Prior to the initial layer removal and after each of these layer removals, the sample was analyzed with a G-M detector, UV photography, and autoradiography. The G-M detector was used by placing the probe, which was about the same size as the sample, on the sample face and recording the count rate. Layer removal and analysis were continued until the level of contamination was below the threshold of detection (background level). The G-M detector was used because of its sensitivity to the beta particles emitted by the uranium daughters which represent the contamination.

Qualitative Destructive Analysis

When uranium is exposed to an oxygen-containing environment, such as air, uranyl ions (UO_2^{+2}) are formed. These ions fluoresce visible green light when exposed to UV light. Thus, when a sample is contaminated with uranium, exposing that sample to UV light provides a technique for localizing the presence and extent of contamination as the intensity at which the sample fluoresces is proportional to the uranium concentration. Consequently, the presence of uranium contamination can be determined qualitatively by direct observation. UV photography provides a direct measure of the distribution of contamination on the surface of the

sample, illustrating surface contamination homogeneity. Furthermore, through the use of standards to determine relative intensities, image analysis could likely produce quantitative results. Because UV light only interacts with the surface of the sample, this method provides information about contamination on the surface, and is very quick, simple, and inexpensive (4,5). For the UV photography in this study, the transite samples were placed in a light box equipped with ultraviolet fluorescent bulbs which emitted light at a 254 nm wavelength. A 35 mm camera was attached to the viewport with 200 speed film and an exposure duration of 4 seconds. For comparative purposes, consistent settings and development were crucial.

Autoradiography differs from typical radiography only in that the source of radiation is provided by the sample itself and a separate radioactive source is not required. Classical radiography involves capturing the image of the sample on a photographic plate based on the attenuation of radiation from an external source by the intervening sample, while autoradiography captures the actual pattern and intensity of radiation from a sample. Consequently, the only requirements for autoradiography are radiosensitive film and a means of handling the light sensitive media for exposure purposes. Since autoradiography also provided a spatial representation of contamination across the surface of the sample, illustrating surface contamination homogeneity, it was used for comparison to the UV photographic results for verifying which regions contained uranium contamination. Autoradiography provides surface or near surface information because the energetic charged particles that are most likely to interact with and register on the thin film are significantly attenuated with depth. The autoradiographs were produced using standard X-ray imaging film with a central polymeric base coated on both sides with a thin emulsion covered with an anti-scratch layer. The film was placed in direct contact with a sample and stored in a light-tight box for an appropriate exposure time. Consistent developing was provided by a standard automated developer.

Non-Destructive Analysis

The contamination distribution results from the destructive analysis were used to both characterize the transite and to provide verification of the novel non-destructive technique using gamma-ray spectrometry proposed by Chung, et al.(3). This non-destructive method was based on measuring the gamma-ray spectra from both sides of the sample. Figure 1 illustrates the implementation of this technique. Note the different photopeak areas (C1 and C2) recorded by the two detectors in the two gamma-ray spectra. In conjunction with knowledge of the gamma-ray linear attenuation coefficient for the material, the ratio of photopeak areas at several energies from these spectra can be used to infer the most-probable contamination distribution. Use of a high-purity germanium (HPGe) detector provided sufficient energy resolution to discern all of the photopeaks of interest. Comparing the measured ratio of the respective photopeak areas from both sides of the panel (Fig. 1-b) over a range of energies to computer-generated ratios for possible contamination distributions provided a prediction of the most-probable distribution (Fig. 1-c). The computer generated ratios were based on distributions predicted by diffusion theory for given types of exposures, or initial conditions. In particular, for a single instantaneous exposure, the distribution was based on a gaussian function, and for a constant

exposure, the distribution was based on a complementary error function (6).

