) speed of training design and delivery.

THE TRAINING PLAN (COMPETENCE PROGRAM PLAN) AND THE "COMPETENCE ENHANCEMENT PROCESS"

The NCPP Training Plan lays out the scope, objectives, assumptions, qualification principles, original schedule, resources, management systems and controls of the Competence Program. It was approved as a Stage I deliverable of the NCPP by the DOE.

The Program has three major phases: 1) links to pre-NCPP history of potential employees, employee selection and Base Competence Verification, 2) Additional Skilling & 3) Pursuit of Excellence. Phase 2) & 3) are collectively referred to as Competence Enhancement. Figure 1 shows the relationship between these phases.

Fig. 1

The whole process is guided by and feeds into the NCPP Stage II Mission. See Fig. 2

Fig. 2

BASE COMPETENCE

NCPP employees brought a spectrum of skills to the Project at the time of hiring. For example, office skills, decontamination skills, engineering skills, managerial skills, specialist technical skills, health and safety knowledge, regulatory knowledge and knowledge of Rocky Flats/DOE systems. A key feature of the NCPP Competence Program is the recognition of these skills or "Base Competence."

Evidence of Base Competence is collected and is the baseline for the further training needs of the individual. "Taking credit" for the pre-hiring skills of a workforce is the smart thing to do from the business perspective also (the cost of some of the multimillion dollar Additional Skilling schemes at BNFL Springfields in the UK were halved by carefully integrating existing skills and other training initiatives rather than assuming that the workforce has little Base Competence). However, for quality assurance, adequate evidence of Base Competence MUST exist; in other words (in the 1900s) "if you can't prove it, then you haven't done it."

ADDITIONAL SKILLING

The term "Additional Skilling" is purposely chosen to convey several differences between "traditional training" (specifically as perceived by the workers at Rocky Flats) and the NCPP Competence Program. Additional Skilling has been designed with the comments of the workers in mind:

Table I

The steps for implementing Additional Skilling are systematic. Human resource aspects and the applicable skill areas are also addressed:

Table II

Table III

PURSUIT OF EXCELLENCE

The pursuit of excellence (i.e., pursuit of project specific quality and value as perceived by the customer) is just beginning on the NCPP, and is internally focused for now. The initial steps are: a) small shift towards competence assessment (without training) as the norm rather than training and competence is always the norm, b) scheduling the minimum training for the role up-front, then performing "just-in-time" training as an integral part of the decontamination or manufacturing schedule, c) the introduction of participatory Competence Currency reviews, d) two-way appraisal (upwards as well as downwards) with an emphasis on skills and personal performance, and e) continuous improvement through Quality Improvement Teams made up of practitioners (not theoreticians).

MANAGEMENT SYSTEMS

NCPP personnel have developed procedures covering: a) employee selection and verification of base competence (phase 1 above, b) production of Personal Competence Plans, competence record keeping, competence needs analysis, training package design, training delivery control and quality verification and competence assessment (phase 2 above), and c) training

scheduling and competence currency (phase 3 above). During Stage II of the NCPP, the Competence Program is overseen by DOE as part of the NCPP Quality Assurance process, through the NCPP Quality Program Plan and NCPP Quality Procedures. The net effect of these systems is a streamlining compared to prevailing Rocky Flats systems. The NCPP systems are inexpensive and productive, in that they adequately improve workforce competence without major budgetary impact.

ORGANIZATIONAL STRUCTURE

The NCPP organization has a Teamwork structure and is best illustrated by discussing the Decontamination Work Teams: Each Work Team is a "self sufficient work cell" in a network of such "cells." The Teams support each other and it is common for some members of one Team to temporarily transfer to another Team. Each Work Team has the personnel/skills mix to fulfill their Team's mission. The skills possessed/needed by the individuals in each Team are governed by the competence requirements of that Team as a whole.

In addition, other (small) teams are formed as needed within the whole NCPP network, to deal with specific issues such as technical problems or procedural blockages.

RESOURCES AND SCHEDULE

The Competence Program is a major integral part of the Stage II schedule. This is because the Competence Program has been resourced from within the Project and because it has always been seen as a critical path enabling activity (not an after thought). In particular, key personnel who are also practitioner or experts (such as Team Leaders and other managers/technical staff), with several facets to their role, are utilized as Skill Unit (training module) writers, Trainers or Competence Assessors. This brings workplace "ownership" of the Competence Program. But, to make it credible, the Program must be workable, i.e., well managed with the use of good scheduling tools. Also, most importantly, utilizing Work Team members as Instruction/Procedures writers and Skill Unit developers has been a major success and one of the best examples of Continuous Improvement that this author has seen.

Skill Unit (training module) manuals are developed, typically, by two practitioners or experts and the Competence or Training Manager, on a "lifeboat" basis in a Unit Development Team (UDT). The UDT utilize procedures and the real workplace to create the Skill Unit Manual. The authority to approve the Skill Unit lies with the Unit Development Team. This approach gives fit-for-purpose, workplace credible training. Speed of response is rapid. A typical Skill Unit can be developed within the Project, which has only one full-time Competence Program person, within two to three weeks using the UDT approach. This speed of response has served the Project well when faced with changing regulatory requirements or work scope.

Training and/or Competence Assessment then follows. These activities are also conducted by in-house practitioners or experts, usually by one of the UDT members. The use of the classroom environment is minimized in favor of the real workplace, e.g., presses, rolling mills, furnaces, power tools, elevated surfaces, confined spaces, industrial chemicals. A major emphasis of the program is proving competence in the same circumstances under which real work will be done.

Stage II of the NCPP started in earnest in January 1995. The schedule called for 35 Skill Units manuals to be created by the end of June 1995. Training delivery targets were 700 personunits (Skill Units x

participants) by the end of September 1995 and a further 165 by the end of January 1996.

The project is undergoing rescoping at present and targets for 1996 are not yet set.

CULTURAL CHANGE AND VEHICLES FOR CHANGE

The cultural change issue at Rocky Flats is a highly significant feature of the NCPP. Rocky Flats had slipped into a state of progressive atrophy since the enforced shutdown and subsequent change of mission during the early 1990's. Even though the Project is bold and positive, and the NCPP employees do not work for the Management and Operations Contractor or the Integrating Management Contractor organization, the people on the Project are either ex-Rocky Flats workers, spend a lot of time with current Rocky Flats workers or utilize Rocky Flats IMC systems for some aspect of their work. There is potential for a perceived lack of purpose to influence the day-by-day workplace behavior of Project personnel at all levels. This can be due to "old habits" resurfacing, enthusiastic ex-Rocky Flats NCPP workers being further frustrated or people new to Rocky Flats becoming "infected."

For the reasons above, the NCPP Competence Program was designed to be an integral part of the Project's cultural change initiatives from the start, and it is.

Specific education on cultural change is given to employees which covers the NCPP mission, why success & mission are interdependent, the change process & how people cope with it, team responsibilities towards safety, quality & continuous improvement and how day-to-day activities such as a training course or a dismantling task further the mission. However, it would be naive to believe that this upfront education was a one-shot panacea.

More over, ongoing and positive cultural change depends on planning and managing that change. The NCPP has an annual Cultural Action Plan (CAP). Commitment to cultural change by the workforce is not automatic, but is vital, and is recognized in the CAP. The CAP has an emphasis on participatory change; it is this author's experience that participatory change is much less difficult/"painful" than enforced change (and enforced change rarely works). Cultural change takes time; the implementation process must be monitored constantly, and the "tools" used to steer the change vary and need to be prepared in anticipation. Instant cultural excellence is unknown!

One of the most effective means of converting plans for change into actual change in the workplace is through a network of Work Teams and short-lived Quality Improvement Teams tackling real workplace problems. The Project has around 50 specific examples of words becoming action through this approach, and these vary from Team Mission revitalization to raising the quality of Operator Instructions or solving rigging problems for example.

ACHIEVEMENTS SO FAR AND STATUS OF STAGE II OF THE NCPP

Within six months 35 Skill Units manuals were created, thereby satisfying the initial demand as planned. The original target of 700 personunits of training delivery by the end of September 1995 was successfully met, as was the target of 810 personunits by the end of 1995. Note that the NCPP employs about 50 people.

The first annual Cultural Action Plan has been completed. Half of the first building has been decontaminated and work on the second half started in January 1996.

The reaction of the NCPP personnel to this approach has varied from tacit acceptance to disciple-like enthusiasm. The only negative response is one of frustration in not being able to push the Competence Program and other innovative aspects of the NCPP forward faster. The frustration arises from a realization that the systems experienced in the past were unnecessarily cumbersome, the usual problem for any project, i.e., not enough hours in a day and that the in-house practitioner can and should be empowered, and once empowered is the person most likely to "tune into" and address the competence needs of the Project.

During 1996 the aim is to consolidate the progress made so far and to begin the Project's pursuit of excellence process.

SUMMARY

The NCPP Competence Program has deliberately combined three aspects:

Competence Enhancement: a project managed process which is end-user friendly,

Work in Teams: the management of Team Competence and utilizing the Project's in-house work place experts to spread competence, and

Mission/Vision and managed cultural change.

So far the Program has worked successfully, and enabled the establishment of the NCPP infrastructure and the decontamination/refurbishment of millions of dollars worth of equipment and facilities.

UNDERSTANDING EACH OTHER: THE DOE/NATIONAL ASSOCIATION OF ATTORNEYS GENERAL (NAAG) COOPERATIVE AGREEMENT

Melanie Pearson
Beverly Stephens
U.S. Department of Energy

Brian Zwit
National Association of Attorneys General (NAAG)

ABSTRACT

Since 1993, the Office of Environmental Policy and Assistance has been engaged in activities pursuant to a Cooperative Agreement with the National Association of Attorneys General (NAAG). The primary purpose of this project is to foster open communication among the Department and State Attorneys General representatives, using NAAG as a facilitator on legislative and compliance issues in a nonadversarial atmosphere.

In these scarce budget times, it is hoped that expensive litigation can be avoided by engaging in discussion with the States on compliance problems before these issues become the subject of formal disputes. This project is a benefit to the Department, in terms of potential litigation cost savings, as an avenue to enhance DOE compliance with environmental regulations, and provide a forum for a unique stakeholder (NAAG) to exchange information with Departmental representatives.

INTRODUCTION

Birth of an Idea

As a result of interactions between the Department of Energy (DOE) and the National Association of Attorneys General (NAAG) during the Federal Facilities Environmental Restoration Dialogue Committee (FFERDC) meetings, the Director of the Office of Environmental Compliance (now the Office of Environmental Policy and Assistance), the Legislative Director of NAAG and the Environmental Protection Agency (EPA) Deputy Assistant Administrator of the Office of Federal Facilities Enforcement (OFFE),

began discussions to determine the feasibility of establishing a cooperative agreement among the three organizations for the purpose of facilitating communication on regulatory compliance issues with the goal of avoiding litigation. Such an agreement would also educate all parties on Departmental policies and procedures, provide a historical perspective of DOE's environmental programs and establish an atmosphere conducive to resolution of environmental issues prior to litigation.

The impetus to establish such an agreement was the realization that legal and technical issues regarding compliance and enforcement at DOE facilities will continually arise as the weapons complex is reconfigured and downsized. A large number of compliance agreements are currently either in place or being renegotiated in the twenty-two states hosting DOE facilities. These facilities have required substantial resources for operating regulatory and enforcement programs, and will continue to require considerable expertise, time and resources of the states and the Department.

The State Attorneys General play an important role in environmental enforcement and compliance issues, however, they usually are consulted only when negotiations fail and litigation is necessary. NAAG, in its role as the membership organization of the Attorneys General of the 50 states, Commonwealths, Territories, and the District of Columbia, assists the legal officers in fulfilling the responsibilities of their offices and assists in the delivery of high-quality legal services. NAAG was therefore particularly well-suited to facilitate communication among DOE, EPA, and the Attorneys General.

One benefit of the FFERDC discussions was the opportunity for the Department and NAAG to exchange information and gain an understanding of each other's roles in environmental restoration. To capitalize on the momentum of these discussions, DOE researched potential approaches to jointly work with NAAG. In 1994, the Department entered into a one-year interagency/ cooperative agreement with the Environmental Protection Agency (EPA) and NAAG. Upon the expiration of that agreement, DOE entered into an eighteen month cooperative agreement with NAAG in 1995.

Goals of the Agreement

The goals and objectives of this agreement are to: examine the relationships between enforcement and compliance at DOE facilities; analyze the roles of the states, DOE and EPA in facilities' matters with the goal of improving understanding of these issues at the state and federal level; ensure increased compliance by DOE with federal and state requirements; identify alternative dispute resolution mechanisms to reduce the need for enforcement through litigation by EPA and the states; enrich the states' understanding of and interaction with EPA regions and DOE on enforcement and compliance matters, with a focus on enhancing the states' role; and, provide an opportunity for state and federal personnel to interact and become aware of each other's professional responsibilities, expectations, and limitations.

ACCOMPLISHMENTS OF THE PROJECT

Since the inception of this project NAAG has periodically published the DOE Environmental Issues Bulletin. The bulletins have focused on major DOE environmental issues, such as renegotiation of environmental agreements and budget cuts. Articles are provided by State Attorneys General representatives and/or DOE environmental representatives. The bulletin is distributed to over 300 persons, including state regulators,

State Attorneys General, EPA staff, and representatives of DOE headquarters (HQ), field and contractors.

A DOE/NAAG workgroup has been established to promote open dialogue between DOE and the states on environmental compliance related issues with an eye toward developing creative solutions to potentially litigious issues and to provide an opportunity for State Attorneys General representatives and DOE representatives to examine and have joint discussions on legal issues related to statutes such as the Clean Water Act (CWA), the Resource Conservation and Recovery Act (RCRA), the Comprehensive Environmental Response Compensation and Liability Act (CERCLA) and the Endangered Species Act (ESA). This workgroup has been working on guidance which addresses provision of radionuclide information to the states upon request. Preliminary discussions by this workgroup have also focused on legal issues related to reauthorization of the CWA -- specifically issues related to a waiver of sovereign immunity, removal of the exemption for radionuclides and applicability of state groundwater protection laws to federal facilities. Additionally, discussions have been held on the possible impact of the reauthorization of CERCLA and RCRA on DOE restoration and waste management activities.

DOE and NAAG have also held three workgroup meetings to discuss various environmental compliance issues. The first meeting was held at DOE HQ in Washington, D.C. on May 17-19, 1994 and focused on the organizational structure of the Department and issues of interest to the State Attorneys General representatives. Topics discussed included DOE's budget process, the relationship between DOE and its M&O Contractors, CERCLA and CWA Reauthorization, RCRA/Atomic Energy Act (AEA) overlap and RCRA compliance issues.

The second meeting was held in Pasco, Washington on October 25-27, 1994 hosted by the Richland Office of Chief Counsel. This meeting began with a tour of the DOE Hanford site and approximately fifteen Attorneys General representatives, State Agency Attorneys, and EPA Region X representatives, DOE Field Attorneys and Program representatives participated in the meeting and the tour. The discussions focused on issues such as the budget process, RCRA/CERCLA integration, RCRA/AEA overlap, and the National Environmental Policy Act (NEPA). One of the highlights was a discussion from the DOE, EPA and Washington State viewpoint on the Hanford Tri-party agreement. The discussion regarding the Hanford Tri-party agreement also focused on the budget provisions in the agreement and how they had served to increase Washington State's involvement in the budget process. The third meeting was held in Washington, D.C. on October 11-13, 1995. Major topics discussed included DOE's Materials in Inventory (MIN) initiative, the Federal Facility Compliance Act (FFCAct) agreements from both a DOE and the state perspective, the Department's RCRA/CERCLA integration draft guidance, and the state perspective on pending federal environmental legislation.

EFFECTIVENESS AS A STAKEHOLDER TOOL

Stakeholder participation is normally perceived as Departmental officials working in tandem with citizens who live near the site and have a vested interest in the decisions that are made regarding cleanup at that site. In fact, the Department has made great strides during the current administration to educate the public to ensure meaningful participation in decisions affecting DOE sites. However, State Attorneys General, who enforce the laws of the state (including environmental laws) are also

stakeholders and traditionally have not been included in this educational process.

This unique arrangement between DOE and NAAG provides a mechanism for that educational process to occur. Attorneys General and their representatives normally do not come into contact with DOE until an impasse has been reached with respect to resolution of an issue. At this juncture, the situation has become polarized and often the only resolution is litigation. Through this agreement, the State Attorneys General representatives and DOE have the opportunity to openly discuss environmental compliance issues that could potentially end in litigation or that have been the cause of some conflict in the past and attempt to devise a way to avoid such conflicts in the future.

There is no magical process or system being utilized to foster openness and understanding between DOE and State Attorneys General representatives under this cooperative agreement. The key is communication, discussion and sharing of information about the DOE organizational structure, and current DOE issues through the use of vehicles such as: the DOE Environmental Issues Bulletin, joint conference calls, and workgroup meetings.

The DOE Environmental Issues Bulletin is a useful tool for educating the states about current issues at various DOE sites. Since the inception of this project, the bulletins have focused on a variety of issues of importance to DOE and the States. For example, the April-May 1994 issue focused on activities related to the Hanford site, such as the January 1994 amendments to the Tri-party agreement and the Mentoring Program at the Hanford Tank Farms. The March-April 1995 issue featured articles on DOE's Environmental Management (EM) program proposed budget cuts and the Federal Advisory Committee on External Regulation. The September-October 1995 issue featured articles on criminal liability concerns for federal officials and implementation of DOE's strategic alignment. This type of information is especially useful during these austere budget times when DOE must prioritize its cleanups. The Attorneys General's understanding of the total picture can only make prioritizing cleanup activities at DOE facilities easier.

The workgroup meetings are another useful tool in facilitating openness and communication between DOE and the State Attorneys General representatives.

The first meeting which was held at DOE HQ was invaluable because it gave NAAG and the Attorneys General representatives an overview of DOE's organizational structure. For example, a presentation was given on the relationship between DOE and its M&O contractors. A presentation was also given on the budget process which in the last couple of years has become of increasing interest to the States.

The second workgroup meeting held in Pasco, Washington, near the Richland Operations Office, was especially beneficial in facilitating openness because the State Attorneys General representatives were given an opportunity to tour the Hanford site, one of the largest sites in the DOE complex. By taking our enforcement officials on a tour of the site, DOE is promoting an air of openness and cooperation that has not always been the case in the past. It also provided the Attorneys General with a new perspective on some of the environmental issues DOE faces everyday.

The most recent meeting in October, 1995 continued to build upon the success of the two prior meetings. The members of the workgroup openly discussed contentious issues such as criminal liability. All parties left

the meeting with a greater awareness of the problems faced by the regulator and regulated communities.

Openness and cooperation between the States and DOE is also being fostered by the level of DOE participation in this project. For example, Field and Headquarters Counsel representatives have been designated to participate in discussions with NAAG and the States. It is especially important for DOE Counsel to participate in these nonadversarial discussions because they are the DOE officials most likely to come into contact with the Attorneys General representatives. Although we may not always be able to avoid litigation on a particular issue, it is hoped that the interactions that have taken place pursuant to this agreement will at least enhance DOE's credibility in the eyes of its enforcement officials.

FUTURE INITIATIVES

Natural Resource Damage Assessment Discussions

Under CERCLA, as amended by the Superfund Amendment Reauthorization Act (SARA) and the National Contingency Plan (NCP), monetary damages may be assessed when natural resources (NR)--land, fish wildlife, biota, air, water, groundwater, drinking water supplies and other such resources--are "injured by a release of oil or hazardous substances." That is, when the selected CERCLA remedy is incomplete in addressing the NR injury produced by a release, the Natural Resource Trustees may file a Natural Resource Damage Claim against the party responsible for the release. The claim is made for the value of the "residual" injury that was not or could not be addressed by the selected remedy. This liability for NR damages is in addition to cleanup costs for a release, and under SARA 120, federal agencies can be held accountable for the additional costs. Liability for NR damage claims based upon injury to natural resources was established under 107(a)(4)(c) of CERCLA.

In dealing with injured natural resources under its jurisdiction, DOE is required to play a "dual role." Pursuant to CERCLA, as amended by SARA, DOE, as a federal agency, serves as the CERCLA Lead Response Agency for removals and response actions at its facilities. Under Executive Order 12580, and the revised NCP, the Secretary of Energy is appointed to serve as the Primary Federal NR Trustee for natural resources on, over, or under land that DOE manages. This situation is further complicated in cases where DOE may be responsible for a release and the subsequent injury to natural resources under its jurisdiction (or in cases where the releasee may have caused injuries to natural resources under the jurisdiction of other Trustees). DOE's mandate to function in multiple roles does not, however, reduce the standards to be met for each particular role. For example, DOE's NR Trustee responsibilities are not intended to supplant the requirements for the Remedial Investigation/Feasibility Study (RI/FS) process mandated for CERCLA Lead Response Agencies. (1)

Under this agreement, an NRDA discussion group has been created. Preliminary discussion among the Departmental staff and State personnel indicates that the states perceive that the Department does not take the natural resource damage issue seriously. The states have also indicated the need for funding to perform their natural resource assessments. During 1996, this group will propose a pilot in conjunction with a DOE operations office, and state and EPA regulatory personnel to develop a plan to maximize existing funding to enhance NRDA projects. Additionally, this group will examine success stories and will create a "Lessons

Learned" report to inform both state and DOE personnel of the NRDA process.

Alternative Dispute Resolution Discussions

The Administrative Dispute Resolution Act (ADRA), 5 U.S.C. 571 et seq., authorized and encouraged federal agencies to employ consensual methods of dispute resolution. Under the ADRA, each federal agency is required to designate a senior official as a dispute resolution specialist, establish a policy addressing the agency's use of alternative dispute resolution (ADR), review contracts and grants for appropriate inclusion of ADR clauses and provide for department-wide training on ADR.

DOE established an Office of Dispute Resolution in the Office of General Counsel in 1995. The Department's interim ADR policy statement was recently published. It emphasized the Department's commitment to the use of ADR as a management tool to prevent or minimize the escalation of disputes, and to resolve disputes at the earliest possible stage. One focus of the Department's ADR efforts is on the prevention of disputes, or at least early intervention, i.e., before litigation has been initiated. (2) The Department recently drafted proposed environmental compliance agreement dispute resolution language. This proposed language has been shared with NAAG members and it is hoped that through meetings and discussions, a streamlined dispute resolution process will be developed in 1996. Staff will also propose a workshop session conducted jointly with NAAG to highlight the benefits of the ADR process.

State Laws and Regulations Workshop

A recent analysis of environmental enforcement actions issued against the Department indicated that over 90% of the actions were violations of the Resource Conservation Recovery Act (RCRA). Section 3009 of RCRA allows states to enact their own programs as long as they are at least as stringent as the federal program. Further analysis of the violations revealed that over 90% of the RCRA violations were issued by state enforcement agencies. To reduce the number of violations against the department, it has been proposed to develop in conjunction with NAAG, a State Laws and Regulations workshop in 1996 for DOE and Contractor personnel to highlight the differences between state and federal laws.

Workgroup Meetings

The Spring, 1996 workgroup meeting will be held in Albuquerque, New Mexico with a tour of the Los Alamos National Laboratory. Due to anticipated budget constraints, the location of the Fall, 1996 meeting has not been determined; however, in order to maximize participation among DOE HQ and Field staff, the rotation of meetings among operations offices is planned.

DOE Environmental Issues Bulletin

Publication of the DOE Environmental Issues Bulletin will continue. In addition to highlighting specific DOE facilities, up-to-date information on the Department's downsizing initiatives will be prominently featured. The states will also have the opportunity to voice their concerns/opinions through this vehicle which has a circulation of over 300. It is anticipated that this circulation will increase substantially with the availability of this document on the Environment, Safety and Health homepage which can be accessed through the Internet.

Resource Conservation Recovery Act (RCRA)/Atomic Energy Act (AEA) Issues

One issue identified by NAAG and DOE as deserving of joint discussions is the state's request that DOE develop a policy on providing radionuclide information to states upon request. To this end, NAAG provided DOE with a

survey of eight states on their experiences with regard to collecting radionuclide information from DOE. The survey revealed that in a few cases DOE resisted providing radionuclide information to states because the information was classified or DOE did not feel that the states had the authority to request such information.

After discussions on this issue at the Richland workgroup meeting, DOE agreed to review and discuss specific policy language proposed by NAAG and the states. Earlier this year, DOE provided NAAG with a counter proposal in the form of a draft memorandum setting forth principles to be used by DOE employees in voluntarily providing states with requested radionuclide information. The focus of the draft is on voluntary provision of radionuclide information and not issues related to whether the states have the right to require DOE to provide such information. Under the 1995-96 cooperative agreement with NAAG, joint discussions on these issues will continue.

CONCLUSION

As federal agencies have instituted massive environmental restoration programs designed to investigate and remediate contamination at their facilities, there has been a growing desire by those affected by these cleanup efforts (who are referred to as affected stakeholders) to have a greater role in the cleanup and decision-making process. (3) The NAAG members do not represent the typical stakeholder interested in cleanup processes and procedures, rather, the Attorneys General are interested in legal interpretations of federal and state environmental regulations, precedent setting legal opinions, and states' rights to enforce against the federal government and the rights of states to enforce their laws at DOE facilities.

With the goals to identify alternatives to litigation, educate and exchange information while improving compliance, this model of stakeholder involvement has served to open discussions on a variety of legal and procedural issues and opinions. Although consensus is not always reached, by providing a forum for these unique stakeholders to interact with the Department's policy makers and legal staff a successful model has been developed for future interaction with federal and municipal government legal officers.

INTERACTIVE ENVIRONMENTAL BROADCAST DISTANCE LEARNING FOR INDUSTRIES, GOVERNMENT AND UNIVERSITIES

Connie Callan
National Environmental Technology Network
The University of New Mexico

ABSTRACT

Budget cuts and increasing demands for a technically competent workforce are problems facing industry and government today. Training requirements must be met in a cost-effective manner. The videoconference format is a proven method that saves money on training and travel costs. The videotapes produced from training programs extend the productivity in any facility. However, designing a training series that meets the needs of a diverse audience composed of scientists, engineers, and management from government, industry, and universities is extremely challenging.

National Environmental Technology Network (NETN), a program of The University of New Mexico's School of Engineering, has a proven track record in developing and producing effective videoconference training programs for industry, government, national laboratories, and universities. To date, nine successful series have been completed: Total Quality Management (two series); Hazardous Waste Management; Waste Minimization and Pollution Prevention; Environmental Risk Management; Radioactive Waste Management; and Mixed Waste Management. The two newest series are Decommissioning and Pollution Prevention. National awards from the United States Distance Learning and the United States Environmental Protection Agency attest to NETN's leadership in providing advanced technical training using distance learning techniques.

INTRODUCTION

Professionals must continue their education throughout their careers to stay abreast of latest technologies. For example, to keep up with developments in their field, engineers require retraining on an average of every four years. The need varies, depending on the precise discipline. Additionally, many technical professionals currently face significant changes in their careers, as their positions shift from defense-related activities to environmental fields.

With budget cuts and increasing demands for a technically competent workforce confronting industry and government today, the emerging training requirements must be met cost effectively. The videoconference format represents a proven method for communicating the most up-to-date information concerning technical, environmental, and management topics. According to Daniel Barron, distance education is a means of "taking quality education to the people who need and want it. Distance education is to instruction what bookmobiles and branch libraries are to reading."(1)

Through videoconferencing, thousands of professionals can receive the most current information and participate in training programs simultaneously, via satellite, without incurring the cost of travel. Each series is structured to stimulate creative interaction and promote a significant exchange of information among technical professionals and stakeholders confronting the increasingly complex environmental challenges of today's world.

Broadcast on C-band, Ku-band, and through the National Technological University (NTU), these videoconference series can be received anywhere in the United States. Most organizations and facilities already have the necessary equipment for receiving these broadcasts. Those not having this capacity can purchase a satellite dish for a minimum investment, a one-time cost for equipment.

Training program videotapes and manuals extend the capacity for training in any facility. Those who participate in the live training sessions have an opportunity to review the material and clarify important points. The programs offer every participant the opportunity to interact through

question/answer sessions, via a toll-free phone number, e-mail, or the use of a fax machine. Questions are accepted before, during, and after the programs. Those who cannot attend the live broadcasts can watch the videotapes and complete the training as their schedules permit. Designing a training series that meets the needs of a diverse audience of scientists, engineers, and managers from government, industry, and universities is extremely challenging. As Reza Azarmsa explains, "Much like any other area of mediated communication, teleconferencing is both a science and an art."(2)

NETN, an international program of the University of New Mexico's School of Engineering, has an exceptional record for developing and producing effective videoconference training programs for industry, government, national laboratories, and universities. NETN is part of an environmental consortium funded by the Department of Energy (DOE). The Waste-management Education and Research Consortium (WERC) is composed of The University of New Mexico, New Mexico State University, New Mexico Institute of Mining and Technology, Sandia National Laboratories, Los Alamos National Laboratory, and Navajo Community College. Members have teamed together to help solve the environmental problems facing our nation, collaborating in three areas: research, education, and training.

Distance Learning at NETN

To date, NETN has produced the following nine successful videoconference series: Total Quality Management (two series, one for service organizations and one for manufacturing); Hazardous Waste Management; Waste Minimization and Pollution Prevention; Environmental Risk Management; Radioactive Waste Management; Mixed Waste Management; and the two newest produced during 1995. The first, Decommissioning, is a six-part series addressing decommissioning within the U.S. Department of Energy's Environmental Management Program. The second series, Pollution Prevention, examines technologies for applications from government installations to cottage industries.

The live, interactive programs produced by NETN have been broadcast to over 167 sites with diverse audiences. The training has spanned the United States, reaching 8,000 participants in 48 states at 100 industry sites, 64 military and government installations, and 32 universities. National awards from the United States Distance Learning Association (USDLA) and the U. S. Environmental Protection Agency attest to NETN's leadership in providing advanced technical training using distance learning techniques. These series have received awards for the past three years, and in 1993, NETN earned an award for "Most Outstanding Distance Education Network" from the USDLA.

How to Produce a NETN Television Series

The process described below is accomplished over a 9-12-month period. To select a topic for distance learning series, NETN surveys the various receive sites, requesting information about their current training needs. When sufficient interest is expressed in one particular area, and the funding for production secured, the topic becomes the focus of the next distance learning series.

Step 1: Experts Meeting

In the early stages of developing a series, NETN conducts an "Environmental Experts" workshop, where environmental professionals meet to listen to speakers and participate in panel discussions and question/answer periods. To simplify information exchange, workshop participants complete surveys for NETN. These surveys ask respondents to describe the

issues they consider critical for professionals in these fields to address; list the concepts that need to be communicated to stakeholders; identify recognized national experts in the fields; and provide names of periodicals, national organizations, and associations important for people involved in the particular area of expertise.

Step 2: Advisory Board Meetings

The next step involves of advisory board meetings, which lay the foundation for the development of the series. National experts involved in previous programs, scientists from the institutions that comprise WERC, and stakeholders are all invited to attend. To provide an overview of a series' production, speakers with past experience in televised training describe the roles and responsibilities of those involved in the process.

Step 3: Identification of Nationally Recognized Program Leaders

As the topics develop, the technical advisors and the advisory board suggest possible program leadersexperts in the field with backgrounds in industry, business, and government. NETN contacts these individuals and those who agree to join the advisory board and NETN staff to form the nucleus of the evolving series.

During the next portion of the advisory board meeting, members begin the planning process by developing a proposed series outline. The outline consists of specific program topics, any particular emphasis to be considered for each topic, and possible case studies.

Step 4: Identification of Presenters from Diverse Backgrounds

The program leaders then select about five people with expertise in their program topics to serve as presenters. The technical advisors understand the overall program content and make sure all aspects of appropriate topics are covered. They also work with the NETN staff and may provide a final review of the programs' instructional manuals.

The individual program leaders recruit nationally recognized experts in the field for their program. They maintain a balance in the program content and sometimes also serve as presenters. The program presenters need good communication skills to deliver their material and to interact with the participants during question/answer periods. Presenters are encouraged to incorporate graphics, videos, humor, and real-life examples to keep their presentations interesting. Each presenter submits charts, suggested readings, test questions, glossary of terms, and a brief biography to NETN, all of which is incorporated in the manuals.

Step 5: Production/Conference Calls

Because NETN seeks presenters from all over the United States, much of the program design occurs during a series of conference calls. Once a plan is established for the individual programs, the program leaders meet with the NETN staff in Albuquerque to define the content of each program and assure continuity for the series as a whole. This not only reduces redundancy, it also confirms that the participants will receive an adequate amount of technical background information. Then, as the scheduled broadcast dates approach, conference calls among those involved in individual programs continue as needed.

Step 6: Instructional Manual Preparation

Meanwhile, the presenters' materials are prepared for the instructional manuals and returned as final drafts to the presenters and the technical advisors for review. The manuals for each program contain the following information: program description, presenters' charts, suggested readings, test questions, presenters' biographies, and various NETN feedback forms.

A reproducible master of each program manual is sent to each receive site prior to the program broadcast. The master is duplicated at the site, and copies are distributed to all participants attending the training. One bound copy of the manual is sent to the site to be used as reference and to augment the site's videotapes of the programs.

Simultaneously, the video producer pulls together all the elements necessary for live broadcast. Scripts are written and case studies are chosen. Arrangements for on-location recording at the sites are made; the case studies are videotaped and edited for the broadcasts. All elements for live broadcast are orchestrated, down to the selection of soundtrack music.

Step 7: Training Facilitators Across the United States (diverse audience)

Prior to the first program's broadcast, NETN conducts a facilitator training program. Experience has shown that site facilitators contribute to the overall success of this televised training when they function as proactive members of the team. The facilitator training program covers a wide range of instructional material. Facilitators learn technical details, such as how to establish a comfortable environment for the viewers and how to check the operation of the equipment. They learn how to find the appropriate audience and publicize the upcoming training at their site. They receive tips about effective ways to interact with series advisors and are encouraged to seek experts within their organization who can enhance the learning experience.

In addition to the televised training, facilitators receive a training packet to serve as a reference during the course of the series. Given this overview of what to expect from the distance education experience and how to make it meaningful for the participants, the facilitator often serves as the foundation for the partnership that develops between the university and the audience.

Step 8: Publicizing/Marketing

Publicizing the training event occurs at two levels. NETN can assist the sites with publicity by developing a customized brochure, news releases, and advertisements. A brief promotional tape is also sent to each receive site. On the broader spectrum, NETN notifies former participants of the upcoming series, writes press releases, and develops detailed brochures for distribution. To help ensure a wide array of participants, the NETN director publicizes the training at trade shows and at national meetings on distance education and environmental issues.

Step 9: Series Broadcasts

One to two weeks after the facilitator training program, the first program is broadcast on alternating Wednesdays. Facilitators are instructed that every program within a series contains a minimum of six presenters from industry, government, and universities with varied scientific backgrounds and expertise. Included in many programs is a segment on the regulations that pertain to the topic being discussed. To increase effectiveness, live presentations are mixed with video that demonstrates the technology involved in the program topic, as well as relevant case studies that illustrate practical uses of the material. Customized workshops and on-site training are also available.

Step 10: Modifying Programs to Feedback and Evaluations

Regular feedback from the participants following each program enables the production staff to constantly improve on the quality of the series. After the final program, the participants complete both NETN Feedback and

Evaluation forms. The facilitator returns these forms to NETN, where a thorough review of the evaluations is completed. This direct input from the receive sites allows the technical advisors, program leaders, presenters, and production staff to improve the quality of the series by capitalizing on what went well, and modifying the programs to make improvements where indicated.

The Keys to Success

The keys to producing effective videoconference series extend into every facet of production. In the preliminary stages, well-defined topics and carefully selected presenters with excellent credibility are essential. Comprehensive instructional manuals enable the audience to follow along easily and record their notes. Question/answer periods with ample time for discussion encourage interaction that facilitates information exchange and lasting partnerships among the sites.

Timing is also an important consideration. Experience shows that short (3 hrs) programs, regularly offered, are the most effective. NETN broadcasts these live videoconferences at regular intervals, for example, on the second and fourth Wednesdays of each month. Finally, the role of the on-site facilitator cannot be overemphasized. Well-prepared facilitators can play a proactive role in distance education, as they bridge the gap between the television studio and the audience and promote an open exchange of ideas and information.

Advanced Technical Training Through Distance Learning

As the workforce shifts from defense to environmental careers, working professionals need environmental information for current and future jobs. They require immediate, high-level training in specific environmental fields. NETN's goal is to assist the U.S. Department of Energy (DOE) in complying with the Congressional mandate of a 30-year remediation initiative.

Interactivity

Advanced technical training and technology transfer represent a proven method of disseminating valuable information to engineers, scientists, researchers, hospitals, universities, and laboratories around the world. Video conferences provide unique networking opportunities, allowing participants to exchange ideas with recognized environmental experts. During the interactive sections, participants are encouraged to ask specific questions that pertain to their particular site. Throughout the series, audience members develop the tools to change directions in their careers, with a strong emphasis on environmental clean-up and future use of a site.

Cost Effectiveness

Transmissions via satellite offer economic advantages, such as savings on travel and workshop registrations. The price per site allows unlimited attendance during the live broadcasts. To prolong the life of the information contained in these series, the sites have access to videotapes of the programs and a bound copy of each instructional manual for their library.

Certificates and Continuing Education Units

DOE currently receives NETN's environmental series in all DOE Operations offices across the US and at DOE Headquarters. This is part of the DOE effort to retrain their workforce from defense to environmental careers and to support environmental information exchange. After each series concludes, participants receive certificates of completion and earn Continuing Education Units (CEUs) through The University of New Mexico.

Endorsements

Recognition and endorsement for this educational effort have been extended to NETN by the American Society of Mechanical Engineers (ASME) and the Hazardous Waste Action Coalition (HWAC). Sponsors include DOE, the U.S. Environmental Protection Agency (EPA), and the Waste Management Education and Research Consortium (WERC).

How Evolving Partnerships Enhance the Training

NETN achieves balance and diversity by seeking presenters from industry, government, and universities. Working closely with experts from such varied backgrounds has enabled NETN to develop strong partnerships among the presenters and the receive sites.

The ongoing interactive programs promote mutual awareness and understanding. Unique partnerships can evolve through a distance education experience. For example, Sandia National Laboratories and Los Alamos National Laboratory subscribed to NETN's first series on Total Quality Management in 1990. Both organizations have participated in every subsequent series, and a mutually beneficial understanding has developed between The University of New Mexico and these national laboratories. Because individuals feel free to ask site-specific questions, participants throughout the nation come to understand each other better, discovering common ground in the search for common solutions.

Technical Aspects of the NETN Series

As mentioned earlier, the technical aspects of a videoconference seriesprogram content and specific emphasisare determined through the input from viewers of previous series, advisory board meetings, and an Environmental Experts workshop.

The Total Quality Management (TQM) series were NETN's first two distance education initiatives pertained to Total Quality Management (TQM). A14-part series offered an engineering/management approach to TQM, and a 6-part series focused on TQM as it applies to service organizations.

Hazardous Waste Management, the next series, consisted of the following programs: 1)Introduction: What Is Waste?; 2) Risks Associated with Hazardous and Radioactive Wastes; 3) Transport Processes Related to Wastes; 4)Waste Form Modification; 5) Site Characterization; 6) Sampling and Analysis; 7) Soil and Groundwater Remediation I Physical/Chemical Processes; 8) Soil and Groundwater Remediation II: Biological Processes; 9) Radiation and Radioactive Materials; 10)Radioactive and Mixed Wastes Management; and 11)Waste Minimization and Series Close.

Waste Minimization and Pollution Prevention, adhering to the logical progression of the content, NETN followed the previous series with an 8-part videoconference: 1) OverviewWhy Minimize Waste?; 2) Where Do We Start Waste Minimization?; 3) How Does Recycling/Reuse/ Reclamation Make Economic Sense?; 4) Are the Right Product/Process Designs Being Addressed?; 5)Solvents and Organic Chemicals; 6) How to Implement Minimization in Metals, Plating, and Electrical Interconnects; 7) How to Minimize "End of Life" Problems; and 8) Planning and Preparing for the Future.

Environmental Risk Management sought to bridge the gap between technical issues and social concerns. Program titles included 1) Risk: Terminology, Concepts, Methods, Applications and Why Risk Communication Is Difficult; 2) How Do We Decide What Is Risky?; 3) Identifying the Gap: Divergent Technical and Social Methods for Risk Characterization; 4) Quantification of Models for Risk Assessment; 5)Risk Characterization:

Synthesis and Communication; 6) Risk Assessment: Communicating Results and Public Perception; and 7) Risk-Based Decision Making: A Final Act?

Radioactive Waste Management was produced concurrently with the Environmental Risk Management series. These programs were 1) An Introduction to Radioactive Waste Management; 2)Interactions Between Radiation and Matter; 3)Decommissioning and Decontamination; 4)Transportation Issues in Radioactive Waste Management and UMTRA; 5) Low-Level Radioactive Waste Management; 6) High-Level Radioactive Waste; 7)Transuranic Radioactive Waste Management; and 8) New and Other Technologies for Radioactive Waste Management.

Mixed Waste Management was broadcast in 1994. Generated by government facilities, research laboratories, hospitals and universities, mixed waste is a major concern in remediation projects, including the cleanup activities on the U.S. DOE weapons complex and old radioactive waste disposal sites. The series consisted of 1) Generation and Characterization of Mixed Waste; 2) Storage of Mixed Waste; 3) Minimization and Treatment of Mixed Waste; 4) Technical Development of Mixed Waste Issues; and 5)Remediation Activities.

Decommissioning, a new 6-part series, was broadcast in 1995, with an introduction to the series with a goal and vision statement from U.S. DOE. The inventory and history of the major decommissioning sites with overviews and the various phases of the decommissioning process are included. Each program consists of technical presentations by experts focusing on decommissioning terminology, problems involving contamination and radiation along with successful approaches, and existing and evolving decommissioning techniques. This series stresses the importance of good planning, pre-job briefings, and dress rehearsals with mock-ups to uncover problems and save time. Participants learn the techniques for dismantling and segmenting equipment and structural members and demolishing structures.

Pollution Prevention, a 5-part series, was also aired in 1995. Pollution prevention is far more powerful, more painless, less costly than continually degrading the environment by just "managing waste." Only through massive educational and awareness programs can the attitudes and values of the people be made sensitive to the need for pollution prevention. It is everyone's responsibility and moral obligation to protect the environment for future generations.

The end-of the pipe approach to waste management is a losing strategy. Striving to be in environmental compliance is not the answer; and managing waste is not only expensive, but poisonous to the environment and to the health of the public. Pollution prevention the front-end approachmakes business sense and is less destructive to the environment.

CONCLUSION

There is a growing need for information about environmental issues throughout the world. Delayed broadcasts and taped programs have been received by ISTEC (a Latin American Network) and tapes used as far away as Estonia.

Communication and participation are critical elements in our national efforts to identify and explore environmental challenges. NETN develops distance education programs that explore technologies for the ultimate protection and preservation of the environment, while sustaining economic growth. We are proud of our role in building partnerships between the public and private sectors in working toward a sustainable global future for the environment.

ABSTRACT
Implementation of the Government Performance and Results Act of 1993 (GPRA) has provided a unique challenge for Federal Agencies, such as the Department of Energy (DOE) Office of Waste Management (OWM). While performance measurement, as required by GPRA, is new to Federal Agencies, private industry has applied it at all organizational levels to better manage their operations for some time. There has been significant discussion about how the private sector uses performance measures, but there have been very few empirical studies systematically examining their use.
To gather information on comparable private industry practices, waste management industry firms were surveyed through questionnaires and follow-on interviews. Questionnaires were sent to 75 waste management firms throughout the United States and Canada. Twenty-four percent of the firms responded to the questionnaire and participated in the follow-on interviews. The questionnaires were typically completed by vice-presidents or senior financial officers. Information collected from the questionnaire and follow-on interviews provided valuable insight into industry practices in the area of performance measurement. This paper discusses the study results and how they can be incorporated in the DOE OWM performance measures and influence the character of the "critical few" metrics used by senior DOE managers.

INTRODUCTION

The Government Performance and Results Act of 1993 directed Federal Agencies to develop annual performance measurement plans for their program activities. Private industry successfully uses performance measurement at all organizational levels to better manage operations. These private enterprises, particularly those in the waste management industry, are a valuable source of information for DOE OWM on current performance measurement practices. Of particular interest is the character of those "critical few" performance metrics or indicators used by corporate executives, the position which best corresponds to the operational oversight responsibilities of the DOE Deputy Assistant Secretary for Waste Management and the Assistant Secretary for Environmental Management.

To gather information on private industry practices, waste management firms were surveyed, first through the distribution of a survey questionnaire, and then with follow-on discussions after the questionnaires had been returned and reviewed. The survey was sent to 75 waste management firms throughout the United States and Canada. Information collected from the survey and follow-on discussions provide valuable insight into industry practices in the area of performance measurement.

The responding firms represent a cross section of the waste management industry. The core businesses of over 50% of the respondents is waste disposal and/or waste treatment, though the wastes which they manage pose less handling problems than those faced by the DOE. Of the firms which responded, eight (44%) have annual revenues of over $100 million and several core business lines, requiring the chief executive officer (CEO) to manage multiple performance centers, a management complexity similar to that facing the Deputy Assistant Secretary for Waste Management.

SURVEY METHODOLOGY

Although performance measurement is used across all industry sectors, those firms in the waste management business were judged to be in the best position to provide the type of performance measurement practices most useful to the DOE OWM. Candidate firms were identified using a variety of sources, and a screening process. Telephone contacts were made to identify the specific types of services the companies provided and the corporate representative who should receive the survey questionnaire. The survey form transmittal package included a cover letter summarizing the DOE efforts to increase the use of performance measurement practices. Twenty-four percent of those receiving the survey responded. As the survey questionnaires were received, data was compiled and analyzed. This information was reviewed and used during follow-on discussions with the eight largest responding firms. A profile of the participating firms is shown in Fig. 1. The follow-on discussions with the respondents, who were typically vice presidents or senior financial officers, and the corporate CEOs were worthwhile. However, it was evident that though they were interested and supportive of the study, other time demands limited their participation and accessibility.

Fig. 1

FINDINGS

The survey findings are divided into those performance metrics or indicators used by the chief corporate executive, typically the CEO, and those used by other organizational levels. Universally, the performance measures used by the CEO subsume the more detailed measures from other organizational levels.

Overall Performance Measurement Practices

Key results extracted from the questionnaire are:

- 94% of the respondents use organizational goals as the focus of performance measures.
- 78% of the respondents use performance measures to monitor organizational progress toward corporate mission and goals.
- 67% of the respondents share mission statements and goals with employees.
- Smaller firms tend to use fewer performance indicators.
- Performance measurement information is distributed to the executive level at least monthly and often weekly.

No organization used purely financial measures, such as revenue or cost per ton of waste stored or treated. While 17% of the respondents used purely nonfinancial performance measures, such as customer satisfaction or volume of market share captured, the majority used a combination of financial and nonfinancial measures. The performance measurements used at one level in the organization often helped explain the performance results at the next higher level. Examples of typical measures appear in Tables I and II.

Table I

Table II

Senior managers generally rely upon five to seven key financial and nonfinancial indicators and focus on division or product line performance. Below senior management, the variety and number of indicators increases and are predisposed toward quantitative measurements such as unit cost, resources expended, and achievement verses time unit. Middle managers tend to focus on their specific work centers. Performance measures for each work center are defined and collected for consolidation into divisional or product measures and for comparison with similar corporate operations. Such a systematic approach was the basis for the Fiscal Year 1996 OWM performance measures for waste treatment, storage, and disposal.

While the OWM does not generate revenue or operate for profit, the underlying principle of producing quality products for the least possible cost is consistent in both sectors. The respondents use performance measures for monitoring, evaluating, and controlling costs. The performance metrics used for financial measures were similar among the firms surveyed. The key condition for optimum use of performance measurement indicators, which seemed to be taken for granted by the respondents, were effective communications and cost collection, and a quantity tracking system which provided relevant, timely, accurate, and consistent information. Unique financial, cost estimating and collection systems across the DOE complex could make consistent performance data collection difficult. Standard definitions for direct labor, material, and indirect cost pools are necessary for credible complex-wide measures for waste management operations.

Qualitative measures, while fewer than quantitative measures, did also exist at all management levels and tended to focus on customer satisfaction. This is akin to stakeholder interest measures for DOE. Because of the diverse DOE stakeholder population, measurement focus should start with an objective area such as satisfying regulatory issues and as the system matures, proceed toward the more esoteric stakeholder issues. Stakeholder-related measures are important but will require OWM and stakeholder cooperation for mutual acceptance.

Corporate Oversight

Specific chief executive performance measurement practices were solicited through follow-on discussions from the eight largest respondents. This approach validated the questionnaire input and provided the opportunity to discuss how performance measures were used. These discussions were used to validate methodology for developing "critical few" measures for DOE management. The title "critical few" indicates the awareness by senior DOE management that they could not evaluate each performance measure for every EM office, a fact supported by the CEO interviews. The discussions provided significant insight and focus for the OWM "critical few."

While each firm uses a variety of indicators or metrics to monitor performance within the organization, at the highest corporate level, typically the CEO or president, financial/business indicators were primarily and universally used to measure performance. These included corporate earnings, earnings per share, return on investment or assets, total revenue, and total cost. This is the type of information included in annual reports issued by the company and is targeted toward stockholders.

Financial/business performance metrics, in the form of tables, charts, or curves were typically provided monthly. This provided actual versus planned performance through a specified period and occasionally included performance projections. These metrics conveyed "what" had occurred but did not typically provide much analysis or detail. Supplemental information on operational performance at the product or service level was available, however, and provided insight into trends. Consequently, corporate executives could look down into their organizations and pinpoint those areas or operations which had contributed to the successes or problems.

There were no reported instances where aggregating or indexing of dissimilar performance metrics, produced through sophisticated mathematical modeling, was used by the CEO. In one case, the aggregated performance of similar activities, landfill operations, were provided to the CEO as a key performance measure. The differences in the waste handled and landfill sites were normalized, using weighting factors. Variance from the corporate planned cost would be explained by examining the actual volumes handled by each site as compared to the planned volumes for each site.

At several companies, along with key financial performance indicators, the CEO received performance metrics which evaluated customer satisfaction such as: on time deliveries, work in progress, milestones achieved, and other performance measures which they considered significant when evaluating overall performance. The selection of metrics appeared to reflect the overall size of the company, the variety of products and services it provided, and the management style of the CEO.

The CEO feedback supported the position that no single metric could be developed to measure the performance of the DOE Waste Management Program. A single metric would have been especially difficult in the case of the Waste Management Program anyway, because managers must deal with various types of existing waste and an indeterminate amount of waste generated by ongoing operations and decommissioning of closed facilities. Several metrics would be required to measure performance in key program areas. To mirror its private sector counterparts, the DOE Waste Management "critical few" should be composed of metrics measuring production, cost of operations, and customer satisfaction. A program analysis by staff and management should be conducted to determine what measures, reported at the operations level, meet these key program parameters.

CONCLUSION

Private waste management firms generally use performance measures to monitor their operations. Performance metrics used within the organizational levels complement those received by the chief executive by identifying areas which have contributed to overall corporate performance. Performance indicators recognized as significant by senior and executive management generally ranged between five and seven. This suggests that too many performance indicators are either not manageable

and/or useful. From the study results, chief executives use two to three key performance metrics. These high-level performance indicators most often measure financial/business performance. Below the executive level, managers use a combination of financial and nonfinancial indicators which relate to a specific product, process, service, or organizational unit. The objective of this study was to examine private sector performance measurement practices and to identify potential areas where the DOE OWM could benefit. As the DOE moves toward implementing GPRA, the practical lessons from the private sector are helpful in designing the performance measurement system. Key lessons learned from this study are:

Focus on a small number of meaningful measures.

Develop a system where more detailed information is available, if requested.

Establish an effective process for defining and communicating the performance measures within the organization and for relating measures to the overall organizational goals.

Implement a cost collection and quantity tracking system that provides relevant, timely, accurate, and consistent information.

While the DOE neither generates revenue nor is operated for profit, performance measures can monitor operations execution and efficiency. The cornerstone to these measures is a consistent system for measuring output and collecting costs. The ability of the existing systems to meet the criteria of consistency will have to be evaluated as part of the performance measure development effort. Additionally, the "critical few" program parameters must be clearly defined, and they should contain production, cost of operations, and customer satisfaction measures. Additional interactions with private sector waste management firms, both at the headquarters level and in the field, can be beneficial as the DOE continues to improve the overall effectiveness of waste management operations.

OPTIMAL PROJECT SELECTION TO MINIMIZE LIFE CYCLE COSTS

Kenneth S. Redus

ABSTRACT

Sound economic methods are required to selectively fund projects that address significant environmental restoration, deactivation, decontamination and decommissioning, surveillance and maintenance, and waste management challenges. The funded projects must offer the greatest environmental and health risk reduction, significantly reduce sources or inventories, generate the highest public stakeholder acceptance, or ensure that worker safety is maximized for the least cost.

This paper presents a proven approach that identifies the optimal selection of projects so that the total Life Cycle Cost (LCC) is minimized for all selected projects. Annual budget constraints, risk reduction requirements, and multiple project combinations are considered. Scenarios based on annual funding levels, desired relative risk reduction, and project cost factors are examined. The approach was developed and is currently being implemented at Oak Ridge National

Laboratory (ORNL) Environmental Restoration Program Characterization and Remedial Decisions Office.

INTRODUCTION

Environmental restoration and waste management (ER/WM) program managers need to choose the optimal number of projects to fund during a given Fiscal Year (FY). The total Life Cycle Cost (LCC), i.e., the sum of the annualized costs of all the funded projects, must be minimized.

At the same time, ER/WM managers must deal with other major constraints. Projects must be selected that maximize the reduction in environmental and health risk. Budgets cannot be exceeded within the specified planning horizon. Some projects, or a combination of projects, must be funded for a variety of programmatic, regulatory, public stakeholder or technical reasons. In some cases, if one project is funded, another project cannot be funded for similar reasons.

STATEMENT OF THE PROBLEM

The critical challenge facing ER/WM managers is:

"It is a fact of life that we have limited dollars. What projects should be funded that demonstrate success?"

The problem statement is:

What is the best selection of $K < N$ projects that minimizes total LCC, meets or exceeds a specified level of risk reduction, satisfies available budget and LCC constraints, and meets project combination constraints within a given planning horizon?

The term "risk reduction" corresponds to the decrease of human health and environmental risk. Risk is the probability an individual will develop cancer (1). Inventory or source-term reduction, stewardship, public acceptance, or worker safety could be substituted for risk reduction in the problem statement.

An alternative way to express the problem statement is:

What is the best selection of $K < N$ projects that maximizes risk reduction, is less than a specified total LCC, meets available budget constraints, and satisfies project combination constraints within a given planning horizon?

This is a rearrangement of the objective and the primary constraint of former problem statement. The objective is to maximize risk reduction subject to the primary constraint of minimizing total LCC. The constraints for available budget and project combinations within the planning horizon remain the same. The solution to both ways of expressing the problem is the same. (2)

REVIEW OF CURRENT APPROACHES

Three approaches are currently used for ER/WM project selection. The benefits and the limitations of each approach are presented in Table I.

The purely economic approach assumes cost is the only evaluation criteria. Although this approach is simple, it is rarely used in a standalone manner. The total current year cost and the LCC for all candidate projects are determined. A funding line is defined. Projects are rank-ordered from minimum LCC to maximum LCC. Projects are selected based upon minimum LCC until the funding line is reached for the current year costs. All projects that fall below the funding line are discarded until the next planning horizon's budget exercise.

Multiple Criteria Decision Making (MCDM) uses a quantitative metric to prioritize the projects independent of cost and then applies the purely economic approach. One common metric is a weighted linear additive function. Weights are assigned to decision variables such as public

acceptance, risk reduction, worker safety, or regulatory compliance. Each project is "scored" for these variables, and the overall weighted score is computed. Projects are prioritized by this overall score. The economic approach is then used to select projects for funding.

Effectiveness-Cost Analysis prioritizes projects using an effectiveness-cost (E/C) ratio. The effectiveness measure may be expressed in dollars, or it may be an MCDM-like quantitative metric. Cost is LCC or cumulative annualized outlays for some planning horizon. Projects with the highest E/C ratio are selected for funding until the funding line is reached. The remaining projects are not funded.

Unfortunately, project combinations are examined after the first cut of project selection is accomplished. Several iterations in the project selection process are required, and these are usually accomplished in a heuristic, brute-force, manner.

There are obvious benefits of each approach. There are also significant limitations. The greatest limitation is that a quantitative metric is always required for the MCDM approach and Effectiveness-Cost analysis. The project scores and the weights of the decision variables must be calibrated and repeatable. If this is not the case, the project selection credibility is questionable regardless of how reliable or repeatable the subsequent application of the pure economic approach.

Table I

THE OPTIMAL PROJECT SELECTION APPROACH

The optimal project selection approach employs an operations research principle known as mathematical programming. Mathematical programming is a method that deals with the allocation of resources among competing activities (2). This type of approach is useful for a variety of ER/WM problems including identification of transportation routes for waste shipments to disposal facilities, personnel scheduling, and, as the topic of this paper, project selection. It is assumed that any project being considered for funding meets some minimal acceptable level of stakeholder acceptance and worker safety.

The optimal project selection approach is summarized in Table II. The problem statement is formulated as an integer mathematical programming problem. All results are deterministic, i.e., the formulation cannot handle random variation in the objective function coefficients or the constraints. The decision variables are binary, namely, projects are either selected or not selected. The objective function is linear, and the coefficients of the decision variables are the total LCC for each project. There are several of constraints: 1) all decision variables are either 0 or 1, 2) a linear combination of projects and associated risk reduction is required to be greater than some threshold value, 3) a linear combination of projects and planned budget for each project for one or more separate FY is required to be less than a specified value, and 4) a series of logical rules associated with project combinations must be met. The logical rules associated with the project combination constraints is presented in Table III. The computational approach is implemented using Microsoft Excel, Version 5.0a.

Table II

Table III

The details for optimal project selection are presented in Table IV. There are six major actions that must be performed:

- Describe projects in terms of cost and risk reduction
- Describe the planning horizon and associated budgets

Identify scenarios in terms of budgets, desired risk reduction, and allowable project combinations

Identify optimal projects in terms of projects than minimize total discounted LCC and meet specified budgets, desired risk reduction, and allowable project combinations constraints

Evaluate optimal projects in terms of rank-ordered scenarios

Select optimal projects based upon the results of the evaluation and associated sensitive analyses and scenario evaluations.

The optimal project selection approach does not include management challenges such as changes in mission, client or ER/WM re-organization, market share loss or gain, or crises and emergencies.

Table IV

Candidate projects are first described in terms of cost and risk reduction. Cost is expressed as both a discounted and an undiscounted LCC. For example, if the undiscounted LCC cost for a project is $25M, the discounted LCC at an 8% discount rate over 15 years may be $21.5M. Risk reduction is expressed as a percentage of total risk reduction that would occur if the project were successfully implemented based upon the project's geographic domain. For example, the current human health and environmental risk for a project may be 1.0E-03. If the project were successfully completed, the risk would be less than 1.0E-04 that would represent a linear risk reduction of 90%. (As discussed earlier, inventory or source-term reduction, stewardship, etc. could be used instead of human health and environmental risk).

The planning horizon and budgets are then described. The planning horizon is defined to be those periods (in years) for which the optimization is applicable. Up to three planning horizons may be examined. The optimization approach requires one planning horizon to be the maximum duration for all projects. The first FY is strongly recommended as the second planning horizon, and it is suggested the third planning horizon may be either two, three, or five years. The budget for each project is determined from the undiscounted LCC. The total budget for all projects is the sum of the undiscounted LCCs for all projects. Annual budgets for the projects for FY (the FY1 and FY2, FY3, or FY5) are expressed in current year dollars.

Scenarios are developed to compare optimal project selections. There are no strict rules for scenario identification other than scenarios for the optimization can only be expressed in terms of the decision variables of budget, risk reduction, and project combinations. For example, a reasonable Baseline scenario is: maximum funding levels and budgets are available, risk reduction is the highest, and project combinations represent current planning thought. A Worst Case scenario can be developed in which expected funding levels and budgets are minimal and risk reduction is very low. The worst case project combinations explicitly depend on user perceptions. Currently, the model can examine as many scenarios as desired.

The optimal project identification is determined using data from the previous actions. Using mathematical integer programming, optimal projects are identified for the Baseline and Alternate scenarios. All projects identified result in the minimum total discounted LCC and meet risk reduction, budget, and project combination constraints.

Optimal projects are evaluated in terms of the rank-ordered scenarios. This is because a sensitivity analyses of the constraints is not meaningful since project selection has been formulated as an integer

programming problem. The rank ordering of the scenarios may be based upon 1) likelihood (i.e., probability that a scenario will occur), 2) utility (i.e., the relative worth of the scenario to program challenges), or 3) whatever ordering makes sense to decision-makers.

Optimal projects are selected based upon the results of the project evaluation. The optimal project identification and evaluation provides a recommendation for funding a selected set of projects based on cost and some measure of project effectiveness; however, there are many management challenges that are not included, nor attempted, in the optimal project selection approach. As such, the final selection always rests in the hands of the decision-maker.

ILLUSTRATION OF APPROACH

An example that is representative of project selection activities at ORNL is presented in this section, Table V. Ten projects are candidates for funding. Each project is an Environmental Restoration (ER) project, a Decontamination and Decommissioning (D&D) project, or a Surveillance and Maintenance (S&M) project. Project duration ranges from one to 15 years. The undiscounted LCC of each project is $25M. Risk reduction for each project ranges from 1% to 100%, where large values of risk reduction are preferred to small values.

Project duration ranges from one to 15 years, hence this is the maximum planning horizon. Two other planning horizons are considered, FY1 and FY2. The discounted LCC is the total annualized Net Present Values of capital and operations and maintenance costs using an 8% discount rate. Budgeted current year costs for each project are identified for FY1, FY2, and FY3.

Table V

Seven scenarios are developed to compare optimal project selections. These are presented in Table VI. As the shading of the entries in table darkens, the scenarios get progressively worse. The scenarios are subjectively rank-ordered by likelihood from most likely to least likely. No numerical likelihood estimates are used to create the rank-ordering. The Baseline Scenario considers the maximum funding level of $250M over 15 years with full funding for FY1 and FY2. Projects 2, 9, and 10 must be funded. This is denoted as "2, 9, 10" in Table VI. Disjunctive project constraints are 1) Project 4 or Project 5 can be funded, but not both, and 2) Project 7 or Project 8 can be funded, but not both. This is denoted as "(4,5) (7,8)" in Table VI. No conjunctive constraints are considered in any scenario. Risk reduction is required to be at least 75%.

Scenario 1A is the same as the Baseline Scenario except that (1) the maximum funding level is reduced to $200M, and (2) there are no disjunctive project constraints. Scenario 1B is the same as the Scenario 1A except that 1) risk reduction is required to be at least 70%, and 2) the disjunctive project constraints "(4,5) (7,8)" are present.

Scenario 2A represents 1) the maximum funding level is reduced to $200M, 2) FY1 funding is cut by 10%, 3) FY2 funding is cut by 20%, 4) Risk Reduction is required to be at least 65%, and (4) there are no disjunctive project constraints. Scenario 2B is the same as Scenario 2A except that the maximum funding level is reduced to $150M.

Worst Case Scenario 1 represents 1) the maximum funding level is reduced to $150M, 2) FY1 funding is cut by 10%, 3) FY2 funding is cut by 20%, (4) risk reduction is required to be at least 60%, and 4) the disjunctive project constraints "(4,5) (7,8)" are present.

Worst Case Scenario 2 represents 1) the maximum funding level is reduced to $150M, 2) FY1 funding is cut by 20%, 3) FY2 funding is cut by 20%, 4) risk reduction is required to be at least 60%, and 5) the disjunctive project constraints are not present.

Table VI

The optimal project identification is presented in Table VII for each scenario. Several observations are provided:

Although the Baseline Scenario considers maximum funding level of $250M over 15 years with full funding for FY1 and FY2, risk reduction cannot exceed 77%. This is due to the presence of the disjunctive project constraints.

All projects identified result in the minimum total discounted LCC. The discounted LCC ranges from $142M when the full $250 funding is available to $121M when only $150M is available.

All projects meet risk reduction constraints. The maximum risk reduction possible is 77%. When funding is at the worst case level, risk reduction ranges from 61% to 65%.

All projects meet FY1 and FY2 budget constraints for full funding availability. When the full $106M is available for FY1, budget requirements range from $76M to $92M. When the full $32M is available for FY2, budget requirements range from $18M to $28M.

All projects meet FY1 and FY2 budget constraints for reduced funding availability. When $90M is available for FY1, budget requirements range from $87M to $90M. When $80M is available for FY1, budget requirements are $71M. When $25M is available for FY2, budget requirements range from $14M to $22M.

All projects meet project combination requirements. Although there are only a few project combination requirements, most problems may contain several hundred such constraints.

Table VII

Optimal projects are evaluated using the rank-ordered scenarios. This is illustrated in Table VIII. Risk reduction is as presented earlier. Slack represents the difference between the constraint requirement and the result of the scenario optimization. As the shading of the entries in table darkens, the outcomes of the scenarios get progressively worse. Several observations are made:

The Baseline scenario seems reasonable until FY2 slack is examined, i.e., $8M may be too little slack for the ER/WM program.

Scenario 1A offers greater slack ($14M) for FY2 than the Baseline ($8M). Scenario 1B offers twice the slack for FY1 ($30M) than the Baseline ($14M). There appears minimal difference in risk reduction between the Baseline and Scenarios 1A and 1B.

Although both the Worst Case scenarios look bad, the benefit of some slack in FY1 and FY2 may offer some hope to the ER/WM manager.

Table VIII

Optimal project selection is made based upon the evaluation results. The Baseline and Scenarios 1A virtually equivalent. Scenario 1B offers slack (read "insurance") in FY1 but a gamble for slack in FY2. Scenarios 2A and 2B are to be avoided. The worst case scenarios offer fiscal challenges to the decision-maker, but, like Scenarios 1A and 1B, there is some slack present that could be judiciously managed. As stated earlier, there are other management challenges not included in the optimal project selection approach.

CONCLUSIONS

A proven approach to identify projects combinations that minimize total LCC and meet annual budget constraints, risk reduction requirements, and multiple project combinations has been presented. Scenarios based on annual funding levels, desired relative risk reduction, and project cost factors have been examined. Optimal projects to be selected have been evaluated and recommended.

ACKNOWLEDGMENTS

The mathematical optimization approach for project selection was developed for the Oak Ridge National Laboratory (ORNL) Environmental Restoration Program Characterization and Remedial Decisions Office. The approach supports ER/WM, D&D, and S&M project identification, evaluation, and selection.

Foster Wheeler Environmental Corporation
Oak Ridge, Tennessee

ABSTRACT

This paper identifies the many opportunities presented in the planning and initial implementation of a large Environmental Restoration and Waste Management (ERWM) task order contract. The U.S. Department of Energy-Oak Ridge Operations (DOE-ORO) ERWM Remedial Design Contract with Foster Wheeler Environmental Corporation is used as a model for exploring these topics. The program has been highly successful and has obtained from DOE outstanding marks for achieving quality, responsiveness, timeliness, and subcontracting goals. Potential traps are identified in this paper so that they can be recognized and avoided or mitigated. Teaming and subcontracting are also addressed.

INTRODUCTION

Program management for a large Environmental Restoration and Waste Management (ERWM) task order contract is both a skill and an art. Unlike project management, program management deals with global and political issues, with both client and home organizations, as well as with day-to-day operations. Program management requires up-front planning and nurturing, for no contract matures successfully by itself. This paper identifies the many opportunities presented in the planning and initial implementation of the contract. Potential traps are identified so that they can be recognized and avoided or mitigated. Teaming and subcontracting are also addressed. The authors rely on years of program management experience to explore such questions as the following: Can you have an integrated team? What needs to be done before you sign your contract? Do you know who your client(s) is(are)? Have you incorporated the relevant, especially any new, procurement strategies?

The U.S. Department of Energy-Oak Ridge Operations (DOE-ORO) ERWM Remedial Design Contract with Foster Wheeler Environmental Corporation is

used as a model for exploring these topics. This ERWM Programwhich focuses on the Oak Ridge National Laboratory, the Y-12 Weapons Plant, and the K-25 Site (formerly the Oak Ridge Gaseous Diffusion Plant) in Oak Ridge, Tennessee; the Paducah Gaseous Diffusion Plant in Paducah, Kentucky; and the Portsmouth Gaseous Diffusion Plant in Portsmouth, Ohiois in its fifth year with over 225 task orders. The program has been highly successful and has obtained from DOE outstanding marks for achieving quality, responsiveness, timeliness, and subcontracting goals.
Planning is a term that is overused when discussing management philosophies. However, strong, competent initial planning has proven critical to the success of this large ERWM task order contract. Most companies begin planning for such large contracts well before they are published in the Commerce Business Daily. Marketing groups develop teams, alliances and strategies to win these contracts. This effort may cover a period of several months and incur costs into the hundreds of thousands of dollars. As the proposal becomes formulated, it sets the stage for the operations and management of the contract. This effort cannot be done in a vacuum by the marketing groups. It is imperative that the operations managers, especially the ones who are designated in the proposal as key staff, play an active part in the formulation of the teams, alliances and strategies.

TEAM STRUCTURE

The structure of the team is the first aspect to be developed. Questions that must be asked include the following: Can your company show strong expertise to cover all aspects of the Request for Proposal (RFP)? Can your company provide adequate resources to support the depth of the contract proposed? Does the RFP outline subcontracting goals or targets for small businesses (SBs) and small disadvantaged businesses (SDBs)? Does your company have the key resumes required to sell the team? After answering these questions honestly, additional issues need to be considered: If you are putting together a team, who should be on it and how will it be structured? Any team members should be chosen based on specific expertise that they bring to the project. Homework that should be done on these potential team members, whether in-house or subcontractor, includes ensuring that they are in good standing with your potential client. If more than one large company is to be part of this team, it is very important that the two companies complement each other. It is also important that SB and SDB firms complement the prime contractor wherever possible. Track records of working with these companies should be considered. Remember that you may be stuck with someone with whom you do not want to work over the long haul. Like a marriage, these relationships often can be difficult to dissolve.

Integrated Team Structure

After selecting your teaming partners or subcontractors, you must choose one of the two main organizational structures: a strong prime contractor with separate subcontractors or a strong prime with an integrated team of subcontractors. If the nature of the work under the contract will allow you as the prime to discretely subcontract pieces of work, a strong prime with separate subcontractors would be the best approach. If discrete packages cannot be broken out, an integrated team approach is best as an organizational format.

An integrated team consists of a prime contractor whose responsibility is to manage, control, and provide technical expertise and other support to the program. Under the DOE-ORO ERWM Remedial Design Contract, Foster

Wheeler Environmental is the prime contractor with staff in the following key positions: Program Director, Deputy Program Director, Operations Manager, Engineering Manager, Program Controls Manager, Quality Assurance Manager, and Health and Safety Manager. This structure enables the prime to maintain control and provides the client with one entity with which to work. Senior positions such as project managers, lead engineers, and lead scientists are filled by the most competent individuals regardless of company affiliation.

To help assure that your integrated team will function smoothly, it is ideal to have the team collocated under one roof. Foster Wheeler Environmental's ERWM Contract has six contractors and subcontractors under one roof. It seems that by their nature, engineers, scientists, technicians, etc., are task oriented. It has been Foster Wheeler Environmental's experience that once individuals are assigned to a particular task/project and are collocated to that project, they become project team members foremost and their company affiliation becomes secondary. Integration in that manner has been achieved rather seamlessly. The organizational challenges come not at the team member level but at the supervisory level, especially if there are supervisors at the same level, representing different companies. Supervisors will tend to place billability interests for their company employees above the interest of other teaming companies. This tendency must be monitored and managed by the prime contractor's senior management. The key to managing this situation is to have up-front agreements with written guidelines for all to follow. On the ERWM contract one subcontractor that does not have its own local office occupies offices under this roof that have been set aside for its corporate functions. Other than this, it is virtually impossible to tell for which company individual staff members work.

Integrated Team Personnel

As these teams are assembled, another major opportunity arisesthe selection of key individuals. The key members of the organization must be able to work and to live together. The key staff must be chosen based not just on their technical and managerial expertise and their abilities to sell the team, but also on their personal traits. Can they work together over long hours, days and weeks in the same cramped quarters? Can they leave their egos at the door for the benefit of the program? Can they be on long-term assignment if required? Technical and managerial superstars may not be ideal team members.

As the prime contractor, an important responsibility is your concurrence concerning key individuals selected from your subcontractors. Remember that they must operate as an integral part of your team. If you have an integrated team, it is also important that you have a subcontractor manager/supervisor located with you on whom you can rely to support you and get things done within his/her own company.

If your team is composed of SB and/or SDB subcontractors, the following considerations must also be taken into account: Can the SB/SDB supply the staff required without hiring new personnel? Is the SB/SDB a viable firm or just a body shop? What is the SB's/SDB's professional reputation? What degree of commitment has the owner/president given you? As the prime contractor, you may have to establish goals for SB/SDB participation. As with your own staff and the staff of your large subcontractors, it is important that you concur with the individuals offered by your SBs/SDBs to support your contract. In these days of tight and dwindling budgets,

it is very important that everyone on your team carries his/her own weight.

Once your program has started and you have selected your initial cadre of staff, a likely scenario is for your client to bring you additional work that is going to increase your staff by over 50%. What do you do? If you are unsure that this upsizing is permanent, you may want your subcontractors to supply the required staff. Whether or not the additional staff comes internally or from your subcontractors, it is very important that you maintain control over your team. Whenever possible, concur with all new hires or transfers into your program. Remember that many of the individuals offered to you may be offered because their managers view this as a viable way to get rid of performance problems. You must be careful whom you accept.

CLIENT INTERFACE

A crucial task as you develop your proposal is to make sure that you know who your client or clients really are. Foster Wheeler Environmental's ERWM Contract, for example, was held by the DOE-ORO Project Management Division of DOE Construction and Engineering. DOE's Office of Environmental Restoration and Waste Management determines the ERWM work to be done and controls the budgets to implement the work. The Maintenance and Operations Contractor, Lockheed Martin Energy Systems, oversees all work done on the DOE-ORO reservations. Energy Systems transferred funding from its accounts to the DOE Project Management division so that Foster Wheeler Environmental's DOE Contracting Officer's Representative had the funding in place to release work to the Foster Wheeler Environmental team. Although the contract was with one entity, several groups and organizations played major roles in the day-to-day operation of the program.

Contract Negotiations

After the notice of intent is received, you will begin contract negotiations with your new client. You must know to what you are entitled and to what the client is entitled. If this is a government contract, use the Federal Acquisition Regulations (FARs) as the basis for your negotiations. The FARs protect both the government and the contractor. If your preplanning is adequate, you will have in hand written agreements with your subcontractors. These good faith agreements will need to be modified as your prime contract is finalized, but they give you the necessary latitude in negotiations with the client. In addition, new procurement strategies that are being popularized must be evaluated for relevance, including the cost plus incentive fee and fixed price strategies. Due to Cabinet-level interest in procurement reform, you must take an aggressive approach to these new procurement scenarios.

Client Communication

During the initial months of your program, it is imperative that frequent communications be held with your client(s), even on a very informal basis. One of your primary goals is to support and to be responsive to your client in order to ensure continuing and, hopefully, new work. One way to improve communication is to become very active in the community. Not only does that provide for excellent public relations, but it also provides access to information that is vital to your existence, such as what your competitors are doing and how are you being perceived in the community and by the client. This is where you will first hear warning signals of any problems with your team. Caution is merited because

perceived problems can have effects that are just as real as the effects of real problems and must be dealt with immediately.

Particularly as your program starts to produce deliverables, it is important that quality and responsiveness go hand in hand. Initially your reputation is very fragile or nonexistent. What your team does in the first several months will set the tone for the next several years. Adequate preplanning and key staff involvement will establish your reputation with the client as a team that operates in a responsive mode, rather than in a reactive mode. It is virtually impossible to change initial impressions. In fact, your contract may not last long enough to change those impressions.

One common mistake made by contractors hired as "experts in their field" is to place too much emphasis on their internal ability to determine what the client needs for any given project. More often than not, the client has a good grasp of the problem at hand and the required solution. The contractor's expertise is required to effect that solution within the allocated resources (budget, schedule, etc.). Today's client is usually very well informed and can be expected to provide resource constraints. The operational phase of a program can be expected to be a continuous process of tailoring work and deliverables to effect the predetermined solution within the resource constraints while at the same time managing no compromise in quality.

CONCLUSION

In summary, the success of an ERWM task order contract is directly related to the preplanning and initial operational involvement of the key individuals on the team. These key individuals should be involved in all phases of structuring the team. Senior staff involvement and their review of all deliverables are crucial to ensuring the quality, and providing adequate control, of the product delivered to the client. Frequent communication, both with the client and with others in the community, is critical to the survival of your contract. Planning to incorporate these recommendations, drawn from the experience and success of the DOE-ORO ERWM Program, into your program will be a first step towards assuring that your contract meets with similar success.

ABSTRACT
An Accelerated Site Action Project (ASAP) is being developed at the Rocky Flats Environmental Technology Site to address the fundamental problem at Rocky Flats, that the current nuclear material stabilization and environmental cleanup activities are too slow, too uncertain in outcome, and too costly. A draft Phase I ASAP plan was developed to shatter certain cost and schedule paradigms and described a single, feasible alternative among many for achieving the most rapid and economical stabilization of the Site. This feasible alternative provided for interim closure of the Site and would make the Site nearly risk free for onsite and offsite populations and enable alternative uses of most of the Site's 6500 acres. ASAP Phase II, currently in progress, builds on the Phase I work to develop and evaluate additional alternatives based on technical and stakeholder input. The ASAP represents a step change in the mindset and management approach to achieve the vision of the future for the Site.

INTRODUCTION

An Accelerated Site Action Project (ASAP) is being developed at the Rocky Flats Environmental Technology Site (Rocky Flats or "the Site"), to radically decrease the Site risks and increase land availability for potential other uses as compared to the Site's previous course of action. A draft plan document dated October 9, 1995 was prepared as Phase I in the process to accelerate the closure of the Site. The document described a single, feasible alternative among many to achieve the most rapid and economical stabilization of the Site. This feasible alternative provided for interim closure of the Site and would make the Site nearly risk free for onsite and offsite populations and enable alternative uses of most of the Site's 6500 acres.

The ASAP Phase I feasible alternative began to bracket what is possible at Rocky Flats before the next phase of planning began. This initial feasibility was necessary to shatter certain cost and schedule paradigms at the Site that, if left unchecked, could have prevented or significantly lengthened the eventual cleanup. ASAP Phase II, currently in progress, builds on the Phase I work to develop and evaluate additional alternatives based on technical and stakeholder input while continuing to seek the optimum mix of solutions to create an integrated project for Site closure.

PROBLEM DEFINITION AND PROJECT STRATEGY

The fundamental problem at Rocky Flats is that the current nuclear material stabilization and environmental cleanup activities are too slow, too uncertain in outcome, and too costly. The Department of Energy (DOE) Plutonium Vulnerability Study identified the Site as having the highest-risk plutonium facilities in the nation, and these facilities are located within 50 miles of the Denver metropolitan area's 2 million people. Compounding this problem is that even with past high funding levels, the Site has had difficulty making meaningful progress toward cleanup. In July 1995 a new contractor operating under a new performance-based contract took over operations at Rocky Flats. Now just as the Site is poised to make progress, the budget is falling to levels that allow for little expenditure on mortgage and risk reduction in the face of high nuclear facilities baseline safety costs. The projected outyear funding profile cannot address DOE's commitments for plutonium and waste treatment and stabilization, or environmental cleanup.

At the heart of ASAP is a shift in management focus to achieve tangible and meaningful results for the funds expended. The Site's new management strategy is based on the following elements:

To establish a unifying vision of an interim state for the Site that will simultaneously reduce risks and budget outlays and that can be achieved in the professional lifetime of the people working at the Site

To continue to seek ways to achieve early removal of plutonium and waste from the Site

To enable DOE, the Contractor, and the workforce to bring the Site to a stable, interim closure state at the earliest possible date, with additional closure actions accomplished after this date at a lower overhead rate and higher efficiency than the current Site work structure allows

To challenge current strategies for environmental restoration, waste management, and plutonium stabilization and storage to achieve risk reduction and land-use value for much lower costs and with faster schedules

To recognize that the march of time represents the greatest cost at the Site. The Site has spent over $700 million per year in the recent past with little highly valued progress. The annual baseline for keeping the plutonium facilities safe and stable is about $400 million. Therefore, every month of inactivity or indecision on a path forward is costing taxpayers more than $30 million. This lost opportunity cost, which was simply accepted in the past, must be factored into all future decisions.

To aggressively challenge existing baseline activities and costs, including both DOE and environmental regulatory burdens

To view and manage Site activities as projects to better align DOE, the Contractor, and the employees, and to increase accountability for scope, schedule, and cost

THE INITIAL FEASIBLE ALTERNATIVE

The ASAP Phase I was intended to develop an integrated alternative to test the hypothesis that with unrestricted funding the Site could be substantially closed in eight years for around $5 billion. The key features of the Phase I feasible alternative, Plutonium and Waste, Land Use, and cost and Schedules, are described below.

Plutonium and Waste

The plutonium and containerized transuranic waste will be in safe, interim storage awaiting the earliest possible shipment from the Site.

Land Use

The following land uses would be enabled by this alternative:

The outer 5,000 acres of the Buffer Zone would support unrestricted use, including open space.

An inner 1,000 acres of the Buffer Zone would meet standards for use as restricted open space.

Of the remaining 500 acres associated with the industrial area or landfills, 300 acres would be cleaned up to allow future industrial or commercial development, if desired. The 200 most contaminated acres, including the current plutonium processing area, would be safely closed with a long-term barrier cap with long-term monitoring to ensure cap performance and integrity. A groundwater diversion system and passive reactive barriers would be installed to protect offsite ground and surface waters.

Bulk low-level cleanup and demolition waste would be placed under the cap.

Most buildings, except those deemed by local stakeholders to have a future economic value, would be demolished or covered by the cap.

The feasible alternative would not compromise the ability to clean up the entire Site in the future.

Cost and Schedule

As shown in Fig. 1 this plan can be accomplished for about $6 billion, compared with the current Baseline Environmental Management Report (BEMR) estimate of more than $22.5 billion. However, it requires larger annual budgets through the year 2002 than are currently anticipated. Alternatively, preliminary estimates indicate that the work represented by this feasible alternative could be accomplished by about 2015 for about $10 billion with a slightly more aggressive funding scenario than is currently planned. Figure 2 depicts several different funding scenarios being explored. Funding variations greatly impact the schedule. The critical path items are plutonium processing (stabilization), the final decommissioning of Building 707 and its support buildings, and the placement of the barrier cap over the Protected Area.

Fig. 1

Fig. 2

By the end of 2003 (or 2015), the Site population could drop to less than 300 from the current figure of more than 5,000. The annual operating cost could be less than $40 million, down from more than $600 million currently. The remaining facilities would be configured so that the final closure cost, and the demolition of the interim plutonium and waste storage facilities, would cost less than $200 million. In ASAP Phase II the technical logic, schedule, and costs for several different alternatives are being studied. Preliminary analysis indicates that bringing the 1,500 acres that are currently not designated as residential-capable to that standard would cost an additional $10 billion and take at least an additional decade to complete.

There will also be additional costs, yet to be estimated, associated with the final disposition (shipment) of stored plutonium and waste. These outyear (beyond 2003) costs could be several hundred million dollars depending on ultimate disposal costs and criteria.

KEY ISSUES TO BE RESOLVED

ASAP Phase I has elicited extensive interest among DOE and non-DOE stakeholders. Comments have been provided at meetings with DOE Headquarters, regulators, and citizens' groups. A number of issues have been identified, many of which are currently being addressed in the ASAP Phase II work. Some of these key issues to be resolved include the following:

Considering the logical array of alternatives that address most stakeholder concerns, and determining aggregate stakeholder priorities.

Evaluating methods to expedite plutonium and transuranic waste shipment from the Site.

Considering onsite disposal of low-level and low-level mixed wastes.

Achieving a fundable alternative. It is not clear that the current alternative, even with its dramatic cost and schedule savings, will be funded in preference to a project of longer duration.

Achieving consensus on the strategies for plutonium and waste storage and facility decommissioning.

Determining the level of plutonium and waste processing, consistent with national interests, that should be done before the materials are placed in potentially long-term storage.

Establishing a prudent planning horizon for the possibility of long-term storage of plutonium and waste.

Determining the optimum remediation or stabilization strategy for soil and groundwater to identify the cost-benefit tradeoffs.

Determining the appropriate authorization basis and safety controls necessary to balance safety and efficiency in proceeding with plutonium, waste, and decommissioning activities.

STAKEHOLDER INVOLVEMENT AND PROJECT PRECURSOR EVENTS

The ASAP concept, which had its formal beginning on August 1, 1995, had many important precursor events that contributed to the idea in many ways. The ASAP incorporates many of the features of previous work at Rocky Flats and represents an integrated compendium of the major issues and agreements needed to achieve acceptable closure of the Site eventually.

In 1993, the Site mission changed from nuclear weapons production to cleanup.

In 1994, DOE responded to the mission change by issuing a request for proposals to procure a new performance-based integrating management contractor for the Site to carry out the new mission.

In early 1994, the Site began negotiating a new cleanup agreement with the US Environmental Protection Agency (EPA) and the State of Colorado to reflect the fact that the previous agreement, the Interagency Agreement (IAG), did not reflect the mission change.

In 1994, the Defense Nuclear Facilities Safety Board issued two important recommendations (94-1 and 94-3) dealing with plutonium stabilization and storage at the Site.

In 1994, with input from various stakeholder groups, a Strategic Plan was issued that focused on nuclear material stabilization, waste management, and environmental restoration.

In early 1995, several public meetings were held regarding the then-proposed solar ponds remediation plan, which involved construction of a Corrective Action Management Unit (CAMU) waste facility at the solar ponds.

In early 1995, several important interactions with regulators and stakeholders were held to review the path-forward options for the Site. One of the most important of these was the March 4, 1995 summit. At the summit there was a consensus to place a higher priority on risk reduction by stabilizing plutonium than on environmental remediation. Onsite disposal was also discussed by many attendees as a way to cut costs to enable more risk reduction. Another important event was the April 1995 regulatory summit, at which similar conclusions were reached.

In early 1995, Kaiser-Hill was selected as the new contractor to carry out the Site mission. Kaiser-Hill assumed responsibility for the Site on July 1, 1995.

In June 1995, the Future Site Use Working Group issued a consensus opinion that the Buffer Zone should generally be maintained as open space and that the Industrial Area should be for industrial use. No onsite residential use was anticipated.

A series of meetings were held in the summer of 1995 with the state of Colorado, regulators, and many stakeholders regarding the alternatives for plutonium storage at the Site, including the possibility of constructing a new vault. The possibility of long-term storage of plutonium at the Site was addressed.

Information related to the ASAP Phase I plan was shared with a broad cross-section of stakeholders in many different private and public forums. Participants' key areas of concern align very well with the alternatives being analyzed in the ASAP Phase II. In general the stakeholders require that:

Everything is being done to remove the plutonium and waste from the Site at the earliest possible time.

The plutonium is stored in the safest possible configuration.

The implications and decisions are clearly outlined and openly made.

There will be an adequate stakeholder involvement program.

The tradeoffs among cost, schedule, and final cleanup criteria have been properly balanced.

Future land use options, including both dedicated open space and economic conversion, have been accounted for and enabled.

TECHNICAL SUMMARY

The ASAP Phase I document presented the feasibility analysis that was performed to determine whether an accelerated closure of Rocky Flats is possible. The analysis was structured into six major tasks: 1) Plutonium Consolidation and Stabilization, 2) Waste Management, 3) Facility Decommissioning, 4) Interim Closure, 5) Site Infrastructure, and 6) Implementation. Just as the ASAP is a logical integration of many precursor events, so a number of the technical tasks discussed below are continuations of currently planned activities, such as major plutonium stabilization.

Plutonium Consolidation and Stabilization

Highly enriched uranyl nitrate (HEUN) solutions would be bottled and shipped off the site.

Plutonium (Pu) metal and oxides will be packaged to meet DOE-STD-3013-94 in double, welded stainless-steel containers.

Pu solid residues will be processed to meet safe, long-term storage criteria. Where possible, residues will only be repackaged and managed as Transuranic (TRU) waste.

Pu liquid residues will be moved from their current containers and stabilized for long-term storage.

The Pu and residues to be managed as Special Nuclear Material (SNM) will be stored in a newly constructed storage facility (vault) after consolidation for staging in Building 371.

Pu and residue processing will be conducted primarily in Building 707.

Pu pits will be packaged in approved shipping containers.

The estimated cost for this activity is $800 million, of which about $150 to $200 million is for a new passive plutonium vault. The critical path schedule for both residue and Pu stabilization is expected to continue through 2001. Continued planning and analysis are needed to shorten the required schedule. The post 2003 operating costs are estimated to be $20 million.

Plutonium consolidation and stabilization issues that remain to be resolved include the following:

The onsite Pu storage location (new vault, Building 371, or other alternative)

The implementation methods to meet the criteria for safe, long-term storage of residues

Schedule compression, including technology choices for residue stabilization

The quantity and types of materials to be shipped to Waste Isolation Pilot Plant (WIPP) or other locations

Waste Management

A new hardened TRU waste storage facility would be constructed. This facility may store up to 3,000 kgs of plutonium within the waste matrix of approximately 20,000 drums.

Bulk Low-Level Waste (LLW), Low-Level Mixed Waste (LLMW), and remediation and decommissioning waste would be disposed of in an onsite disposal facility located in the Industrial Area (probably in the Protected Area). Some waste may be shipped offsite and most waste will be disposed in such a way that will facilitate future offsite disposal if it becomes cost-effective.

Waste treatment would be accomplished only as necessary, regardless of regulatory imperatives to ensure safety for long-term storage or disposal.

Waste would be stored temporarily in existing buildings outside the Protected Area while long-term storage capacity is constructed.

All landfills and waste facilities would be closed by the end of 2003. The cost for this alternative is about $550 million with about $100 million required for the new hardened TRU waste storage facility. This new facility would be expected to be operational in the year 2000. Long-term Operations and Maintenance costs after 2003 are estimated to be about $3 million per year.

Some waste management issues for further consideration include:

Onsite as opposed to offsite storage/disposal of all waste types

Treatment criteria for long-term storage or disposal for all waste types and regulatory alignment with criteria

Lower-cost options for storing TRU waste other than in a hardened facility

Facility Decommissioning

Most buildings of the 425 facilities at the Site are not radiologically contaminated and will be dismantled except for those deemed economically valuable (e.g., National Conversion Pilot Project).

The major plutonium buildings and Building 881 will be partially dismantled with the lower-level portions entombed. This would involve removing significant contamination and then filling the basement areas with demolition debris, entombing the basement with material such as impervious clay slurry, and covering it with a landfill cap.

Many of the plutonium buildings must remain operational for several years in order to consolidate and stabilize plutonium and waste. The approach will therefore be to remove administrative and ancillary buildings first in order to clear space and to level the workload. Major plutonium facilities, such as Buildings 371 and 707, will be the last to be completely decommissioned.

Current planning indicates most facilities can be decommissioned by the end of FY02 at a total cost ranging from $1.5 billion to $2 billion.

The remaining facility decommissioning issues to be addressed include:

Further refinement of building sequencing and further development of a detailed logic, safety authorization basis, and cost estimates for all buildings

Ensuring onsite and offsite safety during decommissioning

Determining the cost-benefit tradeoffs regarding the degree of contamination to be left with the building rubble or placed in a disposal cell

Defining the regulatory process for decommissioning

Determining the workforce composition and skill mix

Interim Closure

The potential exists for unrestricted use (from a contamination perspective) of 5,000 of the Site's 6,500 acres. An additional 1,000 acres would be suitable for use as unoccupied open space, and 300 acres would be suitable for industrial reuse. The remaining 200 acres would be placed under a landfill cap, which includes the current landfill (OU7), the 800 old uranium processing area, and the plutonium processing area (Protected Area).

Groundwater and surface water would be protected to national standards for water leaving the Site by upgradient diversion and downgradient passive reactive barriers.

About 40 of the 173 individual hazardous substance sites (IHSSs) that are high or medium ranked from a risk perspective would be remediated. The remaining 133 Sites have low enough contamination and risk levels that they can be cleared without further action.

The cost for this activity is about $400 million with about half the cost for IHSS remediation and half the cost for landfill caps and water management. Long-term monitoring will cost about $3 million per year after 2003. The final cap is on the critical path schedule, will take about two years to complete, and extend about six months after the last building (Building 707) has been fully decommissioned.

Interim closure Issues to be resolved include:

Acceptability of the land use restrictions of the feasible alternative and the standards that apply to those land-use criteria. Additionally, there are many who favor a 'greenfield' site cleanup that would cost another $10 billion or so to achieve.

The methods to be used for surface and groundwater control (e.g., reactive barriers) and water quality standards;

Integration with the issues to be resolved for waste management and facility decommissioning regarding onsite disposal of waste and decommissioning materials;

The design of the landfill cap to ensure long-term integrity; and

The impacts of excavating and placing the more than 2,000,000 cubic meters of material needed for the landfill cap.

Site Infrastructure

The feasible alternative requires a site infrastructure to support the remaining plutonium and waste storage facilities and about 300 total staff.

Relocate most infrastructure offsite. This would be accomplished by using public or commercial utilities to provide utilities services directly to buildings. Sewage would be managed onsite in a small lagoon or septic system.

Most emergency and health services would be contracted for offsite, except for the nuclear material protective force.

All office and support facilities would be located offsite to reduce the demand for expensive onsite infrastructure.

Cost of development of the infrastructure for commercial service to the Site and conversion of other site infrastructure to the new configuration is estimated at about $70 million. The post 2003 annual operating costs are estimated to be $12 million. There are no critical path schedule items in this conversion.

Site infrastructure issues to be resolved include:

Verifying the desirability of this fairly radical reconfiguration and the ability and willingness of the commercial and public utilities and emergency services to serve the Site

Timing for implementation (sooner or later) of individual components

Implementation

Regulatory Alignment - The regulatory structure and process needs must be aligned to accomplish the Site closure mission. Currently, the Site is regulated as an operating production facility, which creates regulatory road blocks to an expedited cleanup that would not exist at a typical Superfund site.

Workforce Restructuring - DOE and the contractor will need to coordinate realignment of required work, skills mix, and retraining to provide the most productive use of the workforce. A human resource plan must consider the inevitable downsizing of the workforce.

Stakeholder and Political Alignment - A scope, schedule, and funding package needs to be developed that meets the consensus needs of both the funders (i.e., Congress, DOE/HQ) and the beneficiaries (e.g., Colorado and the nation at large) of the project.

Site Productivity - The Contractor and DOE need to continue to evaluate procedural and motivational methods to increase the Site's productivity and cost, scope, and schedule accountability.

Projectizing - The implementation plan calls for projectizing the Site, as indicated by the word "project" in the ASAP. Projectizing has some significant structural and process implications for DOE, the Contract, and the Contractor.

NEXT STEPS

This paper primarily summarizes the Phase I of ASAP. Adjustments in the FY96 operating activities are currently being made to accommodate the most basic features of the strategy. Phase II of ASAP, to be accomplished by early February 1996, will develop and evaluate alternatives to address the key policy choices and issues described at the beginning of this paper. This process will also look at outyear (beyond 2003) alternatives to ensure that the final Site strategy is represented and will include rigorous stakeholder and regulator involvement. It is expected that ASAP Phase II will facilitate mutual understanding of the key issues and allow DOE to arrive at a best solution during Phase III that balances competing needs and concerns.

Once the overall integrated ASAP plan has been developed and necessary consensus reached, key decisions and issues will be segregated to determine decision pathways and time frames. A plan will also be developed for more detailed stakeholder involvement in the alternatives in those second-tier decisions.