Fig. 1

RESULTS

Destructive analysis was conducted on both sides of one A sample and eleven C samples using the G-M detector to obtain quantitative contamination distributions. Approximately six layer removals were required per side to reach background level. As representative G-M detector data, sample C5a produced the results shown in Table I and Fig. 2. Figure 2 also illustrates the correlation of the measured contamination distribution with the distribution predicted by the non-destructive technique. The shape of the measured contamination distribution is consistent with the diffusion theory predictions of the non-destructive technique. For this study, the condition of constant exposure was approximated and the complementary error function proved to be applicable. Similar contamination distributions were predicted and measured for the other ten C samples.

Table I

Fig. 2

To determine how the contamination distributions vary from sample to sample, the depth at which count rates from the G-M detector approached background were recorded. Table II lists the sample sides analyzed and their corresponding depth to background level. For the twenty-two sample sides analyzed from Building 2, the average background depth was 0.1460.0815 cm. Although the results in Table II illustrate significant variation and uncertainty, it is apparent that there are differences between samples with different process histories.

To further verify the penetration of uranium contamination into the thickness of the transite panels, both UV photographic and autoradiographic analyses were performed on several samples. Since the detection thresholds for both UV photography and autoradiography are significantly larger than that of the G-M detector, these analyses became insensitive prior to reaching background levels. Consequently, only about four layer removals of 0.03 cm each provided useful image information. The autoradiography required an exposure time of either 24 or 48 hours, depending on the contamination level. It was empirically determined that a G-M detector reading of about 1000 counts per minute (cpm) or greater could be exposed for 24 hours to produce a sufficient image. Lesser activity required a 48 hour exposure.

As representative of UV photographic and autoradiographic results, sample C5a produced the images shown in Figs. 3 and 4, where Fig. 3 shows the sample prior to layer removal and after a single layer removal and Fig. 4 shows the sample after two and three layer removals. The progression of decreasing contamination and image correlation for the same layer are illustrated by the dark green areas in the UV photographs which correspond to the light areas in the autoradiographs.

One concern with results based on layer removal using a belt sander was the possibility of cross-contamination between subsequent layers due to embedding by abrasion. The well-resolved contamination pattern images from the UV photography and autoradiography and the ability to achieve background level after several layers have been removed indicate that this effect is negligible.

Fig. 3

Fig. 4

CONCLUSIONS

The UV photographic technique proved to be a good qualitative tool for quickly analyzing the samples. The autoradiographs were used as a reference to provide a gross, qualitative indication of what aspects of the UV image corresponded to contamination. The autoradiographs were not limited by extraneous background imaging (visual noise), as the UV images were, since exposure of the film resulted only from radiation produced by the contamination. The threshold of detection is theoretically better for the autoradiographs than for the UV photographs, given sufficient exposure time. However, this autoradiographic exposure time is quite lengthy, on the order of days. Both UV photography and autoradiography provide the degree of surface contamination homogeneity.

Given the primary concern of determining whether the transite can be decontaminated such that the bulk of the material meets free release criteria, a key characteristic of interest is the depth to background or the thickness of material that potentially requires removal. Should this characteristic be too large, decontamination may not be viable for a given method of removal. Samples with a more significant contamination exposure history (group C samples - Building 2) had a background depth that resulted in approximately 40% of the total thickness of the transite being contaminated to some level. For samples with a process history that resulted in significantly less contamination (group A samples - Building 7), the background depth represented about 8% of the total thickness of the transite. The viability of decontamination is illustrated to be heavily dependent on the process history. For future studies, it is recommended that a greater variety of sample contamination exposure histories be used for a stronger correlation to background depth.

The contamination distribution results indicate the degree to which a given sample can be labeled as surface or volumetrically contaminated. The quantitative data provided by the G-M detector produced distributions consistent with the non-destructive technique. Therefore these G-M detector distributions adhere closely to what was predicted by diffusion theory, a complementary error function distribution, given the appropriate condition of constant exposure. The value of this technique is its concept of using gamma-ray spectrometry without destroying the samples and that the computer simulations produce a reasonable representation of the actual contamination distribution.

While this study has focused on the characterization of Fernald transite, other radiologically contaminated materials could also be characterized using these techniques. As long as gamma-ray spectra can be acquired from two opposing sides, a range of photopeak energies are available, and the assumption of uniform contamination across the surface is not restrictive, the non-destructive gamma-ray spectrometry technique can be used. To accurately predict the contamination distribution for a particular sample, a reasonably accurate knowledge of the manner in which the sample was contaminated is also required. In lieu of this knowledge, the destructive techniques can be used to establish appropriate mathematical representations of the contamination distribution. In any case, the destructive techniques should likely be used on a few samples from any new set of building material samples to confirm the results of the non-destructive technique. This recommendation will be necessary until the non-destructive technique has been further validated for a broader set of contaminants and exposure scenarios. However, it is envisioned that at some point the non-destructive technique will

accurately predict the contamination distributions without the need for any destructive measurements for confirmation. These techniques are well-suited for analyzing transite samples from other DOE sites. While the non-destructive technique and the destructive G-M and autoradiography techniques are applicable for any radiological contaminant that emits beta particles and gamma-rays, the UV photography technique is not applicable unless uranium or other contamination that fluoresces under UV excitation is present. Nonetheless, the techniques developed in this project would only require minor modifications, if any, to be useful for analyzing transite or other building material samples from other DOE sites for the contamination distribution through the thickness of the samples.

This study established a reliable means of determining the penetration of contamination in flat transite panels by destructive layer removal and analysis. In addition, the novel non-destructive technique using gamma-ray spectrometry has been validated. Specific sample contamination distributions have been shown to be dependent on exposure history, as consistent with diffusion theory, and should be applicable to materials other than transite.

ACKNOWLEDGEMENTS

SOLID LOW-LEVEL RADIOACTIVE WASTE VOLUME PROJECTIONS AT LOS ALAMOS NATIONAL LABORATORY

K. Art
J. Minton-Hughes
Benchmark Environmental Corporation
White Rock, New Mexico 87544

ABSTRACT

In response to regulatory requirements, the current economic environment, and diminishing on-site low-level radioactive waste (LLW) disposal capacity, Los Alamos National Laboratory (LANL) needed to develop a system to collect data on future LLW generation that would comply with DOE Order 5820.2A and be an effective facility planning tool. The LANL Volume Projections Project (VPP) was created to meet these needs. This paper describes the objectives, scope, and components of the VPP that will provide information essential to future facility planning and development.

The VPP potentially involved the accumulation and evaluation of a large volume of data. The minimum data requirements were determined by considering the waste management facility's preliminary performance assessment results, on-site disposal space limitations, treatment options, and off-site disposal options. Using these data requirements, a questionnaire was developed to obtain the necessary waste stream information from the waste generating facilities. A pilot program was implemented to evaluate the sufficiency of the data gathered and the ease-of-use of the questionnaire.

An Oracle database will be developed to manage the information. When the database is completed, the questionnaire will be distributed to the five largest waste generating facilities (accounting for 75 percent of the solid LLW disposed of at LANL). The LANL-wide implementation of this program is scheduled for the following fiscal year.

DEFINITIONS

Container. A receptacle used to hold materials or waste for shipment, storage, or disposal.

Low-level radioactive Waste. Solid waste that is radioactive and is not classified as high-level waste, TRU waste, spent nuclear fuel, or tailings from the milling of uranium or thorium ore (1).

Normal Waste. Waste that is not generated through an environmental restoration project, a decontamination/decommissioning project, a spill clean-up, or an abatement project.

Performance Assessment. A systematic analysis of the potential risks posed by waste management systems to the public and environment, and a comparison of those risks to established performance objectives (2).

Waste generator. Any person by site whose act or process produces waste or whose act first causes a waste to become subject to regulation (3).
Waste Stream. A waste or group of wastes generated by a process at regular intervals or continuously over time that varies only within a narrow range of parameters (4).