CONCLUSION

The Accelerated Site Action Project represents a step change in the mindset and management approach for driving the Rocky Flats Environmental Technology Site to closure (Fig. 3). It radically alters the vision of the future for the Site, and moves the reality of Site closure into the personal career time frame for most of the Site workforce and local stakeholders. Most important of all it shatters the cost and schedule paradigms for closure of DOE nuclear sites that say closure must take many decades, and demand budgets that the Congress may never appropriate. ASAP presents the argument that the closure can be done quickly, safely, economically, and in a manner that greatly reduces the risks posed to the Site workforce and surrounding communities. ASAP will be neither easy to

implement nor without controversy, but it offers a feasible solution to achieve the closure of the Rocky Flats Environmental Technology Site and thus conclude a major chapter in the nation's nuclear weapons legacy.

35-5
HOW TO ACCELERATE THE FERNALD REMEDIATION

Michael K. Yates
Fernald Environmental Restoration Management Corporation

Johnny Reising
Fernald Area Office
U. S. Department of Energy

ABSTRACT

The Fernald Environmental Management Project is unique among Department of Energy (DOE) sites by virtue of successful efforts by the Fernald Environmental Restoration Management Corporation (FERMCO) and DOE-Fernald Area Office (FN) in securing a stakeholder-assisted final site closure vision and all Record of Decisions (ROD) or Interim RODs required to set the stage for final remediation. DOE and FERMCO have agreed in principle on a Ten Year Plan which accelerates all activities to remediate the site in approximately half the target schedule.

This paper presents the path that led to the current Ten Year Plan, the key elements of the plan, and the implementation strategies.

PATH TO THE TEN YEAR PLAN

The Fernald site is divided into five operable units (OUs) pursuant to the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) process. RODs are in hand for all five OUs. These RODs summarize the results of the Remedial Investigation/Feasibility Study (RI/FS) reports and detail the selected remedial actions. The five OUs and the primary remedies are:

OU1 - Waste Pits: excavation, drying and shipment to an off-site disposal facility.

OU2 - Other Waste Units: excavation and disposal in an on-site facility.

OU3 - Former Production Area: Dismantlement of structures and disposal on and off-site.

OU4 - Silos: Vitrification of the waste and disposal at the Nevada Test Site.

OU5 - Environmental Media: excavation of soil and disposal in an on-site facility; pump and treat groundwater.

With the remedies chosen and the RODs in place Fernald is in a position where it has the technical scope, schedule and budget defined for each Operable Unit. The first step in the development of a site remediation plan was the integration of the schedules of the five Operable Units into one comprehensive overall plan, with the duration of the work for the five OUs optimized and with a defined critical path. Once the schedule was defined, the scope and costs were reviewed to put them all on a consistent technical basis and to identify efficiencies which were realized by the integration of the OUs.

Initially, two unconstrained funding scenarios were developed: a seven-year plan and a ten-year plan. The seven-year plan contained many of the same assumptions as the ten-year plan, however, it assumed that some of the DOE Orders, requirements and restraints were removed. Funding for these plans peaked at $351 million and at $331 million for the seven and

ten-year plans, respectively (unescalated). The site at the end of either of these plans was completely remediated except for the continuing pump-and-treat operation needed to complete remediation of the aquifer. Nothing was left on site except for the disposal facility, the wells and the treatment facility.

These plans were provided to DOE Headquarters and to stakeholder groups. When challenged by DOE Headquarters to determine how quickly the site could be remediated if the funding from FY97 on was set at $276 million in FY96 dollars and the seven-year assumptions were used, the current Ten Year Plan ($276 Million Case) was developed.

At the time the Ten Year Plan was completed, Fernald was projecting a 25-year remediation schedule and a cost from FY96 to completion of $5.8 billion (escalated), in accordance with the then-current target budgets. The cost estimate for the Ten Year Plan is $3.4 billion. Its shortened schedule and substantial cost savings made it an attractive proposal. In addition, Fernald will be the first DOE site of major consequence to be totally brought to clean closure. Successful implementation of the Ten Year Plan will set benchmarks and pave the way for similar successes at other major DOE facilities simply by showing it can be done if the right approach is used.

Key to acceptance of the Ten Year Plan were the substantial cost savings, the acceptance of the plan by the regulators and public stakeholders and their active support of the plan with DOE and Congress. The regulators involved are the US and Ohio EPAs. Public stakeholders include the Fernald Citizens Task Force and the citizens' group Fernald Residents for Environmental Safety and Health (FRESH). Ohio Congressmen and Senators also supported the adoption of the Ten Year Plan.

Once the Plan was accepted by DOE-HQ, Fernald was requested to undertake detailed FY96 and FY97 planning to support it. The plans for FY98 to FY05 were also requested, at a planning package level of detail. These plans will be completed in February 1996 and will provide the baseline for Fernald's final remediation .

KEY ELEMENTS OF THE TEN YEAR PLAN

Figure 1 illustrates the Fernald site in the years 1995 through 2005. The progress of decontamination and dismantlement (D&D) of site facilities and the construction of the on-site disposal facility can be clearly seen. In the year 2005, all that will remain at Fernald is the disposal facility and a groundwater pump-and-treat system. The final land use has not been determined, except that residential or farming use will not be permitted. The final land use will be determined by DOE and the stakeholders with additional public input.

Fig. 1

Figure 2 depicts the overall schedule and indicates the critical path activities. Once the remaining nuclear materials are removed and the safe shutdown activities (removal of in-process material from lines, tanks and equipment) are completed, the critical path consists of D&D of the buildings, excavating the soil and underground foundations, piping, and utilities and building the on-site disposal facility.

Fig. 2

Figures 3 through 10 provide the key indicators or performance measures for the remediation of Fernald. They are:

Fig. 10

TEN YEAR PLAN IMPLEMENTATION STRATEGY

Several changes have been made or are being implemented to streamline project operations, procedures or requirements to allow the Ten Year Plan to proceed within its schedule and budget constraints. They include projectization of the work, streamlining the DOE requirements which apply to the work, the use of innovative ways of working to achieve accelerated results, and the adoption of the performance-based fee approach.

Projectization

The five Operable Units as originally defined included all remediation within their physical boundaries. For example, OU4 included both vitrification of the silo materials and the remediation of the underlying soil. However, now that all RODs are in place, it is more efficient to handle OU4 soils under a Soil Remediation Project and to have this Project manage the soils from the other four OUs as well. The Soil Remediation Project will define the excavation parameters, contract for the excavation, and select the parameters that verify that the soil remaining is below the action levels. They also have the burden of defending these items to the regulators. There are other items within the five OUs that could be more efficiently handled by a single Project as well, such as the D&D of the remediation facilities and off-site shipment of waste to a commercial disposal facility. Therefore, these items were transferred to single Projects after consultation with the regulators. Five Projects were set up, each one containing the primary work in the OU, with the peripheral work transferred to the relevant Project. The five Projects are:

- Waste Pits Remedial Action Project
- Facilities D&D Project
- Fernald Residues Vitrification Plant Project
- Soil Remediation Project
- Aquifer Restoration Project

In addition to the scope movements, the projectization of the OUs was completed by changing their internal organization to a well defined project structure instead of a functional structure, defining various subprojects and naming project managers responsible for the subprojects and projects. In addition, the support groups Cost/Schedule Control, Procurement and Document Control were reorganized and aligned to this project structure.

DOE Requirements

The Fernald site was the first DOE site to have it Standards/Requirements Identification Documents (SRIDs) approved. These SRIDs define the DOE Orders and Requirements that apply to the Fernald Project. After completing the basic document, FERMCO has been active in streamlining these requirements to shorten schedules and reduce costs. Examples of these requirements are the request for waiving the requirement for a Performance Assessment for the on-site disposal facility, by showing equivalence through the CERCLA process, and waiving the requirement for disposal of waste in DOE off-site facilities. Eliminating these two requirements allows the shortening of the schedule and substantially reduces costs. FERMCO is actively pursuing the waiver or reduction of

numerous other requirements, many of them administrative in nature and applying more to an operating facility than a remediation site. The inclusion of standard commercial procurement practices is one of the areas being pursued.

Innovative Ways of Working

Fernald is exploring new ways of working on site that maximizes the use of off-site expertise. Recently Chem-Nuclear Systems Inc. (CNSI) was contracted to stabilize 6,000 gallons of thorium nitrate as a CERCLA removal action on-site. By using an off site subcontractor with experience in the treatment of significant quantities of thorium nitrate, a fully-trained work force and a proven "off-the-shelf" mobile treatment system were brought together as a unit, resulting in a highly successful remedial action. Use of experienced technicians to operate the system expedited training and increased safety. The entire project was completed less than six months after FERMCO contracted with CNSI to perform the work. Project costs were reduced by over 40 percent and the schedule accelerated by one year from the original plan which was based on design, construction, and operation of a treatment system in-house.

The accelerated schedule was possible because FERMCO used CNSI's Nuclear Regulatory Commission (NRC) field license to meet DOE requirements for handling radioactive material. DOE requirements and NRC requirements implemented by CNSI during the project were shown to be equivalent for project management systems; the quality assurance program; environmental, safety and health programs; training; and conduct of operations. Demonstrating that DOE and NRC requirements were equivalent provided the following benefits:

Eliminated review of CNSI engineering, design, quality assurance, procedures, and training programs during readiness assessment. CNSI's experience and attainment of an NRC license demonstrated their ability to conduct the operation.

Use of an "off-the-shelf" mobile treatment system tailored to meet the requirements of thorium nitrate treatment eliminated extensive design documentation and reviews and reduced the planning and design phase by approximately 10 months from the original plan.

Operation and control of the solidification process equipment was solely CNSI's responsibility under their NRC license. The project site was designated an "NRC compound" for processing thorium nitrate. CNSI's license requirements applied in this compound in conjunction with the DOE requirements. Extensive coordination was required to ensure that both DOE and NRC requirements for radiological protection were met.

The FERMCO on-site union personnel worked along side CNSI technicians in the NRC area. It was the first time such joint operations had been conducted at this DOE nuclear facility. To address the union issues, roles and responsibilities of FERMCO and CNSI were established early in the planning process, with support from Industrial Relations and input from the union. These roles were incorporated into the subcontract. Ultimately, the relationship was successful because CNSI made the union workers an integral part of the project team and listened to their suggestions and concerns for safety and the operation. The team produced outstanding productivity and safety records with operations completed without safety incidents and with radiation exposures below expected levels.

Another area of innovation under consideration at Fernald is the privatization of some of the project activities. Two that are being

considered now are the privatization of OU1 and the treatment of mixed-waste residue from production processes. Benefits expected to be derived from these efforts are reduced up-front cash flow and thus funding requirements to the project as the contractors will amortize their capital costs over the term of the work; utilization of off-site expertise in allowing contractors maximum flexibility applying their skills and methods to solve the problem; and lower overall costs due to the conversion of the efforts from cost reimbursable to fixed price/unit rate efforts. Studies are underway to work out the funding, contractual, technical, regulatory and other considerations of privatization. Decisions will be made in the first half of 1996 on whether to pursue the privatization of these two efforts.

Performance-Based Fee

Fernald was the first site to adopt the contract reform principles of performance-based fee contracting. In this concept, as described in detail in Ref. 1. the basic objectives are set for each six month period in alignment with the Ten Year Plan and include hard milestones linked to key deliverables where quality, safe work is required to maintain the schedule and soft objectives set to measure progress on procurement, safety, stakeholder involvement and other measures. By aligning both DOE and FERMCO personnel to the fee plan, a win-win situation is produced. Both DOE and FERMCO benefit if excellent performance is achieved in accordance with the fee plan. The use of this plan will keep the achievement of Ten Year Plan in focus and a high priority for all parties.

CONCLUSION

All of the prerequisites are in place to allow the Fernald site to proceed at an accelerated pace of remediation. The basic elements of the Ten Year Plan are laid out and are being detailed. Performance Measures have been selected to monitor the progress, and changes in project structure, organization, and requirements are being implemented to allow the Ten Year Plan to succeed.

INTEGRATION OF EM ACTIVITIES AT THE INEL A SYSTEMS ENGINEERING APPROACH

O. K. Earle
J. E. Ferguson
J. F. Jaggers
N. C. Williams
Lockheed Idaho Technologies Company

ABSTRACT

This paper describes the status of the Idaho National Engineering Laboratory (INEL) systems engineering approach to integrating Environmental Management (EM) activities. It provides a detailed description of how a team of technical and environmental program experts was assembled to examine integration opportunities and solutions to manage EM programs across the INEL. Using a conventional systems engineering approach, the team selected a preferred path that treats and stabilizes waste and material for disposal, accomplishes maximum volume

reduction of waste and materials for disposal, prepares the appropriate waste and material for shipment to the Waste Isolation Pilot Plant (WIPP) and the deep geologic repository, and minimizes the total cost by doing the work in the near-term rather than deferring it. Further, it details the work that has been accomplished to streamline EM activities at the INEL to meet the Department of Energy (DOE), Lockheed Idaho Technologies Company (LITCO), and stakeholder objectives in managing EM programs. Preliminary results of this integration effort identified savings of approximately seven billion dollars over the life-cycle of the program, when compared with the FY 1995 BEMR submittal. Additionally, this integration effort identified an alternative that moves the waste and materials from Idaho within a time frame acceptable to stakeholders and maintains acceptable risk levels. This activity has received wide acceptance at the INEL and within the State of Idaho, and has captured the attention of DOE-Headquarters and other DOE sites.

Integration activities have continued since the original March 1995 effort. The most recent product is the FY 1996 BEMR submitted to reflect changes to the INEL EM programs. This submittal includes reduced budget targets, except for FY 2001 and 2002, and the recent settlement agreement between the DOE and Governor Batt of Idaho. The accelerated schedules required by the settlement agreement generate a cost curve that spends more money from FY 2002 through 2015 to achieve significant savings over the life cycle of the INEL EM program, while simultaneously fulfilling the intent of the agreements and reducing costs to the targets. (See Fig. 1)

Fig. 1

WHAT IS THE PROBLEM WE ARE SOLVING?

The INEL must treat, dispose, and otherwise manage 405,000 cubic meters of waste, 700 cubic meters of spent nuclear fuel, and other materials in a time of declining budgets and increasing regulatory requirements. This could prevent the INEL from achieving final disposition of wastes in a time frame that is acceptable to stakeholders and from meeting the requirements of the settlement agreement between the DOE and the State of Idaho.

Historical funding mechanisms fostered compartmentalization or "stovepiping" of EM activities. This stovepiping restricted integration and synergism between the activities and impeded efforts to identify cost-efficient, effective solutions to managing EM programs across the INEL.

WHAT IS THE INEL'S SOLUTION TO THE PROBLEM?

In March, 1995 the INEL assembled a team of technical and environmental program experts to examine the problem. Using a conventional systems engineering approach, the team selected a preferred path, the Full Treatment Alternative, that:

- Treats and stabilizes the maximum amount of waste and material for disposal,
- Accomplishes maximum volume reduction of wastes destined for repositories,
- Prepares the appropriate waste and material for shipment to the WIPP and the deep geologic repository, and
- Minimizes total costs by doing work in the near-term rather than deferring it.

The team integrated waste streams and materials with treatment processing, treatment technologies, and facilities. All EM wastes and

materials were considered. The scope of this effort included all waste management, environmental restoration, technology development, facility transition, and infrastructure activities planned for the INEL. For all alternatives considered, risk was maintained within acceptable limits.

HOW DID THE INEL ACHIEVE THE SOLUTION?

Systems engineering, practiced successfully by the Lockheed Martin Corporation, was used. It emphasizes the management of change and the careful control of requirements, decision criteria, and costs. A computer model was developed for this task to allow comparison of alternatives. This combination of systems engineering and technical expertise, as illustrated in Fig. 2, produced an integrated solution.

Fig. 2

The systems engineering staff developed an eight-phased approach to developing the alternative set. The phases consisted of:

1. Requirements Analysis and Data Gathering
2. Functional Analysis
3. Scenario Development
4. Alternatives Development and Evaluation
5. Trade Studies and Systems Analysis
6. Refinement of Alternatives
7. Presentation of Results
8. Alternatives Verification and Post-Workout Activities

Joint DOE and contractor teams initially had difficulty tackling the requirements definition process because systems engineering requirements are somewhat different than requirements as usually defined in the DOE culture. Some resistance persisted through the identification of functions. But once the requirements and functions were displayed by waste stream and each team reviewed other teams work, team members began to accept the process. They quickly recognized the value of increasing their understanding of the interconnectedness, similarities, and differences between EM programs. Additionally, they began to understand that having clear requirements that aligned with work activities facilitated the identification and elimination of non-essential activities and the defense of essential activities. During scenario development it became apparent that the group was convinced of the value of the workout. (See Fig. 3)

Fig. 3

Breaking traditional ways of thinking was especially challenging. Systems engineers used innovative methods to involve team members in creative thinking. Various approaches to instilling paradigm shifts were attempted, with some success, but intervention from executive management finally got things moving. The teams, entrenched in tradition, needed to be encouraged to consider eliminating work and jobs, as well as to discover ways to relax perceived requirements while maintaining acceptable risk levels. As opposed to the former views of cutting costs by slipping schedules, teams began to modify scope and decrease associated costs. This was finally achieved in mid-December, just in time to meet the deadline for the BEMR submittal.

WHAT IS THE PATH FORWARD AT THE INEL?

At the INEL, technical integration across the programs is largely achieved. The INEL will continue to follow the systems engineering approach to managing EM programs. At the present time, the path forward is simply a modification of the original effort, an approach known as the Full Treatment Alternative. This alternative maximizes treatment and

minimizes final waste form volume for shipment to deep geologic repositories. It does not rely on the granting of a No-Migration Determination for WIPP. And finally, it has a far lower cost than traditional approaches to environmental management.

The path forward, as originally defined, continues to undergo improvement. A team is currently refining a defensible requirements and cost baseline. This activity is being accomplished in preparation for the budget submittal in April, 1996. Integrating the systems engineering approach continues to yield increased opportunities to streamline costs and work activities.

WHAT ARE SOME OF THE DIFFERENCES BETWEEN DOE AND AEROSPACE INDUSTRY SYSTEMS ENGINEERING APPROACHES?

All steps of the Systems Engineering Process are applicable to the DOE. Many parts of the process are infused into the DOE EM Culture, as formerly required by DOE Order 4700.X, Project Management System, and currently implied within DOE Order 430.1 Life-Cycle Asset Management. But since managing waste and materials is substantially different from building a rocket or an airplane, adjustments were made to accommodate the unique situation.

A Systems Management Approach, rather than a Systems Engineering Approach should be used. Systems Management combines Systems Engineering, Program Management, and Program Controls in an interactive attempt to instill discipline into managing programs. This approach still follows traditional Systems Engineering, but infuses the cultural aspects of the system with new rigor through the identification of requirements and functions. The cultural aspect of the DOE makes it resistant to the systems approach. Dynamic environments, role confusion and diffusion, and lack of trust between contractors, and between contractors and federal employees makes implementation especially challenging. (See Fig. 4)

Fig. 4

Efforts to "systems engineer" activities at other DOE sites have met with varied acceptance. Conventional approaches require the systems engineer to design modifications to systems based on specifications received from other functional organizations, and to turn back the final product once the acceptance testing is complete. In the DOE system, specifications are often non-existent for the human systems which require engineering. The most successful strategy identified to date is to have the systems engineers work directly with the program staff, both contractors and federal employees, to facilitate them through the process.

Lessons learned indicated that adjustments must be made when tailoring the traditional aerospace approach to the DOE systems. Some of these required adjustments are described below. Systems Engineers should:

Be sensitive to the requirements and concerns of the stakeholders,

Capitalize on DOE and contractor knowledge in the components of the systems process,

Avoid forcing the approaches or terminology onto processes,

Provide operational definitions of terms so that concepts may be accurately translated in the DOE language,

Teach or train individuals on the systems engineering concepts in a way that the benefits are obvious,

Be flexible in applying rigid approaches to a "soft, fuzzy" culture, and

Be prepared for confusion and rejection, before enlightened acceptance is realized.

Applying systems engineering within the DOE is really human systems engineering, and is less well defined than traditional systems engineering. Creating culture change is not an easy task, so continued emphasis should be placed on integrated systems management. The work of the EM Integration activities will become the INEL EM baseline. The challenge is to infuse that baseline into the way of conducting EM business at the INEL. Additionally, many non-EM systems engineering applications are underway at the INEL. These activities will continue as Lockheed systems engineers become more effective in supporting DOE requirements.

ABSTRACT

At the U.S. Department of Energy's Rocky Flats Environmental Technology Site (RFETS), planning efforts are keenly focused on achieving meaningful progress toward cleanup, decommissioning, and site closure. In the face of declining operating budgets, the site's Integrating Contractor, Kaiser-Hill Company, launched the Accelerated Site Action Project (ASAP). The ASAP proposes to accelerate interim closure of the site so that risks to the environment and surrounding communities can be greatly reduced and lands made available for other beneficial uses.

Rocky Mountain Remediation Services (RMRS) is helping to meet the challenges of the ASAP through preparation of the RFETS Life-Cycle Waste Management Plan (LCWMP). The LCWMP produces a waste management strategy for implementation with the lowest life-cycle cost, consistent with the overall direction and guidelines of the ASAP. The plan assures that waste management systems, facilities, and services at RFETS are configured to satisfy operational mission needs in the most cost-effective manner.

The LCWMP adopts a systems approach, utilizing a defined set of end-state requirements (i.e., disposal site waste acceptance criteria) to derive the preferred path for each individual waste stream. The large number of wastes at RFETS are classified into distinct groupings, defined by common source, bulk material, concentration of contaminants, and/or downstream treatment requirements. The LCWMP provides a comprehensive view of all wastes currently in inventory and those projected from future activities such as 1) consolidation, stabilization, and long-term storage of special nuclear material; 2) remediation of environmental releases; and 3) decontamination and decommissioning of former production and infrastructure facilities. The proposed routings for individual waste streams are analyzed within the context of the overall waste management system to ensure that an appropriate combination of existing and new facilities is planned for treatment, storage, and disposal.

At the core of the waste management planning effort is the application of analytical models to 1) simulate the flow of materials through storage,

treatment, and final disposal locations; and 2) estimate the life-cycle costs, for comparison purposes, of numerous different waste management alternatives. The models assist waste planners in rapidly assessing the technical and economic feasibility of different options in a repeated effort to refine and optimize the waste strategy. An ongoing review allows continuous reduction of the main risks and uncertainties associated with the strategy. Allowance is also made to accommodate any newly identified wastes.

Preparation of the LCWMP is allowing an integrated, comprehensive waste management strategy to emerge. With a clearly defined waste strategy, RMRS and the Integrating Contractor can justify and control the site's waste management baseline. Work projects can thus be integrated with other major programs and support operations at RFETS to assure the success of the ASAP.

INTRODUCTION

The Rocky Flats Environmental Technology Site (RFETS), formerly named The Rocky Flats Plant, is part of the U.S. Department of Energy's (DOE) vast nuclear weapons complex. The facility is located on approximately 6,550 acres in northern Jefferson County, about 16 miles northwest of Denver, Colorado. Constructed in 1952, Rocky Flats was in production for almost 40 years, manufacturing nuclear weapon components from materials such as plutonium, uranium, beryllium, and a variety of stainless-steel alloys. When the production mission was officially terminated in 1992 the site entered a period of transition, focusing future efforts on safe storage of special nuclear material; cleanup of environmental contamination; facility decontamination and decommissioning; waste management; and conversion of facilities for economic development. The major challenge to the Waste Management Program was whether systems and facilities were prepared to handle the types and amounts of waste that could be expected from such a major shift in site mission.

Today the site's goals are established on achieving final closure at reduced fixed and operating costs over previously baselined budgets. The site's Integrating Contractor, Kaiser-Hill Company, has launched an Accelerated Site Action Project (ASAP) with the intent of rapidly stabilizing materials and facilities at the site; reducing risks to the environment and surrounding population; and increasing the availability of land for other stakeholder-desired uses.

This paper presents the approach taken by RMRS to develop a Life Cycle Waste Management Plan (LCWMP) and discusses the importance of this document to achieving the site's current mission and goals. Also presented are elements of the waste management strategy, key waste issues at Rocky Flats, and potential solutions currently under consideration.

PURPOSE AND ROLE OF THE LCWMP

The concept of a life-cycle approach to waste planning was part of RMRS's strategy when awarded the contract for environmental remediation, waste management and decontamination and decommissioning in July, 1995. The techniques used at RFETS are based on previous parent-company (British Nuclear Fuels plc) success with a comprehensive strategy for intermediate level wastes at the Sellafield site in the United Kingdom.

The fundamental problem for the LCWMP is to develop an optimized strategy for managing the large variety and volumes of waste expected from future site decommissioning and closure activities. The plan will lead to an optimized configuration of waste management systems and facilities to satisfy operational mission needs. To be successful, it must blend

technical feasibility, life-cycle costs, and risk acceptance consistent with the overall site strategies and goals set by the ASAP. The LCWMP will provide the in-depth analysis necessary to support the ASAP and compare the costs of alternative approaches for each waste stream currently in storage or expected from future generation.

Additionally, the LCWMP supports the following RMRS objectives:

- Document a waste management program baseline in terms of scope, requirements, timing of events, and costs
- Develop a waste management system model with which to perform cost-benefit analyses on different waste management options
- Apply a "systems" approach to waste management using final waste form requirements to drive the processing and handling strategies for individual waste streams; assure that solutions to individual streams are sensible within the context of the overall waste management system
- Assess treatment, storage, and disposal (TSD) alternatives for each waste stream (i.e., technical approach, timing, life-cycle costs, risks, and uncertainties)
- Identify waste management system and facility deficiencies
- Produce a high-quality strategic planning service to support the Integrating Contractor and the ASAP

PROJECT APPROACH

The importance and anticipated level of effort demands that the Life Cycle Waste Management Plan be established as an individual project. The general approach consists of preparing a project plan; establishing a project team with responsibilities matrix; allocating a separate budget source; and placing the effort under the watchful eye of a senior management review group. Since the LCWMP is such a large-scale integration effort, accommodating plans and strategies of numerous organizations throughout the site, the composition of the project team is crucial to promoting communication across organizational boundaries.

The core team comprises the project manager from the Strategic and Integrated Planning department; support staff from Programs/Operations Support and Technology Applications; and a program lead advisor from the Integrating Contractor. This team is responsible for collection and synthesis of all pertinent waste management data; review of waste processing capabilities; interface with the site"s waste generators; and operation/analysis of system and cost models. The core team develops and issues proposed waste strategies and assures integration with site cleanup, decommissioning, and other risk-reduction activities. They are also responsible for identifying the principal risks and for maintaining an overview of the waste strategy.

Proposed waste strategies are distributed for review and revisement to waste storage, treatment, and disposal operations groups, who will become the eventual owners of the strategy and sponsors of key projects. Their involvement in the concept and scope of projects that arise from the waste strategy is important.

LIFE-CYCLE PLANNING PROCESS

Strategic planning at RFETS is proceeding on several levels. The Integrating Contractor is directing the Accelerated Site Action Project (ASAP) which will define the overall path forward for the site and the conditions under which site closure will occur. The ASAP is being developed through a phased approach to allow analysis of multiple site scenarios and full dialogue with regulatory agencies and other interested stakeholders. Decisions made through the ASAP will form the framework for

a more detailed waste management life-cycle cost analysis provided by the LCWMP. Figure 1 presents an overview of the life-cycle planning process and relationship between planning efforts. RMRS and the Integrating Contractor are working jointly to develop consistent data sets and assumptions for use in the ASAP and LCWMP.

Fig. 1

The process used to develop the LCWMP is explained in the following sections.

Gathering and Maintaining Waste Management Data

Collection, synthesis, and maintenance of adequate waste management data is a time-consuming process in life-cycle planning. Key information required for the analysis includes the status of on-hand waste inventories; waste generation forecasts; assessment of onsite treatment, storage, and disposal capabilities; knowledge of TSD options at other Federal and/or commercial facilities; and waste management costs.

Waste generators are requested to prepare and submit future waste forecasts for their individual programs. It is important that waste planners work closely with the generators to understand the bases and assumptions behind these estimates. Waste projections are a potential source of uncertainty in the life-cycle analysis and they have a tendency to fluctuate based on internal or external conditions imposed upon the programs (e.g., changing program budgets or differing cleanup standards set by a regulatory agency). Also, waste planners, with their understanding of waste processing and disposal criteria, can suggest waste minimization techniques or methods to improve waste packaging efficiencies.

System Modeling

Several analytical models are used to assist planners in visualizing the relative differences between options and the sensitivities of underlying assumptions. The first of these models combines annual waste generation projections with other waste management data such as on-hand inventories; capacities of individual storage units; present and future waste treatment capabilities; waste characterization and certification rates; and shipping/disposal capacities. This model is spreadsheet based and controlled by numerous links between worksheets and graphical output. The data are modeled to simulate the annual waste flow balance and to identify potential deficiencies (either in capacity or capability) or under-utilization in any area of the RFETS waste management system. Once a baseline scenario is analyzed, input parameters are varied to simulate other waste management scenarios or to test the sensitivities of assumptions.

The second model derives the life-cycle costs of each planning case. Its function is to differentiate the economics between optional paths for each waste streams or to project the life-cycle cost of the Rocky Flats waste management system as a whole (depending on system configuration and projected operating lifetime). RMRS has chosen to use the System Cost Model (SCM), developed for the DOE by a joint effort between Lockheed Idaho Technologies Co. and Morrisson Knudsen Corporation. This model has direct application to waste management life-cycle cost analyses and has been used by DOE-Headquarters in a number of prior studies. RMRS will be tailoring this model to reflect site-specific conditions and plans.

The advantage of using system models is that it allows the disposition of a complex arrangement of waste streams to be evaluated over time. These models comprise a flexible planning tool with the means to rapidly

respond to changing site conditions and/or assess modifications to planning assumptions.

Analysis and "Optioneering"

This part of the planning process begins when a specific site scenario or case is presented for evaluation. The objective of this step is to perform iterative analyses of waste management options in a continuous attempt to drive down the total costs of the waste management system. With each iteration, the waste streams contributing most to the system life-cycle cost are identified. Then treatment, storage and disposal (TSD) options are developed and tested through the life-cycle cost model. The relative differences in cost, risk, and/or uncertainty between options are documented.

At this stage, knowledge of the physical, chemical, and radiological characteristics of the waste streams, and understanding of the appropriate waste acceptance criteria is of key importance. Each waste stream option must satisfy the acceptance criteria of the intended receiving facility.

The advantage of this approach is that allows waste planners to focus on optimizing a detailed waste management strategy for the preferred ASAP alternative. The waste strategy functions as a "living" document, subject to continuous review and refinement.

WASTE MANAGEMENT STRATEGY AND KEY ISSUES

The overall policy for the management of RFETS wastes is storage onsite followed by treatment in preparation for either offsite or onsite disposal. The strategies for individual waste streams within this policy are considerably more complex and driven by specific technical, economic and risk factors. The extent and approach to waste treatment and onsite disposal are still under review at this time; however, as the LCWMP continues to evolve, the objective is to ultimately declare a strategy for all waste streams from the point of generation to final disposal.

RFETS generates and/or stores six major categories of radioactive and nonradioactive waste. Radioactive types include plutonium residues, transuranic (TRU), and low-level waste (LLW). The nonradioactive categories are hazardous, municipal solids and other regulated wastes such as asbestos-containing material, polychlorinated biphenyls (PCBs), and infectious medical waste. The radioactive wastes have their mixed waste counterparts, i.e., those waste forms that are both radioactive and bear a hazardous constituent or characteristic. The only major category that will not be generated in the future is residues, which are byproducts from weapons production and were once held in reserve for plutonium recovery.

Annual waste generation is currently ranges between 1,500 and 2,000 m3. As cleanup and decommissioning activities accelerate, large quantities of waste are expected. Annual volumes may total as high as 50,000 m3 per year from 1998 through 2002. Over the next 10 years, the largest sources of waste will stem from processing/stabilization of residue materials, remediation of contaminated areas throughout the site, and decommissioning of former production facilities.

Waste Storage

One of the key waste management problems at RFETS has been the ability to supply adequate storage space to support continuing operations. RFETS has accumulated over 20,000 m3 of waste in storage , mostly due to lack of access to appropriate treatment and disposal facilities. Wastes are stored in a variety of locations throughout the site and under a variety

of different conditions. Radioactive and nonradioactive waste is currently stored in many former plutonium production buildings; in steel framed, warehouse-style buildings; in cargo containers; and in large tents on asphalt pads.

The primary issues relating to life-cycle planning for waste storage are:

- Determination of future storage capacity requirements: this is a complex function of waste generation rates and the capability to permanently dispose of such waste
- Storage facility configuration: ensuring an appropriate and cost-effective mix of facilities are available to safely store wastes of a variety of plutonium concentrations; i.e., from less than 1 g/drum to greater than 200 g/drum
- Storage time frames: longer storage requirements favor the construction and operation of new storage facilities vs. utilization of existing buildings

Waste storage strategies for the next 2-3 years are targeted at increasing operational efficiencies and reducing overall storage costs. Waste Management is consolidating storage units as much as possible and reducing the quantities of waste stored in former plutonium processing facilities. New capacity to cover near-term storage needs is being added by retrofitting existing facilities that were idled when the site's mission changed. An example of this is Building 440, formerly used to manufacture safe, secure transport trailers, is under conversion to a low-level waste storage and shipping facility.

Strategies to cover long-term waste storage requirements continue to be reviewed at this time. In general, the style of facilities used to store low-level and most transuranic waste will be pre-engineered, Butler-type buildings due to their relatively low cost of construction and operation. Specific plutonium content limitations will be placed on these facilities to ensure the safety and exposure protection to workers and the offsite public. It is probable that, because of high plutonium loadings, some transuranic wastes will require storage in a significantly more hardened and protective facility. This building would be a reinforced concrete structure with high-efficiency particulate air filtration.

The storage capacity requirements for radioactive wastes are dependent on projected rates of generation and the availability of disposal sites under the ASAP site alternatives. Options range from utilization of existing facilities to the consolidation of all wastes into new, large storage buildings.

Waste Treatment

Current waste treatment strategies are published in three primary documents: the RFETS Sitewide Waste Water Treatment Strategy; the RFETS Proposed Site Treatment Plan, which addresses low-level and transuranic mixed wastes; and the Site Integrated Stabilization Management Plan , which covers liquid and solid residues. Many wastes at RFETS require various forms of treatment to 1) remove conditions that could compromise the integrity of the waste container and/or jeopardize worker safety; 2) satisfy Resource Conservation and Recovery Act (RCRA) Land Disposal Restrictions (LDR) treatment standards prior to disposal; 3) meet certain waste acceptance criteria imposed by the disposal facility; 4) provide for more efficient (and cost effective) waste packaging; or 5) provide a means to recycle/reuse the waste material.

The treatment requirements for various RFETS waste categories are shown in Table I. These requirements reflect current planning scenarios and the respective disposal site waste acceptance criteria.

Table I

The expected future cost of solid waste treatments has prompted a reevaluation of the expected benefits to be derived from such activity. Much of the low-level mixed (LLM) waste inventory at RFETS could be considered low risk to human health and the environment if disposed of properly. Waste treatment strategies are still under review at this time; however a variety of options are under consideration including no treatment; minimal treatment to LDR standards based on the inherent risks of the waste; and full treatment of LLM waste to LDR. The minimal treatment approach reviews the physical and chemical characteristics of each waste and proposes treatment for only those streams that represent a significant health hazard to the public if disposed of untreated.

As treatment requirements for TRU and TRU mixed (TRM) wastes are established by the WIPP WAC, two primary options are up for consideration. The first option would propose minimal treatment of TRU/TRM waste forms to facilitate safe storage onsite for a period of 20 to 30 years. The second option would offer treatment of current and future TRU/TRM waste to guarantee availability for shipment to WIPP as resources allow. With the second option, there is an economic incentive to combine TRM and LLM treatments in common treatment systems, if the decision is made to locate these facilities at RFETS.

The site's process waste water treatment facility, located in Building 374, has been in service since 1978. This facility is operating beyond its original design life and several systems are either inoperable or marginally operable. Major upgrades are required to restore its original capacity and capability. Following an evaluation of the site's waste water treatment systems, RMRS proposed an alternative strategy for a low-cost, safe, and versatile waste water treatment system for the future. RMRS recommended that existing precipitation and evaporation systems in Building 374 be closed in favor of smaller, more cost-effective units. This strategy will save approximately $58 million in planned capital expenditures and approximately $60 million in operating and maintenance costs over a 10-year period.

Waste Disposal

Life-cycle waste management planning assumes that all wastes at RFETS are eventually placed in approved, final disposal facilities. While municipal solid waste is the only type currently disposed onsite, a number of onsite and offsite options are under consideration for other waste categories. The overall waste disposal strategy is still under review at this time but could incorporate both onsite and offsite disposal facilities. Disposal options, as well as long-term, monitored retrievable storage, continue to be evaluated with regulatory agencies and affected stakeholders.

Proposed onsite disposal options include waste emplacement in either concrete-lined cells or in conventional-style landfills. Either facility would be designed to handle LLW/LLM waste; small quantities of specialty wastes such as radioactive PCBs and asbestos; demolition debris; and other municipal solid wastes. These facilities would be permitted and designed to meet RCRA Subtitle C standards in terms of protective measures and environmental controls installed to prevent contaminant migration. RFETS is currently constructing a new municipal solid waste

landfill which is expected to meet the site's needs for the foreseeable future.

RFETS is currently utilizing offsite disposal facilities for low-level and low-level mixed wastes and will likely continue this practice in the future. Table II lists the current and potential disposal destinations for wastes along with acceptance dates used for planning purposes.

Table II

SUMMARY AND CONCLUSIONS

This paper presents the approach taken by RMRS to develop a Life-Cycle Waste Management Plan and discusses the status of an emerging waste strategy at the RFETS. The planning effort is currently in progress and initial results of life-cycle cost modeling should be ready by late March or early April, 1996. Future technical papers will explore the outcome of the waste strategy in considerably more detail.

As Rocky Flats takes on the challenge of accelerating site closure, it is imperative that the waste management system be ready and capable of supporting the effort. RMRS is meeting the challenge through a life-cycle approach to waste planning and operations. This methodology will provide continuous reduction in the unit cost of waste operations, freeing up the site's limited operating budget to concentrate on high priority, risk-reduction activities.

CONTRACT REFORM: IT'S WORKING AT FERNALD*

Jack Craig
U.S. Department of Energy
Fernald Area Office

Arlen Hunt
Fernald Environmental Restoration Management Corporation

ABSTRACT

DOE's contract reform initiatives at Fernald and the performance-based system DOE is now using to evaluate FERMCO are key elements to the current and future success of DOE and FERMCO at Fernald. Final cleanup of the Fernald site is planned for completion by 2005 per an accelerated 10-year remediation plan which has been approved by DOE and endorsed by the U.S. EPA, Ohio EPA, and the Fernald Citizens Task Force. Required funding of approximately $276 million plus inflation annually for 10 years to accomplish final cleanup is now being considered by U.S. Congress. Contract reform initiatives and modified performance measurement systems,

along with best business practices, are clearing the path for the expedited cleanup of Fernald.

MODIFIED CONTRACT BOOSTS "ON-THE-GROUND" REMEDIATION

When DOE and FERMCO signed a significant modification to the contract in July 1994, it represented the first significant action under DOE's contract reform initiatives nationwide. In effect, it was the beginning of what is now referred to as performance-based contracting.

The modified contract represented a significant departure from the management and operating (M&O) type contract that DOE has traditionally awarded at other sites. DOE wanted a contractor that was project-focused. The modified contract provides FERMCO a financial incentive to manage the environmental remediation process as efficiently as possible. Unlike M&O type contracts, this contract requires FERMCO to accept financial responsibility for its actions at Fernald, including any fines or civil penalties that might arise from FERMCO's own negligence. In return, FERMCO is granted more authority to make aggressive decisions about remediation methods.

Rapidly shifting political and business environments have brought about a number of changes in the post Cold War era. These changes are driven by dramatically reduced federal budgets that require work to be completed faster, better, and at less expense to taxpayers. DOE and FERMCO have formed an effective partnership that is resulting in streamlined environmental remediation efforts at Fernald. To be sure, contract reform is an integral part of DOE's response to President Clinton's mandate to "reinvent government."

PERFORMANCE-BASED FEE A POWERFUL MANAGEMENT TOOL FOR DOE

The goal of both DOE and FERMCO was to make the bonus fee performance-oriented, creating a system that would establish objective, quantifiable criteria as the basis for fee determination. The centerpiece of the contract modification was the replacement of the old Cost Plus Award Fee (CPAF) model -- widely used in the DOE system at the time -- with a fee plan based on quality and performance.

Under the new performance-based fee system, FERMCO and DOE agree upon a set of specific, measurable project goals for every six months. FERMCO earns bonus fee only when it exceeds those goals; satisfactory achievement of Performance Objective Criteria (POC) by itself is simply expected and no longer earns any fee.

NUMERICAL GRADING SYSTEM

Each of the three major performance areas are given ratings of excellent, satisfactory or unsatisfactory. Unsatisfactory performance results in a negative numerical rating; satisfactory performance results in a numerical rating of zero, and excellent performance receives a positive numerical rating. Each six-month evaluation period, FERMCO's performance-based fee depends on the sum of the numerical ratings. If FERMCO receives an overall rating of zero, no performance-based fee is earned. If a positive numerical rating is earned, FERMCO receives a performance-based fee. If a negative number results, FERMCO receives no performance-based fee and has to pay back some of the fee the company previously was paid.

The performance-based fee system provides an opportunity for DOE evaluators to align project objectives with FERMCO managers at the beginning of each six-month fee period. FERMCO is then rewarded on its ability to meet those objectives. This is a prime example of a win-win situation for both DOE and FERMCO.

For example, early last year DOE placed heavy emphasis on neutralizing more than 200,000 gallons of uranyl nitrate hexahydrate, or UNH, which basically is uranium dissolved in nitric acid. It was an intermediate compound in the former uranium recovery process at Fernald. UNH had been an ongoing concern for Fernald management, regulators and stakeholders, primarily due to the poor condition of the tanks in which the material was stored. In the first half of FY 95, FEMRCO missed a milestone for startup of the UNH processing. Successful completion of the UNH neutralization project became part of FERMCO's performance-based fee plan for the second half of FY95. FERMCO assigned a special team to the task, and the UNH project was successfully completed several weeks ahead of the regulatory deadline.

While the performance-based fee system is designed to reward FERMCO for achieving excellent performance, it can result in forfeiture of base fee if FERMCO fails to meet minimum performance requirements. Funds available under the performance-based fee structure are divided into two main categories: General Contract Performance Criteria and Milestone Completion.

GENERAL CONTRACT PERFORMANCE CRITERIA

General Contract Performance Criteria are elements of the Fernald work scope that directly affect our mission of a safe, least-cost, early cleanup of the site. These criteria are further subdivided into three main sections: Safety and Health, Environmental Management and Administrative Management. The three levels of performance are "excellent," "satisfactory" and "unsatisfactory." The objective measures which determine the performance level, and the amount of fee, are assigned to a particular criterion.

For example, the DOE Fernald Area Office may consider shipping one thousand drums of mixed waste to be excellent performance, for which FERMCO would receive two percent of the available fee. Shipping only 800 drums of mixed waste would reflect satisfactory performance, but FERMCO would receive no fee. Shipping any fewer than 800 would be considered unsatisfactory performance, and FERMCO would have to refund two percent of the performance-based fee back to DOE. FERMCO could be required to refund up to 25 percent of its base fee for unsatisfactory performance.

While most of the General Contract Performance Criteria contain these objective performance measures (excellent, satisfactory or unsatisfactory), a few of them have been reserved for DOE's subjective evaluation of FERMCO's performance. In these cases, DOE provides a description of the criterion without any specific performance measures attached to them.

MILESTONE COMPLETION

The Milestone Completion section includes activities that are considered high-risk, and most of them are included in the Amended Consent Agreement between the DOE and U.S. EPA. Milestones have performance measures for "achieved excellence" and "did not achieve excellence" because nearly all of the milestones are based on deliverable dates. That is, FERMCO either met the due date or it did not. FERMCO is not required to refund fee to the DOE for failing to achieve excellence under the Milestone Completion section, but FERMCO is still potentially liable for fines levied by EPA for missed deadlines.

PERFORMANCE AREAS, CRITERIA AND MILESTONES USED FOR EVALUATION

It is important to keep the Fernald mission statement in mind when reviewing the major performance areas negotiated between DOE and FERMCO to assess FERMCO's performance against established criteria:

Together, DOE and FERMCO are committed to protecting human health and the environment through the safe, least-cost, earliest, final cleanup of the Fernald site, within applicable DOE order, regulations and commitments, and in a manner which addresses stakeholder concerns.

FERMCO's performance is assessed every six months of the fiscal year, covering periods from October 1 through March 30 and April 1 through September 30. FERMCO is evaluated on three elements of the mission statement: 1) Safe Cleanup, 2) Least-Cost, Earliest and Final Cleanup, and 3) Addressing Stakeholder Concerns.

Under the Safe Cleanup performance measure, FERMCO is expected to significantly reduce the probability of accidents, exposures or releases from occurring. While DOE recognizes that an effective Safety and Health program cannot prevent all accidents, exposures or releases, FERMCO's Safety and Health programs are expected to identify, categorize and control deficiencies in a timely manner to prevent them from happening again.

In addition, FERMCO's Radiological Protection Program is evaluated on how well it keeps exposure and contamination incidents to workers and the public at a minimum. Therefore, employees must be aware of workplace hazards and safety precautions that can prevent accidents from happening. That is why Safety First initiatives and the Voluntary Protection Program are heavily weighted in evaluating FERMCO's performance.

The Least-Cost, Earliest, Final Cleanup performance measure address the Project Management Control System, which is used to integrate technical, cost and schedule performance data. Success of removal actions and waste packaging and shipping also are considered under this heading. This category also considers FERMCO's ability to improve procurement processes and develop technology programs.

FERMCO also is evaluated on its ability to address stakeholder concerns. FERMCO is expected to comply with requests from the public in a timely manner, and to provide information about project plans at the site to employees and the public. Programs evaluated under this heading include the envoy program, media relations, employee communications, support of the citizens task force, and the success of the Community Relations Plan which is designed to inform stakeholders about public involvement opportunities.

CRITICAL FEW PERFORMANCE MEASURES

DOE and FERMCO recently agreed on a list of "critical few" additional performance areas to be measured. FERMCO will be evaluated under the Program Progress heading for its ability to conduct legacy waste characterization and low-level waste shipping; minimize effluent discharges to the Great Miami River from wastewater treatment systems; achieve design milestones and implement field work in support of EPA-approved Records of Decision, and remove holdup material from equipment and lines under the Safe Shutdown program. FERMCO also is expected to demonstrate a Return on Investment by reducing maintenance and electric utility costs and transferring or disposing of excess government property; measure stakeholder opinions and views about Trust and Confidence in a process to be conducted by independent third parties with results reported to DOE; and meet scheduled commitments for rebaselining

the 10-year remediation plan, upgrading the Progress Tracking System list and successfully completing Project Tracking System milestones.

WHERE WE ARE TODAY

The nature and extent of contamination has been defined, and the selected remedies have been well researched and they're supported by DOE and its stakeholders.

We have a plan and now we are baselining our schedule milestones and developing detailed cost estimates for each of the five areas targeted for remediation at Fernald. It is an aggressive plan designed to expedite cleanup and significantly reduce or eliminate costs associated with overhead, landlord activities, and building maintenance. A concerted effort is being made to spend as little money as possible supplying heat,electricity and maintenance support to buildings targeted for demolition.

We have realized significant cost savings, cost avoidances, and greater efficiency by aligning technical project needs with regulator and stakeholder interests, thereby reducing the obstacles that drive costs up. The modified contract incentivizes FERMCO to produce "on-the-ground" remediation progress. FERMCO also has strategically aligned project organizations which are completely focused on planning and executing final remedial activities. The project concept works well at Fernald, because start-and-finish timelines exist and the work scopes are easily measured.

DOE and FERMCO developed this accelerated cleanup plan in conjunction with federal and state regulatory agencies and Fernald stakeholders to achieve the most cost-efficient, aggressive approach to cleanup without compromising safety principles or regulatory guidelines. This can be accomplished within 10 years. The focus has been to create a dedicated project team that will be disbanded in a programmed manner as each phase of the job is finished.

Under the accelerated cleanup plan, as work progresses we will continually collapse and consolidate radiologically contaminated zones. They will get smaller and smaller and fewer in number until there are no more.

The U.S. EPA, Ohio EPA and Fernald stakeholders agree with DOE and FERMCO that an accelerated cleanup approach is well-timed, doable, and fiscally responsible, saving taxpayers an estimated $2.7 billion in escalated funds. We are moving forward in an aggressive manner.

Session 36 -- IMPROVED TECHNIQUES FOR LIQUID LLW

ABSTRACT

The U.S. Department of Energy (DOE) will rely extensively on efficient chemical separations technologies to treat radionuclide containing waste left behind from nuclear weapons production. The waste varies in composition over extreme ranges of pH from acidic to basic. A new approach uses technology which has been developed to incorporate almost any sorbent particle into membranes and then fabricate these into versatile, highly efficient chemical absorbing cartridges.

This is particularly attractive because the process is based on selective sorbent technology instead of traditional wet chemical extractions, chemical precipitations or large ion exchange columns. It provides the capability of removing contaminants down to detection levels at high flow rates, if necessary in the presence of high levels of radiation, concentrating the contaminants while generating a minimum of secondary waste. The full system is projected to have a lower capital cost and smaller footprint than conventional technology. In many ways, the process is as simple as filtering the liquid through a cartridge.

DISCUSSION

In early 1989, 3M introduced this technology as an alternative form of solid phase extraction (SPE), which is used to extract dissolved species from water (1)(2). The sorbent is loaded into a web or membrane which is used in a filtration-like process.

Figure 1 shows a typical example of Emporem membranes in which inert PTFE fibrils are used to hold the sorbent particles. Several classes of materials have been successfully incorporated into the 3M membranes, including commercial organic ion exchange materials, inorganic adsorbents, unique zeolyte structures and elaborate macrocycles. The resulting membranes are characterized by high separation efficiencies, radionuclide loading, fast flow rates and kinetics and physical ruggedness. A radiolytically resistant (up to 2,000 megarad) material may be used as the membrane matrix. Because the membrane is very densely packed (up to 95% particle by weight), with small (5-25 mm), high surface area particles the flow rate can often be 10 to 100 times greater than in standard column ion exchange processes while achieving equal extraction efficiencies. Particles of this size would result in unacceptable back pressure if used in columns. Channeling, or wall effects, which can be a severe limitation for columns, is absent in membranes and offers another reason why high flow rates are possible. This membrane separation technology allows the use of a number of known, high performance, chemical adsorbing powders, which previously could not be put into a useful engineered form because of their small particle size (3). It provides the ability to concentrate materials into much smaller volumes than alternative technologies.

Fig. 1

Laboratory scale experiments at Idaho National Engineering Laboratory (INEL) (3)(4) showed that strontium and cesium could be selectively removed from actual radioactive acidic waste with extremely high efficiency even in the presence of relatively high concentrations of other ionic species. The membranes used were 22 mm diameter, 0.5 mm thick filter-type disks with either IBC Advanced Technologies, Inc., Superligm particles for the removal of strontium and lead, or crystalline titanium phosphate (PhTiA) (5) particles for the removal of cesium. The waste composition is shown in Table I.

Table I

Table II summarizes the test results and Figs. 2 and 3 show the breakthrough curves describing the separation of cesium and strontium respectively .
Table II
Fig. 2
Fig. 3
When the membrane is fabricated into a pleated cartridge large volume separations are possible. Cartridge capacity varies according to sorbent type and mass and the composition of the process stream.
In August 1995, Empore cartridge technology was tested at the West Valley Nuclear Services site. The goal of the project was to test the system for removal of technetium (as pertechnetate) and cesium from waste water. The cartridges used were 4" pleated cartridges containing carbon/Aliquat 336m and potassium cobalt hexacyanoferrate for, technetium and cesium removal, respectively. The flow rate used was 0.1 gallons/minute and the test continued for about eight days, or a volume of almost 1,500 gallons. To summarize the results, the technetium cartridge was loaded to a 50% breakthrough after about 90 gallons (see Fig. 4) and the cesium cartridge ran for 40 hours (about 250 gallons) with no detectable breakthrough of cesium. The cesium in the feed was present at 1,200 pCi/L, while the detection limit for the cartridge effluent was about 2 orders of magnitude lower. These results are particularly interesting because the feed had already been processed through traditional ion exchange columns for cesium removal.
Fig. 4
In September 1995, the technology was tested at Idaho National Engineering Laboratory, Test Area North (TAN) (6). The purpose of the demonstration was to evaluate the performance of the cartridges on injection well water which had already been processed through ion exchange columns.
Figure 5 is a schematic of the equipment used at INEL. The flow rate was 0.25 gallons per minute, (i.e. 1,250 gallons were processed over the 80 hour demonstration), using a feed whose composition is shown in Table III. Species to be removed in this case were strontium and cesium using 4" cartridges of, respectively, sodium titanate and potassium cobalt hexacyanoferrate, (Table IV).
Fig. 5
Table III
Table IV
The presence of non-radioactive strontium in the groundwater resulted in a much higher concentration of total strontium, an important consideration since there is no measurable recognition of sorption for different isotopes of the same element. The high total strontium concentration, coupled with absorption of calcium and magnesium, resulted in Sr breakthrough of 50% (breakthrough =C/Co *100%) after approximately 800 gallons of water had passed through the Sr absorber. Concentrations of Sr, Ca, and Mg in the effluent are shown as a function of time in Fig. 6. Calcium and Mg, present as divalent cations at substantially higher concentrations than Sr in the TAN groundwater, compete with Sr for the active sites in the adsorption medium.
Figure 6 indicates that both Ca and Mg breakthrough occurs more rapidly than the Sr breakthrough and implies that Sr is preferentially adsorbed in the sodium titanate cartridge. Analysis of radio-strontium, 90Sr was performed independently on several samples of the effluent during the

course of the experiment. Analytical results for 90Sr are also shown in Fig. 6. The analytical results for total and radio strontium are in excellent agreement and serve to indicate consistency of the two data sets. Note that the "leveling" of the Sr curve at approximately 55% breakthrough may be attributed to displacement of Ca or Mg by Sr, or it may be an unrealistic nuance of the curve-fitting routine. Irrespective of the cause, the Sr curve would eventually climb to a breakthrough of 100% if enough water had been pumped through the cartridge.

Fig. 6

Cesium showed no detectable breakthrough for the for the entire demonstration, with a detection limit of 9 pCi/L. Again it is important to note that this water had already been through the groundwater treatment facility.

CONCLUSIONS

Strontium, cesium and technetium have been successfully removed from radioactive waste using a new and innovative technology. Laboratory scale experiments at Idaho National Engineering Laboratory (INEL) showed that strontium and cesium could be selectively removed from actual radioactive acidic waste with extremely high efficiency even in the presence of relatively high concentrations of other ionic species. Larger scale technology demonstrations, removing trace quantities of technetium (as an anionic species) and cesium from process water at the West Valley Nuclear Services site in New York state and removing cesium and strontium from previously processed injection well water at INEL show the feasibility of applying the technology on an industrial scale.

Additional large volume technology demonstrations are planned involving wastes of different characteristics in terms of contaminants, pH and ionic strength and using a variety of sorbents.

ABSTRACT

Two different reverse osmosis systems were investigated in this work. The first was a 50-element plant-scale system that is used to treat 2200 cubic metres of AECL liquid radwastes annually. It uses thin film composite (TFC) membranes and operates at an applied pressure of 2760 kPa, with a fixed crossflow of about 40 L/min. The other system uses the same thin film composite membranes for waste processing, but is a 2-element pilot-scale system. It is operated at pressures ranging between 1500 kPa and 7000 kPa, at a fixed crossflow of 55 L/min.

The average lifetime of the thin film composite membranes in the plant-scale processing application at AECL is about 3000 hours. After this service life has expired the rejection efficiency (for total solids) declines rapidly from 99.5% to about 95% as the membranes become impaired from chemical cleaning procedures that are required after each hundred cubic metres of waste are treated. The permeation flux for the plant-scale system decreases from about 2.2 L/min/element to below 0.5 L/min/element at the end of the membrane's useful service life.

The plant-scale membrane elements, fouled by an assortment of chemicals including calcium phosphate and various organics, were successfully regenerated by exposing them to a three-step chemical cleaning procedure (in the pilot-scale system), using detergent, HCl, and an alkaline-based cleaning with EDTA. The 3-step procedure was successful in elevating the flux from 0.5 L/min for the spent membrane, to 1.2 L/min after cleaning. The 1.2 L/min post-cleaning flux could be maintained provided that the crossflow velocity remained high.

The DF for cesium for the plant-scale system (at the operating pressure of 2760 kPa), decreased from about 100 when the membranes were new, to about 30 after they were replaced. After cleaning the fouled membranes with the pilot-scale system, the DF for cesium increased from about 30 to 50, if the applied pressure to the system was increased from 1500 kPa to 5500 kPa. By comparison, the strontium DF increased for the fouled membranes at the operating pressure of 2760 kPa, from about 1000 (when they were new), to about 4000 for the spent membranes. The strontium DF was unaffected by the applied pressure. The increase of strontium DF is believed to be due to the exchange of strontium with deposited calcium on the fouled membrane.

INTRODUCTION

In the mid 1970's, AECL, at the Chalk River Laboratories (CRL) site, built a Waste Treatment Centre (WTC) for treating low-level solid and aqueous liquid wastes. The objective was to demonstrate processes for converting Canadian Deuterium Uranium (CANDU) wastes to a form suitable for disposal. The liquid waste streams are effectively volume reduced by a combination of continuous crossflow microfiltration (MF), spiral wound reverse osmosis (SWRO), and tubular reverse osmosis (TRO) membrane

technologies (Fig. 1). Backwash and chemical cleaning wastes from the membrane plant are further volume reduced by evaporation. The concentrate from the membrane plant is ultimately immobilized with bitumen using a thin-film evaporator in a shielded cell. The ability of the MF/SWRO technology to remove impurities non-selectively makes it suitable for the treatment of radioactive effluents from operating nuclear plants, with proper membrane selection, feed characterization, system configuration, and system chemistry control.

Fig. 1

Currently, there are two streams routinely treated at CRL. One originates from the Decontamination Centre (DC waste) and the other collects waste from the Chemical Drain (CD waste) system. The compositions of the two streams are given in Table I. A total of about 2200 m3 of blended liquid (low to intermediate-level) waste are currently treated by the membrane plant annually. The current overall volumetric recovery of the two stage (concentrate-staged) reverse osmosis train employing SWRO and TRO is 96.6%. For a 35 m3 batch of waste treated there is 0.7 m3 of backwash concentrate and 1.17 m3 of TRO concentrate sent to the evaporator for further volume reduction in a small evaporator, and subsequent immobilization with emulsified bitumen in a thin-film evaporator. The bituminized product from the facility occupies 0.175 m3. The immobilization of the concentrate with emulsified bitumen has been described in a companion WM'96 paper (1). The overall volume reduction of the fresh feed through the integrated plant (employing both membranes and evaporation) is about 250.

Table I

SPIRAL WOUND REVERSE OSMOSIS SYSTEM

Reverse osmosis (RO) is a technology which is well established for the production of potable water from brackish water or seawater. It has been successfully used to produce high-purity water for the electronics, pharmaceutical, and power industries. Because of its versatility to remove ionic impurities, particulates and colloids, organics, microorganisms and pyrogenic material from water, RO has attained a prominent role in water purification (2).

In spiral wound reverse osmosis treatment, feedwater containing dissolved and suspended solids is pumped into the system at a desired feed pressure greater than the osmotic pressure of the solution. The feed stream is pumped into a pressure vessel containing one or more membrane elements connected in series. The feedwater then flows into the channels between the membrane sheets. These feed channels are composed of a plastic netting which breaks up the flow into small turbulent areas above the membrane surface.

Immediately above the membrane surface a concentration boundary layer forms whose thickness depends on feedwater ionic strength, particulate level, and flow in these small turbulent areas. The water and ions are transported by a solubility-diffusion process to the permeate water carrier. The purified water or permeate is recovered at atmospheric pressure. The remaining water, dissolved solids and particulates form the reject stream. The pressurized concentrate or retentate is dropped to atmospheric pressure through a back pressure regulating valve, immediately downstream of the system.

The performance of an RO membrane is usually described in terms of permeate flow, or "flux", contaminant rejection efficiency, and volumetric recovery. Permeate flux refers to the amount of flow across

the membrane per unit area, at a particular operating pressure and dissolved solids concentration. The flow of water across the membrane is proportional to the effective pressure (applied pressure minus pressure drop minus the osmotic pressure of the solution). Increasing the applied pressure will increase the permeate flow without increasing the solute flow.

Rejection is the relative change in contaminant concentration from the feed stream to the permeate stream. RO membranes are not absolute barriers, and some small percentage of the solute (typically about 0.5%) does pass through the membrane. The amount of solute transport is a function of the membrane type and is proportional to the differential concentration across the membrane.

Spiral wound RO membrane types can be broadly classified as cellulosic or noncellulosic. Cellulose acetate membranes are still widely used because of their resistance to fouling, and their low cost. They are, however, easily damaged by bacterial attack and have relatively low rejection efficiencies. Noncellulosic membranes, such as the thin film composite membranes used at CRL, can operate over a wider pH range and exhibit high solute rejection efficiencies. The SWRO configuration achieves a large specific surface area per unit volume, which is typically 1000 m2/m3. This can be compared to 165 m2/m3 for plate modules and 335 m2/m3 for tubular modules.

The ratio of permeate to feed in a RO system is referred to as volumetric recovery, or simply, "recovery". To achieve high recoveries (up to 85% currently employed at CRL), it is necessary to stage the concentrate stream or recycle the concentrate for reprocessing. This is normally accomplished in a tapered system design. For instance, a two-stage system may have four pressure vessels in the first stage, feeding two vessels in the second stage. The tapered configuration compensates for feed flow loss by permeation, therefore maintaining optimum cross-flows in both stages.

Plant-Scale SWRO System Description

The CRL plant-system is a three-stage 5:3:1 tapered system with 10 cm diameter by 6 m long pressure vessels. Each pressure vessel contains six membrane elements. The system is fed with a Goulds 3333 multi-stage centrifugal booster pump. Typical feed crossflows are maintained at about 40 L/min, with an inlet pressure of 2760 kPa.

Pilot-Scale SWRO System Description

The pilot-scale system is equipped with a 5 mm cartridge filter upstream of the two high pressure pumps, both of which can deliver a maximum of 7000 kPa. The pressurized feed flowing at about 55 L/min is directed to one of two membrane pressure vessels, each containing two 10 cm diameter by 100 cm long membrane elements. The purified permeate stream exits the vessel, then passes through a flowmeter, and can be rejected from the system or recycled back to the feed tank. The majority of the retentate (concentrate stream with 99% of the contaminants in the feed), recirculates back to the suction side of the high pressure pump to maintain the high crossflow rate. The remainder of the retentate is directed back to the feed tank. The operating pressure of the system is manually controlled by adjusting the backpressure control valves on both retentate streams leaving the vessel. A system is provided to flush the vessel and piping with clean water after an experiment. An onboard cleaning tank is also provided if chemical cleaning of the membranes is required.

The primary difference between operations of the pilot-scale and the plant-scale system was the effective crossflow rate through each vessel; for the pilot-scale system it was 55 L/min/vessel, while for the plant-scale system it was about 40 L/min/vessel. A more subtle difference between the units is the actual processing method to achieve the desired volumetric recovery of between 85 - 95%. For the plant-scale system retentate was recirculated to the feed tank, and a small bleed fraction was continuously removed. Filtrate was continuously added to the feed tank from the MF system, and so the operation was continuous. By comparison, the pilot-scale rig was operated in a batch mode of operation where a given volume of fresh MF filtrate was volume reduced to the predetermined volumetric recovery.

PERFORMANCE OF THIN FILM COMPOSITE MEMBRANES FOR LIQUID WASTE PROCESSING

Normalised Permeation Flux

The permeation flux from an RO system is a function of several variables including temperature, pressure, and pH. The plant-scale system used 50, 40-inch elements in nine pressure vessels, which were staged as 5:3:1. The permeation flux data obtained was normalised to an applied pressure of 2.76 MPa and a feed temperature of 25oC using a method given by Bukay (1984) (3). The observed permeation flux (OBF) was normalised for temperature using a temperature correction factor (TCF) obtained from the membrane manufacturer, an effective pressure, and for the total number of elements using Eq. 1.

Eq. 1

From a processing perspective it is desirable to maintain a permeation rate of between 0.80 and 1.0 L/min/element at all times, so that the throughput of the 50-element plant-scale system matches the filtrate production rate of about 42 L/min from the MF system situated upstream. In the continuous mode of operation, downtime of equipment is minimized and maximum utility is made of the equipment.

Figure 2 shows the normalised permeation flux for the plant-scale system after liquid processing was initiated. The data shown is a continuation of normalised permeation flux data reported in a paper presented at WM'95 (4). Membranes were changed at about 3800 hours and again after 7000 hours of operation, when the NPF decreased below 0.25 L/min/element. By comparison, the NPF for the pilot-scale system, which is operated at higher crossflow velocity, is consistently at 2.2 L/min/element. The scatter of the data in Fig. 2 is not due to errors in measurement; rather, it is the result of permeation flux declines during a given run, and the subsequent recovery after a chemical cleaning with an appropriate solvent. After a chemical cleaning it was possible to have up to a 100% improvement of normalized permeation flux or more, although this improvement of performance could not be maintained.

Fig. 2

When the membranes were replaced after 7000 hours of operation (Fig. 2), several precautions were taken to minimize the large flux loss observed at 3800 hours. These included: i) operating at a volumetric recovery 5% lower than for the previous set which was processing to 85%; ii) using recommended anti-scalant chemicals in the feed solutions and; iii) cleaning at more regular intervals. Yet, none of these preventative measures appeared to be of much benefit in the resulting loss of throughput that was observed. Regular chemical cleaning cycles appeared to decrease the pressure drop across the membrane plant, but had less impact on improving permeation flux than similar chemical cleanings

performed on the previous membrane set. After about 7000 hours of cumulative service the membranes were replaced due to i) the deterioration of membrane rejection efficiency, and ii) inefficient plant operation due to the frequency of equipment shut-downs from excessive chemical cleaning requirements.

Rejection Efficiency of TFC Plant-Scale Membranes

Another performance indicator that can be used to assess the RO membranes is the overall removal efficiency of conductive ions. The many aggressive chemical cleanings that were required to restore the permeation flux (Fig. 2) may have had a detrimental effect on the membrane integrity, resulting in the considerable loss of membrane rejection performance. Physical abrasion of the polyamide rejecting layer over time may also have been a contributing factor.

A plot of the conductivity rejection efficiency versus the elapsed processing time in the plant-scale system is shown in Fig. 3. The feed conductivity in the present application ranged between 100 and 1000 mS/m, while the permeate conductivity varied between 0.6 and 20 mS/m. Figure 3 is a continuation of rejection efficiency information reported previously at WM'95 (4). The membranes were replaced after 3000 hours because the flux decreased to very low permeation throughputs (Fig. 2), and the rejection efficiency decreased to values below 95% (Fig. 3). A rejection efficiency of 95% indicates that the thin film composite polyamide membranes have degraded to a point where they were no longer useful for the specific processing.

Fig. 3

After the membranes were replaced at 3000 hours (Fig. 3), the rejection efficiency increased back to 99.5% overall. The rejection remained at about 99.5% until about 7000 hours of operation, when the overall efficiencies again declined back to about 95%, and the membranes were subsequently replaced. For those runs between 3000 hours and 7000 hours where the removal efficiency was lower than 99%, leakage took place of excessive nitrate and sodium ions into the permeate following a chemical cleaning. Monovalent ions have low rejection efficiencies (5). Since the plant feed would have been temporarily overloaded with monovalent ions, this situation resulted in a reduced overall rejection efficiency. After the cleaning chemicals were flushed from the system, the rejection efficiency was restored to about 99.3% overall.

Cause of Flux Decline in Plant-Scale System

The flux decline with time observed in Fig. 2 at 3800 hours and 7000 hours, is the result of concentration polarization and/or surface fouling. (6) Surface fouling occurs when there is deposition of submicron particles on the surface, as well as crystallization and precipitation of smaller solutes. It is manifested when rejected solids are not transported from the surface of the membrane back to the bulk stream. In general, there are five types of fouling: namely membrane scaling, fouling by metal oxides, device plugging, colloidal fouling, and biological fouling (7). The different types of fouling frequently occur at the same time and can influence each other. Unfortunately, the interactions between the types of fouling are poorly understood.

The chemical scale on the fouled CRL reverse osmosis membranes is comprised primarily of aluminum, silica, calcium, phosphorous, and to a lesser extent iron and sulphur (4). Calcium hydroxylapatite and octacalcium phosphate scale have been identified as a major fouling species. Clay and aluminum silicate-based scale is thought to account for

the initial large flux decline associated with concentration polarization, and represents the scale which is the most difficult to remove by standard chemical cleaning procedures. Precipitates approaching 10 mm in diameter have been observed on the surface of the membrane, and these precipitates are hard to dissolve in even the most concentrated acids. This is further supported by the observation that alkaline cleaning chemicals at pH 12 are the most effective for permeate flux restoration where silica solubilizes to silicic acid (8). The precipitates in the 50 membrane elements of all three SWRO stages are similar in chemical composition.

While operating, thin film composite membranes take on an anion charge on the surface. This causes cationic foulants, such as aluminum and ferric hydroxides, along with cation coagulant polymers, to be attracted to it. Further, because of the high flux rates on thin film composite membranes, fouling occurs faster and is more noticeable than with other membranes (9). Moreover, in the CRL plant-scale application the volumetric recovery is maintained at about 85%. This high recovery leads to increased solute concentrations at the boundary layer, leading to more concentration polarization and a higher deposition of fouling substances.

Performance of Pilot-Scale System

The primary difference between operations of the pilot-scale and the plant-scale system is the effective crossflow rate through each vessel; for the pilot-scale system it was 55 L/min/vessel, whereas for the plant-scale system it was about 40 L/min/vessel. To compare the performance of the two systems, the fresh feed to the pilot plant was the same 50:50 blend of the CD/DC waste streams. The pilot-scale system was run in parallel with the plant-scale system, and both of the systems were targeted to achieve 85% volumetric recoveries overall. By comparison with the plant-scale system, which was only able to maintain 0.5 L/min/element (at the start of a processing campaign), the pilot-scale system was able to sustain a permeation rate of 2.7 L/min. During the course of a run, the flux typically decreased from 2.7 L/min to about 1.7 L/min, depending upon the final volumetric recovery that was sought. However, the loss of flux during a run was always reversible (after flushing the system with permeate), indicating it was due to concentration polarization, and not irreversible fouling. If the system was placed in total recirculation at any time during the run the permeate flows would not decrease further.

Regeneration of Spent Plant-Scale Membrane Elements with Pilot-Scale System

Since the performance of the pilot-scale system was so much superior to the plant-scale system for CRL liquid waste processing applications, a test was undertaken to evaluate the cleaning effectiveness for spent plant-scale membranes in the pilot-scale system. The spent membranes were removed from the plant-scale system at 7000 hours (Fig. 2), and two were chosen randomly for cleaning tests.

A chemical cleaning campaign of a fouled plant-scale thin film composite membranes was carried out using a three-step procedure at an applied pressure of 2760 kPa (the same operating pressure as the plant-scale system). The fouled membrane was taken from the first stage of the three-stage system. During the first cleaning step a detergent formulation (1 wt.%) was used to remove surface oil and grease. In the second step, HCl (at a pH of 2 and ambient temperature), was employed for the dissolution of metals. In the third step, NaOH (at pH of 12) and 2 wt.% EDTA was used to complex metals and remove silica deposits by dissolution.

A 73.5% improvement of permeability was observed after cleaning with the detergent. A total of 0.8 kg of oil and grease was removed from the element with the detergent cleaning process. After the second cleaning procedure with HCl, a further improvement of 14% was observed. After the third step where chemical cleaning was carried out with NaOH and EDTA, an incremental improvement of 20% was noted for the element. The overall improvement for the element based on the three-step cleaning sequence was 137%; the water permeability increased from 0.48 L/min before cleaning to 1.14 L/min after cleaning. The same cleaning tests were carried out on another fouled element, and the results could be replicated.

A complete regeneration of the fouled membrane elements was not achieved. The permeation flux for a new element was about 2.2 L/min (Fig. 2), and hence the pilot-scale cleaning procedure was capable of restoring about 50% of the membrane's original performance. The cleaned elements could be reused in the plant-scale system at a throughput of 1 L/min, however, because this would match the filtrate production from the MF system situated upstream (Fig. 1).

Following the 3-step cleaning procedure, a series of three further experiments were carried out in which blended CD/DC MF-filtered waste was processed in the pilot-scale unit to evaluate the long term benefit of the cleaning methods. Results are shown in Fig. 4, for the flux curves before cleaning and after cleaning (represented by Tests 1,2,3). In the first experiment a batch of CD/DC waste was passed through the system with a 5 micron prefilter in place. The feed was reduced to a final recovery of 90%. After flushing the system with permeate at the completion of the run, the same test was replicated (Test 2). The purpose of Test 2 was to determine if the permeate flux after a pure water flush could be restored to the same initial value (which had previously been observed for CD/DC waste processing). Finally, a third test was carried out in which the 5 micron prefilter was removed from the system to determine if a coarse filter was required upstream of the membranes at the higher crossflow velocities.

Fig. 4

At a volumetric recovery of 90% in Test 1, the permeation flux decreased to 0.88 L/min. The flux decline curve was identical for Test 2, indicating that the performance curve was reproducible. It also provided evidence that the chemical cleaning procedures had been effective in displacing scaling materials. In Test 3, where the 5 micron prefilter was removed from the system, the permeation rates at all volumetric recoveries mimicked the previous two tests. The results of Test 3 indicate that a coarse 5 micron prefilter is not required upstream of the RO system.

Pure Water Permeability after Spent Membrane Regeneration

A water permeability test was carried out before and after the chemical regeneration procedures, so that comparisons of the cleaning efficiency could be made on the basis of membrane permeability. Pure deionized water was passed through the element at various applied pressures ranging between 1500 kPa and 5500 kPa, and the permeation flux was recorded as a function of the operating pressure.

The results of the permeability tests for the two different membrane elements are shown in Fig. 5. Prior to the chemical cleaning procedure, the flux for element #1 varied between 0.25 and 0.9 L/min/element, as the pressure increased from 1500 kPa to 5500 kPa. After cleaning the flux for element #1 increased to between 0.6 and 2.2 L/min/element over the same

pressure range. A similar improvement of pure water permeability was observed for element #2 after the cleaning procedures. The pure water permeabilities for both elements after the chemical cleaning procedures were approximately the same (at all pressures), even though element #1 was more fouled. This would indicate that the membranes were cleaned to the maximum possible extent by the three-step cleaning procedure, which is about 50% of the new membrane's performance.

Fig. 5

Effect of Pressure on Decontamination Factor

Tests were carried out to evaluate the impact of the chemical cleaning procedures on the removal efficiencies of cesium and strontium. The results are plotted in Fig. 6 in terms of a decontamination factor (DF), rather than a rejection efficiency for clarity on the figure. The decontamination factor (DF) is defined by Eq. 2.

Fig. 6

Eq. 2

It was necessary to use stable isotopes of cesium and strontium instead of radioactive isotopes to determine the DF of each accurately. This was required since the resolution of the analytical instruments were not sufficient to detect radioactive contaminants reliably at low concentrations in the permeate. The results of these tests showed that the DF before cleaning for cesium was 30 (at 1500 kPa), and increased to 50 (at 5500 kPa) before cleaning. However, the cesium DF for a new element was about 100, which indicated that there had been some permanent loss of rejection after its 3000 hour service life was over. There was no increase of cesium removal after the three-step cleaning procedure with the pilot-scale system. The tests demonstrated that the aggressive chemical cleaning carried out did not impair the membrane'a ability to remove contaminants.

The DF for strontium increased from about 1000 for a new membrane element to roughly 4000, after the membrane had been exposed to about 3000 hours of liquid waste processing. The strontium DF was relatively independent of both the applied pressure and the chemical cleaning procedures. The increase of DF after waste processing can be rationalized by noting that the dominant scale on the plant-scale membranes is calcium phosphate. It is probable that strontium replaces the precipitated calcium on the fouled membrane (as strontium phosphate), liberating calcium in the process. Evidence of this phenomenon can be gleaned from the contact beta radiation fields on the fouled membranes. Following their removal from the plant-scale system at 7000 hours (Fig. 2), the fouled membranes had contact beta fields that sometimes approached 20 Rads/h. The high beta field is evidence of Sr-90 deposits; there are no other abundant pure beta emitters in the CRL waste streams.

CONCLUSIONS

Membrane replacements are required after approximately 3000 to 4000 hours in the plant-scale liquid waste processing application at AECL. After this period, the average permeation flux for the 50-element plant-scale system decreased below 0.3 L/min/element, and the bulk conductivity rejection efficiency declined rapidly from 99.5% to 95%. By comparison, with the pilot-scale system, where there is 50% higher feed crossflow, it is possible to maintain a permeation flux of about 2.2 L/min/element.

The fouled CRL membrane elements could be regenerated by exposing them to a three-step chemical cleaning procedure (at higher crossflow in the pilot-scale system), using detergent, HCl, and an alkaline-based cleaning

solution containing EDTA. The 3-step procedure was successful in boosting the flux from 0.5 L/min for the fouled membrane element to 1.2 L/min for both elements that were cleaned.

The decontamination factors for cesium and strontium were not affected by the aggressive cleaning procedures in the pilot-scale system. The DF for cesium increased from about 30 to 50 as the applied pressure increased from 1500 kPa to 5500 kPa. However, there was no variation of the cesium DF after the cleaning procedures were completed. For strontium, the DF varied between 3000 to 4000, and was unaffected by the applied pressure. The strontium DF did not change after the chemical cleaning. In addition, the strontium DF increased from 1000 (for the new element) to 4000 for the fouled membrane. The increase is believed to be due to the exchange of strontium from solution with deposited calcium on the fouled membrane surface.

ABSTRACT

Advanced Liquid Radwaste Treatment processes can be defined as those technologies which provide substantial solid radwaste reduction and improved water quality when compared to conventional processes such as demineralization and evaporation. Nine Mile Point - Unit 1 (NMP1) has successfully processed over 6 million gallons of outage and non-outage generated floor drain water through an advanced treatment system since January of 1995. Operating results show that advanced systems are capable of processing widely varying waste water streams while lowering product water impurities and solid radwaste generation rates. This paper relates full scale operating experiences encountered since startup, as well as, feed and effluent chemistry results. Information provided in this paper will specifically benefit two groups of nuclear facilities: 1) those operating under a zero-liquid discharge scenario, where restrictive product water quality standards are imposed, and 2) those facilities that require less than minimum detectable activity (<MDA) concentrations of gamma emitting isotopes in the water discharged to the environment. Specific operational techniques used to maintain Total Organic Carbon (TOC) concentrations under 50 ppb and post UV-IC anion concentrations under 5 ppb are discussed. Advanced systems show promise for aiding nuclear facilities in meeting solid radwaste, fuel integrity, ALARA, and offsite dose goals.

INTRODUCTION

Changes in social and political affairs have placed increased emphasis on concerns for the environment resulting in new laws, rules, and regulations. Improvements made in analytical instrumentation have had a great impact on analysis limits, with smaller and smaller concentration of impurities detected and evaluated in water returned to the reactor. And, competition from independent power producers dictate cost cutting and expense minimization in every aspect of radwaste operations - from operator overtime to radwaste disposal. These factors drive Nine Mile Point (NMP) to continually research and utilize advanced systems for the treatment of liquid and solid radioactive waste.

Plant Processing History

NMP - Unit 1 is a 610 MW Boiling Water Reactor that operates under a "zero-liquid" discharge philosophy. No water has been released from this facility in over four years due to good water management practices and an effective water treatment program. A forced circulation evaporator was utilized for processing the floor drains from start-up until 1992 when a portable, granular based filtration and demineralization system was installed. The change from evaporation to demineralization provided the following improvements: 1) lowered radwaste volumes 2) increased product water purity 3) lowered operator/maintenance personnel exposure and 4) lowered overall operating cost. In fact, due to the shut down of an

electric fired steam boiler that heated the evaporator, NMP1 set all time electrical generation records. Instead of using the electricity for heating water, it was put on the grid and sold to customers.

In 1994 a new, advanced technology was conceived, cooperatively developed by Nine Mile Point, and tested offsite. After offsite testing provided substantial promise for increased performance and benefits THERMEX was installed at NMP1. This advanced system reduced waste generation rates by over 500% when compared to the demineralizer system. The system has also maintained high product water purity levels despite encounters with high conductivity and high TOC feed water conditions. A second THERMEX is currently being installed at NMP-Unit 2 with start-up scheduled for March of this year.

Goals of the Advanced Processing System

The first goal of the new system is to reduce liquid treatment system solid radwaste generation rates by over 500%. With the uncertainty of disposal site access, NMP1 wanted to extend the life of the on-site solid radwaste storage facility. Replacing the floor drain and equipment drain systems with a more advanced system would increase the life of the radwaste storage facility by a factor of 5 or 25 - 30 years.

The second goal is to process waste water feeds with widely varying concentrations of impurities while maintaining ultrapure product quality standards. NMP's zero liquid discharge philosophy dictates that all water generated within the plant has to be returned for recycle. Lake water in leakage and chemical intrusions into waste water collection tanks periodically caused significant processing problems for the conventional treatment systems. In Table I, "Product Water Quality Requirements", the product water quality standard for the advanced system are compared to those imposed on the demineralizer when it went into service in 1992.

Table I

An ancillary goal of the system was to reduce the concentration of organo-anions that were recycled to the reactor. Standard ion chromatography (without ultraviolet oxidation as a pre-treatment), showed that anions exiting the floor drain demineralizer system were < 5 ppb. After ultraviolet oxidation, the anion concentrations in samples of product water would increase into the tens of ppb. Reducing the amount of anions returning to the reactor will increase fuel integrity and minimize corrosion, thereby reducing overall utility/plant life cycle costs.

The final goal of the system is to reduce onsite processing costs. Niagara Mohawk's cost reduction program dictates budgetary justification all change requests.

PILOT TESTING

Since the advanced process was a new development, pilot scale testing was performed to ensure that equipment installed onsite at NMP was appropriately sized and specified to treat the plant specific waste stream. To minimize costs and reduce the complications associated with testing at a nuclear power plant, two 1,200 gallon samples of floor drain water were shipped from both Nine Mile Point Units to Chem-Nuclear's licensed pilot test facility in Barnwell, SC. The objectives of the pilot test program were to:

1. Obtain operating and performance data necessary to verify full scale system performance. (This will verify the claims made earlier related to improved product water quality and reduced radwaste volumes.)
2. Develop radiological and chemical characterization of typical waste water at various points in the system through monitoring and analysis.

3. Aid plant personnel in developing an understanding of how the equipment operates.

The pilot system is 1/25th scale (2 gpm) and has all the components provided with the full-scale equipment.

Pilot Sample Characteristics

Multiple samples of waste water from other nuclear facilities had been processed through the pilot system prior to the NMP1 sample. To minimize the amount of equipment changes, NMP1 was considering the use of deep bed filters that were already onsite and in use with the portable floor drain demineralizer system. Accordingly, to simulate full scale operation, the test sample was taken from the effluent of the deep bed filter. The concentration of contaminants in the NMP1 waste water was 15-30 umho/cm in conductivity. The sample from NMP1 was cleaner than that from other facilities for several reasons: 1) A few of the other plants obtained their samples by flowing through systems that are not typically used for water treatment. In doing so, a large amount of suspended solid material was added to the sample; 2) The NMP1 sample was filtered through a deep bed filter to aid in simulation of the full scale system. This significantly reduced suspended solids concentrations; 3) The sample from NMP1 was taken from a waste collector tank that contained ion exchange resin. Turbulence associated with recirculating this tank prior to sampling caused the waste water to be mixed with the ion exchange resin, thus lowering the tanks conductivity.

Pilot Processing Results

Physical and chemical results from the operational testing were reviewed by Chem-Nuclear and NMP1 personnel immediately after the tests were completed. The test results were then used to: 1) Custom tailor the system design to specific plant needs; 2) Predict full scale advance processing efficiency; and 3) Final radwaste volumes. Results from the pilot testing are presented in Table II, "Pilot Scale Test Results". The higher than expected concentration of organics can be attributed to an insufficient rinse down of the pilot scale system prior to pilot testing. The pilot system is chemically cleaned and preserved between sample to maintain membranes within their baseline or "clean" performance specifications. Additional rinsing to remove residual chemicals prior to startup would have likely reduced the product TOC. The volume reduction factor was extremely high due to the low conductivity and small amount of solids present in the waste sample.

Table II

Positive results from the pilot scale sample provided justification for implementing the full scale onsite advanced treatment system.

ONSITE OPERATIONS

After completing the 10CFR50.59 safety evaluation and operator training, the full scale advanced system was installed and operations began in January 1995 prior to refueling outage number XIII. Feed and product values for conductivity, pH, and TOC are monitored on a daily basis. The following sub-sections provide additional information on each of the monitored parameters.

Feed Conductivity

Conductivity has averaged 76 mS/cm since start-up. Figure 1, "Feed Conductivity", shows that conductivity averaged 25 mS/cm prior to the outage. The outage lasted from mid-February through mid-April. Outage related maintenance activities caused lake water and decontamination solutions to be put into the floor drains raising the conductivity to

over 100 mS/cm. Now that the outage is over conductivity values are beginning to trend down. One disadvantage of having a resilient water treatment system is that personnel tend to put miscellaneous materials down the drains that would have normally been segregated out and treated through a separate process.

Fig. 1

Feed pH

Feed pH has been neutral to slightly alkaline. During the refueling outage the pH range from 4 to 10. These spikes were likely caused by rinse solutions entering the floor drain after an advanced system chemical cleaning. It should be noted that the flush solutions were very dilute - the conductivity of the flush solutions was lower than the average conductivity experienced during the same time period. No operational difficulties were caused by the pH ranges experienced to date.

Feed TOC

The feed TOC concentration averaged 18 ppm primarily due to unusually high values encountered at the end of March. The high values were possibly caused by a water soluble cationic polymer that overflowed from a clarification tank. Figure 2, "Feed TOC", does not account for oils that were fed to the advanced system several times during the outage. Even though oils entered the system and high concentrations of soluble TOC's were encountered, product quality was not compromised. In fact, the advanced system was the only treatment system at NMP1 that was capable of making water of an acceptable quality for recycle to Condensate Storage Tanks (CST's). During the TOC transient also known as the "swarf event" both floor and equipment drains were processed through the advanced system. If the advanced system had not been onsite water would have likely been released because the plants conventional filter/ demineralizer could not remove the organics associated with the swarf. The oils and TOC did affect the operational performance of the advanced system, it had to be shut down and chemically cleaned after the transient waste water was processed in order to remove high membrane differential pressure.

Fig. 2

Product Conductivity and pH

Conductivity trends are provided in Fig. 3. Product conductivity averaged 0.063 mS/cm or almost 16 MOhm and product pH averaged 6.29. Several of the values reported were determined through the use of a dip cell. These values tended to have higher conductivities and lower pHs due to the reaction of the product water with carbon dioxide in the air to produce carbonic acid. The measurement of pH for high purity water can easily be changed by as much as 1 or 2 units by only trace amounts of CO_2 and other impurities.

Fig. 3

Product TOC

Many organics are non-ionic and highly soluble in water - making them extremely difficult to remove. The TOC concentrations in the product water from the NMP1 advanced system have remained amazingly stable considering that the system has been challenged with feed TOC concentrations of over 600 ppm. To date, the product water has averaged 63 ppb TOC. Since the end of the outage TOC values have ranged between 20 and 50 ppb. Figure 4, "TOC - Feed Vs. Product", shows that the product TOC values are not necessarily dependent on the feed TOC concentration.

TOC removal efficiencies depend on the molecular make-up of the contaminants. Large ionic organics are easily removed and non-ionic low molecular weight organics are difficult to remove. The processing of miscellaneous soluble non-ionic organics, such as, ethylene glycol and hydraulic fluid resulted in several TOC concentrations over 100 ppb.
Fig. 4
Radionuclide Decontamination Factors
Advanced systems offer those facilities that discharge waste water significant promise for the reduction of curies released to the environment. The concentration of gamma emitting radioisotopes have always been at less than minimum detectable activity limits in the product water from the advanced system. Table III, "Decontamination Factors", provides typical concentrations of feed and effluent radionuclides encountered at NMP1.
Table III
Radwaste Generation
The advanced system at NMP1 utilizes multiple process technologies, consequently several types of waste are produced. One waste stream contains ion exchange resin, another is high in dissolved solids, another is high in suspended solids, etc. All of the waste generated at NMP1 has either been shipped to Chem-Nuclear's THERMEX Central Volume Reduction Facility for dehydration or deposited on partially exhausted condensate polishing resin. Since the partially exhausted condensate polishing resin was already considered radwaste, no net radwaste increase was incurred by depositing additional materials on the media.
To date, less than 4 cu-ft of waste has been generated from the advanced system at NMP1. This calculates out to a waste generation rate of less than 2 cu-ft per million gallon of product water. None of the ion exchanges resin contained within the system have exhausted to date; therefore, this rate of radwaste generation is unrealistically low. Based on the waste water characteristics at NMP1, including outage generated water, the projected rate of radwaste generation is 7.8 cu-ft per million gallons of product.
SUMMARY AND CONCLUSIONS
The following conclusions can be developed based on the advanced system test results and the NMP1 operational experience:

Advanced treatment systems that utilize membrane based process components can successfully process waste water from a nuclear power plant.

The industry trends show that the use of an advanced system for the treatment of liquid waste has provided improved water quality and a reduction in radwaste generation when compared to evaporation and demineralization.

Oils and certain polymers are detrimental to the performance of membrane based systems. Prolonged operations with these types of materials will likely result in frequent chemical cleaning.

The rejected contaminants or brine produce a Class A / Type A waste after dehydration.

Conductivity and TOC ranges experienced had little impact on product water quality and overall system performance.

ACTIVE OPERATION OF A MODULOX PILOT PLANT
FOR VOLUME REDUCTION OF ORGANIC

CONTAINING WASTES

ABSTRACT

A wet oxidation system, ModulOx, for the removal of organic material from radioactive waste has been developed in the UK as a mobile plant concept by AEA Technology in conjunction with Nuclear Electric as part of a four year development project supported by the European Commission and the UK Government (1). The system can effect a significant reduction in waste mass and volume by converting organic carbon to carbon dioxide and water and concentrating the mineral residue prior to subsequent conditioning processes such as drying or cementation. The process operates at atmospheric pressure and aqueous boiling temperature, with organic destruction proceeding by metal ion catalyzed, free radical mediated oxidation with aqueous hydrogen peroxide.

This paper describes the process development and mobile pilot plant design, and presents the results of radioactive operation. Wastes treated by the ModulOx plant include bead ion exchange resins of the type used routinely in PWR/BWR operation, decontamination resins and effluents containing organic chelates such as EDTA, and mixed radioactive sludge.

INTRODUCTION

A variety of radioactive waste streams which contain organic materials are in storage and many continue to be generated. These arise as a result of power reactor operation, fuel reprocessing and decontamination operations, together with contributions from industrial, educational and medical uses of radioactive materials.

Substantial or complete removal of the organic component of radioactive waste can provide one or more of the following benefits :

A significant reduction in the volume of radioactive waste which requires storage, transport, conditioning and final disposal.

Elimination of organic components which may specifically impair safe disposal (toxic chemicals or chelating agents, for example).

Enhanced compatibility of the treated waste with secondary conditioning processes (such as cement encapsulation), producing a conditioned wasteform with better physical or chemical properties for interim storage and final disposal.

Thermal processes, in particular incineration, are the most widely used methods of organics removal from radioactive waste, especially Low Level Waste (LLW). Some organic waste types, notably ion exchange resins, are associated with the production of corrosive by-products which can severely affect incinerator and thermal plant integrity. Complex treatment of the large volumes of radioactive off-gas produced during incineration is usually required, and secondary waste volumes may be large. The volatility of caesium isotopes in particular is a recurrent problem for high temperature processes.

Recognizing that alternative technologies may overcome some of the technical limitations of incineration for several organic waste categories, a non-thermal, atmospheric pressure wet oxidation process using catalyzed hydrogen peroxide has been developed by AEA Technology and Nuclear Electric (2, 3,4).

The ModulOx system does not offer the universal solution to organic radioactive waste treatment optimistically claimed for some thermal technologies. Most plastics, rubbers and oils, together with concentrated organic solvents are not suitable for wet oxidation treatment by this method. Nevertheless, it can be applied to important radioactive wastes such as ion exchange resins, sludges and contaminated liquid effluent which form a significant proportion of organic waste, by volume and activity content, in many countries.

The use of very mild process conditions has allowed the design and construction of a pilot plant which is both modular and mobile, since support systems, power requirements and off-gas treatment requirements are much reduced in comparison to typical thermal technologies. The latter benefit stems from the retention of most of the radioactivity in dissolved ionic or solid forms within the aqueous phase.

This modular wet oxidation system, ModulOx, has been used to process spent radioactive ion exchange resin, solid decontamination waste containing EDTA and citrate, and mixed reactor sludge waste. Preceding the work described in this paper, laboratory and/or non-radioactive plant trials on decontamination solutions and foams, cellulosic waste and organic scintillant solutions have also been conducted (1), as have extensive laboratory and pilot plant trials on toxic effluents (5).

NON-THERMAL, NON-PRESSURIZED PROCESSING OF ORGANIC RADIOACTIVE WASTE

Hydrogen peroxide in aqueous solution can act as a strong oxidizing agent, reacting with nucleophilic organic molecules under appropriate, often mild, conditions. This oxidizing ability forms the basis for its historical use as an industrial bleaching agent.

When trying to oxidize polycarboxylic acids without nucleophilic sites, Fenton found that the reaction with hydrogen peroxide was strongly promoted by the ferrous ion (6). It is generally accepted that in the Fenton system this enhanced oxidizing power is due to the formation of the hydroxyl radical, OH.:

Eq. 1

At ambient temperature and under acidic conditions, the hydroxyl radical has a reported electrochemical oxidizing power higher than any other species except fluorine (7).

With originally insoluble organic polymers such as ion exchange resins, the electronic rearrangements which accompany the initial stages of hydroxyl radical attack have been shown to cause fragmentation by cleavage of benzyl ring systems and alkyl cross-linkages (8). The now hydroxylated resin fragments are more water soluble and their oxidation proceeds in solution. GC-MS analysis of the reaction intermediates present in solution during ion exchange resin oxidation (mixed polystyrene DVB resins) with catalyzed hydrogen peroxide has identified a wide range of oxidized species, including aliphatic acids, ethanol, other short chain alcohols, acetone and primary, secondary and tertiary amines (from anion resin degradation). The large number of different oxidized intermediates found would suggest that the attack on the resin structure is largely indiscriminate.

Ultimately almost all the original organic carbon structure is converted to carbon dioxide, water (from hydrogen abstraction by OH.) and inorganic salts from any functional groups. The overall reaction is therefore analogous to incineration and can be represented approximately by the stoichiometry given below.

Eq. 2

where (X) is a functional group

The rate of reaction of hydroxyl radicals with almost all water soluble organics is extremely fast (7), with reported second order rate constants for hydrogen abstraction in the range 107 - 1010 M-1s-1. In comparison the overall second order rate constant for catalyzed hydroxyl radical production from hydrogen peroxide has been reported as 41.4 M-1s-1 at 20oC in the same study, and although the rate rises with temperature free radical production is under most conditions the rate determining step. It is this latter step, the catalytic cleavage of the peroxide bond, which is controlled in the plant scale wet oxidation application by control of hydrogen peroxide addition rate, temperature, catalyst concentration and pH. The reaction rate must be balanced with the rate at which the exothermic heat and gaseous products can be effectively removed by engineered systems. To maintain relatively stable temperatures and to allow the removal of excess water as steam, the process is operated at or near the boiling point of the aqueous system.

DESIGN OF THE ModulOx PILOT PLANT

The design specification for the pilot ModulOx unit required a plant capable of safely treating radioactive waste, in particular ion exchange resin, containing up to 370 GBq m-3 as 60Co. Another important requirement was the ability of the unit to be readily transported from site to site without dismantling. The design throughput for the plant was 50 - 100 litres of ion exchange resin per 8 hour day.

Following an options study and process selection, the ModulOx unit has been built within its own transport container, and uses a semi-continuous treatment process in preference to batch or continuous operation. This option provides advantages in throughput and process efficiency whilst maintaining the engineering simplicity desirable in mobile radioactive facilities. The pilot ModulOx plant is shown in Figs. 1 and 2. The wet oxidation reactor has a volume of 160 litres.

Fig. 1

Fig. 2

The ModulOx unit design allows ion exchange resins, sludges and liquid wastes to be metered into the wet oxidation reactor, provides for concentration of the mineral residue product using evaporation, and additionally includes a gas treatment system consisting of demisting, wet scrubbing and HEPA filtration components.

The steel ISO container enclosing the plant is 2.6m high, 2.4m wide and 6m long. The plant requires only a 415V 3-phase supply for operation, together with a modest volume of service water for chemical make-up and washdown.A remote control and data acquisition unit, which may be sited up to 100 m away from the ModulOx container, is used for the control of all plant systems during processing of radioactive waste.

NON-RADIOACTIVE TESTING

Ion Exchange Resin

This spent resin had been used to deionize water from steam generator blowdown at a nuclear power station, but was not radioactive. Its chemical and physical characteristics (Table I) were broadly similar to typical nuclear grade ion exchange resin.

Table I

A total of 0.52 m3 of settled resin was processed, at a rate of 60 litres per working day, and reaction profile data obtained (9). Following treatment in the ModulOxm plant, the primary product was an alkaline

mineral sludge containing 90-95% calcium sulphate in the solid phase. A summary of processing results is given in Table II.

Table II

Decontamination Liquor Simulant

A solution consisting of 7% EDTA dissolved in a dilute ammonia solution with added iron and copper salts was processed by the pilot plant. Key results are summarized in Table III. The average throughput achieved whilst removing >99% of organic carbon from the solution was 40 l hr-1. (300 l per day).

Table III

RADIOACTIVE OPERATION OF THE ModulOx PILOT PLANT

Examples of radioactive wastes treated during the first phase of active operations are described below. The ModulOx pilot plant is currently being recommissioned in readiness for a demonstration program involving transport and operation in several European countries.

Spent Ion Exchange Resin

The composition of this organic waste type is given in Table IV below. A waste with relatively low levels of radioactive contamination was chosen to provide information on real waste treatment and distribution of active species without the need for remote waste handling.

Table IV

250 l of settled IX resin was processed at a rate of 40 l day-1 . The residue after wet oxidation consisted of a 35% slurry of calcium sulphate and minor amounts of other salts such as ammonium sulphate, sodium sulphate and calcium hydroxide (the last is added for control of pH). The volume of sludge discharged from the ModulOx plant was 116 litres. 96% of the organic carbon originally present in the ion exchange resin had been removed. The small residual amount of organic matter is almost entirely present as an inert solid. Preliminary analysis suggests that it comprises fragments of unfunctionalized polystyrene present in the original resin polymer.

Spent Decontamination Resin

A similar campaign with real waste comprising ion exchange resin used for decontamination of chemical cleaning solution was carried out. The high levels of the chelating agents EDTA and citrate prevent disposal of this type of waste under current UK Waste Acceptance Criteria for LLW.

The original waste composition is given in Table V. In addition to 60Co contamination, 55Fe and 3H isotopes were also present. Treatment of 360 litres of this waste was carried out at an average processing rate of 50 l day-1 . The organic carbon content was reduced by 95% and specifically the levels of EDTA and citrate were reduced from 4200 mg l-1 and 850 mg l-1 respectively to below the analytical detection limit of 50 mg l-1.

Table V

Following solidification in cement, the waste packages produced met UK waste acceptance criteria for LLW disposal at the engineered near-surface facility at Drigg.

SGHWR Reactor Sludge

The waste treated was a mixture of real and simulant sludge material to reduce the radionuclide inventory to contact handleable levels. The three principle isotopes present in the sludge were 60Co, 137Cs and 55Fe. The organic content of the sludge is associated with powdered ion exchange resin (POWDEX). ModulOx treatment removed 94% of the organic carbon content in this waste, at a net throughput of 60 litres per day. Importantly, the ratio of the three main contaminants present in the

primary waste was preserved, at very much lower activity, in the secondary scrubber liquor and distillate produced. This confirmed that caesium isotopes are not volatile under the ModulOx reaction conditions, and that the likely mechanism for activity carryover of these species into the secondary waste is via particulates or aerosol only.

RESIDUE CONDITIONING AND DISPOSAL VOLUMES

Reference Conditioning Processes for Ion Exchange Resins

In the UK, the current favored option for the treatment of LLW and intermediate level waste (12 GBq t-1 bg and/or 4 GBq t-1 a) organic ion exchange resins is direct encapsulation in cement. This produces a solid product and enhanced stabilization of the radionuclide content with regard to leaching. The waste loading of ion exchange resin in cement is limited by the requirements for the mechanical strength and other physical properties of the resulting conditioned wasteform. For cementation plant currently operating in the UK, the waste loading of both LLW and ILW organic IX resin in cement is typically 50% by volume. Each cubic metre of ion exchange resin waste therefore produces 2.0 m3 of solidified waste for storage and disposal .

Cement Conditioning of Primary Wet Oxidation Residue

The effect of variation in the waste loading of the inorganic residue in cement was examined, using samples of primary residue from the inactive plant trials on mixed ion exchange resin.

The wet oxidation treatment itself produces a volume reduction, with 1m3 of mixed IX resin producing approximately 0.46m3 of residue at 35% solids.

Using a mixture of Blast Furnace Slag (BFS) and Ordinary Portland Cement (OPC) in the ratio 9:1 by mass, the maximum waste loading of residue which produced a product with acceptable mixing and physical properties was established. Mixing trials were carried out at 20 litre scale using 13.3 litres (17.3 kg) of ModulOx residue with a total solids content of 35% by mass.

After 2 days, the cemented residue possessed a compressive strength of 2.6 N mm-2, rising to 19.1 N mm-2 after 90 days. The initial set time was 9 hours. Only small dimensional changes were measured in prism samples of the conditioned residue, suggesting that expansive calcium sulphoaluminate phases had not been formed.

Since each cubic metre of mixed ion exchange resin is reduced to 0.46m3 of residue, at this optimized formulation only 0.69m3 of solidified waste would be produced.

In comparison to the reference method of direct cement encapsulation of the untreated IX resin, treatment by wet oxidation prior to encapsulation of the treated residue should reduce the volume of conditioned waste for storage and disposal by around 66%.

Other Conditioning Methods

In other countries, for example Germany, drying of radioactive wastes prior to storage in high integrity containers is an established conditioning option. To ascertain the potential of this approach for wet oxidation residue, small samples of inactive residue, as used in the cementation trials described above, were evaporated to dryness at 105C. This produced a fine mobile powder. The powder was then loaded into an stainless steel die and compressed with a pressure of 19.6 N mm-2 (commercial waste supercompactors exert pressures in the region of 50 - 100 N mm-2). The compressed product consisted of a solid with a density of 1800 kg m-3. From the results of these small scale drying trials, in

which 100 cm3 of residue was converted to 24cm3 of solid dry product, it may be predicted that a cubic metre of ion exchange resin, treated by ModulOxm and then dried and compacted would only produce 0.11m3 of solid waste. If this conditioning method was acceptable as an alternative to direct cementation, the volume of conditioned mixed IX resin waste could be reduced by 95%.

SECONDARY WASTES

Aqueous Distillate

Water is removed from the wet oxidation reactor during processing by evaporation. The treatment of 1m3 of organic ion exchange resin waste typically produces 5 m3 of aqueous distillate, although the aim is to reduce this quantity by a combination of recycling (e.g. using distillate as a waste transport fluid rather than clean water) and improved waste transfer. The organic content of the distillate, associated with low molecular weight species such as ethanol and acetic acid, varied little between different treatment runs, with organic carbon measurements having an average value of 650 mg l-1 .

By measurement of the 60Co and non-volatile b levels present in the distillate following each radioactive treatment using the mobile pilot plant, decontamination factors (DF's) have been calculated, relative to the original radioactive inventory of 60Co and non volatile b in each run. Variation in DF from 5 x 101 up to >5 x 103 were measured, with activity carryover increased for treatment runs where reagent frothing was more prevalent. The first radioactive run using mixed IX resin, with a 'clean' plant, produced a distillate with the highest DF of >5 x 103. Improvements in process control and plant design may be required if direct discharge of distillate produced during ILW treatment is to be always viable. If DF's cannot be increased sufficiently by these methods alone, then decontamination of the distillate using a small IX resin bed may be utilized. This small amount of secondary spent IX resin can be recycled into the oxidation process, and should only increase the total volume of primary waste by 1% or less.

Airborne Discharges

The non-condensable gas mixture produced by the wet oxidation process consists predominantly of carbon dioxide and oxygen, but may potentially contain small amounts of particulate or volatile radioactivity. For each cubic metre of radioactive IX resin waste processed, approximately 550 m3 of gas is generated. After passing through the ModulOx plant packed tower scrubbing column, the gas stream was mixed with ventilation air from the secondary containment outlet and the combined off-gas filtered using a circular High Efficiency Particulate Air (HEPA) filter.

In all the radioactive treatment runs carried out using the mobile plant, the measured decontamination factor for b particulate activity in the discharged gas was greater than 106 and contained no detectable activity of this type above background levels.

In the case of the decontamination IX resin waste, which contained 7MBq of tritium in the free water associated with the waste, approximately 1.5 kBq of tritium was discharged in the off-gas as tritiated water vapor, corresponding to 0.02% of the original tritium inventory in the waste, or a tritium partitioning equivalent to a DF of 2 x 104.

Scrubber Liquor

The liquid recirculated through the packed tower scrubbing column of the mobile plant was initially 10% by mass sulphuric acid solution. For organic wastes which include nitrogenous material, including most anionic

IX resins, ammonia and amines may be discharged from the treated primary residue during neutralization with calcium hydroxide. Ammonium sulphate dissolved in the scrubber liquor is therefore the main product. If necessary the modest amount of spent scrubber liquor generated during operation can be decontaminated in a similar way to the distillate phase described previously, as similar low levels of active contamination are likely to be present in both streams.

CONCLUSIONS

For the treatment of the important group of organic radioactive wastes which include spent ion exchange resin, decontamination effluent, organic sludges and dilute aqueous liquids contaminated with toxic organics, this demonstration program confirms that ModulOx provides an effective option with several important advantages:

Significant reduction in the volume of spent ion exchange resin without the release of SOx , NOx and volatile metals into the off-gas system, at process conditions which cannot form recombination products such as dioxins and furans.

In comparison to direct cement encapsulation of ion exchange resin, pre-treatment by ModulOx can reduce wasteform disposal volumes by around 66%, or by over 90% if the potential of waste drying and compaction as a conditioning method can be realized.

Chelating agents or toxic organics can be removed by ModulOx from solid or liquid wastes to meet specific Waste Acceptance Criteria for existing or planned disposal facilities, or to meet effluent discharge criteria.

Cement encapsulation of primary calcium sulphate residue from ion exchange resin processing has been shown to produce a solid wasteform with good physical properties suitable for interim storage or disposal.

Operation at 100oC, atmospheric pressure and without the use of any highly corrosive chemicals allows the use of an "off-the-shelf" glass lined mild steel reactor, and standard stainless steel process engineering equipment.

The relative simplicity and standardization of the ModulOx pilot system will minimize the design and development requirements for larger mobile, modular units with throughputs for ion exchange resin of up to 1m3 per day.

ABSTRACT
Disposal and safe storage of contaminated nuclear waste is a problem of international scope and concern. Probably the greatest concentrations of waste requiring attention resides with the current nuclear superpower, the USA, and former nuclear superpower, the Soviet Union, from their nuclear power and weapons activity. However, there are also concentrations of similar waste in Western Europe and Japan where disposal and storage could be more acute than in the large land masses of the USA and former Soviet Union because of population density, particularly Japan.
In Japan reducing the radioactive contaminated waste volume needing safe storage is being encouraged. Decontaminating LOW LEVEL radioactive waste reduces or eliminates its demand for safe storage opening up space for the more critical wastes, TRANSURANIC and HIGH level radioactive waste. Chemical decontamination of low level radioactive waste is economical and can be safely achieved without creating any mixed waste because the chemical cleaners can be recaptured, refined for recycling or decomposed into nontoxic elements. Since the decontaminated objects may be recycled as scrap or reusable tools the waste stream is considerably reduced.
As a preface to its main topic this paper will touch briefly on a successful method of chemical decontamination being developed in Japan utilizing methylene chloride and CHELATE SOLUTION for decontaminating low level radioactive waste consisting of tools, scaffolding components and other steel and iron items that are used or removed in routine maintenance programs at nuclear power plants.
In particular this paper will examine the decomposition of CHELATE SOLUTION and the reduction of its waste stream to a negligible amount as developed by Genden Engineering & Construction Company in cooperation with Morikawa Industries Corporation, both of Japan.

INTRODUCTION and BACKGROUND

Japan's problem with nuclear generated radioactive waste disposal, reduction and storage is similar to that of the USA. Japan's waste is mostly created by nuclear power plants, giving it less waste volume to manage since they have no military or defense weapon's volume. However, their problem may well compare to that in the USA when you consider that their population, roughly half that of the USA's, inhabit an area the size of California. It may not be too far fetched to think that if everyone's back yard was in California, the USA could very well have an unsolvable nuclear waste storage problem.

Viewing this as an opportunity to contribute to solving a national problem with a parallel opportunity for commercial reward, Morikawa Industries Corporation (Morikawa) of Koshoku City, Nagano Prefecture, Japan, began research and development activity decontaminating low level radioactive metal objects seven (7) years ago. Morikawa has committed considerable of its resources to this research and development over the past several years, and as designers and manufacturers of special machinery for many years they are able to bring special electro/mechanical/pneumatic engineering skills and knowledge to solving these unique problems.

Recently Morikawa entered into a technology agreement with Genden Engineering & Construction Services Company (GESC), an affiliate of Japan Atomic Power Company, which should enhance both companies abilities and efforts in these developments to substantially reduce the quantity of low level waste (LLW) being placed in extended time storage thus contributing to an environment more safe for the Earth's inhabitants.

As a preface to our principal topic this paper will present equipment with mechanical and chemical processes, developed over the past several years by Morikawa and more recently in cooperation with GESC, for decontaminating LLW metal objects.

Following the preface, this paper presents our principal topic, the development, made jointly by GESC and Morikawa, for successfully and effectively removing low level radioactive contamination from various contaminated components that are generated in nuclear power plants by the use of chelate solutions, which after use in decontaminating objects are decomposed by electrolysis into clean water and harmless carbon dioxide gas thus considerably reducing secondary radioactive waste.

BACKGROUND FOR ATTENTION PAID TO, and EMPHASIS ON DECONTAMINATION

With continuous operation of nuclear power plants in Japan over an extended period of time, a considerable amount of low level radioactive waste has been generated, stored in drums or solidified in concrete, all which is kept at power plant sites. Furthermore, components, pipe and fittings, structural parts, tools, etc. replaced, used and/or discarded during annual plant maintenance programs have been continuously increasing in quantity. Dealing with this problem has become "a real headache" at all nuclear power plants.

Two techniques are commonly used in decontamination. 1) Mechanical processes that physically remove contamination from objects and 2) chemical processes that remove contamination from objects by the use of chemical solvents and/or cleaning agents. Although each technique has favorable and unfavorable features, neither can be said to be an effective decontamination method as a stand-alone process.

DECONTAMINATION USING CHELATE SOLUTION

Chelate agent is also known as a rust removal agent, as its molecular structure has a carbolic acid radical, which has the ability to remove matter adhered to the surface of metals enhancing decontamination. GESC and Morikawa, in order to establish an optimum decontamination method using chelate agent, concentrated on developing a technique to decompose the residual solution containing chelate agent into nontoxic carbon dioxide, CO2, and water, H2O, thus yielding permanently harmless residuals. The joint effort has succeeded in establishing an effective decontamination method that safely decomposes liquid waste.

DECONTAMINATION PROCESSES

REMOVAL OF PAINT COATING ON METAL SURFACES

Chemical Dissolution Method

Low level radioactive objects are put into a methylene chloride (CH2CL2) washing tub. The solution is circulated around and pressure sprayed onto the contaminated objects. This process removes oils and fats from the metal surface and also exfoliates the paint coating exposing the metal surface itself. Then the contaminated object is exposed to supersonic washing inside the methylene chloride tub, where supersonic vibration is induced, which removes even microscopic size paint coating. The spent contaminated methylene chloride from this process is vaporized and distilled purifying it for reuse, which also concentrates the contaminated paint and oil sludge for packaging and safe storage or responsible disposal.

Mechanical Plastic Media Blasting Method

For contaminated objects with paint coatings that methylene chloride cannot successfully remove the mechanical plastic media blasting method may be used. The object's contaminated metal surface is shot blasted with plastic beads accelerated to high speed by compressed air, which upon impact physically removes paint coating and rust that still adheres to the surface. Since plastic media impacting with the object causes no deformation or harm to its surface, this method is effective for decontaminating turbine blades, shafts, bolts, nuts, etc. Spent plastic bead media may be safely disposed of by incineration.

RUST REMOVAL

Contaminated objects that have been partially decontaminated by the use of methylene chloride washing and/or plastic media blasting are next placed into a tub containing a rust removal solution, chelate agent or inorganic acid. Refer to Fig. 1, FLOW DIAGRAM: USED CHELATE SOLUTION ELECTRO-CHEMICAL PROCESS, at the end of this paper. Supersonic vibration is applied to the objects immersed in the solution in the tub to assist and enhance rust removal. In the process using chelate agent, the radioactively contaminated object is decontaminated by metal-ionizing its surface. During decontamination the chelate solution picks up metals and other solids becoming contaminated and must be fortified with fresh chelate to maintain the solution at an efficient processing level. The contaminated chelate enters the waste stream, which in most decontamination processes previously applied entombed the entire waste stream in concrete for safe storage disposal.

Fig. 1

DECOMPOSING TECHNIQUE FOR RESIDUAL CHELATE SOLUTION

The residual chelate agent waste solution that has been used in the rust removal process is placed into a reaction precipitation tub where sodium hydroxide is added to precipitate metallic ions as hydroxides, which results in separating metallic ions from the chelate solution. Again

please refer to Fig. 1, Flow Diagram: Used Chelate Solution Electro-Chemical Process.
The chelate solution is transferred to an electrolytic cell where it is decomposed into carbon dioxide and water and where sodium hydroxide (NaOH) is added supporting the electrolysis process and improving reaction efficiency. The discussion immediately below, supported by several graphs (Figures), demonstrates some of the factors influencing EDTA chelate decomposition.
Figure 2 illustrates how electrolysis lowers the EDTA concentration from 10,000 PPM to less than 10 PPM over a 2-1/2 hour processing time frame. The Y axis uses a logarithm scale to obtain a near-straight-line curve. This data was derived using the following test setup and specifications:
Current density: 8.3 amps/dm2
Waste liquid volume: 3 liter.
Anode surface area: 6 dm2
Added chemical: 0.1 mol NaOH/liter
Fig. 2
Figure 3 shows the effect electrolysis current level has on the time to achieve lowered EDTA concentrations. At 20 amperes current 4 hours is required to reduce EDTA concentration to approximately 60 PPM, while at 60 amperes current 2 hours is required to reduce EDTA concentration to approximately 4 PPM. Expressed another way, the electrolysis process at 60 amperes current requires half the time (2 VS 4 hours) to achieve a 93% lower concentration (4 PPM VS 60 PPM) than occurs at 20 amperes current. These data were derived using the following test setup and specifications:
Electrolyte volume: 3 liter.
Electrode area: 6 dm2
Electrolyte: NaOH.
Fig. 3
Figure 4, following on page 6, illustrates the reduction of radioactivity that occurs during the various decomposition processes shown in Fig. 1, Flow Diagram.
Spent or used EDTA solution has a radioactive level of 30 Bq/cm3.
Step 1 Metal Ion Separation/Filtration process reduces used EDTA solution radioactivity to 1.8 Bq/cm3.
Step 2 Electrolysis further reduces used EDTA solution radioactivity to 0.5 Bq/cm3.
Step 3 Dedicated Filtration reduces EDTA radioactive level to 0.08 Bq/cm3.
Step 4, Reverse Osmosis Membrane processing, reduces used EDTA solution radioactivity to a level lower than the natural background or surroundings.
Fig. 4
Following dedicated filtration and before reverse osmosis membrane processing, as an option, the spent partially processed chelate solution may be processed through an ultraviolet ray reactor tower equipped with low voltage mercury lamps. Bubbling air, which becomes saturated with Ozone when it passes near the mercury lamps, flows into the residual chelate solution. Exposure to the ozone rich air oxidizes the remaining organic matter dissolving it.
The sodium hydroxide contained in the water solution that has passed through the ultraviolet reactor tower is then recovered in the reverse osmosis membrane and recycled.

COMPARISON OF CHELATE AGENT DECONTAMINATION METHOD WITH OTHER METHODS

Morikawa compared methods using chelate agent with other chemicals.

Using inorganic acid the processes involved include:

- Cleaning contaminated objects using inorganic acid.
- Concentrating the liquid waste.
- Solidifying waste in concrete.

This method requires 20 man-hours of labor and produces about 1.5 drums of waste needing storage space.

Using chelate agent solution the processes involved include:

- Precipitation treatment.
- Electrolysis treatment.
- Secondary waste treatment.

The chelate agent method requires 4 man-hours of labor producing about 0.04 drums of waste, principally filter media, needing storage space.

As these figures for the competing processes show, the chelate agent method uses 4 man-hours while the inorganic acid method uses 20 man-hours of labor. The Chelate agent method saves 80 percent of the labor man-hours. Also the chelate method generates 0.04 drums of waste while the inorganic acid method generates 1.5 drums. Chelate agent generates less than 1/100 of the waste requiring storage that the inorganic acid method generates.

HOT TEST RESULTS, LOW LEVEL RADIOACTIVE OBJECTS.

Morikawa conducted decontamination hot tests of contaminated objects using processes including Organic Solvent Decontamination, Rust Removal Decontamination and Washing. This test was conducted at Tokyo Electric Power Company's (TEPCO's) Fukushima No.1 Nuclear Power Plant.

The steel tools and objects subjected to decontamination processing numbered 159 as shown in Table I at the end of this paper. For the various tool and steel objects decontaminated in the hot test, data in Table I show the Level of Radiation and Count of Objects successfully decontaminated in the first step. During the first step 131 objects were successfully decontaminated to radiation levels below 50 cpm out of 159 objects processed. The test was not 100% effective in decontaminating all objects because the test equipment consisted of laboratory units not suitable for processing some tools and several steel objects, such as the unacceptable 28 objects having levels over 50 cpm readings following first step decontamination. These 28 objects had heavy welds, thick rust and/or deep cracks. After hand grinding these 28 unacceptable objects were processed again in a second step through the decontamination equipment. These data as displayed in Step 2 at the bottom of Table I show that all previously unacceptable 28 objects dropped to acceptable levels below 50 cpm or below background level readings.

Table I

FUTURE PROJECTS

Morikawa's initial prototype equipment for decomposing contaminated liquid waste Chelate solution has proved to be technically satisfactory. Another prototype machine has been assembled using the same test equipment components and is being shown and demonstrated at nuclear power plants now around Japan.

A basic patent application for the technique of chelate agent decontamination and liquid waste decomposing equipment was issued in 1993. Additional patent applications for peripheral technology and related applications are being filed now. These additional patent

applications are also being filed in the USA and other major industrial countries.

SUMMARY

We believe this decontamination method for steel and iron metal substrates using cleaning chemicals and/or chelate solutions for removal of radiation bearing coatings. corrosion or rust, grease, oils and other solid contaminates where the cleaning chemicals can be purified for recycling/reuse by vaporizing and distilling, and/or where other chemical chelate solutions can be decomposed into nontoxic elements or substances for safe release to the environment, to be an economically viable and responsible decontamination method substantially reducing the volume of low level radioactive waste and mixed chemical waste that requires expensive long term storage thus freeing up space for the more critical storage of transuranic and high level radioactive waste. Not only do these processes avoid long term storage for a considerable volume of material, they make it possible to safely recycle steel and iron scrap through normal primary metal industry channels.

Responsible avoidance of storage for radioactive waste, wherever possible, is not only highly desirable economically, socially and politically, but should be aggressively pursued and could well be, if not already established, as a major nuclear industry objective and policy.

DRYING OF LIQUID OR SUSPENDED RADIOACTIVE WASTE UNDER ATMOSPHERIC CONDITIONS

K. Tscheschlok
M. Szukala
J. Czuberny
Hansa Projekt Anlagentechnik GmbH
Tarpenring 4
D-22419 Hamburg

ABSTRACT

The German regulations for the final disposal of radwaste prescribe, that these waste neither contain nor release free liquids, apart from reasonably achievable and unavoidable residual content. In addition, the volume reduction of radwaste is to be the preferred treatment prior to all other methods for conditioning.

Referring to these requirements, a new designed system is now available for drying water-containing, pumpable operational radwaste. The separation of the water from the solid matter is performed under atmospheric conditions with a hot-air heating. The solidified product is generated within the disposal container. The process and the system design offers economical, operational and radiation protection related advantages.

INTRODUCTION

In the Federal Republic of Germany, the legal situation stipulates volume reduction of radioactice waste is to be the preferred treatment prior to all other methods for conditioning. On the other hand, the regulations for the final repository require avoidance of fermentation, rotting and corrosion processes, as well as the generation of radiolysis/hydrolysis gas set off by reactive water (1).

An advantageous and acceptable treatment for meeting these requirements is the drying of the material, especially when it contains mostly water as liquid and is non-burnable.

Liquid waste has already been partially dehydrated mechanically or thermically with the existing systems of the nuclear power station (sedimenting, centrifuging, evaporation etc.). Pre-treated liquid wastes with a high water content are for example Evaporator concentrates and Filter sludges (suspensions of ion exchange resins, filtering aids etc.). However, because of the remaining high water content, this pre-treated liquid waste is not suitable for final disposal, so it must be subjected to thermic residual drying. As a result, a significant reduction in volume will take place.

For this purpose, various techniques have been developed in Germany. The drying system that will now be described offers an advantageous, proven dryer unit which conditions liquid waste in accordance with the regulations for the final disposal of radwaste (2,3).

SYSTEM DESCRIPTION OF HPA DRYER WITH POST-FEEDING

The flow chart of the process is shown in Fig. 1:

Fig. 1

The drying of liquid waste is carried out in standard disposable containers (200-l-drums or 180-l-cartridges). The movement of the containers is carried out with a transport carriage which can be transported, depending on the individual controls activated on the control panel, to the lid removal unit or the lidding unit.

The heart of the process is the drying chamber. After the lid has been removed, the container is transported into the drying chamber, positioned appropriately, lifted by a lifting carriage to the permanently installed docking plate and, at the same time, sealed.

The receipt of the liquid waste from the nuclear power station for the dryer takes place in the storage tank. To prevent sedimentation processes effectively, the liquid waste is constantly stirred and circulated. The liquid waste from the circulation system is fed into the container with a regulated level by means of the post-feeder. The heating operation will be started during the feeding of the liquid waste into the container. Therefore, the air contained in the drying chamber is circulated in the electrically heated flow channel by means of a hot air fan and, depending on the type of waste, heated to 130 to 190 C (heating circulation). The heated air is fed to the container in the drying chamber by an optimized flow.

After a short heating phase, the drying process begins under atmospheric conditions. The resultant water vapor is extracted via a separate steam pipe and condensed in the subsequent condenser. The condensate that arises is measured in the condensate measuring vessel and, after interim storage in the condensate collecting tank, it is returned to the waste water line of the nuclear power station.

During the drying process, liquid waste is again added to a controlled level, and the non-watery waste components, including the radioactive nuclides, are concentrated in the container. By this means, the drum volume is fully utilized.

Depending on the moisture content and the composition of the waste, different drying times occur. The process control is determined by the rate of condensation. With an increasing concentration of solids, the amount of condensate decreases over time. As soon as the rate of condensation is below a specific level, the post-feeding is interrupted. Simultaneously, the after-drying process begins. The after-drying process is deemed to be complete when no noticeable amount of condensate is produced.

During drying of evaporator concentrates, a solid salt block is finally formed.
After the drying process has been completed, the cooling operation is begun, and the filled container is removed from the chamber with the transport carriage, the lid is fitted and the container is transported to the unloading position.

EQUIPMENT DESCRIPTION

The liquid waste drying system shown in Fig. 2 is built as a tandem installation. This enables a higher throughput to be achieved.
Fig. 2
The system consists of two drying chambers (each with a post-feed system), one storage tank, one transport section (consisting of carriage for receipt and positioning of containers, lid fitting machine for lid removal and lid fitting, cartridge grapple to remove compressed cartridges from the container, cartridge lid fitting machine for lid removal and lid fitting and weighing system), Control panel, Process control system "BIKON", Video monitoring feature, Shielding system and Sampling system.
The technical data and consumption of operating materials are shown in Table I.
Table I

AUTOMATIZATION

In order to comply with the radiation protection regulations it is necessary to handle the full containers by remote control . The system is therefore shielded and prevents be entery by personnel during normal operation.
In the shielded zone, all functions are fully controlled automatically from a separate control panel. The automatization includes the transport of the container into and out of the appropriate lid fitting and lid removal stations and the packaging unit and the transport of the containers to the loading and unloading of the drying chamber, the filling of the storage tank, the feeding of liquid waste and the supervision of the drying process.
All functions can be addressed individually and can be carried out under video supervision.

DOCUMENTATION

In accordance with the regulations for the control of radioactive waste, the waste conditioning must be appropriately documented. This includes the precise recording of the operating data relevant to the process. This makes it possible to demonstrate that the waste product for permanent storage has been produced correctly.
The processing of each batch is recorded with a proprietary process control system "BIKON". The advantage of this system is, that the important data for the batch documentation can be taken directly from the process monitoring system. At the same time the entire process can be visualized on screen. The batch documentation which is saved on disk can be analyzed at any time with separate PC.
Furthermore, the operating parameters relevant to the process are documented in fail-safe form with a multi-channel printer.

OPERATING RESULTS

Since October 1994, extensive operating experience has been gathered with a drying system with post-feeding feature, configurated as a tandem installation. Several drying experiments have been carried out, which have produced major insights into the optimum control of the process. As

a result, the installation has been optimized with regard to the maximum evaporation rate and optimum product quality.
The typical behavior of the drying process is shown in Fig. 3:
Fig. 3
Because of the isothermic heating of the container with the liquid waste, a maximum evaporation rate is achieved at the beginning which is dependent on the feed temperature of the heating circuit, the material of the container (thermal conductivity) and the filling level of the container (heat transfer surface area).
As the drying process progresses, the evaporation decreases as a result of the corresponding increase in the salt concentration. This enables a gentle evaporation to be achieved. The end of the drying process is indicated by the sudden reduction in the evaporation rate.
The principle of the salt block formation as a result of isothermic heating of the container can be seen in Fig. 4:
Fig. 4
In the interior of the filled container, a flow profile is created by the convective transfer of heat to the liquid waste (natural circulation). This creates a temperature gradient from the container wall to the central area. As a result of the permanent removal of water, a compact salt block (monolith) forms under isothermic heating in the cooler area, and in the drying process this mass grows slowly outwards (evaporation crystallization). Therefore the structure of the monolith is layered in cross section.
Carrying out the drying process under atmospheric conditions leads to less water content during the salt block formation. At the end of the drying process, the container will be heated without post feeding of liquid waste. In this drying operation, the isothermic heating leads to firm products. The overall mass balance of the process shows, that it will produced 15 to 20 % solids, formed as a monolithic salt block in the container (calculated on the basis of 100 % evaporator concentrate). The salt block is characterized by a high specific weight (r = 1.7 kg/l), a high solidity, thermic stability up to 70C and a residual moisture content less than 10 % (crystallization water, no free water). The volume reduction factor of the liquid waste is between 8 and 11 : 1.

SUMMARY

The German regulations for the final disposal of radwaste prescribe, that these waste neither contain nor release free liquids, apart from reasonably achievable and unavoidable residual moisture. In addition, the volume reduction of radwaste to be preferred treatment prior to all other methods for conditioning.
Referring to these requirements, a new designed system is now available for drying water-containing, pumpable operational radwaste. The described drying system with postfeeding of liquid radwaste during the drying process offers the following advantages:
Drying under Atmospheric Conditions
High degree of drying
(lower residual water content of the dried product leads to maximum volume reduction in comparison with vacuum dried products)
Isothermic Drying with Hot Air
Monolith formation
(high end product solidity, no local overheating in the final drying phase)
Minimal Contamination Risk

Drying in containers
(no filling process after drying, separate vapor extraction)
Highly Automated
Fully automatic control from a shielded control panel with video supervision
High Documentation Standard
Immediate process visualization throughout the drying process
Simple quality control of product
High Level of Flexibility
Designed as a small compact unit on a modular principle
Supply of mobile or stationary installations,
on request, service operation possible

Los Alamos National Laboratory

ABSTRACT

The tank waste characterization process is an integral part of the overall effort to identify, quantify and control the hazards associated with radioactive wastes stored in underground tanks at the Hanford Reservation.
Characterization of the current waste tank contents through the use of waste sampling is only partly effective. The historic records must be exploited as much as possible. A model generates an estimate of the current contents of each tank, built up from the estimated volumes of each of the defined waste components. The model combines the best estimate of the waste stream composition for each of the major waste generating processes. All available waste transfer records were compiled and integrated to track waste tank fill history. The behavior of the waste materials in the tanks was modeled, based on general scientific principles augmented with specific measurement data. Sample analysis

results were not used directly to generate any of the tank contents estimates, but were used to determine the values of variable parameters such as the solubility. By considering all available information first (including historical model estimates, surveillance data, and past sample analysis results), future sampling resources and other characterization efforts can best be spent on tanks that will provide the largest returns of information.

INTRODUCTION

The Hanford Reservation system of underground storage tanks contains approximately 230 million liters of waste material distributed among 177 tanks. The waste in these tanks was produced as a part of the nuclear weapons materials processing mission that occupied the Hanford Site for the first 40 years of its existence. Waste tanks (149 single-shell and 28 double-shell tanks) contain a wide variety of waste compositions generated by three distinct chemical separations processes, several waste management/waste volume reduction operations and two tank waste reprocessing flowsheets. Characterization of the tank wastes is required to maintain the safe storage of the wastes, and to guide retrieval, processing, and disposal technology development.

MOTIVATION FOR CHARACTERIZATION

The tank waste characterization process is an integral part of the overall effort to identify, quantify and control the hazards associated with radioactive wastes stored in underground tanks at the Hanford Reservation.

Knowledge of the physical, chemical and radiological properties of the wastes is prerequisite to operations to store, retrieve, process and dispose of the wastes safely.

The Tank Waste Characterization Project currently addresses the information needs identified for the Tank Waste Remediation System (TWRS) through the Data Quality Objectives (DQO) process (1).

Safe Storage of the Waste

Characterization for safe storage of the waste includes the screening of all tanks for key parameters that may indicate potential safety issues. The areas of concern are:

The presence of energetic compounds in the condensed phase of the waste in a configuration that could support a propagating exothermic reaction (i.e. dry, in the presence of an oxidizer, located where an initiating factor is feasible).

The presence of flammable gases in the dome space above the waste surface at sufficient concentrations that combustion is feasible.

The presence of fissile materials concentrated in the absence of significant neutron absorbers so that a criticality event is feasible.

In all areas of concern, several factors must interact to give rise to an actual safety issue. The presence of specific waste components, addressable by characterization, is only one of the contributing factors. Characterization can be used to identify and quantify hazards and develop the most appropriate responses for dealing with them. A combination of active and passive controls can provide multiple safeguards that prevent an event from occurring.

Safe Operation of the Waste Tank Facilities

Although many of the tanks are currently stabilized and undergo no operations, several operations are ongoing in a subset of tanks. A waste evaporator unit concentrates liquid waste to provide additional storage space in the existing tanks. Removal of pumpable liquid from single shell

tanks is performed to prevent leakage into the soil. Transfers of waste between operating double shell tanks is necessary to support these operations. Other specific operations may occur, such as the addition of caustic to a tank to maintain operating specifications.

All operations must be performed in accordance with all applicable regulations. Intrusive operations must be carried out in a manner that ensures that none of the safety issues identified above (see Safe Storage of the Waste above) are generated during operations. This requires the review of existing characterization information prior to initiation of the operation, and may require acquisition of new information.

In addition, other information on waste characteristics may be required to support physical operations. For example, prior to transfer of waste material, the physical parameters of the waste must be well enough understood to ensure that the material will not solidify during transfer, clogging the transfer lines.

Resolution of Safety Issues

The above areas address characterization needed to ensure that safety issues are recognized so that they may be corrected, are not created during waste management and disposal operations. Separately, a thorough understanding of the mechanism behind the safety issues is needed in order to select the appropriate response. For example, one needs to understand how flammable gas is generated in the waste material, and what causes it to be retained or released at a given rate. This understanding ensures that the symptoms of a potential problem are correctly identified, that the correct controls or treatment for the problem are applied, and that sufficient foresight is applied in the future to prevent occurrences during waste management and disposal operations. The information to resolve safety issues is obtained from many sources, including theoretical work, laboratory experimentation, and in some cases characterization data.

Preparation for Waste Disposal

Safe storage and operation of the waste tanks is an interim step until facilities are available for the retrieval, pretreatment, processing and final disposal of the material. The equipment and facilities for these steps are still in the design phase. Characterization of the waste requires that the physical and chemical properties be adequately quantified, both in terms of average values and of bounding values, to support design. In addition, physical samples of waste material are required for small and large scale testing of various treatment processes.

TANK WASTE CHARACTERIZATION PROCESS

Characterization of the current waste tank contents through the use of waste sampling is only partly effective. The waste tanks contain very few access ports, limiting the number of samples obtainable. The access port locations do not necessarily support obtaining representative samples, particularly in tanks where the waste material is heterogeneous. Sampling is expensive and complex because of the radioactive and chemically hazardous nature of the waste. The historic process records must be exploited as much as possible to improve overall waste characterization. By considering all available information first (including historical model estimates, surveillance data, and past sample analysis results), future sampling resources and other characterization efforts can best be spent on tanks that will provide the largest returns of information (2).

The Overall Process

The approach to characterization of each tank is to compile all available information about each tank to provide an estimate of the contents. Information sources include models of waste contents developed from historic records of processes and waste transfers, surveillance and monitoring data, sampling and analysis results, and models of chemical behavior. The estimates developed from these sources are improved by sampling or other measurement to provide additional data. Grouping of similar tanks is employed in developing the estimates (3,4). Based on the amount and quality of data extant, an estimate of tank contents and the identified needs, a plan is developed to obtain additional data (5,6). The development of a defensible plan requires an understanding of the quality of existing data and the capabilities and limitations of the tools which may obtain new data.

Role of Historic Modeling

The waste tanks contain a wide variety of waste compositions, principally generated by three distinct chemical separation processes, several waste volume reduction operations and two tank waste reprocessing flowsheets. All of the processes contributing to the waste generation underwent significant evolution over time. Extensive (albeit incomplete) records were kept describing the initial placement of waste in specific tanks and the later transfers of waste between tanks. The complete reconstruction of current tank contents through use of the records is complicated by several factors:

Although the flowsheets for the waste-generating processes are well known at the start of a process, the evolution of the process during plant operation is not well documented. In addition, process vessel corrosion and impurities in process chemicals can dramatically affect the nature of the waste stream.

Active concentration of tank waste supernatants in six different evaporator campaigns spanning the fifty years of processing have not been thoroughly documented. There are many uncertainties in the tank transaction histories for these campaigns. The waste heating during evaporator campaigns may also have accelerated chemical reactions, changing waste properties from those described in the flowsheets or in early sample analysis.

The waste transactions associated with the removal of tank waste for the two major tank waste reprocessing campaigns, the Uranium Recovery campaign in the 1950's and the Cesium/Strontium removal campaign in the 1960-70's, are incomplete. These processes were based on assumed waste characteristics, not actual waste characteristics. Significant changes were performed as the processes evolved during the course of the reprocessing campaigns. In many cases these changes were not well documented.

The construction of a model of tank contents combines the best estimate of the waste stream composition for each of the major waste generating processes and several minor processes. Altogether, 48 distinct waste types are modeled, referred to as the Hanford Defined Wastes (7). All available waste transfer records were compiled and integrated to track waste tank fill history (8-11). The behavior of the waste materials in the tanks is modeled, based on general scientific principles augmented with specific measurement data (12,13). Although sample analysis results are not used directly to generate any of the tank contents estimates, sample analysis is used to determine the values of variable parameters

such as the solubility and precipitation rates of specific analytes in specific waste materials.

The model generates an estimate of the current contents of each tank, built up from the estimated volumes of each of the defined waste components (14-17). The quality of these waste content estimates is now being reviewed and quantified through several parallel activities. A Monte Carlo simulation has been performed to quantify the uncertainty of the model estimates for several tanks, based on the variability of key model parameters such as limiting solubility. This intial variance or uncertainty estimate has been used in the systematic comparison of tank contents estimates with actual sample data (18). Initial results are promising in most cases (i.e., relatively good agreement between model estimates and sampling estimates). However, some results indicate that there are significant differences between the model estimates and sampling results. This observation could indicate:

- incomplete modeling of the major error sources in the Monte Carlo simulation,
- overly optimistic estimates of variance based on sampling results,
- systematic errors in the model that require correction,
- or some combination of the above factors.

Additional samples of key waste types are being acquired and analyzed to allow better definition of the composition of the defined wastes types used in the model (19). The evaluation and improvement of the historic model will continue until a quantitative variance estimate can be provided for each of the contents estimates. The availability of the resulting tank contents estimates will allow reduced sampling of many tanks, better grouping of similar tanks, and more effective planning of sampling events.

The Role of Sampling and Analysis

Analysis of sample material alone will not provide adequate characterization information for the Hanford underground storage tanks. It is not possible to design a sampling scheme that provides a statistically significant number of truly random samples.

Most tanks have very few available access ports or risers (many have no more than two accessible risers). The locations of the risers often leads to sampling of non-representative material. The risers have in some cases been used for dumping of additional waste material. Previous samples may have been taken from the risers, disrupting the solid materials. Instruments may have been introduced into the waste through a riser. Removal of instruments may have required decontamination, introducing water or other solutions into the waste near the area where samples are taken.

Given these constraints, the value of sample analysis may be called into question. However, when combined with the historic model and contemporary surveillance data, and allowing for potential biases and sampling error, a well thought out sampling scheme can provide significant information. The first step in the development of the sampling scheme is to consider the historic information, including the waste type predictions, records of any previous sample activity and photographs of the waste tank contents. After this initial assessment, contemporary surveillance data is considered. Review of the available risers is necessary so that any factors that may make a specific sample different from others in the tank are understood. Review of the photographs can reveal surface heterogeneity and give clues to the relationship between a sample at a

specific location and the overall tank content. It must be noted that some tanks may be so heterogeneous that very little information can be gained from any small number of samples. In these cases, an alternative approach (such as adding liquid to turn the waste into a homogeneous slurry and retrieval into an interim storage tank) must be considered. When a sampling approach is selected, it is also necessary to consider how the acts of acquiring, removing, transporting and analyzing the sample may affect the parameters being measured (20). Any systematic biases that are introduced during the sampling process need to be considered when using the results to reconstruct the total tank contents. Given all the constraints, the most realistic approach to tank waste characterization must consider all available data, start with a model of the waste generated from the historic records, and then use sampling to confirm or refine specific aspects of the model.

Optimization of the Process

Programs requiring data regarding waste composition document their issues and information needs and identify tanks which must be characterized to meet the needs. The programs identify criteria by which all tanks can be prioritized with respect to each issue. The Characterization Project integrates the information needs and tank priorities to define an overall plan for obtaining new information through sampling. The process for developing the priority list and generating a sampling schedule includes the application of technical and operational constraints. The most effective overall prioritization of tank sampling events ensures that early events provide data that supports characterization of multiple tanks. High priority sampling events are those that provide data to:

Allow resolution of safety issues affecting multiple tanks.

Define the appropriate approach to characterization of multiple tanks for safety issue identification and resolution.

Improve the estimates of waste content for multiple tanks, particularly with regard to important safety and disposal parameters.

It is not yet possible to determine the total number of samples needed to characterize the wastes adequately (either for an individual tank or for the entire tank farm system). An initial set of 28 tanks has been identified as high priority to address the above issues (2). It is anticipated that the information gained from those samples will support resolution of issues (reducing the characterization needs associated with other tanks) and provide quantitative information about the quality of the tank content estimates developed from historic data. Once the uncertainty associated with the historic models is quantified, it may be possible to use the model estimates alone to make future decisions regarding the operation and disposal of specific tanks. This application of the historic model has the potential to greatly reduce future sampling requirements.

CONCLUSIONS

Continued evaluation of historical information and modeling techniques is needed to enhance the value of that information and potentially reduce the need for future in-tank sampling operations. As additional knowledge is gained, that knowledge is fed back into the process to help prioritize, guide and define future efforts so that the most important information is obtained as soon as practicable. Continued evaluation and improvement of sampling and measurement methods is required to improve the ability to obtain new information and to understand its meaning and limitations.

ABSTRACT

Over 2,000 tons of irradiated zirconium alloy clad uranium metal fuel are stored in the water-filled Hanford K Basins. Half of this N Reactor fuel is in open top aluminum and stainless steel canisters (in K East Basin) and half is in sealed vented canisters (in K West Basin). On the basin floor and associated with this fuel is an accumulation of sludge containing fuel, fission products, corroded structural material, and wind blown debris. Previous papers discussed plans and equipment for the sampling of gas and liquid from sealed canisters, sampling of sludge from the basin floor, and the movement of fuel to the Hanford hotcells. These sampling activities have now been accomplished. Various lessons have been learned from the execution of various sampling campaigns at the K Basins, and analytical characterization data resulting from the examinations continue to support decisions for the storage and disposal of fuel and sludge.

1. Data obtained from the sampling of gas and liquid in sealed canisters include radionuclide concentrations in the liquid and the degree of displacement of the nitrogen canister cover gas by significant quantities of hydrogen. The macroscopic condition of fuel and the volume of in-canister sludge, observed when selected canisters are opened has been shown. Inferences on the degree of fuel corrosion in canisters can be drawn.

2. The recent sludge sampling campaign for the K East floor has been much more comprehensive than any previous attempts with respect to both

quantity of sludge retrieved and the number of physical/chemical properties addressed. Sludge composition and properties are now known as a function of both basin location and of the position of various layers within the sludge.

3. Fuel elements from the K West Basin have been examined both visually and metallographically at the Hanford hotcells. Detailed observations on the condition (including corrosion) of damaged and undamaged elements have been made.

4. A controlled-atmosphere furnace has been installed in the Hanford hotcells. This new capability has allowed small sections of fuel elements to be subjected to the dewatering and conditioning processes envisioned for the fuel now stored in K Basins. Moisture reduction and hydrogen evolution have been monitored as a function of temperature and system pressure (vacuum and flowing gas scenarios). With this system, oxide layers have been applied to fuel samples to reduce the chemical reactivity of the exposed surfaces and the stability of these protective layers has been assessed.

INTRODUCTION

Characterization is in progress for the N Reactor fuel stored in the Hanford K Basins. These activities (1) support the strategy for removal of fuel from the basins and storage of fuel in a dry condition at an area remote from the Columbia River. This strategy currently consists of placing fuel in a Multi-Canister Overpack (MCO), drying the fuel while it resides in the MCO and conditioning some portion of the fuel to reduce its chemical reactivity. (2) Characterization includes the examination of fuel, canisters, and associated sludge. It consists firstly of in-basin activities such as visual examination, sludge depth measurements, and sampling of gas and liquid in canisters. Secondly characterization encompasses the examination of samples of fuel and sludge which have been removed from the basins and shipped to laboratories. This paper presents observations made in the basins during the most recent attempts to ship samples from the basins and data obtained in the laboratory hotcells.

EXAMINATION OF CANISTERS AND FUEL

Of the 2,000 metric tons of uranium metal spent fuel at the two Hanford K Basins, roughly half is stored in sealed aluminum and stainless steel canisters in the K West Basin. Each water-filled canister contains 14 fuel assemblies (14 inner elements and 14 outer elements distributed between two barrels). In March of 1995 three canisters were opened in K West Basin and three fuel elements were shipped to the Hanford hotcells. In-Basin observations were made during the fuel retrieval operations and the fuel was subsequently utilized in detailed hotcell examinations and conditioning tests summarized in the following sections. Specific canisters to open were chosen through a review of the data base of available fuel inventory and through sampling of canister gas and water to identify presence of uncontained fission products (which implies damaged fuel in a given canister). Only those canisters which were stainless steel, which showed evidence of gas generation and which contained fairly long fuel elements were considered candidates for opening due to emphasis, for this first shipment, on evaluating particular corrosion mechanisms.

Gas and Water Samples From K West Canisters

In order to identify canisters likely to contain failed fuel, liquid samples were obtained from 10 canisters (20 barrels). Also, in a few cases, gas samples were obtained from the sealed barrels. (Note canisters

nominally are water-filled and have a 2.5 inch nitrogen gas space when they are first loaded into K West Basin). Gas and water samples obtained in this manner were first evaluated by a mobile laboratory which provided immediate analysis for fission products i.e., cesium in the water and krypton in the gas. Subsequently gas and water samples were sent to laboratories at Hanford for additional identification of chemical species.

Analysis of cesium in K West canister water did lead experimenters to the desired fuel elements for hotcell examination. The most badly damaged element removed from the canisters was indeed from the canister with the highest cesium content (approximately 0.5 curies). Hydrogen gas was found to be the major constituent of all of the gas samples. Thus the original nitrogen cover gas had been largely replaced. Krypton gas concentrations correlated well with hydrogen which in turn correlated with cesium concentrations in the liquid. Thus krypton is a credible indicator of corrosion but krypton and hydrogen concentrations do saturate as the original nitrogen covergas is replaced.

Reaction of Basin Water with Fuel

After three canisters were opened in the K West Basin, no energetic reaction was observed between the newly introduced basin water and the fuel. After three fuel elements were placed in shipping containers the associated containers were capped with inverted graduated cylinders to trap bubbles and indicate any further reaction (i.e., hydrogen production). At the end of 2 to 5 days of monitoring, no accumulation of gas was found in any of the three cylinders even though at least two of the resident elements were failed with obvious exposed fuel.

Observations of Sludge During Fuel Handling

When canisters lid valves were opened during the canister flooding operation a continuous stream of bubbles was observed. Often accompanying this stream was a distinctly separate stream of reddish-brown liquid which appeared to have the character of a suspension and which was easily distinguishable from the surrounding basin water.

When canister lids were opened to remove fuel, large amounts of sludge were not observed. For two of the canisters no significant sludge was visible in the canisters even when fuel elements were removed. No sludge was seen to accompany the fuel elements retrieved from these two canisters during their transfer to shipping containers. For the fuel element retrieved from a third canister, sludge was seen trailing behind the element during its transfer to a shipping container. Removal of the target element from this latter canister stirred up sufficient flocculent sludge to fill the canister barrel to within a few inches of the top for several hours. Variations in observed sludge content may however be linked to variations in flooding and opening procedures.

Visible Condition of the K West Fuel

The retrieval of fuel went as follows:

1. When the first of three canisters was opened, it was found that a known fuel element breach (identified in the loading video tapes circa 1983) had not greatly deteriorated, if at all, since the time it was placed in the canister. This outer fuel element, with obvious missing fuel/cladding piece, was selected for hotcell examination and moved to a shipping container. Subsequent hotcell examinations did in fact identify some additional corrosion which can be attributed to in-canister storage.

2. The second canister was opened based on its high cesium concentration. One outer element with split cladding (Fig. 1, inset) was

easily visible. The fuel in this element certainly had reacted with the canister water (i.e., reaction was not apparent in video tapes made during original loading) and the element was selected for hotcell examination.

3. The third canister (Fig. 1) was opened based on written records of a breached element and on a moderate cesium content measured in its water. An inner element was selected for shipping to hotcells based on the desire for an intact element and on a visible dent in the end cap of the selected element.

Fig. 1

Metallographic Examination for Hydrides

Emphasis during the metallographic examination of the three K West elements was placed on the identification of uranium hydride due to its association with reported pyrophoric events. Specimens were cut using a tungsten-carbide slitting saw mounted on a remote-operated milling machine. Argon gas was used to cool the fuel element during the cutting, to provide an inert cover and thus, preserve the fuel microstructure as near to the as-received condition as possible. Cut samples were mounted, polished, attack-polished using chromic acid, and examined. The presence of uranium hydride was detected by a heat-tinting technique which delineates the oxidized hydride inclusions from the uranium matrix. Uranium hydride inclusions were found to be randomly distributed throughout the fuel matrix. It is not possible at this time to unambiguously determine the source of the hydrides. Possible sources include: 1) residual hydrogen which has been in the uranium alloy since fabrication, 2) hydrogen present as a result of corrosion processes and subsequent migration within the fuel, and 3) hydrogen present as a result of diffusion through the cladding. Thermodynamically, the zirconium alloy cladding is a favorable sink for hydrogen and therefore hydrogen diffusion through the cladding is the least likely source of hydrogen in the fuel.

Fuel Conditioning

Fuel samples (with cladding intact) from the K West elements were tested in a controlled atmosphere furnace to determine drying characteristics, dehydriding behavior, and oxide film formation for exposed uranium surfaces. These experiments are the first attempt to study a process whereby at least some of the fuel in K Basins will be conditioned in an oxygen containing atmosphere to reduce chemical reactivity through application of an oxide layer. Specimens were taken from a corroded fuel element but from areas which were not immediately adjacent to the principal corrosion sites. They were placed in a furnace system located in a hot cell and tested according to the following heating cycles:

A fuel drying step in which the fuel is dewatered for approximately 10 hours (free water removal) either at 373K in dry argon or at 323K in vacuum. The fuel is then dried at 573K under dry argon (or vacuum) for approximately 24 hours (to remove water of hydration and partially decompose any uranium hydride present).

A fuel passivation step, in which the fuel is exposed to a 98% argon-2% oxygen atmosphere at temperatures ranging from 423 K to 523 K for about 10 hours. The objective is to create if possible, an adherent passive oxide film on any exposed uranium-metal or hydride surfaces. In the testing runs to date, this step was conducted at near atmospheric pressure.

The evolution of moisture during the tests was monitored continuously by a moisture monitor while the total water release during the experiment was measured by trapping in a drying column. Hydrogen and oxygen in the off-gas stream were monitored by a gas chromatograph. Solid residues (spalled oxides) were analyzed by X-ray diffraction.

Specimen temperature, hydrogen in the off-gas stream, moisture concentration in the off-gas stream, and the oxygen concentration are presented in Fig. 2 for a typical two step drying cycle (Fig. 2a) followed by a conditioning cycle (Fig. 2b). The results indicate an increase in the moisture content of the gas stream for the low temperature drying cycle during the transient heat-up of the specimens, with the hydrogen concentration below detection limit. During the higher temperature drying cycle, both hydrogen and moisture concentration peaked during the transient heat-up of the specimens. The moisture eventually decreased to the detection limit of the moisture monitor, but the hydrogen maintained a steady concentration in the off-gas stream.

Fig. 2

Figure 2b shows the initial depletion of oxygen in the gas stream that occurs during the conditioning cycle. The total oxygen pick-up by the specimens was estimated by integration of the oxygen depletion curve and by specimen weight change.

The results of the furnace testing indicate evolution of both moisture and hydrogen from the fuel specimens. The probable sources of the observed moisture are absorbed water on the metal specimen, oxide layers, and accompanying sludge. The hydrogen, however, could be from uranium hydride decomposition and/or reaction. Recent tests with defueled cladding have ruled out cladding as a hydrogen source. The low limit of solubility of hydrogen in uranium cannot account for the level of hydrogen measured but can contribute a small fraction to the amount of hydrogen measured. The depletion of the moisture source even though hydrogen is being released, and the moisture response to the oxygen addition seems to diminish the likelihood of uranium reaction with gas as the principal hydrogen source.

SAMPLING OF BASIN FLOOR SLUDGE

Associated with Spent Nuclear Fuel is an accumulation of particulate layered material which is generally called sludge. Sludge is found on the basin floors, in canisters, and in the basin pits which are used for miscellaneous tasks such as cask handling. In fact, numerous different types of sludge have been identified depending on which basin, canister type, or pit location that the particular sludge is found. Each type of sludge is a unique nonhomogeneous mixture possibly containing corroded fuel, debris such as windblown sand or insects, rack and canister corrosion products, and/or fission products. All of the various sludges will need to be transported away from the K Basins and disposed with different types of sludge possibly having markedly different disposal paths. Characterization of sludge found on the K East Basin floor and that currently found in one K East Basin pit has been completed and is discussed below.

The central problem addressed in the current sludge characterization effort is "What is an acceptable way to retrieve sludge from the K East Basin (and Weasel Pit) and to process, transport, and store the material until a permanent repository becomes available?" The first part of this effort (i.e.,retrieval, transportation, and processing of the sludge) will possibly require the specification, design, and fabrication of

sludge handling/processing/dewatering equipment or the procurement of similar commercial services. Sludge will, for example, need to be pumped and dewatered with devices such as filters and hydrocyclones. Such an effort will require the knowledge of various physical parameters (i.e., fluid viscosity, particle size, etc.) which could be used directly to design apparatuses and/or could be utilized to specify simulants which can be used for evaluation of candidate equipment. Knowledge of the Special Nuclear Materials content of the sludge will be necessary to maintain accountability of material which leaves the Basins.

The second part of the problem is to designate a storage method whereby sludge can be stored away from K Basins in a more environmentally acceptable area. Two prime alternatives for storage have been identified. These are 1) transferring of sludge to Hanford double shell waste tanks and ultimate disposition along with other tank wastes, or 2) processing the sludge into a form appropriate for solid waste disposal. In these two cases the chemistry of the sludge must be determined, either to ensure compatibility of sludge with any non-fuel waste encountered in the tanks or to ensure that sludge does not contain chemicals which are incompatible with storage as solid waste.

Measurements of sludge depths in the K East Basin and Weasel Pit were reported previously (3) and have shown that the floor is covered with sludge to a depth of 5 to 19 cm (2 to 7.5 inches), with the Weasel Pit containing sludge approaching a meter in depth. Some of the fuel canisters in K East Basin have screened bottoms and slotted sides, and all of the K East canisters have open tops. This means that fuel corrosion products (uranium oxide and fission products mostly) found in canisters have, to some extent, mixed with the expected wind blown debris and corrosion products (from aluminum canisters and steel racks) in basin areas which are in close proximity to canisters.

A campaign to retrieve 20 representative samples of sludge from K East Basin and Weasel Pit has been completed. Locations for sampling were chosen to span a diversity of expected sludge constituents and to supply information needed for sludge removal in a statistically valid manner. Equipment was designed and utilized, Fig. 3, which assured that full representative core samples of material were collected from only specific localized areas. Sludge was found to contain significant iron, aluminum, and uranium and to be flocculent. Most particles are in the sub-micron range with most of the volume in 10 to 50 micron sizes.

Fig. 3

CONCLUSION

Canisters in the K West Basin do contain failed fuel. However the first shipping campaign demonstrated conclusively that serious deterioration of this fuel, even when failed, is not universal. Removal of this fuel, even when failed, is possible with the proper tools. For the specific type of fuel targeted by this examination, deterioration to rubble had not occurred and in fact large amounts of sludge were not observed. That sludge which was observed in canisters had a definite flocculent character and took some time (hours) to settle. Corrosion of fuel is certainly occurring in some of the damaged fuel elements but it is also possible for some exposed fuel to have undergone only minimal corrosion. The predominant constituent of the canister cover gas sampled was hydrogen produced either from radiolysis or more likely from corrosion. A good discriminator for finding canisters with failed fuel appears to be the concentration of cesium in the barrels. Chemical and physical

property data to facilitate transfer of sludge from K East Basin floor have been obtained. Campaigns to recover fuel samples from the K East Basin canisters and sludge from inside of canisters from both basins are planned for the near future.

VENDOR ASSESSMENTS OF RADIOACTIVE/MIXED WASTE PROCESSING/DISPOSAL FACILITIES

Joseph Bourassa
Yankee Atomic Electric Company

ABSTRACT

This paper was developed based on Yankee Atomic Electric Company experiences gained through the performance of vendor assessments of radioactive and mixed waste processing and disposal facilities. This paper will provide insights to companies or organizations who have radioactive and/or mixed waste which requires disposal. The paper will discuss the technical, legal and programmatic issues which should be considered when evaluating waste processing and/or disposal options. The discussion focuses on the methods utilized for the preparation, performance and reporting of assessments of waste disposal vendors. The paper includes a discussion of the scope and purpose of the assessment process, and the methodologies and approach taken to evaluate the technical and programmatic areas. This paper provides guidance and direction to those individuals involved in evaluating the capabilities of the waste processing and or disposal vendors. The paper is also a resource which identifies regulatory and industry guidance available for consideration in the planning for a waste disposal/processing vendor assessment.

The purpose of an assessment will primarily be based upon due diligence so as to support control of company production activities which result in the generation of radioactive and or mixed waste product which require disposal. The company needs to determine what is the most practical disposal method. This disposal method may be a combination of waste processing and direct disposal, which is consistent with the methodologies utilized by the Yankee Atomic Electric Company at the Yankee Nuclear Power Station and by other Yankee plants. Due to the anticipated/active need for utilizing a number of vendors for performing these activities. The determination has been made that assessments of the vendors supplying the services are required to ensure that activities are being effectively performed in order to minimize potential liabilities. The assessments need to consider not only the technical aspects of the operations, but also require an evaluation of the quality system(s) being utilized to ensure the consistent and effective implementation of applicable process controls.

ASSESSMENT PREPARATION

One of the first and most important activities in preparing for, and performing a vendor assessment, is developing a scope which is consistent

with the purpose of the evaluation. The key parameters which should be included in the evaluation are determined based on the vendor's activities which will be utilized in support of the waste disposal processes. Depending on the intended utilization of the vendor's services (disposal or processing activities), certain programmatic and technical activities need to be considered in developing the assessment plan. Sample assessment plans are provided in Attachment A (Disposal Facility) and Attachment B (Processing Facility). These assessment plans were developed based on services being utilized in support of the disposal of YNPS radioactive and mixed waste generated during operational and decommissioning activities.

In developing assessment plans, specific consideration must be given to the licensing organization and the associated governing regulatory bodies (State and/or Federal). The licensing agency determines which of the governing requirements the facility must be licensed under to support the vendor's operations. Many facilities have multiple licenses depending on the activities they are performing. Licenses may be issued in support of radwaste processing activities in accordance with 10CFR20, 30, 40 and or 70 requirements. If the vendor is performing mixed waste processing or disposal activities, the facility will be permitted under 40CFR261 requirements to operate a Temporary Storage and Disposal Facility (TSDF), which requires consideration within the assessment plan. Additional licensing requirements could be governed by state agencies, depending on whether the state is an Agreement State. Under these situations, the licenses will be issued to the facility in accordance with state regulations. Waste disposal facilities can be similarly licensed, although the licensing requirements will include 10CFR61 or the Agreement State's comparable regulations. These regulations should be factored in the assessment plan developments.

In addition to the technical requirements being considered, the quality systems which are in place need to be evaluated to determine if sufficient process controls are implemented within the vendor's operations, to ensure an effective and consistent approach to waste-related activities. The facility should have a formal Quality Assurance Program that is consistent with the criteria of 10CRF50, Appendix B. Although required, the program may be the bases for the quality assurance program to meet the quality control requirements of 10CFR61. Additional guidance is provided in NUREG-1293, "Quality Assurance Activities for Near Surface Disposal Facilities." The specific guidance that should be considered in the evaluation is included in Attachment C to this report and can be utilized for developing an assessment plan. The sections that should be included in the assessment plan are the purpose, scope, applicable requirements, assessment dates and makeup of the assessment team.

Once an assessment plan has been developed and the regulatory bases have been identified, the allocation of personnel resources needed to support the assessment should be determined. Since the waste generator has potential liabilities, e.g., potential Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) responsibilities, the assessment team should comprise both technical and quality assurance personnel. The assigned technical specialists should have expertise in the activities being evaluated. Ideally, the assessment team should include an Assessment Team Leader, an expert in licensing activities (radiological and hazardous waste), an individual with expertise with

radwaste and mixed waste, an individual with expertise in geology and hydrology (waste disposal facility only), and an individual with expertise in radiological effluent and environmental monitoring. This assessment team is consistent with the teams utilized by YAEC to evaluate waste disposal facilities. Smaller assessment teams have evaluated waste processing facilities. Consideration should also be given for the development of teaming arrangements, in which several facilities can provide resources to perform the vendor assessment. Teaming arrangements improve the depth of the assessment, while reducing costs to the clients. Yankee's experience in utilizing expertise from other waste generators in teaming arrangements has proven to be an effective method for performing these assessments.

There are many resources that may be considered in developing the assessment plan. See Attachment C for a list of documents that have been considered during YAEC vendor evaluations.

It is important to obtain the key documents prior to performing the vendor assessment. The vendor should be contacted approximately 30 days prior to performing the assessment to establish a point of contact. This individual will usually be a quality assurance representative, but may also be a customer service representative. The assessment plan should be sent to the vendor to facilitate obtaining information, in preparation for the assessment. The following documents are important in preparing for the assessment and should be obtained prior to the start of the assessment:

- Radioactive Material License
- Quality Assurance Program
- Index Of Vendor Procedures
- Organizational Chart
- State Regulations for Agreement States
- Environmental Assessment Report (Disposal Facility Only)
- Design Documents
- Facility Capability Document
- Associated Purchase Order

After obtaining these documents, a checklist may be developed to incorporate specific program requirements to be considered during the performance of the assessment. Once the assessment plan and checklist have been developed, a meeting with the assessment team members should be conducted to ensure that the expectations for the assessment are clearly defined and understood by all participating individuals.

ASSESSMENT PERFORMANCE

The initial phase of the assessment should consist of conducting an entrance meeting to ..... This meeting is an integral part of the assessment because there is limited time and there are a number of activities to be evaluated. At this meeting the purpose and scope of the assessment should be presented to management. The assessment team members should be introduced and the specific activity that each one is assigned should be discussed. The vendor contacts for the assessment should be established at this time. The schedule for the assessment should be conveyed to the vendor's contacts. The team should have a well-defined approach for the assessment. At this time, the vendor's representatives should be provided with a list of additional documents that may be considered for review and evaluation during the assessment. While the vendor is preparing the documents requested, the assessment team should be provided with a tour of the facility.

During the tour of the facility, the team should evaluate the vendor services being considered for use. The tour may need to be limited in scope based on time constraints for the assessment. The tour provides an opportunity for all assessment team members to become familiar with the facility and the overall setup of the organization. The tour of the facility will also provide an opportunity for the assessment team to ask questions about the capabilities of process equipment and operators. It also enables assessment team members to identify areas that may require further evaluation. Once the tour has been completed, the document review should be initiated. These reviews should include a variety of technical and administrative procedures and records. The following is a sample of documents that should be considered in the review:

- Internal Quality Assurance Audits and Inspections
- NRC and/or State Inspection Reports
- Vendor Audits from Other Facilities
- Radiological Effluent and Environmental Reports
- Nonradiological Environmental Monitoring Reports
- Geologic and Hydrologic Studies of the Facility Site
- Financial Reports
- Sureties and Closure Funding
- Operating and Administrative Procedures
- Organizational Charts and Responsibilities
- Quality Assurance Program

At this time, the assessment team members should begin evaluating the activities assigned as determined during assessment planning. The team members should attempt to gather sufficient information to determine whether the vendor's programs and processes are sufficient to ensure compliance with regulatory and state requirements. The review of documents and records should also evaluate if the programs are sufficiently established to assure the vendor's compliance with the applicable purchase order requirements. This evaluation needs to consider where potential liabilities may exist and where the vendor may have potential weaknesses. While assessing the vendor's programs and processes, it is important to ensure that sufficient information is gathered to support the development of the assessment report. This information should support the overall conclusions of the audit, including whether the vendor is capable of effectively providing the services being considered. Refer to the Audit Plans in Attachments A and B for specific activities that should be considered in the evaluation.

Quality Assurance Program Evaluation

Evaluation of the vendor's Quality Assurance Program is a very important facet of the assessments. The initial part of this review should be performed by evaluating internal and external audits and assessments, if possible. The review of these documents will enable the assessment team leader to quickly determine the quantity and types of issues being identified by the vendor. (Whether the issues are technical or administrative in nature.) The evaluation will also help determine the effectiveness of the vendor's corrective action program. These enable the assessment team leader to assess the Vendor's credibility and may enable the focus of the assessment to be better defined.

The Quality Assurance Program should be evaluated to determine whether the vendor has quality systems in place that will ensure the effective implementation of program and regulatory requirements. These systems should cover the activities being performed at the vendor's facility. The

assessment should focus on the systems being utilized for these vendor services being considered for use. Guidance for Quality Assurance Programs for low level radioactive waste disposal facilities is provided in NUREG-1293. This document provides a good basis for evaluating the adequacy of the attributes of the vendor's Quality Assurance Program. Most facilities will have Quality Assurance Programs that are consistent with the 18 criteria of 10CFR50, Appendix B, which are defined as follows:

- Organization
- Quality Assurance Program
- Design Control
- Identification and Control of Material, Parts and Components
- Inspection
- Test Control
- Control of Processes
- Inspection
- Test Control
- Procurement Document Control
- Instructions, Procedures and Drawings
- Document Control
- Control of Purchased Material, Equipment and Services
- Control of Measuring and Test Equipment
- Handling, Storage and Shipping
- Inspection, Test and Operating Status
- Nonconforming Materials, Parts or Components
- Corrective Actions
- Quality Assurance Records
- Audits, Surveillance and Managerial Controls

The review should consider each of the elements of the Quality Assurance Program, as applicable to the vendor's services being considered. The evaluation should determine if the vendor has developed sufficient controls to ensure the effective implementation of the vendor's processes. The evaluation should be performed utilizing personnel interviews, a review of records and program assessments. There should be sufficient awareness of the Quality Assurance Program requirements and management's expectations to enable the effective implementation of the program. The program should enable the vendor to self-identify and correct program and/or process weaknesses.

Technical Evaluation

The technical evaluation should be performed to determine whether sufficient controls have been developed for the processes being evaluated. The assessment should also determine the effectiveness of the controls which are being utilized for controlling the day to day operations of the facility. The evaluation should be performed utilizing personal interviews, a review of procedures and records, observations of activities in the field, and tours of the facility. The technical evaluation should focus on issues that are important to the safe and effective operation of the vendor's processes. For example, if the vendor is supplying waste disposal services to your facility, the evaluation should determine if the vendor has procedures in place for receipt, tracking and preparation of the waste for processing and/or disposal. The vendor should have individuals who are trained and qualified to perform the activities defined in the procedures. The vendor should be performing the processing and or disposal activities as described in the vendor's

procedures, regulatory requirements and license commitments. The vendor should have records that support and document the performance of these activities. An effective methodology in performing an evaluation similar to this is to select a small sample of similar type material as your facility's waste, review the records from arrival through processing to disposal, including verifying the current location. This provides assurance that the processes are in place for tracking waste through disposal. Individuals involved in the receipt and handling of waste prior to processing and disposal should be interviewed. Observation of any activities that are ongoing at the time of the assessment should be conducted. This may be performed at any phase of the assessment and will provide some assurance that the vendor is utilizing the programmatic controls that have been developed. Observations can also be utilized to determined if the individuals performing the work are knowledgeable of the programs controlling the activities they are performing. This approach can be utilized for any vendor service being evaluated, whether it is mixed/radioactive waste processing, packaging or disposal activities.

During the performance of the assessment it is very important for the team leader to keep in constant communication with each of the assessment team members. At the conclusion of each day, the assessment team leader should conduct an informal meeting to discuss the progress of the assessment. Additionally, any concerns should be discussed amongst the entire team, along with the next days' scheduled activities. The assessment team leader needs to ensure that the assessment is progressing on schedule and that the entire scope of the assessment will be completed, based on the time constraints of the assessment. During these meetings, consideration needs to be given to the effectiveness of the programs and processes being evaluated. The discussions should also include a determination as to whether any findings have been identified and or any concerns require further evaluation.

The team leader should maintain good communications with all assessment team members also to ensure the effective preparation for the close-out meeting which is conducted at the conclusion of the assessment. The close-out meeting is conducted with the vendor's management and quality assurance representatives. This meeting is an important part of the assessment performance because it provides a forum for the assessment team and the vendor management to discuss any issues that were identified during the assessment. The meeting also provides an opportunity to listen to any proposed corrective actions being considered by the vendor. The adequacy of the responses and the attitude of the vendor's management should be considered in determining whether the vendor's services can be utilized. The close-out meeting also provides an opportunity for the assessment team to discuss the impressions of the facility and its operation. At this meeting, a documented list of concerns should be provided to the vendor's management. It is important to utilize at least two (2) categories of concerns, e.g., Findings and Observations or Recommendations. This provides the assessment team with an opportunity to present not only any violations of program or regulatory requirements, but also allows the team to indicate areas that may require enhancements. At this time the vendor should be informed of the process for assessment reporting and follow up corrective action response and verification. The vendor should be informed of the time table expected for the report issuance and when any vendor responses would be expected.

ASSESSMENT REPORTING

The method of reporting the results of the assessment is vitally important, in order to properly reflect the evaluations performed by the assessment team. Reporting can be difficult, if the approach to documenting the evaluation was not determined during preplanning. The assessment may be documented in several different ways depending on who will be reviewing the report and how the information will be used. The documentation may be in the form of an elaborate checklist, which is utilized during the performance of the assessment. The assessment team leader may decide to utilize a report format that is primarily narrative in form, or the report may consist of some combination of the two methods. If the assessment is being used primarily for internal use, the detailed checklist may be the least time consuming approach for documenting the results of the assessment. However, if the report is intended for external distribution, then a detailed presentation may be the most appropriate reporting mechanism. In either case, a formal assessment report should be developed which delineates the effectiveness of the processes which were evaluated and whether the programs are consistent with regulatory and license requirements. The report should also discuss the adequacy of the Quality Assurance and Technical Programs which were evaluated and the adequacy of the processes utilized to implement the vendor's activities.

The assessment report should be completed in a timely manner to facilitate rapid notification and quick resolution of any concerns identified during the assessment. The distribution of the assessment report should be similar to that of the assessment plan, including cognizant groups in the assessment results, e.g. the user department, purchasing, management, etc. The report may be issued to the vendor, but is at the discretion of the evaluating organization. However, any identified findings and/or observations should be issued to the vendor to ensure the concerns can be evaluated and corrective actions can be taken. The report should include the following:

- Assessment of the Effectiveness of the Activities Evaluated
- Assessment Team Members
- Purpose
- Scope
- Details of the Assessment
- Personnel Contacted
- Findings, Observations and/or Recommendations

Each of the activities described in the assessment plan should be identified and discussed in the "Details of the Assessment" section of the report. The depth and details of the assessment report should have been determined during the planning phase of the assessment and should be the basis for the development of the report format.

Upon issuing the report to the vendor, responses to any concerns identified should be requested within a specified time period, e.g., 30 working days. The responses should be submitted to the assessing organization for review and approval. For significant concerns, consideration may be given to performing a follow-up evaluation to verify the effectiveness of the corrective actions. The final phase of the reporting process includes documentation of the assessment responses, evaluation of the proposed corrective actions for adequacy, verification that corrective actions and final closure of any concerns have been identified during the assessment. The documentation and reporting of the

assessment allows some flexibility, as long as the reporting process and methodology is defined up front and ensures closure of any identified concerns.

ATTACHMENT A

WASTE DISPOSAL FACILITY ASSESSMENT PLAN

PURPOSE:

The purpose of the assessment is to evaluate the effectiveness of the vendor's operations for adequacy and effectiveness of the quality controls, management practices and supporting processes governing the land disposal of radioactive/mixed waste(s).

SCOPE:

The assessment will evaluate the adequacy of the handling, processing, and disposal of radioactive and mixed waste(s), as well as evaluating both the current and historical execution of the Quality Assurance Program. The assessment will include the following elements:

Adequacy and effectiveness of the vendor's PROCESS CONTROLS for receiving, handling and burial of radioactive waste.

Adequacy and effectiveness of the vendor's GEOLOGIC AND HYDROLOGIC MONITORING Program.

Adequacy and effectiveness of the vendor's RADIOLOGICAL ENVIRONMENTAL AND EFFLUENT MONITORING Programs.

Adequacy and effectiveness of the vendor's PROCESS CONTROLS for receiving, handling, processing and burial of mixed waste.

Adequacy and effectiveness of the vendor's QUALITY ASSURANCE Program and its implementation.

Adequacy of the vendor's site CLOSURE PLAN.

APPLICABLE REQUIREMENTS:

State and Regulatory Requirements (10CFR, 40CFR, 49CFR, Agreement State Regulations,...)

(Reference Appendix C for Additional Guidance.)

ATTACHMENT B

WASTE PROCESSING FACILITY ASSESSMENT PLAN

PURPOSE:

The purpose of the assessment is to evaluate the vendor's operations for adequacy and effectiveness of quality controls, management practices and supporting processes governing the processing of radioactive and mixed wastes.

SCOPE:

This assessment will evaluate the handling, processing, storing and shipping of radioactive and mixed waste(s), as well as evaluating effectiveness of the implementation of the vendor's Quality Assurance Program. The assessment will include the following activities:

Adequacy and effectiveness of the vendor's ADMINISTRATIVE CONTROLS for activities being performed.

Adequacy and effectiveness of the vendor's WASTE TRACKING SYSTEM for the entire processing evolution.

Adequacy and effectiveness of the vendor's RADIOLOGICAL SURVEYS AND MEASUREMENT capabilities.

Adequacy and effectiveness of the vendor's RADIOLOGICAL ENVIRONMENTAL AND EFFLUENT MONITORING Programs.

Adequacy and effectiveness of the vendor's PROCESSING METHODS being considered for use.

Adequacy and effectiveness of the vendor's MIXED WASTE OPERATIONS, including facility design, safety, security, management and facility history.

Adequacy and effectiveness of the vendor's QUALITY ASSURANCE Program.

APPLICABLE REQUIREMENTS:

State and regulatory guidance (10CFR, 40CFR, 49CFR, Agreement State Regulations ...)

(Reference Appendix C for additional guidance.)

ABSTRACT

For the proposed Central Interstate Compact (CIC) low-level radioactive waste (LLRW) disposal facility, simulations of transport of radionuclides in ground water with variable annual recharge were made to compare the results with those obtained when a constant, "bounding" recharge was used. This was done to ensure that the constant "bounding" recharge resulted in bounding concentrations of the radionuclides in ground water.

To generate a long-term annual series of recharge rates, the calibrated recharge rates for the years for which ground water level data exist were first correlated with annual precipitation using regression analysis. It was found that the logarithm of the recharge rate for any year correlated closely with the precipitation of that year and the preceding two years. Next, a long-term series of annual precipitation was generated by correlating the existing record at the site with the longer record at a climatically similar station. This, together with the regression relation between recharge rate and precipitation was then used to generate a long-term series of annual recharge rates.

Analytical solutions of ground water transport equations for a system representing the actual system were used to generate concentration histories for various nuclides for both the variable and constant recharge cases. It was demonstrated that the concentration history of a radionuclide for constant, "bounding" recharge rate bounded the concentration history for the variable recharge rate.

INTRODUCTION

A low-level radioactive waste disposal facility is being proposed for the Central Interstate Compact (CIC) member states consisting of Nebraska, Kansas, Oklahoma, Arkansas, and Louisiana. The proposed waste disposal facility will be located on a 100-acre (0.4 km2) site in Boyd County, Nebraska, near the town of Butte.

To support the site characterization and the performance assessment analysis, a regional and a local three-dimensional flow model and a two-dimensional transport model were developed. A key calibration parameter of the flow models was the deep percolation (recharge) rate. The region in which the Butte site is situated is semiarid, with the hydrologic regime characterized by low annual rainfall and relatively high potential evaporation. Recharge rates are typically low. Calibration recharge rates were in the range of 0.04 to 0.1 in/yr (0.1 to 0.25 cm/yr).

To provide a bounding case analysis, hydraulic conductivity values in the flow and transport models were set equal to the 95 % upper confidence

limit of the geometric mean of all measured values (i.e., given the number of hydraulic tests performed within each layer, the probability that the mean does not exceed the conductivity value used in the model is 95 percent). Furthermore, the bounding case was calibrated by requiring that the rate of recharge be high enough to produce a high water table very near the ground water surface and remains there at all times. This condition is considered to be extremely conservative assumption because the water table at the site is known to fluctuate, and in average years it has been observed to be approximately 8 feet (2.4 meters) below the ground surface. The recharge rate needed to sustain these conditions was estimated to be 0.18 in/yr (0.46 cm/yr) which is more than 4 times the base case recharge rate.

Although the bounding case analysis provides a long-term high level of conservatism, it does not specifically account for individual years of extreme rainfall when the actual deep percolation rate might exceed the bounding case recharge rate of 0.18 in/yr (0.46 cm/yr). The purpose of this paper is to assess the impact of variable annual recharge rates on radionuclide transport by comparing radionuclide concentrations obtained with the constant bounding case analysis to those obtained with a variable rate of recharge. This analysis consists of the following steps:

Estimation of annual recharge rates for the individual years of the period of water level observations (1990 through 1994) using the local flow model

Regression analysis of estimated recharge rates and precipitation data

Generation of long-term annual time-series of recharge rates.

Transport simulations with the variable recharge rates.

ESTIMATION OF THE ANNUAL RECHARGE RATES FOR THE YEARS 90-94

The model was calibrated for recharge year by year for years 1990 through 1994, by matching the time-averaged yearly observed well water levels. For these yearly simulations, the boundary conditions in the local model were altered only to account for the yearly prevailing climatic stresses. These simulations were made using an exponential evapotranspiration (ET) function for the dependence of ET on the depth to the water table. The calibrated recharge rates are shown in Table I.

Table I

GENERATION OF LONG-TERM RECHARGE RATES

Extension of the Butte Rainfall Record

The 46-yr rainfall record of Butte (1949-1994) is considered short relative to the time scale of the transport simulations for the performance assessment which is in the thousands of years. Since there are no readily available climatic records of this scale within the region of the site, the extension of the Butte rainfall record was sought. The advantages of extending the record is that longer record may contain yearly extremes, and dry or wet sequences not seen in the 46-yr record. Therefore, Butte record was extended to year 1899 based on the rainfall record of Atkinson, Nebraska using a linear regression equation developed between the records of these two gages. The Atkinson gage is located about 25 miles (40 km) south of Butte at latitude 42 degree and 33 minutes and longitude 98 degrees and 58 minutes, and at elevation 2130 feet (650 m) MSL. The coefficient of determination for the linear regression was 0.8, indicating that 80 percent of the variability of the annual rainfall amounts at Butte can be explained by the regression equation. The annual statistics of the extended record shown in Fig. 1 are quite similar to the 46-yr record at Butte. The minimum and the

maximum of the 96-yr record both occurred within the period of site observations: the minimum in 1989, and the maximum in 1993. These extreme events have approximately a 100-yr return period. Also the 1992-1993 two-year period had the highest rainfall for any consecutive two-year period of the 96-year record.

Fig. 1

Generation of Long-Term Recharge Rates

The recharge rates generated by the local model for 1990 through 1994 were 0.055, 0.048, 0.115, 0.75 and 0.51 in/yr (0.14, 0.12, 0.29, 1.91 and 1.3 cm/yr) respectively. The rate of recharge depends on precipitation, runoff, evapotranspiration and antecedent soil moisture conditions. The only one of these parameters which is directly measurable is precipitation. Antecedent moisture conditions depend on precipitation in the preceding year or years. Therefore it is reasonable to assume that the rate of recharge in a particular year depends on precipitation during that year and the preceding years. This dependence was evaluated by performing a linear regression analysis between recharge and precipitation at every year and the two preceding years, i.e. by assuming that:

Eq. 1

The coefficient of determination of the multiple linear regression was 0.82. To explore if it is possible to obtain a relationship with a higher coefficient of determination, a multiple linear regression analysis was performed on the precipitation and logarithm of the recharge:

Eq. 2

The regression coefficient of determination was 0.96, indicating that 96 percent of the variability of the annual recharge rates is explained by the regression relationship. The high regression coefficient of determination suggests that the dependence of recharge on precipitation is exponential. The regression coefficients were B=-7.01967, b0 = 0.0656, b1 = 0.06066, and b2 = 0.07493.

Therefore, the nonlinear multiple regression relationship thus established between the recharge rates and the annual rainfall amounts was used to model the variability of recharge rates. The generated relationship accounts for both the nonlinear dependence of recharge on water levels as well as the for the dependence of the water levels on antecedent rainfall (storage or persistence effects).

Based on the annual rainfall record for the 1899-1994 period at Atkinson and using the above equation, annual recharge values were generated for Butte, and are shown in Fig. 2. The maximum recharge rate is 0.75 in/yr (1.91 cm/yr) and the minimum is 0.03 in/yr (0.08 cm/yr). The mean recharge rate is 0.12 in/yr (0.3 cm/yr) with the lower and upper 95% confidence limits of 0.097 and 0.137 in/yr (0.25 and 35 cm/yr). The median of the data is 0.092 in/yr (0.23 cm/yr), with the lower and upper 95% confidence limits of 0.078 and 0.102 in/yr(0.2 and 0.26 cm/yr). The distribution of the recharge rates can be best approximated by the lognormal distribution, therefore the long-term average recharge rate is best estimated with the median of the data which is 0.09 in/yr (0.23 cm/yr). The maximum recharge rate which occurred in 1993 has a 100-yr return period approximately.

Fig. 2

TRANSPORT SIMULATIONS

Mathematical Derivation

If the rate of recharge varies from year to year, the mass flux of nuclides leaching from the waste area also varies with time. A simplified and conservative description of nuclide transport under these conditions can be obtained by neglecting transport through the vadose zone and assuming that nuclides from the waste storage area reach the water table instantaneously. If we assume that the flow through the saturated zone remains constant in time, and that the nuclides reaching the water table mix vertically within the uppermost saturated layer providing a pathway to the site boundary receptor, then the variable-in-time recharge and associated nuclide flux produce a variable concentration source at the water table, with the concentration varying in proportion to the rate of recharge. Under these assumptions the effect of a variable source on concentrations at the site boundary receptor can be evaluated with the aid of an analytic solution of the one dimensional transport equation. This equation provides a simplified description of transport in the saturated zone under the assumption that flow is uniform, the aquifer is homogeneous, and there is no lateral dispersion. The transport equation used for this purpose accounts for advection, dispersion, decay and retardation. The solution of the general one-dimensional transport equation and its solution are listed below (1).

The partial differential equation describing the one-dimensional advective-dispersive solute transport is

Eq. 3

Equation (3) can be solved for the following initial and boundary conditions:

Eq. 4

Eq. 5

Eq. 6

where

l decay constant [T-1],

Ca time-independent component of the boundary concentration, and

Cb the time-dependent component of the boundary concentration [M/L3].

The analytical solution of Equation (3) subject to the initial and boundary conditions described by (4)-(6) is given by van Genuchten and Alves (1)

Eq. 7

Because of the linear nature of the advection-dispersion equation, the solution for a time variable source, e.g. for a year-to-year variable source concentration, can be obtained with the aid of the principle of superposition. The solution of the transport equation for a variable source obtained by superposition is given in the following section.

For the special case where:

a. initial concentration Ci=0,

b. production rate g=0,

c. boundary concentration c(0,t)=C0e-lt (i.e., Ca=0), and

d. decay rates m=l,

the solution to the one-dimensional advective dispersive equation is given by:

Eq. 8

Furthermore, when there is no retardation (i.e., kd=0 and R=1), w=v and the concentration is given by:

Eq. 9

For the case with no decay (l=0) Eq. (8) is reduced to the solution given in page 391 of Freeze and Cherry (8).

Eq. 10a

When the boundary concentration is variable with time and, at the same time, undergoes decay, the following model can be used to represent the boundary concentration:

Eq. 10b

where j = 1,...,N is a time index and N is the total number of time steps. Because Equation (3) is linear the principle of superposition can be used to estimate the concentration function c(x,t). This can be achieved by representing the system by a series of individual boundary concentrations (Cj - Cj-1) for the time intervals [tj-1,tj] and summing up the contribution of each:

Eq. 11

where Dtj=t-tj is the time since the concentration c(o,t) = Cje-lt is imposed at the boundary.

Simulation Results

The analytic solution was used to compare concentrations at the site boundary receptor for a time dependent source scaled in proportion to the year-to-year variable recharge and for a constant source scaled in proportion to the recharge rate for the bounding case analysis (0.18 in/yr, 0.46 cm/yr). It is noted again that this calculation accounts for transport through the saturated zone only. The additional travel time and attenuation through the vadose zone will lead to lower concentrations than those obtained from the calculations.

The variables used in this simulation are representative of the conditions observed at the site. Specifically the flow velocity was assumed to be equal to 3 m/year (~10 ft/year) and the dispersivity equal to the longitudinal dispersivity value of 5 m. The source concentration was assumed to vary in proportion to the rate of the recharge for the 94 years of the synthesized recharge record. It is also assumed that the 94-year cycle repeats itself. Figure 3 shows the variability of the assumed source over a period of 500 years. Figure 3 also shows the calculated concentrations at a distance of 250 m (~ 820 ft) from the source, a distance representative of the distance between the B/C cells and the north site boundary. The results presented in Fig. 3 are for three combinations of parameters corresponding to:

Fig. 3

- non-retarded nuclides with very long half-lives, i.e. practically non-decaying nuclides such as iodine and technetium (Fig. 3b),
- carbon-14 with kd=0.1 ml/g and a half life of 5723 years (Fig. 3c), and
- americium with kd=0.1 ml/g and a half life of 459 years (Fig. 3d).

Figure 3 shows also the solution for a constant-in-time source corresponding to a recharge rate of 0.18 in/yr (0.46 cm/yr). The concentrations presented in Fig. 3 are normalized by the initial concentration of a source associated with a nuclide mass flux form the waste area corresponding to a recharge rate of 0.18 in/yr (0.46 cm/yr). As can be seen from Fig. 3, in all cases the solution obtained for the constant recharge of 0.18 in/yr (0.46 cm/yr) is bounding the solution for the year-to-year variable recharge rate, despite the fact that few individual recharge values, representing extremely wet years, are higher than 0.18 in/yr (0.46 cm/yr).

CONCLUSIONS

The effect of the annual variability of recharge rates on concentrations at the site boundary receptor was evaluated by combining the results of the local ground water flow model with 94 years of hydrologic data to synthesize a record of recharge rate, and then employing an analytic solution of the one-dimensional transport equation to calculate concentrations under two different conditions. Concentrations were estimated first for a year-to-year variable mass flux of nuclides, proportional to the synthesized annual recharge rates, and then for a constant mass flux corresponding to the recharge rate of 0.18 in/yr (0.46 cm/yr), used in the bounding case analysis. These calculations account for transport through the saturated zone only. The additional travel time and attenuation through the vadose zone will lead to lower concentrations than those obtained from the calculations. The calculations were repeated for several combinations of parameters corresponding to those that describe the major contributors to the dose, i.e. technetium, iodine, carbon-14 and americium. In all cases the calculated concentrations for the recharge rate of 0.18 in/yr (0.46 cm/yr) were higher than the peak concentrations for the variable recharge rate, even though few individual recharge values, representing extremely wet years, were higher than 0.18 in/yr (0.46 cm/yr).

ABSTRACT

Approximately 230,000m3 of defense nuclear wastes is stored in underground tanks at the US Department of Energy site in Hanford, Washington. Retrieval and pretreatment will lead to a low level waste stream that contains sodium nitrate and nitrite salts in a highly alkaline liquid slurry. Westinghouse Hanford has been evaluating alternative vitrification technologies for treating this low level waste stream. GTS Duratek and the Vitreous State Laboratory of the Catholic University of America demonstrated low temperature vitrification (11500C) on the DuraMelterTM 100 and 1000 joule-heated vitrification systems. The Hanford LLW simulant was successfully vitrified at sustained feed rates that were twice the nominal capacity of the melters. Approximately 610 kg and 10,700 kg of glass was produced in the DuraMelterTM 100 and 1000 tests, respectfully. All glasses produced far exceeded stated leach resistance requirements. The off-gas system performed effectively with

reduced nitrogen oxide emissions, and final particulate and metal emissions from the process were all below measurable and regulatory limits.

INTRODUCTION

There are 177 underground storage tanks storing approximately 230,000 m3 of defense nuclear wastes containing 242 MCi of radioactivity at the U.S. Department of Energy (DOE), Hanford site in Washington State. The Tri-Party Agreement (TPA) signed between the U.S. Environmental Protection Agency (EPA), the DOE, and the Department of Ecology, Washington State, calls for separating this waste into a high-level and low-level radioactive fractions and then stabilizing these fractions. The low-level radioactive waste stream will consist mainly of sodium nitrate and nitrite salt in a highly alkaline liquid/slurry. Vitrification has been selected as the treatment technology for this waste stream which will produce approximately 400,000 metric tons of vitrified waste. Seven vendors, selected by Westinghouse Hanford Company (WHC) conducted tests of several alternative vitrification methods on a non-radioactive surrogate for this waste.

This paper presents the findings obtained from the melter tests using the WHC supplied simulant performed by the Vitreous State Laboratory of America of the Catholic University of America (VSL) and GTS Duratek, Inc. (GTSD). These tests were carried out in GTSD DuraMelterTM 100 and DuraMelterTM 1000 vitrification systems at the VSL. The first test was carried out on in late September 1994 with the DuraMelterTM 100 and satisfied a TPA September 30, 1994 milestone.

TEST OBJECTIVES

The primary objectives of the test were:

Conduct proof of principle tests to demonstrate that the DuraMelterTM vitrification systems will process a highly alkaline, high nitrate/nitrite, LLW feed and produce a glass of consistent quality.

Demonstrate a practical and reliable feed system.

Demonstrate the ability to produce a durable, homogenous glass with a target composition.

Determine specific requirements for feed preparation, secondary waste, and off-gas treatment systems.

Describe general operating behavior during the tests including upsets and operating problems.

Collect mass balance data across the system for potentially volatile components such as Cs, Na, B, K, Mo, to determine partitioning of these components between the glass, condensed deposits, off-gas entrained particulates, and scrub solutions.

Measure NOx and SOx concentrations, flow rates, and quantities and composition of entrained particles.

Collect data to assess melt characteristics including phase separation, foaming events, cold cap behavior, etc.

Collect glass samples throughout the tests for assessment of glass composition consistency and uniformity as well as leach resistance testing. Collect feed, product glass, off-gas scrub solutions, and off-gas sampling every few hours after steady state operation achieved to supply WHC for analysis and archiving.

Perform pre-test and post-test inspection of equipment to identify solids buildup, deposits, plugging, corrosion, erosion, refractory wear, electrode wear, and equipment damage.

SCOPE OF TESTING

A series of crucible melts was completed first and each characterized for key processing information such as melt viscosity, electrical conductivity and liquidus temperature. PCT tests were conducted to assure that the selected composition met the WHC requirement for a normalized sodium release of below 1 g/m2/d. The results, obtained by the VSL and an independent analysis by the Pacific Northwest Laboratory, showed the glass to be well within this criterion

Two DuraMelterTM systems were used for these tests which allowed a factor of ten scaling (nominal glass production rates of 100 and 1000 kg/day, respectively) in the data sets. The operation of the smaller DuraMelterTM 100 first provided information which was useful in the operation of the DuraMelterTM 1000. The smaller system is large enough that the general behavior is similar to the larger system and is scalable. The power supply for the smaller melter has greater connected power relative to melter volume than the power supply for the larger system. This would have allowed higher relative production rates to be investigated int he smaller system if connected power was the controlling factor. Production rates of over twice the nominal values were comfortably demonstrated and higher rates were certainly achievable.

The DuraMelterTM 100

The DuraMelterTM 100 is a Joule-heated ceramic-lined melter with a nominal glass melting rate of 100 kg/day. The actual melting rate depends upon a variety of factors such as composition of feed, melter temperature, glass properties (viscosity etc), rate of bubbling (mixing), and other operational parameters. This melter is approximately 3 feet by 3 feet with a discharge chamber on one side that is 1.5 feet by two feet. The glass refractory is a Monofrax K3 refractory which forms a 14" by 14" melt pool. The normal glass depth is maintained at 15" and the K3 refractory extends several inches above that level. There are two 1" thick flat plate Inconel 690 electrodes on opposing walls of the melt chamber. The surface area of each electrode is 162 square inches. The resultant glass volume is 2500 cubic in. (41 liters). This is 100 kg for a glass with a density of 2.5 g/cm3. There is a 15" air space between the melt surface and the ceiling. The melter contains an inner shell to prevent leakage of any molten glass into the layers of insulating refractory. The melter has three drains, one is on the bottom for direct discharge of the entire melter, one is a side discharge to drain any floating, secondary phases and the third drain exits the bottom through a side port and riser to a pour trough. This, along with an air lance, forms an airlift, which is activated by bubbling air through the air lance. Glass drains through the pour trough into the waste container that is sealed to the discharge flange.

The melter uses a patented bubbling system to promote mixing and increase the melt rate. This bubbler is designed to produce a curtain of bubbles rising form the melter floor between the electrodes. This not only mixes the glass pool, it also keeps the melt well oxidized.

The off-gas system consists of a melter exhaust film cooler, evaporative quencher, packed bed scrubber, air reheater, heated air dilution port, air-jet bag filter and HEPA filter units. The off-gas systems for both DuraMeltersTM are functionally identical. Both are designed to treat particulate, aerosol, and acidic gaseous emissions other than NOx.

The DuraMelterTM 100 was successfully operated with a slurry feed system as well as the larger DuraMelterTM 1000 system. Several feed additives were evaluated with respect to their effects on emissions and based on

these tests, urea was selected as the primary additive to reduce NOx emissions.

The DuraMelterTM 1000

The DuraMelterTM 1000 is very similar in design to the DuraMelterTM 100 and is more than an order of magnitude greater in size. The nominal production capacity is 1000 kilograms per day but actual production capacity may but much larger depending on feed composition and operating conditions. This is also a Joule-heated melter with a pair of Inconel 690 electrodes on opposing walls. The outside dimensions are approximately 6 3/4 ft. by 6 3/4 ft. By 9 ft tall with a 2 ft. By 4 ft. Discharge chamber on one end. The surface of the glass pool is 42" by 42" and is nominally 38" deep. The melt volume is 67,000 cubic in. (1100 liters) of glass at a density of approximately 2.3. The refractories are contained in an inner shell with penetrations for drains and electrodes. The melter has a bottom drain and the normal drain via an airlift. The off-gas system is functionally similar to the DuraMelterTM 100.

Off-Gas Monitoring and Sampling

Off-gas monitoring and sampling was performed by CUA-VSL staff and a certified air monitoring laboratory. Two different monitoring modes were performed: continuous emission monitoring (CEM) of the gaseous compounds NO, NO2, SO2, O2, CO, and total hydrocarbon concentration (THC), and standard isokenitic sampling for metals and particulates. Periodically, VSL staff monitored HCl and NH3 during the DuraMelterTM 1000 steady state run.

Glass Formulation

A series of formulations consisting of glass-forming additives and chemicals representing the waste stream were prepared. The target glass was to have the following characteristics: waste loading of 25 wt% (corresponding to sodium oxide at 20 wt%); viscosity below 100 poise at melt temperatures between 1100o C and 1150oC; electrical conductivity between 0.3 and 0.5 Siemens/cm at melt temperature; liquidus temperature below 950oC; and normalized Product Consistency Test (PCT) release rates below 1 g/m2/d. Five separate glasses were prepared. All met the above conditions and the one that exhibited superior processing rates and good PCT performance was chosen.

DuraMelterTM 100 Runs

Prior to the start of the first run, the melter was flushed (three turnovers) with the Hanford simulated waste feed to remove the standby glass before the start of the steady-state tests. The turnover runs occurred between September 21-24, 1994 and the steady-state runs between September 26-29, 1995. Approximately 300 kg of glass were produced in the turnover and steady-state periods from approximately 370 liters of feed for each of these runs. The average glass production rate for the steady-state run was 7.7 kg/hr which is above the nominal 100 kg/day production rate. The primary consumption of energy is through the electrodes, the lid heaters and the discharge chamber heaters. The average power usage was 33 kW (4.3 kWhr per kg glass produced).

Two of the glasses produced during the steady-state run were subjected to PCT leach test procedure by the United States Geological Survey (USGS). Leach rates were well below the SRL-EA standard glass. The normalized average leach rates for sodium were approximately one order of magnitude below the 1 g/m2/day goal. Corrosion tests were performed on coupons of the following melter materials: Inconel 690, Inconel 601, K-3 brick, and

Zirmul brick. On visual inspection at the conclusion of the tests, there did not appear to be any sign of corrosion of any of these coupons.

DuraMelterTM 1000 Runs

The melter was flushed with Hanford simulated waste feed for three turnovers to establish the starting conditions for the test. The steady-state run was conducted on January 19-21, 1995. Approximately 7000 kg of glass was produced in the turnover run and 3700 kg of glass was produced in the steady-state run (from 4500 and 3500 liters of feed respectively). The average production rate during the steady-state run was 1800 kg/day, well above the nominal 1000 kg/day production rate. Unlike the DuraMelter 100 run, there was significant drum-to-drum variation in the nature of the supplied simulant. The total average power consumption for the electrodes, lid heaters and discharge chamber heaters was 145 kW or a power consumption rate of 2 kWhr per kg of glass produced during the steady-state runs. This rate is about half of the rate for the smaller melter. The fraction of the total power supplied to the lid and discharge heaters is considerably smaller for the larger melter, as is also the effect from thermal losses. The leach rates from the PCT were well below that of the SRL-EA standard glass and the leach rates for sodium were more than one order of magnitude below the goal of 1 g/m2/day.

NOx Emission Control

The LLW stream at Hanford contains significant amounts of nitrogen in the form of nitrates and nitrites. Various NOx treatment options were investigated in several sets of experiments. NOx removal of over 50% was demonstrated with liquid scrubbing alone although this process is highly dependent on the residence time of the gasses in the scrubbing tower ant he temperature of the scrubbing solution (the lower the temperature the greater the amount of NOx removed). Spraying hydrogen peroxide into the gas stream at vaporizing temperatures was observed to lower the NOx emissions by an order of magnitude. Urea addition also proved to be very effective to lowering the NOx emissions to 5% of the original amount. The effectiveness of the urea addition depended upon the size of the coldcap on the glass. As the cold cap increased to 100%, the NOx emissions increased by a factor of four.

SUMMARY AND CONCLUSIONS

The melters were successfully operated to demonstrate the vitrification of Hanford LLW simulant. The objectives detailed in the WHC test plan were met during the turnover and steady-state runs. The feed rate that was achieved and maintained was nearly twice that originally planned. Excellent material mass balance were achieved for the steady-state runs which shows minimal carry over from the melter. Urea was effective in reducing the NOx emissions-forty to fifty per cent of the nitrogen entering the DuraMelterTM 1000 was decomposed to N2 in the plenum area with no additional engineering controls.

CYCLONE VITRIFICATION OF HIGH NA CONTENT LOW-LEVEL RADIOACTIVE WASTE

Mark Scotto
Babcock and Wilcox
1562 Beeson St.
Alliance, OH 44601

ABSTRACT

The suitability of a cyclone furnace was investigated for the vitrification of a low level radioactive, high sodium content waste

simulant. Vitrification was accomplished by blending the waste simulant with glass formers prior to thermal treatment. The simulant and glass former recipe was designed to achieve a "target" composition in the glass that was anticipated to yield a glass with suitable properties for long term disposal, a durable glass not susceptible to leaching of any of its constituents. The primary objective, the demonstration of continuous glass production for over 24 hours was successfully completed. The process streams, feed solids, off-gas solids, and glass, were subject to material balances, chemical analyses, and microanalytical analyses, and provided information which will be useful toward selecting process modifications leading to process improvements in future testing.

The off-gas solids (cyclone carryover) are comprised of mechanical carryover and volatile carryover. Mechanical carryover are injected feed solid particles which escape the cyclone furnace through physical entrainment with the combustion gases. Volatile carryover are glass constituents which vaporize off the glass stream at high temperature, enter the off-gas stream and condense at cooler temperatures downstream to contribute to the cyclone carryover. During the Demonstration Test, approximately 32% of the total carryover was due to vaporization, and 68% was mechanical carryover. Therefore, total cyclone carryover was enriched in the volatile constituents B, K, and Na. With 26.7% of the total solid feed partitioning to the cyclone carryover during the Demonstration Test, 72.5% of the B, 54.5% of the K, and 43.0% of the Na, partitioned to the cyclone carryover. Mechanical carryover is expected to have a composition very close to the target composition. However, volatile carryover caused significant deviations of the actual glass composition from the target glass composition. In addition, the high Al content furnace refractory was physically and chemically eroded, and blended into the glass stream. Microanalytical analyses of the glass indicate macroscopic inhomogeneities caused by refractory contamination, but with relatively homogenous regions comprised of glass formed from feed solids. As a result of the deviations from the targeted glass composition, leach rates of several glass constituents which were determined by the Product Consistency Test were actually lower than the ideal laboratory glass with the targeted composition.

INTRODUCTION

The Department of Energy (DOE) Hanford Site, covering a 560 square mile area of Washington state's southeastern desert, was constructed during World War II to produce plutonium for atomic weapons. The storage of large quantities of hazardous and radioactive wastes occurred at this site during the cold war period. This ultimately lead to the Hanford Federal Facility Agreement and Consent Order, also known as the Tri-Party Agreement in 1989 among the State of Washington Department of Ecology, the U.S. Environmental Protection Agency (EPA), and the DOE. This agreement established a multi-phase program to clean up the site over a 30 year period. As part of this program, the DOE contracted the Westinghouse Hanford Company (WHC) to coordinate and evaluate seven technologies to convert 60,000,000 gallons of low level waste, separated off from underground storage tanks, into a silicate glass. The technologies currently under evaluation include joule, slagging furnace, plasma, and carbon arc melters. This paper covers research performed by the Babcock and Wilcox Company on the applicability of the cyclone furnace for the vitrification of the low-level radioactive liquid waste.

The cyclone furnace is a B&W designed high intensity slagging combustor originally designed for the combustion of low grade coals. The cyclone furnace has been used for commercial steam generation since the 1940s. However, more recently, the cyclone combustor has been investigated for its applicability in the thermal treatment and vitrification of hazardous waste. To date, B&W research in cyclone vitrification includes the treatment of dry soil contaminated with organic compounds, dry soil contaminated with organics and radionuclide surrogates, an industrial waste sludge, and a simulated Hanford low-level waste, the subject of this paper. The most comprehensive of the previous studies was the U.S. Environmental Protection Agency (EPA) Superfund Innovative Technology Evaluation (SITE) Demonstration (1).

The Small Boiler Simulator (SBS), a B&W pilot scale facility was constructed to simulate the gas side environment of large utility boilers for the purpose of research and development on equipment utilized on these systems. With the SBS in its cyclone fired combustion mode, slag forms from the inorganic constituents of the coal. Since the cyclone was designed to produce molten slag from the coal ash, it was thought that the cyclone had potential application in the vitrification of hazardous inorganic wastes. Based on the positive results from B&W's early cyclone vitrification studies, the cyclone furnace was assessed for its potential for the vitrification of Hanford low level tank waste using a simulated liquid radioactive waste formulated and prepared by WHC.

Figure 1 illustrates the SBS cyclone vitrification configuration utilized in Phase I of the current program. Vitrification was achieved by mixing the simulated waste with glass formers before introducing the mixture into the cyclone. Glass formers included boric acid, coarse sand, fine sand, hydrated alumina, and limestone. The various glass melter subsystems include the feed system, the cyclone furnace (glass generator), the SBS radiant furnace and convective pass, and the back-end cleanup system including a pulse jet baghouse and dry scrubber. The feed system maintains a well mixed waste slurry (glass formers and waste simulant), and pumps the slurry into a cyclone combustor through a feed injector that propels the slurry toward the hot cyclone walls. The SBS radiant furnace and convection pass extract heat from the flue gas to lower flue gas temperature while boiling water to generate steam. The baghouse removes essentially all particulate, and the dry scrubber removes acid gases from the flue gas. The locations for sampling molten glass, and solids that escape through the convective pass with the flue gas are also depicted in Fig. 1. Chemical analyses of these samples were necessary to perform the material balances presented in this paper.

Fig. 1

OBJECTIVES

The primary goal of Phase I was the execution of a 24-Hour Demonstration Test to generate a vitrified product of a surrogate waste specified by WHC. Additional objectives of Phase I were aimed at providing key information for the WHC assessment of this technology, and include:

1) Formulate a feed with the desired physical properties and composition
2) Characterize the feed and the individual feed ingredients
3) Set up and check out a pilot feed handling system
4) Evaluate glass/refractory interactions and glass build-up in the pilot system
5) Identify the flue gas composition
6) Evaluate volatilization and partitioning of the constituents

7) Determine the glass quality and identify possibilities for improvement
8) Provide technical inputs (engineering and life expectancy/reliability information).

All the objectives were completed successfully, and are covered by Holmes (2). This paper focuses on data analysis pertaining to objectives 4, 6, and 7.

RESULTS AND DISCUSSION - PARTITIONING

In the development of this technology, the partitioning of major and minor glass components between the glass and the off-gas streams is important to characterize in order to establish the basis for off gas treatment and material recycle. The portion of solids material that partition to the off-gas stream is called cyclone carryover, which necessitates off-gas treatment to remove potentially hazardous particulate prior to emission to the atmosphere. The quantity and the nature of the off-gas particulate determine the design of particulate removal equipment necessary for proper performance. Cyclone carryover can be collected for treatment as a secondary waste stream and recycled back into the cyclone feed.

The extent to which glass constituents partitioned to the flue gas (off-gas) rather than the process glass stream was estimated with an overall material balance. The following data was utilized to perform the material balance: 1) calibrated feed rates of simulated waste, fuel, and combustion air, 2) off-gas suspended solid concentrations at the convective pass outlet by EPA method 5, and 3) elemental analyses by Inductively Coupled Plasma (ICP) of feed, glass, and carryover solids. The material balance is described by the following equation.

Eq. 1

Wfsolids: The total estimated solids input from the waste feed as oxides (751.7 kgs)
R: The total weight of the refractory loss
G: The total glass weight collected in the quench tank (576.3 kgs)
CP: The total solids measured exiting the convection pass (131.6 kgs)
g* The fractional weight change of the volatile glass elements by existing as gas phase compounds other than the oxides.
D: The total weight of the deposition on internal surfaces as oxides

Solids that deposited on internal boiler surfaces (D) and refractory loss (R) from the cyclone and lower furnaces walls were not measured quantities. These quantities were estimated by the simultaneous solution of Eq. 1 and Eq. 2 shown below.

Eq. 2

xAl : The average measured mass fraction Al for the glass (0.0761)
yAl The average mass fraction of Al for the EPA-5 particulate samples (0.0292)
WF: The total weight of the injected feed (DAS recorded)
fAl: The average "as fed" elemental Al concentration of the feed (0.0294).

Equation 2 is a material balance of the element Aluminum (Al). Al was chosen since it comprised the major portion of the furnace refractory (Plibrico 88-Special), and consequently provided the best tracer for

refractory contamination. The refractory manufacturer specified an Al content of 0.4455 mass percent. The refractory loss (R) and solids deposition of internal surfaces (D) were estimated as 25.0 kgs and 80.4 kgs respectively. Since measured solids at the convection pass outlet yielded 120 kgs as oxides, the total mass % carryover was 26.7%, with 40.1% depositing on internal boiler surface prior to the convection pass outlet.

Average cyclone carryover for specific elements for the Demonstration Test is shown in Fig. 2, representing the overall material balance. Exact mass recovery (100%) is expected for total mass and Al since Eqs. 1 and 2 must be satisfied when D and R equal 25.0 kgs and 80.4 kgs, respectively. The calculated values of D and R lead to excellent mass recoveries for the other elements. Recovered mass for Na, B, K, Si, and Ca amounted to 98%, 105%, 103%, 98%, and 103% of the feed, respectively. Feed concentrations were very accurate by the fact that the feed recipe composition was confirmed by the close agreement with the elemental feed analyses of feed samples. Since feed rates were also accurately calibrated, the calculated mass of each glass element into the process is very accurate. Consequently, Fig. 2 shows the percent partitioned to the glass and carryover streams normalized to yield 100% recovery of the feed for all elements. Since high temperature vaporization significantly contributes to the cyclone carryover, the percent elemental carryover correlates with the vapor pressure of common compound forms of the respective elements.

Fig. 2

Trace species were selected for inclusion in the waste simulant to act as surrogates for radioactive species in the real waste. These included Cs, Mo, Cl and F. Mo was the surrogate for radioactive Technetium (Tc). There was a detection problem in the fluorine analysis, and thus fluorine carryover is not included in these results. Average cyclone carryover for Cs, Mo, and Cl were estimated for the Demonstration Test as shown in Table I.

Table I

RESULTS AND DISCUSSION - VOLATILE VS. MECHANICAL CARRYOVER

Cyclone carryover is comprised of mechanical carryover and volatile carryover. Mechanical carryover is defined as the solid particles that remain physically entrained in the highly turbulent cyclone fluid flow and exit the cyclone with the off-gas. Volatile carryover pertains to the solid glass constituents that vaporize at high temperature. These off-gases ultimately condense and contribute to the cyclone carryover solids. Insight into what caused cyclone carryover is critical in determining how to minimize it through process modifications. For example, if carryover is predominantly volatile, it is critical to control the process temperature. On the other hand, if mechanical carryover dominates, more attention may be given to an optimal design and placement of the feed atomizers.

A method was developed to approximate the relative fraction of total carryover that was generated by mechanical entrainment versus vaporization. It is assumed that the feed solids initially have the designed target composition before any volatilization occurs. The feed recipe was formulated to produce a glass with the optimal (target) composition, and assumes that no glass constituents will preferentially partition to the off-gas. This target glass composition was determined in separate laboratory studies performed by Pacific Northwest Laboratories.

The measured deviation of glass and carryover solids composition from the target composition was a measure of vaporization off the glass to the carryover, and was represented by "T" in Eq. 3.

Eq. 3

yi : Measured carryover solids mass fraction of element "I".

xt,i : The target glass composition of element "I" assuming formation of the pure oxide glass with no preferential partitioning to carryover solids.

Ti : The elemental mass transfer rate (kg/hr) from the glass at the target composition to the carryover required to achieve the measured particulate elemental concentration, yi.

Ytotal: The total mass flow rate (kg/hr) of carryover.

bj: For Na, B, and K only (major volatile constituents).

j : Mass conversion factor for element j to its assumed compound form in the oxide glass (i.e. Na2O, B2O, K2O).

(Ytotal /g - SbjTj): The mass flow rate (kg/hr) of mechanical carryover as oxides.

The equation above represents six separate equations for each of the major glass elements. Since the volatile loss of Si, Al, and Ca are negligible relative to B, Na, and K, only these volatile elements are included in the summation term. Each solution set "Ti" applies to an hourly data set acquired during the demonstration test or a preliminary scoping tests.

An estimate of mechanical carryover is computed as the total carryover minus the total volatile loss from the glass stream. Of the total carryover, the relative proportions of the mechanical carryover and volatile carryover were estimated as 68%/32% and 63%/37% for the Demonstration Test and the earlier exploratory tests, respectively. Mechanical carryover correlates with volatile carryover as depicted in Fig. 3. The rate of volatile carryover is normalized by the maximum possible elemental mass transfer rate from the glass stream (xt,i*(X+ SbjTj)), where X is the feed solids flow rate to the glass stream.

Fig. 3

The physical basis for this correlation can be explained as follows. Through much of the preliminary exploratory testing, the accumulation of simulated waste feed occurred on internal cyclone surface, often significantly reducing cyclone volume, and on two occasions causing shutdown due to blockage of fuel and air inlets. This was confirmed by post test inspection after these two cases. A modification to the fuel injection configuration performed prior to the Demonstration Test eliminated the problem by more uniformly distributing the heat of combustion inside the cyclone melter. Low feed accumulation cases could be related to relatively high heat transfer measured to the glass melter water jacket during these periods where feed solids were not insulating the internal cyclone walls as much. Tests for which little accumulation of feed solids had occurred on the feed atomizer and internal cyclone surfaces were associated with tests where mechanical and volatile carryover were estimated to be high. Low feed accumulation (an uncontaminated open cyclone) generated relatively high cyclone temperatures and high volatile carryover because this condition allowed the maximum gas residence time for the combustion of more fuel within the

cyclone, and also allowed a fully developed cyclonic flow pattern which intensified the rate of fuel and air mixing. Low feed accumulation (an unimpeded waste feed atomizer) was also favorable to the generation of a relatively fine spray aerosol which is known to increase mechanical carryover. This also increased the internal cyclone surface area upon which the spray impinges and maximized heat transfer to feed solids, increasing volatile carryover. Thus, high volatile carryover correlated well with high mechanical carryover.

It is important to recognize that operating conditions during the Demonstration Test were not optimized to minimize carryover. Feed rates during the Demonstration Test were low relative to the previous exploratory tests. Low feed rates were maintained because there was still concern over the excessive accumulation of feed on internal cyclone surfaces before the modified cyclone furnace natural gas firing configuration proved to be successful. Therefore, as it turned out, the feed rates were set too low, and led to the relatively high gas side temperatures which exacerbated volatile carryover. By merely increasing feed rates in future testing, it is expected that volatile carryover can be significantly reduced.

It is also expected that mechanical carryover can be reduced by optimal design and placement of the feed atomizer(s). The atomizer(s) can be located in closer proximity to the cyclone wall in the tangentially oriented combustion air flow entrance. Atomizer design affects spray momentum, shape and particle size distribution which all should be optimized to achieve uniformity of feed coverage on the cyclone's internal walls, and the minimization of mechanical carryover. Cyclone design changes such as a larger slag tap and/or a smaller exit area can also reduce mechanical carryover.

RESULTS AND DISCUSSION - GLASS QUALITY

Uniformity and homogeneity are desired physical qualities of the process glass. Inhomogeneities might be indicative of a glass that has not completely formed, or has been contaminated by furnace refractories. A measure of glass durability utilized in the evaluation of the technology was the Product Consistency Test (PCT). This is a standard procedure for determining the elemental leach rate from a ground glass sample into a mildly acidic solution. Leach rates were normalized to the sodium content by dividing by the sodium mass fraction.

To assess the homogeneity of the glass, micro-analytical analyses were performed, and included Light Microscopy, Energy Dispersive X-Ray Spectrometry (EDX), and Scanning Electron Microscopy (SEM). Light Microscopy clearly showed dark streaks embedded in a homogenous phase which were pink regions on these images, an example of which is depicted in Fig. 4. High magnification SEM revealed more physical details of the inhomogeneities, characterized as cords, streaks, and inclusions. EDX analyses of these regions together with manufacturer supplied average furnace refractory material compositions suggest these refractories are the source of the inhomogeneities. Physical evidence of refractory loss was also obtained by collecting refractory specimens off the furnace walls, and also by photographing the lower furnace walls and cyclone surfaces after testing.

Fig. 4

SEM/EDX analyses also showed uniform homogeneous regions where macroscopic inhomogeneities did not exist. The elemental spectra measured in these areas showed consistency in the signal strength intensity of the

major glass constituents, and indicate that these areas are comprised of the glass produced in the cyclone. Back scattered electron imaging showed little atomic number contrast, indicating composition uniformity in these areas. However, due to preferential elemental cyclone carryover, there was significant deviation of the glass composition from the target composition as Table II below illustrates.

Table II

The furnace refractory, predominantly Plibrico 88-Special, contaminated the glass to a significant extent due to chemical attack by the molten glass. The material balance indicated that on the order of 10% of the lower furnace refractory blended into the glass stream. Another refractory material, Shamrock, was tested for resiliency by inserting a 6 inch plug on the lower furnace water wall. It did show improved resistance to chemical attack under the conditions of the test.

An intense effort to find the most chemically resistant refractory may not be the approach in the future development of this process. It is believed that significant refractory loss can occur without any detrimental effect to the process because of experience gained with coal slagging furnaces. The glass that blends with and partially replaces the refractory should form a hard protective scale over uncontaminated refractory closest to the water wall. The sharp temperature gradient near the furnace water wall create sufficiently low temperatures for this to occur. Refractory closest to the gas side will degrade and blend into the glass stream until only molten glass comprises this layer adjacent to the combustion gases. Therefore, a steady state condition will be reached where the rate of refractory loss will fall to zero. This point had not been reached during the Demonstration Test since the glass samples acquired toward the end of testing still displayed refractory contamination. However, in future work, the long term effect of the above process on melter performance should be evaluated. Although this glass may not be as aesthetically appealing during the initial period of contamination by refractory, the data shows that this does not appear to adversely effect PCT results.

A low PCT value is an indication of a stable, durable glass. The ideal laboratory glass formulated by PNL (Pacific Northwest Laboratory) underwent PCT analyses on its major constituents, and acted as a benchmark against which the process glass was compared. The negative PCT deviation from the target glass (Table II) is attributed to the carryover of Na and the dissociation of Al from the refractory. Although PCT values can not be predicted for a glass with a full complement of Na when material recycle is incorporated into an integrated process, the Na that was captured in the glass was reasonably well reacted on a micro scale.

CONCLUSIONS

The 24-hour demonstration test was successfully performed, and therefore, feasibility has been established. A glass product was continuously produced for over 28 hours.

The glass was macroscopically non-homogeneous, but was amorphous on a microscopic level. The macroscopic non-homogeneity of the glass is attributed to the blending of the alumina-based refractory into the glass stream.

The Plibrico refractory used in this project was prone to chemical attack by the glass. A Shamrock refractory plug inserted in the system for comparison was more resistant to the molten glass.

Based on sample analyses performed by Corning and USGS labs, the glass samples all had PCT leaching rates better than the laboratory glass.

The mechanical and volatile carryover are estimated to comprise approximately 68% and 32% of the total carryover during the Demonstration Test, respectively. Total carryover was roughly 26.7% by mass of the injected feed solids. Preferential carryover of relatively volatile compounds caused some deviation from the targeted glass composition, but with no adverse effect on PCT leach rates.

Of the major glass constituents, boron, potassium, and sodium showed the highest cyclone elemental carryovers of approximately 72.5%, 54.5%, and 43.0% by mass of injected feed, respectively.

The trace glass constituents Cl, Cs, Mo showed cyclone elemental carryovers of 80.8%, 87.9%, and 59.9% by mass of injected feed, respectively.

The relative cyclone carryover of glass elements followed the relative volatility of many of their gaseous compound forms. Volatile partitioning was most significant for the volatile elements (B,K,Na,Cs,Mo,Cl).

RECOMMENDATIONS

As with commercial systems, refractory loss can be expected until steady-state operation is reached and the refractory is covered by a protective layer of glass or slag. This is typically the manner in which coal-fired utility cyclones operate. Steady state operation in this regard had not been reached in the Demonstration Test. It is recommended this type of operation be tested, with the glass ultimately providing part of the protective scale on the water wall.

Means for mitigating volatile carryover include such possibilities as lowering the operating temperature of the cyclone, recycling of volatile constituents back to the melter, using less volatile glass formers, or sending volatilized constituents to the high level waste process. Phase II testing will determine the necessary adjustments to the feed recipe to accommodate cyclone carryover and solids recycle so that the targeted glass composition can be closely attained.

Physical entrainment losses (mechanical carryover) from the glass were significant. Cyclone design changes and optimization of the feed injection will be used to resolve this issue.

ABSTRACT
Vitrified intermediate level radioactive waste was obtained during test operation of experimental vitrification plant at SIA "Radon". The behavior of borosilicate glass matrix was investigated in natural conditions simulating shallow ground disposal. Long term tests of vitrified radioactive waste from nuclear power plants were performed in a shallow ground repository as well as on an open testing area. Radionuclide leaching differs significantly in natural conditions in contrast to laboratory behavior. There are many fluctuations -as when the leach rate grows by an order of magnitude- after that it remains almost smooth and slowly decreases as usually. Changes in leaching rates are greater and more frequent for open area tests. Average leaching factors were obtained for open area tests as well as for repository tests. These factors can be used for long term predictions since they take into account the real character of leaching.

INTRODUCTION

Glass now is one of the most useful and utilized material. Historical experience of application of glass gives evidence of high stability of this material and good environmental compatibility. Certain glass specimens on the earth have a few millions age. Glass specimens from the moon are a few hundred million years old.

One of the conventional functions of glass is utilization as packaging for the storage of various materials including dangerous products. Glass was found to be an appropriate host material for the isolation of radioactive waste. Most of radioactive waste components can be included into the structure of glass. Glass incompatible components can be also included into the glass matrix in the form of disperse phase. High physical and chemical durability of glass provides long term retention of radionuclides.

Although glass was initially proposed for high level radioactive waste treatment, now vitrification is considered as possible process for intermediate level radioactive waste immobilization. Equipment to provide waste vitrification in this case is much simpler. Requirements for the glass product are not as stringent as in the case of high level waste. For instance, inhomogeneities in glass are permitted, therefore glass composite materials can be used to immobilize glass-incompatible waste (1). On the other hand, durability of glass provides simplification of disposal facilities, shallow ground disposal being the most suitable. Long term laboratory tests as well as long term in-situ tests of waste glass have great importance for the assessment of vitrified waste behavior. Now there are many well established data on the behavior of waste glass in the case of high level vitrified waste (2-6). Most of these data can be used to understand the nature of glass behavior of vitrified intermediate level waste. Nevertheless some peculiarities of glass products and storage conditions have to be considered in this case. Laboratory testing of glass products is an essential part of waste management program. It provides parameters of glass durability. However natural tests give the most reliable data on the real behavior of materials under conditions close to those of real disposal.

The aim of this paper is to review the results of long term observation on the behavior of vitrified intermediate level waste under conditions close to those of shallow ground disposal. Two types of tests were performed: the first one being in conditions similar to shallow ground

repository, and the second one on a open testing area. These tests were conducted more than 7 years.

SPECIMEN PREPARATION

Vitrification of intermediate and low level radioactive waste is a new perspective trend, providing the maximum waste volume reduction and obtaining a highly durable product. SIA "Radon" began experimental vitrification of radioactive waste in the early 70's. Borosilicate glass was selected as a matrix material for the immobilization of waste components. A ceramic melter with direct Joule heating and capacity up to 50 kg/h for glass mass was used for vitrification Electrical power supply of the system was 150 kW, temperature in melter being 1250C. Many types of wastes with specific activity up to 37 MBq/l and among them wastes from atomic power stations with reactors WWER and RBMK were vitrified. Volume reduction factors for vitrification are 4,2 - 4,5. Losses of radioactive Cs from the melter in the process of melting were not more than 3,5%. Leaching rate for Cs137 from final glass product was within 1,410-5 - 4,410-6 g/cm2day. Total amount of glass produced by ceramic melter constitutes more than 10 tons.

Recently SIA "Radon" has developed a new vitrification method (7). It is based on coreless induction melting of glass in a cold crucible. Glass composite materials, which contain separately radioactive components in the form of disperse phase in the glass matrix, are considered for immobilization of glass-incompatible chemical components (such as sulphates, hard metal oxides, etc.) (8). The new vitrification plant with a capacity of 75 kg of glass per hour is under the test stage.

Specimens for long term tests were selected during the experimental vitrification of real intermediate level radioactive waste from nuclear power plants (NPP). The initial liquid radioactive waste consists of aqueous sludges. About 30 - 40% of waste salts were incorporated into glass The composition of glass product is given in the Table I.

Table I

The main radionuclides in waste were Cs137(63.2 - 82%), Cs134 (17 - 35.1%), Co60 (1 1.6%), Pu239 and Sr90 (less than 0.1%). The parameters of tested specimens (glass blocks) are presented in the Table II.

Table II

Glass blocks were disposed for long term tests during 1987 - 1989. They had a prismatic form.

TESTING CONDITIONS

Two types of testing programs were initiated at experimental testing site of SIA "Radon". The first program comprises long term tests of specimens on an open area. Obviously here the glass is subjected to the maximum influences of erosion and weathering that contribute to radionuclide release (9). These tests give assessment of capability of glass to retain radionuclides in extreme conditions related to the possible accidental opening of waste repository.

Glass blocks (see Table II) were placed on stainless steel trays (52 X 52 cm) at 60 cm height from the surface of the ground. They were able to collect all water which contacted the glass. Atmospheric sediments that contacted waste glass were sampled for chemical and radiometric analysis. Usually water sampling was performed twice per month.

The climatic parameters of the open testing area are presented in Table III.

Table III

The second testing program comprises long term tests in a shallow ground repository. Glass blocks were placed here (see Table II) on stainless steel trays in a loamy soil experimental burial site at the depth 2 - 2.4 m. These blocks were covered first by pure bank sand to exclude direct contact with surrounding soil. After this glass blocks were covered by host soil up to the surface of ground (see Fig.1).

Fig. 1

As distinguished from in-situ tests (3, 6), radionuclide sorption onto soil was eliminated. The trays were supplied by traps for the collection of ground water which contacted the glass. Ground water that contacted waste glass was sampled for chemical and radiometric analysis. Usually water sampling was performed twice per month.

The parameters of experimental shallow ground repository are provided in Table IV.

Table IV

The ground water on the testing place has a hydro-carbonate-sodium-calcium content with a summary mineralization of about 0.5 g/l.

RESULTS AND DISCUSSION

Due to the absence of additional sorption of radionuclides in the host soil (as well as in the case of open area tests) it was possible to calculate leaching rates for every glass block on the basis of the analysis results. In Table V one can see results of long term tests. Here one can compare these parameters for 1 year testing time and 7 years. A special computational method was developed to obtain both the leaching factor, L, and the effective diffusion coefficient, D, for radionuclides in glass (10). The main results of the computations for two specimens are in Table V also.

The leaching factor, L, takes into account the real character of leaching including discontinuities in the leaching rate. Therefore the leaching factor, L, should be used for long term predictions of radionuclide losses.

Table V

The leaching process under natural conditions has some peculiarities when compared to laboratory testing results. The leach rate is higher under open area conditions. Moreover the leaching process is not monotonic. There are many fluctuations. For example, the leach rate grows by an order of magnitude- after that it remains almost constant and slowly decreases in accordance with theoretical prediction. Changes in the leaching rate are greater and more frequent for open area tests.

The changes in the leaching processes can be caused by the generation of new surface regions that contact water. Actually, many small cracks can be viewed on the glass surface after prolonged tests in an open area. In time, they form an entire network over the surface of the glass. Therefore the formation of cracks is responsible for the fluctuating character of radionuclide leaching. Nevertheless one should mention that basically the glass status after prolonged tests remains satisfactory and radionuclide retention is reliable (see Table V).

An important value is the level of contamination of water which contacted vitrified radioactive waste. Obviously this level will be much higher if the water contacts fresh regions of the glass surface. Therefore in the initial stage, when small portions of water contact fresh glass blocks, the contamination level can be high. A similar situation occurs in the case of crack formation when new contacting areas appear on the surface of waste glass.

The specific radioactivity of water which contacted vitrified radioactive waste is shown in Table VI for 1 year testing time and for the 7-th year.
Table VI
Only Cs-137 was detected in the exposed water. As for chemical contamination one can see the results of examination of ion content in water which contacted the glass blocks in Table VII.
Table VII
Changes in the ion composition of water are not significant especially for the main ionic species.

CONCLUSIONS

Long term test of vitrified radioactive waste has given appropriate data on the leaching process and glass behavior under conditions of real near surface disposal. The leaching is discontinuous; however, radionuclide retention by glass matrix remains reliable. Accurate prediction of radionuclide losses can be done by using results of long term tests.

VALIDATION OF THE MCNP MONTE CARLO CODE FOR GERMANIUM DETECTOR GAMMA EFFICIENCY CALIBRATIONS

Frazier L. Bronson
Ling Wang
Canberra Industries
800 Research Parkway
Meriden CT 06450

ABSTRACT
Canberra designs a variety of instruments that are required to accurately measure the radioactivity content of large and/or complex sources. The Monte Carlo code MCNP was evaluated to determine if it would be suitable to predict the performance of these instruments. A series of experiments was designed, starting with simple source-detector geometries and becoming increasingly more complex. For each geometry the full energy peak efficiency was computed with MCNP, and also measured experimentally. Multiple energies (nominally 100-1500 keV) were used for each experiment. The lessons learned from each experiment are described, and were suitably incorporated into later experiments.
Computer run time can be quite long, and therefore a geometrical biasing scheme was developed to make these computations more practical. The speed advantage can be a factor of 10 or greater.
It is concluded that this technique is very powerful and accurate when properly applied. For the geometries tested, efficiency calibrations are accurately predicted to within 5% for simple geometries, and up to 15% for complex geometries at low energies.
INTRODUCTION
The primary purpose of this project was to develop a design tool for the evaluation of the various detector-geometry factors as we create new radioactive waste assay systems. These gamma spectroscopy systems are required to measure large and often complex samples. The sample sizes range from 200 liters to 36000 liters. It is necessary to create the optimum detector placement strategy in order to achieve the lowest minimum detection limit and to minimize sample non-homogeneity errors. The traditional methods we have employed in the past (1) have used real detectors of varying sizes, and multiple geometries made with radioactive sources. While suitable for simple [cylindrical] and small [200 liter] samples, this becomes less practical as the sample size and complexity increases. And, the use of radioactive samples for testing and calibration generates radioactive waste.
A potentially useful tool would be Monte Carlo modeling. MCNP (2) is a well known general-purpose Monte Carlo code commonly used for neutron transport applications. It is also capable of modeling photon problems. There have been a few very useful publications describing the use of MCNP to model gamma ray spectra and efficiencies for Ge detectors (3-6). However, these have generally evaluated fairly simple detector-source geometries, or they have not performed direct efficiency calibrations (6). Important issues such as what are the critical parameters, how much detail is necessary in the model, etc. have not been studied, or reported.
At a minimum, the goal of this project was to develop a tool useful for relative comparisons. This tool could then be used for selecting the optimum size, number, type, and placement of detectors. We could then also investigate the relative error associated with non-homogeneity of the sample in the matrix. The ultimate goal, however, is to demonstrate that we can accurately model these complex geometries, and them be able to determine system performance prior to building the first system. If we can accomplish this goal, then we can use MCNP to accurately and economically perform the primary calibration for a wide variety of sample conditions.

In this report, we present the results of a detailed study showing the validity of the use of MCNP to perform efficiency calculations of complex geometries with Ge detectors.

METHODOLOGY

A sequence of different source-detector geometries was created. Six major geometries with a total of 16 different source-detector geometries were modeled for efficiency determinations. These started with simple geometries, and proceeded to increasingly more complex geometries. The geometry was first modeled and the efficiency computed using MCNP. Then a multi-energy calibration source was used to develop a traditional efficiency calibration for the same geometry.

The test geometries modeled and measured for this study were the following:

1. Full energy peak efficiency for a small multi-energy gamma source positioned at a distance of about 40 cm and at 0, 45, and 90 degrees with respect to the axis of a 32% relative efficiency coaxial Ge detector.
2. Full energy peak efficiency for a Eu-152 multi-energy line source of 80 cm in length, positioned 14 cm from the endcap of a 30% relative efficiency coaxial Ge detector.
3. Full energy peak efficiency for a multi-energy planar gamma source 50 x 50 cm positioned 8 cm from the endcap of a 25% relative efficiency coaxial Ge detector.
4. Full energy peak efficiency for a series of single nuclide sources in a 1 liter water-equivalent matrix in a Marinelli beaker with a 25% relative efficiency coaxial Ge detector.
5. Full energy peak efficiency for a Eu-152 point source successively shielded by 0, 1.0, 3.0, 6.1 and 9.1 cm of steel placed between the source and a 25% relative efficiency coaxial detector.
6. Full energy peak efficiency for a multi-energy simulated volume source in a 200 liter (55 gal) drum at 4 different drum matrix densities in a Canberra Q2 Low Level Waste Assay system with 3 nominally 28% relative efficiency Ge detectors.

The multi-energy source had nuclides from 88 to 1836 keV. Eu-152 was analyzed for each of the lines to give data points from 122 to 1408 keV. The Marinelli beaker sources had energies from 60 to 1115 keV.

Each of the 6 experiments was performed separately and sequentially. The two efficiencies [modeled and measured] were compared. Where there were differences that were statistically significant and greater than approximately 5%, both the calculation and the source measurement were examined carefully. Generally, this resulted in increasing the complexity of the source and/or detector model, and then the recalculations were in better agreement. But some changes were also made in the setup of MCNP, or to the code to improve performance and/or speed. When each experiment was at it's best agreement, then the next experiment was started. What was learned in earlier experiments was successively applied to later experiments. However, we generally did not go back and try to refine the earlier experiments.

MCNP CONSIDERATIONS

The MCNP input files for all of the above geometries were created by following the standard procedure described in detail in reference (2). The input files consist of four parts: a geometry part, a source definition part, a material part and a tally part.

Only the photon mode was used. Electron mode was not used because it takes at least 40 times longer than that with photon mode alone. Although

electron transport was not simulated, the electron-induced photons were not neglected. A thick-target bremsstrahlung model (TTB) was used instead. The TTB model also generates electrons, but assumes that they travel in the direction of the incident photon and that they are immediately converted. The bremsstrahlung photons produced by these electrons are then banked for later transport.

The detailed physics treatment (default MCNP choice) for photon interactions was chosen for all geometries in this report.

There are many tally types in MCNP. For our application, only tally 8 (pulse height tally) was necessary. For this tally, the only possible variance reduction scheme is biasing of the source itself.

The direction of a gamma photon at birth is determined by an azimuthal angle (0-2pi) and a polar angle (0-pi). In reality, photons are emitted isotropically over 4pi solid angle. When a source is far away from the detector, most of the photons will never reach the detector due to the low geometrical efficiency. Since there is no variance reduction scheme to shorten or terminate the life of those photons for this tally type, there is much wasted calculation time. However, if one is only interested in the total efficiency of a detector, and if in the energy range of interest the elastic (Thomson, or coherent) scattering is not important, then directional biasing schemes can be used. In this method, only a small range of the azimuthal and polar angle is used. Instead of the full 4pi solid angle, particles are forced to be emitted from the source in a direction toward the detector, and with all photons in a cone which entirely encloses the detector volume. Since only a small fraction of the particles are modeled (in most cases less than 10 %), this method can greatly reduce the computation time. The results are then corrected by the ratio of the solid angle subtended with the biasing cone to the 4 total solid angle. This will then yield the same efficiency response as if no biasing was used.

When elastic scattering becomes important (which is more likely at lower energies and in heavily attenuated sources), using highly collimated directional biasing will result in somewhat lower computed "efficiency". If this loss is considered significant, then one must use the full 4-pi emission angle in order to achieve the desired accuracy.

Unless otherwise stated, directional biasing was the default method used for most of the MCNP efficiency calculations in this report. The few cases where this method did not give accurate results are discussed.

The MCNP output for pulse height tally is in counts (normalized by number of histories at that energy) vs energy. For all the efficiency calculations, the channel width was set to 1 keV. The efficiencies are obtained from output files by subtracting the background continuum counts (the average of the counts in the left and right neighboring energy bins) from the peak counts. This was done with a custom software routine.

All of the experimental results were taken and analyzed by standard Canberra instruments and software. Because these tests covered over a year in time, various detectors, MCAs, and data analysis software were used. All MCAs were properly calibrated for energy, and had adequate gain to sufficiently resolve the peaks of interest. Although the spectra were analyzed using various Canberra software packages, all of the analysis algorithms used compute the full energy background-corrected net peak count rate for each of the relevant peaks of the spectra in a similar manner. Therefore, the results are comparable.

In almost all of the MCNP calculations for full energy peak efficiency, the statistical precision of MCNP calculations and experimental measurements was kept less than 3% to ensure the statistical validity of the results.

Three kinds of computers were used for the MCNP calculations: DEC Alpha AXP (DEC chip 21064), VAX 4000 and IBM PS/Value Point (Intel 486DX2-66Hz). The ratio of the speed for these machines is roughly 6:1:1 (AXP:VAX:IBM).

RESULTS AND DISCUSSION

Each of the experiments described in this section has an introductory text description, a simple graphical portrayal of the detector geometry, and a graphical presentation of the energy/efficiency comparison, and a discussion of the results.

Unless otherwise mentioned, the total number of particles are equal for each energy (equal weights are given for each energy). However, more CPU time is spent on the higher energy photons because the lifetime of higher energy photons is usually longer than that of lower energy photons in the simulation.

Test 1: Multi-energy Small Source at Various Angles

The detector used was a Canberra P-type coaxial Ge detector (S/N 3155). The detector had 32% relative efficiency at 1332 keV. The detector physical size is 53.4 mm diameter and 62.0 mm length. Other physical features of the detector (e.g. top and side dead layer thickness', detector holder, detector well and groove, detector holder and all endcap features) are included into the model. The source used in the experiment was a mixed gamma source in a 20 cc cylindrical liquid scintillation counting vial from Analytics, Inc. (S/N 46481-121). It contained nuclides with 10 energies from 88 keV to 1836 keV. Three cases were studied:

- source on axis at a distance 36.5 cm from the detector endcap;
- source 45 degrees at 48.3 cm;
- source 90 degrees at 38.5 cm.

The geometry and graphical presentation of the results are shown in Fig. 1. The agreement between MCNP and experimental measurements is excellent. For the 0 degree angle source position, the largest relative difference is 5% for all energies, and the overall average difference is 3%. This geometry is straightforward to model since the shape of the materials, such as the Al endcap and detector dead layer between the source and the detector, is cylindrical. For 45 degrees, the largest relative difference is 6% for all the energies and the overall average difference is 2%. For 90 degrees, the largest relative difference is just slightly higher at 7%, and the overall average difference becomes 4%. For the off-axis geometries, we found it necessary to add many more features to the detector model (holder, endcap, side dead layer, etc.) in order to achieve the results shown.

Fig. 1

Test 2: Eu-152 Line Source

Although in the previous geometry both the source volume and density were included in the model, the distance effect makes it more or less like a point source. The objective of this geometry is to see how accurate MCNP is when the source is extended linearly.

The detector used was a Canberra P-type coaxial Ge detector (S/N 3202). The detector had 30% relative efficiency at 1332 keV. The detector physical size is 53.0 mm diameter and 59.5 mm length. The source used in the experiment is a Eu-152 line source from North American Scientific,

Inc. (S/N A0980). The activity of the source was uniformly distributed in an epoxy matrix with a density of 1.07 g/cc and cast in 6.53 mm O.D. Tygon tubing. This tubing is then inserted into rigid plastic tubing with an overall length of 80 mm and an outer diameter of 10.3 mm. The source was placed horizontally, 14 cm above the detector Al endcap and supported by a plastic disk. The detector axis passes through the center of the line source. All of these factors were included in the model.

The initial results indicated an average 17% bias between the experimental data and the calculated results. Additional features to the model, and repeated measurements of the line source did not change the bias. Other detectors were used for both MCNP and experimental measurements and gave the same bias. But a summation of point source measurements done to simulate the line source had quite good agreement with the MCNP data. This led us to suspect the calibration source accuracy. This was later confirmed by the manufacturer with an amended calibration certificate.

The test geometry are shown in Fig. 2(a) and the final results are shown in the graph of Fig. 2, middle data set. The agreement is excellent at all energies, with largest relative difference of 3% and overall relative difference of 2%.

Fig. 2

Test 3: Mixed Gamma Plane Source

This experiment is intended to extend the calibration validation from a one dimensional source to two-dimensional planar large area source.

The detector used was a Canberra P-type coaxial Ge detector (S/N 3313). The detector had 25% relative efficiency at 1332 keV. The detector physical size is 52.0 mm diameter and 53.0 mm length.

The source used was manufactured by North American Scientific, Inc. It is a thin (1mm) source with an area of 50 x 50 cm, backed by a support plate for a total thickness of 1 cm. It was placed 8 cm above the Al endcap of the detector. The source is supported by a 10.2 cm I.D. 0.64 cm thick plastic pipe. All of these geometrical factors were included in the model.

The test geometry is shown in Fig. 2(b), with the graphical results in Fig. 2, bottom data set. The largest relative difference is 10%, and the overall difference is 6%. There is a positive bias of approximately 7% in the MCNP efficiency over the source efficiency. It is unclear what is causing this bias. The two likely possibilities are that the source has a non-uniform distribution in the source plane, or that the source activity is different than on the source document, as in the line source case. However, by the time this was identified, the source was no longer available for re-calibration to verify these hypotheses.

Test 4: Marinelli Beaker Source

This common geometry is an additional extrapolation of the extended plane source in experiment 3, but with a moderately thick sample.

The detector used was a Canberra P-type coaxial Ge detector (S/N 3313). The detector had 25% relative efficiency at 1332 keV. The detector physical size is 52.0 mm diameter and 53.0 mm length. Three Marinelli beaker sources made by Analytics, Inc. were used (Cs-137 for 662 keV, Am-241 for 60 keV, and Zn-65 for 511 and 1115 keV). These sources are specifically chosen to eliminate coincident summing effects in the experimental data for this high efficiency geometry. The source volumes are all 1 liter with matrix density of 1.09 g/cc. The source sits right

on top of the detector. No directional biasing was used because this is a relatively high efficiency geometry.

The test geometry is shown in Fig. 2(c) and the results are in the graph of Fig. 2, top data set. The agreement between MCNP and experiment is excellent. All the relative differences are within the statistical uncertainty given by the source and MCNP calculation. The largest relative difference is 4 % and the overall difference is 2 % with an uncertainty of 2.5 %.

Test 5: Heavily Shielded Mixed Gamma Source

The objective of this test is to evaluate the ability of MCNP properly calculate the effect of heavily attenuated sources. This is also important for successful calibrations of very thick sources.

The detector used was a Canberra P-type coaxial Ge detector (S/N 3313). The detector had 25% relative efficiency at 1332 keV. The detector physical size is 52.0 mm diameter and 53.0 mm length. The source was made by North American Scientific, Inc. The activity of the source is contained on a 1 mm diameter resin bead in the center of a 2.5 cm diameter by 0.64 cm thick plastic disc. Attenuators made of steel disks with thickness' of 0.0, 1.0, 3.0, 6.1 and 9.1 cm were placed between the source and the detector. The steel shield disks have a radius of 10 cm. The shield is supported by a 10.2 cm I.D. 0.64 cm thick plastic pipe and a Eu-152 button source was placed right on top of the shield. All of these are included in the model.

The test geometry and the graphical results are shown in Fig. 3. The low energy data points are missing in the 6.1 and 9.1 cm cases because the corresponding experimental and MCNP lines are almost completely shielded. For 0 cm thickness, the agreement between experimental and MCNP results is excellent with the largest difference of 3 %. Even at the maximum thickness where there is 99.9% attenuation, the agreement is still very good (within 6%) and all data are individually statistically acceptable.

Fig. 3

Test 6: Multiple Line Sources in a 55 Gallon Drum in a Canberra Q2 System with Three Detectors

This experiment was designed to demonstrate the capabilities of MCNP to accurately model very complex sources.

The Q2 counter is a standard nuclear waste assay system designed and manufactured by Canberra. It is shown schematically in Fig. 4(a). The typical size of the steel shield is nominally 100 x 100 x 100 cm with a wall thickness of 16 cm. A 200 liter drum which contains the sample to be assayed sits on a rotating table. The standard system is equipped with 3 vertically aligned Ge detectors viewing the sample radially through holes in one of the shield walls. The drum is rotated about the axis multiple times during the measurement.

Fig. 4

The Ge detectors used are Canberra standard coaxial (S/N 3292, 3277 and 3290) with similar sizes (50 mm O.D. and 45 mm length) and similar performance (28 % relative efficiency at 1332 keV).

The calibration geometry used by Canberra is shown in Fig. 4(b). It is intended to simulate a uniformly distributed source, but without the expense of constructing 4 different radioactive calibration drums. Six line sources are placed at 6 different radial positions in a non-radioactive drum. The radial distances are each at the center of 6 concentric hollow cylindrical volume elements, with each volume element containing 1/6 of the drum volume. Four different non-radioactive drums

have been constructed, each with a different density. They have standard 200 liter drum shells, and are filled with foam (0.02 g/cc), cellulose board (0.43 g/cc), particle board (0.75 g/cc) and sand (1.70 g/cc). This is a relatively difficult geometry to model because of the number of components involved. The cross sectional view of the 200 liter drum is shown in the top drawing of Fig. 4(b). The line sources are Eu-152, similar to those used in experiment 3. The source is enclosed in a plastic tubing of 7/8" O.D., 11/16" I.D. and 33" length. The drum rotates with a constant velocity through many rotations while being counted. But, since MCNP is not capable of simulating a rotating source, the 6 rotating line sources in the drum were approximated by 6 uniform cylindrical sources with zero thickness. The plastic tubes and source matrices were modeled by adding the appropriate cylindrical layers outside the drum as shown in the bottom drawing of Fig. 4. Since the six Eu-152 line sources have similar activity (about 3 % difference). The gammas have equal probability to be emitted from the cylindrical source surfaces.

Because of the low geometric efficiency, and the high probability for photon absorption, the calculation time would be extensive, even when the standard directional biasing is used. The MCNP general purpose source definition input card only allows the user to bias all of the photons in a single direction and within a single conical angle. But, since the geometry is quite variable depending upon the starting location of the photon in the source, it was necessary to prepare a special subroutine to more efficiently do this task. In this subroutine, each photon is focused toward the detector in it's own biasing cone. The size of the biasing cone is variable, and depends upon the location of the origin of the photon. The cone completely encompasses the detector. The biasing fraction is for each photon is cumulated during the run. After the computations are complete, the biasing is removed with this cumulative factor.

The results are graphically displayed in Fig. 4. For densities 0.02, 0.43 and 0.76 g/cc, except the energy 122 keV, the agreement between MCNP and experiment is quite good. Except for the 122 keV data points, all others are within 1 standard deviation and less than 6% bias. For the 1.7 g/cc density, MCNP shows a consistent bias of approximately 10% (except 122 keV). It is suspected that this bias may be caused by one or a combination of errors in the source measurement. Likely candidates are errors in the true drum size (there was a slight difference in size among the drums which we did not include in the model), the geometrical placement of the drum during the calibration, and/or imprecise knowledge of the true physical location of the outer line source in the drum.

CONCLUSIONS

A series of benchmark tests have been conducted to validate use of MCNP for efficiency calibration of Ge detectors for simple and complex geometries. The analyses result in the following conclusions.

For accurate efficiency calculations, especially at low energies, it is critical that the source and detector model be complete. All source and detector dimensions must be known and entered into the model. The density and elemental composition of the source, the detector, and any intervening absorbers must be accurately known. For example, we have found it necessary to use approximately 20 parameters in the model just to define the detector, mounting structure, and endcap.

For Ge detector peak efficiency, and for energies above 200 keV, MCNP is capable of achieving better than 10 % accuracy (all tests with the

exception of Q2 at 1.7 g/cc density) in a reasonable amount of computer time (less than 24 hours for an AXP), with the use of directional biasing. Abandoning directional biasing can keep the accuracy within 10% down to 100 keV, but at the expense of 10-100 times longer computer time. It is easy to make mistakes in using MCNP. The program is not user friendly. Many physical parameters of the source and the detector must be entered to adequately describe the source-detector geometry. While there are some complementary software programs to provide some degree of error checking of the model, nothing can replace careful multiple checking of all input parameters, and reality checks of the results. First to verify the detector model, we compute a point source efficiency for a source on the detector axis, and at 90 degrees. This is then verified with a multi-energy source measurement. We then independently do something to check the source geometry, (e.g. reduce it to a point source or comparison the results to a previous good calibration).

MCNP, when used properly, is likely to be more accurate for efficiency calibrations of large and complex sources than calibration standards created for such geometries. For small well defined geometries at unit density, it is easy to obtain 3% calibration sources. However for small sources of other than unit densities, for sources with large volumes (tens to thousands of liters), or for complex shapes (long rods, large flat plates, cylindrical shells, etc.), the additional errors in source distribution and fabrication and calibrations are likely to be larger than the 10% MCNP accuracy demonstrated here. And, when a calibration using MCNP run is completed, there is no radioactive disposal cost. It is our plan to make MCNP the calibration method of choice for the large geometries in our gamma spectroscopy Waste Assay product line.

PHASE I RESULTS OF THE WASTE INSPECTION TOMOGRAPHY SYSTEM*

Richard T. Bernardi
Bio-Imaging Research, Inc.
Lincolnshire, IL 60069

ABSTRACT

Waste Inspection Tomography (WIT) consists of a self-sufficient mobile semi-trailer for Non-Destructive Evaluation and Non-Destructive Assay (NDE/NDA) characterization of nuclear waste drums using X-ray and gamma-ray tomographic techniques. WIT is a Program Research and Development Announcement (PRDA) contract funded by the Environmental Management's (EM) Office of Technology (OTD/EM-50) for the United States Department of

Energy (DOE). Bio-Imaging Research, Inc. (BIR), of Lincolnshire, Illinois has completed Phase I involving design, fabrication, factory testing, evaluation and demonstration of WIT. The recently completed 23-month WIT Phase I included the design, fabrication, and initial testing of all WIT subsystems installed on-board the trailer. Initial test results include 2 MeV Digital Radiography (DR), Computed Tomography (CT), Anger camera imaging, Single Photon Emission Computed Tomography (SPECT), Gamma-Ray Spectroscopy, and Active and Passive Computed Tomography (A&PCT) using a 1.4 mCi source of 166Ho. These techniques were initially demonstrated on a 55-gallon phantom drum with three simulated waste matrices of combustibles, heterogeneous metals, and cement using check sources of gamma active isotopes such as 137Cs and 133Ba with activities between 9 Ci and 250 Ci. Waste matrix identification, isotopic identification, and attenuation-corrected gamma activity determination were all demonstrated nondestructively and noninvasively in Phase I.

BACKGROUND INFORMATION

The United States Department of Energy has in excess of 1,000,000 nuclear waste drums currently stored at nearly 50 sites within the United States that need to be characterized over the next few years. The contents of these drums must be characterized as either high-level waste (HLW), low-level waste (LLW) or transuranic waste (TRU), before the drums are assigned to one of three permanent storage locations. Strict permitting regulations also require information to be gathered about the condition and contents of the waste containers.

X-ray imaging is an established method for waste container inspection. The technique generally used is real-time radiography (RTR) using a 420 kV radiation source, in which a TV camera is coupled to a two-dimensional, light-producing X-ray detector, such as an image intensifier or a scintillation screen. The camera output provides a TV image that is viewed on a monitor during X-ray exposure which, as an example, can see the motion of a moving liquid surface.

RTR systems have several disadvantages however. Area X-ray detectors typically suffer from blooming artifacts. Blooming is caused when a saturated signal spills over into neighboring sensor elements resulting in excessive brightness and limited spatial resolution. RTR systems have limited contrast discrimination with a true dynamic range of usually less than 14-bits (16,384 gray levels in the image), meaning that contrast in a single exposure is limited. An image intensifier is also limited to a small area of the drum.

RTR limits geometric depth perception because of super-positioning, and it lacks quantitative information including two- and three-dimensional spatial and density measurements because the data is not in digital form. The combination of 420 kV source and a restricted detector dynamic range limits RTR penetrating and discriminating capability for inspecting the denser waste containers including cement-solidified drums, glass, and sludges, which make up nearly half of DOE's inventory of nuclear waste drums.

Emerging technologies, like WIT, designed for nondestructive evaluation (NDE) of low level, transuranic, and mixed nuclear waste, include high-energy 2 MeV X-ray computed tomography (CT) and digital radiography (DR), with 18-bit dynamic range. Figure 1 shows a 2 MeV transmission with a full-drum, DR projection image of a 55-gallon drum phantom. Clothing in the top layer simulates low-density combustible waste. Cans of liquid, metal rods and plastic in the mid section simulate higher density waste.

Cement in the bottom layer simulates solidified high-density waste. A 133Ba isotope bottle is visible in the upper left plexiglass tube.
Fig. 1
In its conventional approach, WIT CT/DR imaging uses a curved linear array of solid-state X-ray detectors. The array is composed of individual, closely aligned detection channels. The channels are separated by thin septa that minimize crosstalk and blooming, while offering superior spatial and contrast resolution with high image quality, compared to real-time approaches. These detectors have enough dynamic range to provide contrast sensitivity of 18-bits (up to 262,144 gray levels). The greater the dynamic range and penetrating radiation, the greater the advantage in examining denser waste forms mentioned above. Thus, the WIT approach can image nearly all dense DOE waste streams with even faster throughput for the lighter waste forms. This cannot be said for the more commonly used RTR X-ray imaging systems.
For WIT CT, X-ray projection data is collected from a thin plane of the object, using a linear detector array on the arc of a curve while the object rotates within a thin X-ray fan beam with spiral-like motion capability. This technique is called third-generation CT. The data are mathematically combined to form a cross-sectional image of the thin, irradiated plane or slice. The image in Fig. 2 is a 1024 x 1024 reconstruction of a 10 mm thick slice through the upper section of the phantom drum.
Fig. 2
Slices can be stacked to form a volume rendering of drum content such as the one shown in Fig. 3. In WIT DR, the drum is moved vertically in front of the linear detector array while projection data is collected one line at a time. These techniques measure the X-ray attenuation of the waste matrix and drum. The lines are then displayed as a two-dimensional, freeze-frame projection image (like a baggage inspection X-ray) for DR.
Fig. 3
Active CT on WIT is similar to the conventional X-ray CT techniques. The difference is that a radioisotopic source and single-channel high-purity germanium detector are used with a first-generation CT approach. Active CT data result in the absolute determination of the attenuation of the drum and its contents.
Two emission imaging techniques are employed on WIT for characterizing materials in waste containers. The first of these is gamma emission tomography, commonly called single-photon emission computed tomography (SPECT). Rather than measuring gamma-rays from an external radiation source, SPECT measures the gamma-ray emission inherent in the radioactive waste emitting from within the drum. In this case, emission from actual nuclear waste within a container can provide three-dimensional volume or slice data of the radioactive sources within the container. SPECT uses large area sodium iodide crystals with a two-dimensional array of photomultiplier tube (PMT) detectors for rapid localization of gamma-ray emissions in two-dimensional space and in 3-D with SPECT. These area cameras are called Anger cameras.
The second WIT emission technique uses an energy sensitive single-channel high-purity germanium detector for gamma-ray nuclear spectroscopy. This technique, for nondestructive assay (NDA), can directly identify the emitting isotopic species and the external radioactivity.
The mobile feature of WIT allows inspection technologies to be brought to the nuclear waste drum storage site without the need to relocate drums

for safe, rapid, and cost-effective characterization of regulated nuclear waste. See Fig. 4. The combination of these WIT characterization modalities provides the inspector with an unprecedented ability to non-invasively characterize the regulated contents of waste drums as large as 416 liters (110 gallons), weighing up to 726 kg (1,600 lbs). Any objects that fit within these size and weight restrictions can also be inspected on WIT, such as smaller waste bags and drums that are 19 and 132 liters (5 and 35 gallons).

Fig. 4

Bio-Imaging Research, Inc. (BIR), from Lincolnshire, Illinois has completed Phase I over 23 months involving the design, fabrication, factory testing, and evaluation of WIT. BIR has designed the trailer and multiple inspection techniques including DR, CT, SPECT, and area gamma-ray imaging. BIR has also developed the WIT operational software, the computer hardware, and the gantry mechanical systems. Lawrence Livermore National Laboratory (LLNL), as a subcontractor to BIR under a Work-for-Others agreement with BIR, has developed the A&PCT scanning technique and is participating in WIT evaluation. Early BIR efforts prior to WIT involved investigating the feasibility of using CT to characterize nuclear waste between 1990 and 1993 under Small Business Innovative Research (SBIR) grants from DOE.

DETECTOR DESCRIPTION

The three WIT detection technologies include a linear array of solid-state high-energy X-ray detectors, two area gamma-cameras, and a single high-purity germanium detector. The throughput of WIT inspection is dependent on the physics of the drum being inspected. As an example, the lighter the drum weight, the faster the WIT NDE inspection, and the higher the drum radioactivity, the faster the NDA inspection. The reverse is also true where heavier drums with little radioactivity will require longer inspection times. Ideally, WIT is designed to inspect four drums per hour, per technique. Throughput extremes could yield inspection times of between one and seven drums per hour for each technology employed.

The WIT linear detector array is curved and consists of 896 individual channels of cadmium tungstate (CdW4) crystals mounted on individual photodiodes with thin septa between channels to eliminate crosstalk, blooming, and in-plane scatter. These detectors have an 18-bit (262,144 gray levels) dynamic range for analog-to-digital conversion. The wide dynamic range is necessary to image the variety of material densities and geometries found in DOE waste streams, including combustibles, glass, cement, sludges, and metals that may be present in the same drum. The linear array utilizes a 2 MeV high-energy accelerator as an externally transmitted radiation source using a thin fan beam output with a measured flux of 70 rads per minute at one meter. This high-energy source is needed to penetrate the denser and thicker DOE waste forms like glass logs, sludge, and cemented drums, while allowing for an optimum inspection throughput. The use of energies above 2 MeV is not practical for WIT because of WIT's mobile requirements resulting in weight restrictions for radiation shielding limiting close operator interaction.

The WIT linear detector array and 2 MeV source provide for single-pass digital radiography (DR), which yields a freeze frame projection X-ray image of an entire drum (e.g., like a chest X-ray) using an imaging technique similar to X-ray baggage inspection systems with the drum elevating through a stationary horizontal fan beam of X-rays. A single DR drum view at 2 MeV with wide dynamic range can be acquired in less than

60 seconds with only one X-ray technique. Unlike RTR, both high and low density objects can be examined with WIT DR using a single DR image due to the wide dynamic range.

The linear array and 2 MeV source also provide for transmission computed tomography (CT or TCT) with cross-sectional (two-dimensional) slice and volume (three-dimensional) imaging of drum content based on density distribution. WIT TCT slice thickness ranges from 2 mm to 10 mm through the drum. CT images are acquired by simple drum rotation for data collection and drum elevation for slice location. CT is used for waste drum content identification with a spatial resolution of nearly 2 mm and a density sensitivity of nearly 1%. Typical CT reconstructions and DR images have formats of 256 by 256, 512 by 512, or 1024 x 1024 pixels. Individual CT slice scan times for data collection can be as short as eight seconds for a slice or eight seconds for two slices with an optional dual array for imaging lightweight (S.G.>1) combustible waste. WIT has slower CT scan times (as long as 20 minutes per CT slice) for dense solid glass logs (S.G.2.7). As a bench mark, 100 slices for a low-density combustible waste-filled 55-gallon drum could be acquired and volume rendered in less than ten minutes (with a dual array), whereas a glass log with a density of equal dimensions could take nearly eight hours for 100 slices. A cemented drum (S.G. 2.1) could require a scan time of less than 0.5 hours. Drum wall thickness resolution using WIT TCT is between 0.25 and 0.5 mm. Volume measurements (i.e., for free liquids) of pixels with similar density indications has nearly cubic centimeter resolution with WIT TCT.

WIT's two large area (14" x 17") detectors are each single crystals of sodium iodide in what are typically called Anger cameras. These detectors provide for rapid gamma emission drum area imaging and single photon emission computed tomography (SPECT or ECT) for slice and three-dimensional volume localization of gamma-ray emissions from a drum. Both crystals have a combined total of 110 photomultiplier tubes (PMT) for two dimensional gamma ray emission localization within the waste drum with a spatial resolution of nearly 25 mm over a cross-sectional area of the drum. An emission slice through the drum may also have a thickness of nearly 25 mm. Typical gamma emission projection images and SPECT slice reconstructions have image formats of 32 x 32, 64 by 64, and 128 by 128 pixels. Typical inspection times for a single drum can range from seven minutes to one hour, depending on the emitted gamma ray activity. The higher the activity, the faster the scan time and the reverse is also true.

The single-channel, high-efficiency, (>100% of that of sodium iodide), high purity, germanium detector (HPGe) uses a 50 mm on-a-side square collimator and an active source of 1.4 mCi of Holmium (166Ho). The HPGe detector and 166Ho provide for active and passive computed tomography (A&PCT) with excellent energy sensitivity (of less than 2 kV) for nuclear spectroscopy.

A&PCT on WIT are each first-generation CT techniques, each using a single channel energy sensitive HPGe detector. WIT can detect energies between 10 kV and 1.33 MeV using an 8,000 discrete channel multi-channel analyzer (MCA). This detector and source are used to determine an absolute linear attenuation coefficient of the waste drum and matrix. Passive CT identifies and localizes the radioactivity. The active CT data are used to correct the passive CT data for attenuation caused by the waste matrix and drum itself. The combination of both techniques results in a more

accurate nondestructive assay of the waste drum. Lawrence Livermore National Laboratories (LLNL) has developed the A&PCT techniques. This single detector has a spatial resolution of nearly 50 millimeters over the area with slice thicknesses of nearly 50 mm. Typical A&PCT reconstructions have formats of 14 by 14, 28 by 28, and 42 by 42 pixels. Determination of internal radioactivity approximations for waste drums have thus far shown errors between 5 and 10%. Scan time for a single slice can range from one minute to one hour, depending on the level of radioactivity.

RESULTS

The images included in this paper were taken on-board the trailer and demonstrate CT, SPECT, and A&PCT capabilities. Additional analysis such as drum wall thickness, can be determined to help quantify the relative condition of nuclear waste containers and density measurements of drum contents can be analyzed to further identify and quantify drum contents. WIT can quantify the internal radioactivity which has been corrected for attenuation caused by the waste matrix solely with external measurements without opening the drum. The WIT system's combination of inspection technologies lets inspectors choose an appropriate level of characterization for each site or waste container.

FUTURE WORK

WIT is a Program Research and Development Award (PRDA) contract number DE-AC21-93MC30173. The WIT PRDA is funded by Environmental Management's (EM) Office of Technology Development (OTD/EM-50) for the United States Department of Energy (DOE). The program is managed by the U. S. government from the DOE Morgantown Energy Technology Center (METC) in Morgantown, West Virginia.

Phase II, began in December, 1995, and consists of a twelve-month program for the integration and DOE site demonstration of WIT. Phase II, site demonstrations of WIT have commenced at Lawrence Livermore National Laboratories in Livermore, California, and are planned at Westinghouse Savannah River Company (WSRC) in Aiken, South Carolina, and at the Idaho National Engineering Laboratories (INEL) in Idaho Falls, Idaho. These demonstrations will involve characterizing real waste to validate the system's ability to identify regulated contents and to verify system throughput.

BIR plans to commercialize WIT and plans offer drum scanning/characterization services to DOE and other sites requiring mobile capabilities.

CHARACTERIZATION OF LOW-LEVEL WASTE STREAMS AND SUSPECT WASTE FROM THE LARGEST LOS ALAMOS NATIONAL LABORATORY GENERATORS

J. Soukup
G. Erpenbeck
Benchmark Environmental Corporation
Albuquerque, New Mexico 87110

ABSTRACT

A detailed waste stream characterization of four primary generators of low-level waste at Los Alamos National Laboratory (LANL) was performed to aid in waste minimization efforts. Data was compiled for these four generators from 1988 to the present. Previous waste minimization efforts have focused on identifying waste stream processes and performing source materials substitutions or reductions, where applicable. In this

historical survey, the surveyed generators included an accelerator facility, the plutonium facility, a chemistry and metallurgy research facility, and a radiochemistry research facility. Of particular interest in waste minimization efforts was the composition of suspect low-level waste in which no radioactivity is detected through initial surveys. Ultimately, this waste is disposed of in the LANL low-level permitted waste disposal pits, which fills a scarce and expensive resource with sanitary waste.

Detailed analyses of the waste streams from these four facilities have revealed that suspect low-level waste comprises approximately 50 percent of the low-level waste by volume (47 percent by weight). However, there are significant differences in suspect waste density when the type of radioactive contamination is considered. For the two facilities that deal primarily with beta-emitting activation and spallation products (i.e., the radiochemistry and accelerator facilities), the suspect waste has a much lower density than the total low-level waste coming from those facilities. For the two facilities that perform research on transuranics (i.e., the chemistry and metallurgy research and plutonium facilities), suspect waste is higher in density than the total low-level waste from those facilities. It is theorized that the low density suspect waste is composed primarily of compactable laboratory trash, most of which is not contaminated but can be easily surveyed. The high density waste is theorized to be contaminated with alpha-emitting radionuclides, and, in this case, the suspect waste demonstrates fundamental limits in detection.

INTRODUCTION

Los Alamos National Laboratory performs a wide spectrum of research on radioactive and non-radioactive materials in support of the United States Department of Energy (DOE). In the course of performing such work, solid low-level radioactive waste is generated and ultimately disposed of in the low-level waste disposal pits at LANL Technical Area (TA)-54, Area G. Due to the limited disposal volume (approximately 59,000 m3 of pit volume remained as of July, 1995) and the large cost associated with low-level radioactive waste disposal, the Laboratory has a concerted waste minimization effort aimed at reducing laboratory-wide waste volume. Current building upgrades at the Chemistry and Metallurgy Research (CMR) facility will result in a dramatic increase of low-level waste generation. The Laboratory is responsible for examining all waste streams and identifying opportunities for waste reduction where technically and economically feasible. The following study was performed to identify waste from four facilities (i.e., CMR, the Plutonium Facility, TA-48 and TA-53) and quantify the amount of suspect radioactive waste from those facilities. Suspect radioactive waste is waste that originates in a radioactive materials management area (RMMA) and, therefore has the potential for radioactive contamination. However, radioassay and survey measurements on the material detected no radioactive contamination. Cursory analyses have indicated that approximately 50 percent of the waste disposed at TA-54 consists of suspect radioactive waste. By segregating actual radioactive waste from waste that is known through acceptable knowledge to be non-radioactive, Laboratory waste management can develop an approach that will result in non-contaminated waste being sent to the sanitary landfill for disposal and minimize the amount of suspect radioactive waste being disposed of at TA-54. Gross alpha/beta surveys and gamma detection systems would be used to verify the non-

contaminated status of the waste to levels acceptable to the Department of Energy.

FACILITY DESCRIPTIONS

Chemistry and Metallurgy Research Facility

The Chemistry and Metallurgy Research (CMR) facility has served as the primary special nuclear materials analytical laboratory for LANL since 1952. The CMR facility is located in TA-3. The three-story structure contains approximately 550,000 ft2 of floor space and is presently designated as a security "category 1" facility with a safety classification of "moderate hazard." The building consists of eight wings: the Administration Wing and Wings 1 through 5, 7, and 9. The Administration Wing contains office and conference room space occupied by the Chemical Science and Technology Division Office (CST-DO).

Operations

Wings 1 through 5, 7, and 9 house experimental facilities. The experimental facilities are occupied by personnel from several line organizations at LANL. Approximately 48,0000 ft2 of the first floor space is devoted to laboratories, and approximately the same amount of space is devoted to offices. The basement and attic spaces provide utility services to the first floor laboratories and offices. Some basement areas have been modified for use as laboratories. Each wing is designed to operate independently with its own electrical power distribution and ventilation systems. Wing 9, which contains the hot cell facilities for the CMR, was added in 1960 (1).

The Plutonium Facility

The LANL Plutonium Processing Facility is located at TA-55 and occupies a 30-acre location with 70 structures. Only the Plutonium Building (PF-4) and the Health Physics Assay Laboratory (HPAL) contain nuclear materials. Each area is designated as an RMMA. PF-4 is a two-story, 151,000 ft2 building, with support equipment in the basement and laboratory rooms divided among four wings on the main floor. The major laboratory rooms contain over 300 gloveboxes for the handling of plutonium, uranium and other nuclear materials.

Operations

The Residue Processing Group (NMT-2) develops and proves processing technology for plutonium and other actinides through aqueous and molten-salt based technologies. This group supports the LANL Plutonium Facility by recovering and purifying plutonium scrap residues and converting them to an oxide or metal that can be used or placed in long-term storage.

The Advanced Technologies Group (NMT-6) conducts fundamental and applied research in actinide chemistry. This group focuses on new and emerging separation technologies and improving existing technologies.

The Waste Management and Environmental Compliance Group (NMT-7) handles the hazardous and radioactive waste materials generated at TA-55. NMT-7 also assures that the facility complies with all environmental requirements, including those regulating waste, water, and air discharges (2).

Technical Area 48

TA-48 is used for the study of nuclear properties of radioactive materials by using analytical and physical chemistry. Measurements of radioactive substances are made and hot cells are used for remote handling of radioactive materials.

Operations

The hot cell facility includes a number of laboratories and rooms within building RC-1 at TA-48. This area is used to process targets that are irradiated in the proton beam at the Los Alamos Meson Physics Facility (LAMPF) for production of medical radioisotopes. There are large amounts of radioactive materials present in the hot cells within the facility. Virtually all materials present in the facility are beta/gamma emitters; by policy, large amounts of alpha emitters are not handled by the facility (3).

The alpha cell area is the primary area at TA-48 used for plutonium and uranium research. This area is segregated from the hot cell. Waste from this area accounts for a very small percentage of the total waste emanating from TA-48.

Other laboratories at TA-48 consist of radiochemistry laboratories used for the characterization of very low levels of radioactive contamination. Waste generated from the processing of research environmental samples has not included suspect radioactive waste produced over the past 7 years.

Technical Area 53

Located within TA-53 is the Los Alamos Meson Physics Facility (LAMPF). LAMPF is a high energy particle accelerator facility that produces protons, neutrons, and subatomic particles for use in basic research, isotope production, radiochemistry, solid-state physics research, and accelerator technology.

Operations

The accelerator and beam tube provide a primary beam of 800 MeV protons at an average current of one milliampere for basic nuclear and elementary particle physics research. Positive and negative hydrogen ions are generated and injected into a high voltage dome. A low density plasma is produced and protons are extracted and accelerated through a potential field. The beams are steered and focused into the linear accelerator drift tube, into the side-coupled cavity linear accelerator stage, and switched by bending and quadrapole magnets to various experimental areas.

Experimental Area A conducts experiments for particle physics and nuclear structure studies. Pions, muons, and protons are produced and used in a variety of experiments. Using the highest intensity main proton beam from the accelerator, the spectrometers in Experimental Area A measure particle scattering from interactions of the proton beam with targets located along the beam line to determine number, type, direction, momentum, velocity, and electrical charge.

Experimental Area B conducts experiments in the Neutron Physics Laboratory using a medium resolution spectrometer. A negative ion beam is divided into two portions. One portion generates a polarized neutron beam by charge interchange in a deuterium target which is delivered to experiments in the neutron area. The other portion of the negative ion beam is delivered to the External Proton Beam line where it is accessible for experimental setups.

Experimental Area C houses the High Resolution Proton Spectrometer (HRS). It measures the scattering of protons from nuclei and the production of other particles resulting from the incident protons. The HRS can also measure the spin of scattered particles (4).METHODS

Historical low-level waste data from the four facilities was used to determine the composition and nature of all low-level waste over the past seven years. Waste contents, activity, weight and volume were used to identify facility specific trends for actual and suspect low-level waste.

To perform this analysis, the Low-Level Waste Database was used extensively.

Low-level Waste Database

LANL has an effective method of tracking all generated waste (e.g., transuranic, mixed transuranic, low-level, mixed low-level, chemical). Generators must complete a Chemical Waste Disposal Request (CWDR) form for any waste to be disposed, treated, or stored. This form is forwarded to the Waste Management Program, and the form is verified for accuracy and completeness, and subsequently entered into the Waste Management waste tracking databases. These databases track the final disposition of each item of waste received. Volumes, weights, radionuclides, activities, locations of waste generation and generator information submitted on the CWDR is entered into the databases. This provides for a centralized location with comprehensive data accessible to auditors, waste management, and waste minimization programs.

Volume Data

The total volume of solid low-level waste disposed of at TA-54, Area G in 1994 was 2963 m3 (Fig. 1). The four facilities of interest in this study accounted for slightly more than 28 percent of the total volume. The environmental restoration projects at the Laboratory are the single largest generator of low-level waste; however, the waste and waste type are highly dependent on the site and contamination of the site. For the purposes of this study, the four chosen facilities represent a cross-section of laboratory-wide activities.

Fig. 1

Database Analysis

Information from all low-level waste disposal requests from the low-level waste database for the CMR facility over the past 7 years were analyzed for each of the facilities. Since 1994, "suspect radioactive" waste is no longer allowed for disposals. As a consequence, waste originating from an RMMA that has no detectable activity is typically described as having isotopic activities of 1 nCi. Therefore, any waste package with radionuclide activity averaging less than 2 nCi is considered as suspect in the 1994-1995 timeframe for this study.

Since 1988, the four facilities have disposed of 6,639 low-level waste packages with 1,829 of the packages containing suspect radioactive waste. The total volume disposed over the same time period is 14,762 m3 with suspect waste accounting for 7,726 m3.

FINDINGS

Findings for each of the four facilities are summarized below.

CMR Waste Profile

Low-level waste arising from standard operations at the CMR facility consist primarily of contaminated and potentially contaminated laboratory equipment, personal protective equipment (PPE), and laboratory waste products. Currently, the CMR building is undergoing extensive upgrades. Due to these upgrades, CMR low-level waste now includes construction and building debris (e.g., electrical conduit, water pipes, ventilation ductwork) originating in radioactive materials management areas (RMMAs). Typically, this waste is packaged in Scientific Ecology Group (SEG) B-25 boxes (2.66 m3).

Radionuclides present in CMR waste can include virtually any radionuclide found at LANL. However, most waste items contain either fission products (primarily 137Cs and 125Sb) or plutonium-contaminated materials and their progeny (238Pu, 239Pu, 240Pu, 241Pu, 241Am, 237Np, 233Pa and 237U). Most

waste items contain either fission products or plutonium, often both. The form of contamination is dependent on the origination point of the waste.

Plutonium Facility Waste Profile

Virtually all items disposed of as low-level radioactive waste from TA-55 over the past 7 years have been described as contaminated with only plutonium and plutonium progeny (primarily 241Am). The only exceptions have been for disposals of spent radioactive calibration sources. Most waste items are described as either compactable-boxed room trash (e.g., small lab items, PPE, paper) or building debris (e.g., wood, plastic, metal, paper, rubber, glass, waste rags, absorbed liquids, equipment, concrete, general building debris).

TA-48 Waste Profile

Two primary waste forms dominate the waste generated by TA-48. Waste originating from the hot cell areas accounts for more than 80 percent of the waste. This waste is typically compactable laboratory trash contaminated with radionuclides identical to those seen in waste from TA-53. The radioactivity is easily detected, and, contaminated waste usually contains large amounts of activity.

The second waste form comes from plutonium-based work in the alpha cell area. Recently, 67 2-ft3 boxes from this area were assayed. Of the 67 boxes, 27 boxes were found to have measurable amounts of transuranic radionuclides (i.e., 241Am, 238Pu and 239Pu) and nearly all had measurable amounts of 137Cs, 85Sr and 95mTc. In only one box was there contamination from only transuranic radionuclides.

TA-53 Waste Profile

The majority of radioactive waste generated by TA-53 consists of activation and spallation products. These radionuclides are produced when high energy particles collide with matter. Nuclear capture and scattering mechanisms subsequently result in the production of radioactive material. The radionuclides produced are dependent on the scattering and capture cross-sections of the target material. In general, activation of iron accounts for the majority of the activity contaminating waste at TA-53. Past radioassay activities conducted on waste packages from LAMPF and the Los Alamos Neutron Scattering Center (LANSCE) have shown that the common radionuclides contained in the waste packages are strong gamma emitters that are readily detectable by commercially available detection systems. The primary radionuclides include 7Be, 56Co, 60Co, 54Mn, hafnium, lutetium, and europium isotopes.

DISCUSSION

CMR Facility Data

The data for CMR shows that approximately 49 percent of all waste packages from the CMR facility have been suspect low-level. A total volume of 5,978 m3 of low-level waste has been disposed since 1988, with 3,704 m3 being suspect low-level waste. As a point of reference, Pit 38 at TA-54, Area G (the largest low-level radioactive waste disposal pit at LANL) has a total capacity of approximately 37,000m3 below the spill line (5). The amount of suspect waste from the CMR facility over the past 7 years amounts to approximately 10 percent of the volume of the largest disposal pit at LANL.

Every CMR item considered to be suspect over the past 7 years, has, in theory, been contaminated with transuranic radionuclides. Virtually every suspect item has been described in the database as building debris. These items are among the hardest to survey and swipe for contamination;

therefore, it is not surprising that little or no actual values are assigned to these items.

The Plutonium Facility Data

Since 1988, the volume of Plutonium Facility low-level waste disposed at TA-54, Area G is approximately 3,570m3 with 1,910 m3 containing suspect radioactive materials.

Figure 2 shows data for CMR and the Plutonium Facility waste. From the data, it appears that suspect package density is significantly higher than the average density of all waste from these facilities. Because the majority of suspect waste from these facilities tends to be building debris, the packages tend to be larger and more dense than laboratory trash packages. Building debris surfaces are typically very irregular with much of the contaminated surface inaccessible for swipes, smears and direct survey (i.e., ductwork, plumbing and electrical conduit). These waste items tend to be disposed of in SEG B-25 waste boxes rather than 55 gallon drums. The resulting package cannot be counted on the facilities' drum counters. Furthermore, the detection capabilities for B-25 waste contaminated with plutonium is poor. Therefore, if the waste is not grossly contaminated with large amounts of plutonium, the waste will likely be listed as suspect waste. Figure 3 shows the detection limits for the waste management High Purity Germanium Detector and a 2,000 lb B-25 box.

Fig. 2

Fig. 3

Figure 2 shows the density of all waste from these facilities has increased steadily over the past 4 years. This is because of waste minimization efforts to reduce the volume of waste from these facilities. Efforts have been made to pack waste more efficiently with less void space.

TA-48 Data

A total of 1,017 packages accounting for 2,001 m3 of TA-48 low-level waste, have been disposed of at TA-54, Area G since 1988 with 423 packages (1,174 m3) being classified as suspect radioactive waste. The majority of suspect waste packages are described as laboratory trash and laboratory equipment with activation and fission product suspect contamination.

TA-53 Data

Data for TA-53 is strikingly similar to that of TA-48. A total of 654 packages, totaling 3,213 m3 of low-level waste, have been disposed of at TA-54, Area G. Suspect radioactive low-level waste accounts for 198 packages with a total volume of 939 m3 since 1988.

Unlike the data for CMR and the Plutonium Facility, data for TA-48 and TA-53 show that suspect waste tends to be lower in density than the total low-level waste. The waste is typically laboratory trash and, in theory, is contaminated with gamma-emitting activation products.

Because of the nature of the activation and spallation processes, radioactive contamination at TA-48 and TA-53 is expected to consist of fixed contamination of target and beam-line materials. It is very likely that cellulosic materials used in the handling of target and beam-line activities are not contaminated.

CONCLUSIONS AND RECOMMENDATIONS

CMR and the Plutonium Facility

Both the CMR and Plutonium facilities are among the Laboratory leaders in waste characterization capabilities. Because of the nature of the suspect

contaminated waste, it is not likely that current state-of-the-are detection equipment will meet any reasonable criteria for free release. Furthermore, because of the widespread contamination in these aging facilities, most building materials tend to exhibit low levels of fixed radioactive contamination. It is concluded that the majority of suspect waste from these facilities are actually contaminated with radioactive materials, but due to detection limits for transuranic radionuclides, relatively small amounts of contamination pass through characterization systems undetected. Waste reduction efforts for these facilities should concentrate on source reduction/substitution, decontamination and material compaction rather than detection and free release.

TA-48 and TA-55

Because the majority of suspect low-level radioactive materials are low density cellulosics (Fig. 4), a materials segregation and characterization program may be used to verify that cellulosic materials are cleared for free release. Currently, waste box counters are capable of minimum detectable concentrations of less than 1 pCi/g (based on 73As and a 200 s count time). If even one-half of the suspect contaminated cellulosics can be free released as non-radioactive, the saved volume would be approximately 150 m3 annually from these two facilities alone. This method of characterization and free release would require guidance and approval from DOE for volume-contaminated materials (i.e., similar to methods used in the nuclear power industry).

ABSTRACT

To characterize the penetration depth of radiological contamination through the thickness of transite (an asbestos-cement building material) from the Department of Energy Fernald site, both destructive and non-

destructive analysis techniques were used. The destructive techniques were based on progressively removing layers of material and subsequent direct analysis of the exposed surfaces. These layer removal analyses included quantitative measurements using a Geiger-Mueller (G-M) detector and qualitative measurements based on autoradiography and ultraviolet photography. G-M detector measurements during layer removal provided quantitative distributions consistent with diffusion theory, serving to validate a novel non-destructive technique. The ultraviolet analysis provided qualitative information with the advantage of instantaneous results that may be useful for screening samples. The autoradiographic analysis also provided qualitative results for comparison and image analysis. The novel non-destructive technique involves acquiring gamma-ray spectra with high-purity germanium detectors placed on both sides of a panel and relies on relating the difference in gamma-ray attenuation for different energies to the spatial distribution of contamination through the thickness of the panel. Both quantitative and qualitative results from this study indicate that the contamination did penetrate into the volume of the transite. However, this penetration depth was observed to be strongly dependent on the manner in which the transite was exposed to the contamination. Consequently, it is likely that significantly different penetration depths will be observed for different processes, buildings, and sites.

INTRODUCTION

A typical decontamination and decommissioning concern for both Department of Energy (DOE) facilities and nuclear power industry facilities is accurately determining the depth to which radiological contamination has penetrated building materials (1,2). The optimal means of decontaminating or disposing of such materials will often be dependent on this penetration depth. The building material of primary concern in this study is transite, an asbestos-cement material used in construction of both internal and external walls in process buildings at the DOE Fernald site. Transite was used extensively as building panels at DOE sites (Fernald and others) prior to the implementation of asbestos-controlling regulations. Uranium processing at the Fernald site has resulted in the radiological contamination of these panels. In the current era of remediation, prior to the disposal of these transite panels, the multiple concerns of toxic (asbestos-containing) and radioactive (process contaminated) waste must be addressed. Such a mixed waste is much more costly to dispose of than waste which is solely toxic or radioactive. It is therefore desirable to minimize the amount of mixed wastes. In the case of Fernald transite, surface decontamination may potentially restore the bulk of the material to the simpler toxic waste form. The viability of decontamination hinges on the distribution of the contamination through the thickness of the transite panels. Consequently, characterizing this contamination distribution is the first step in the disposal of the transite. Note: the term "contamination distribution" will be used to indicate the distribution of contamination through the thickness of transite samples, and does not refer to the distribution of contamination on the surface of the samples unless specifically mentioned.

The potential exists for a variety of destructive and non-destructive techniques to be used to characterize the contamination distribution through the thickness of transite. In this study, the choice of techniques was based on selective criteria, including minimizing cost,

ability to perform in-house, time constraints, quantitative or qualitative nature of the results, ability to measure contamination distribution, accuracy, and precision. Possible techniques were grouped into three categories based on the ability of the method to provide information about the contamination distribution in the sample: 1) destructive techniques which require destroying the sample to provide any information; 2) non-destructive techniques which only provide information about the surface of the sample and therefore require destructive analysis to determine the contamination distribution; and 3) non-destructive techniques which directly provide information about the contamination distribution. Analytical techniques considered included neutron activation analysis (NAA), atomic absorption spectrometry (AAS), and inductively coupled plasma spectroscopy (ICP), proton-induced X-ray emission (PIXE), X-ray fluorescence (XRF), backscatter spectroscopy, alpha, beta, and gamma-ray detection, ultraviolet (UV) fluorescence, autoradiography and gamma-ray spectroscopy. Requirements for the third category were not met by any known established technique. However, a novel non-destructive gamma-ray spectrometry technique has been proposed by Chung, et al. (3) and was implemented in this study. While the development of other non-destructive techniques was considered, all such techniques required some sort of activation or excitation source. This passive gamma-ray spectrometry technique represents a simple, inexpensive means of quantifying the contamination distribution. Considering the selective criteria, the techniques of beta and gamma-ray detection using a Geiger-Mueller (G-M) detector, UV fluorescence, and autoradiography, as well as gamma-ray spectrometry were chosen. All but the non-destructive gamma-ray spectrometry method required sequential layer removal and subsequent analysis of the exposed surfaces. Use of such destructive techniques was limited due to the difficulties in handling radiologically contaminated asbestos made friable by the destructive process. The establishment of a suitable non-destructive technique would bypass such handling difficulties, allow in-situ analysis, and minimize reliance on inferential statistics by allowing a much larger scale sampling plan. However, prior to validation of the novel non-destructive technique, the destructive methods were required.

SAMPLES

Transite is the brand name of an asbestos-cement construction material consisting of chrysotile asbestos (magnesium silicate) and portland cement. Manufacturing consisted of bonding multiple layers in a hydraulic press to form composite laminar panels. Transite was chosen as a building material for its strength and ability to resist moisture, heat, and corrosion. At the Fernald site, these panels typically have the dimensions of 1.22 m 3.05 m and are either flat or corrugated in form. The flat panels have a nominal thickness of 0.65 cm whereas the corrugated panels have a nominal thickness of 0.95 cm. In general, the flat panels were used for internal walls and the corrugated panels were used for external walls.

The samples used in this study to develop a methodology for determining the contamination distribution were taken from two different buildings at the Fernald site with very different process histories, representing extreme cases. One was Building 7, a dry process area where very little process contamination occurred, and the other was Building 2, a wet process area where more process contamination occurred. Two groups of flat panels (A and C) were taken from these buildings for analysis. Both

of these groups consisted of six panels with each panel being of approximately 25 cm 25 cm. Group A consisted of flat panels from the interior of Building 7. Group C consisted of flat panels from the interior of Building 2. Each panel within both groups was further labeled 1 through 6, resulting in panels A1 through A6 and C1 through C6. Furthermore, these panels were subdivided into 9 samples each, a through i. For example, panel C5 was divided into approximately 7.6 cm 7.6 cm squares: C5a through C5i. Each of these samples represents the basic unit of analysis and has an area of approximately 60 cm2. This sample size allows sufficient area for practical application of analytical techniques while attempting to maximize the degree of contamination homogeneity across the surfaces.

EXPERIMENTAL PROCEDURES

The techniques used in the destructive analysis for this study provided information only about the amount of contamination on the sample surface. To obtain information about the contamination distribution, layers were removed to allow measurements at various depths. In maximizing the number of successive surfaces analyzed by minimizing the thickness of each removed layer, it was possible to approximate the continuous contamination distribution.

Destructive Layer Removal

A 1.0 m 0.5 m 1.2 m high efficiency particulate air (HEPA) filtered glove box, built specifically for this study, was used to contain radiologically contaminated friable asbestos generated during layer removal. Samples of transite were placed in the containment along with a belt sander and micrometer. Each sample was then placed in a vise, such that about half of the sample thickness extended above the top of the vise. The belt sander with rough grit sandpaper was then used to remove layers of material. Applying the sander in a variety of directions ensured as uniform a removal as possible. With extreme care, it was possible to remove a sufficiently uniform layer with a minimum thickness of approximately 0.025 cm. Variation in the thickness measured by the micrometer at eight locations on the sample provided a measure of this uniformity.

Quantitative Destructive Analysis