INTRODUCTION

The LANL Waste Management Program Office and its facilities must provide waste generation projection data to the Department of Energy, the University of California and other stakeholders. Because of the following concerns, the need for accurate waste generation volume projections has increase substantially: projected deep budget cuts for environmental management programs, and the need to assure the availability of waste treatment, storage, and disposal (TSD) capabilities. An annual survey will be used to gather facility specific estimates of future waste stream generation volumes to compile waste volume projection data with TSD capacity data. The questionnaire will be useful in performing compliance, reporting, and planning activities.

REGULATORY DRIVER

DOE Order 5820.2A, Radioactive Waste Management states that "Generators shall provide an annual forecast in the third quarter of the fiscal year to field organizations managing the off-site disposal facility to which the waste is to be shipped" (2). Additionally, the draft DOE 5820.2B, states that "Because of the long time period involved and the nature of the events and processes affecting disposal facility performance, there will be substantial uncertainties associated with the performance projections. A Performance Assessment Maintenance Program should include a process for reducing uncertainties in predictions about the long-term performance of the facility based on experimental and model improvement efforts. Projections should, at a minimum, provide the following: a listing of the types of waste to be shipped and an estimate of the as-transported volume and weight of each waste type and the activity of major radionuclides by isotope in each waste type" (5).

DISCUSSION

Between 1992 and 1995, LANL generated approximately 2600 cubic meters of LLW per fiscal year. Therefore, the VPP involved the accumulation and evaluation of a large volume of data. Because of the large number of LLW generators and the need to ensure that the amount of data gathered was manageable, it was necessary to limit the data requested to those items that directly impact the facility's disposal capabilities and those needed for DOE reporting activities. These items are identified in the PA, the Baseline Environmental Management Report (BEMR), and in the DOE Integrated Database (IDB).

The PA requires information on the volume of waste disposed of, the radionuclide content, the waste matrix, and the type of container used for disposal. Because of space limitations, treatment options, and off-site disposal options, similar information must also be evaluated to ensure that facility operations are not impacted. The disposal facility must ensure that it has sufficient capacity and that the construction of new disposal cells are budgeted for.

Additionally, the data obtain from this project will reported to the BEMR and the IDB. The BEMR includes "life-cycle cost estimates, tentative schedules, and project activities necessary to complete the Environmental Management Program" (6). The IDB provides "radioactive waste inventories and projections, ...for use in the planning and analysis of waste management functions" (7).

Questionnaire Development

Before the questionnaire was developed, representatives from LANL's waste management facilities, pollution prevention program, and waste management program office met to discuss the data required to meet reporting requirements. The following items were identified as minimum data requirements to be provided on the VPP questionnaire:

1. The fiscal year was chosen as the reporting period, since the amount of waste generated correlates with the funding received for the fiscal year. Data will be collected in the first quarter of each fiscal year for the current year as well as the next four years.
2. The volume is reported in cubic meters. Cubic meters was chosen as the reporting unit because it is the unit requested by the BEMR and the IDB.
3. The matrix categories are summarized in Table I and are similar to those used to report to the IDB and the BEMR The matrices are important to the evolution of the performance assessment, as the waste matrix directly effects the migration of radionuclides into the surrounding environment.

Table I

4. The container type is the container used to dispose of the majority of the waste. The container types of interest are listed in Table II. The container type affects the containment of radionuclides and the efficiency of the disposal unit.
5. A confidence level (i.e., low, medium, or high) was requested to determine variance in the data.

Table II

"High confidence indicates that the volume estimates are expected to be accurate to 25 per cent; Medium 50 percent; Low 100 percent or more" (6).

Using the minimum data requirements, a questionnaire was developed (see Appendix A). The data was requested for each waste stream as identified on LANL Form No. 1346, Waste Profile Form (WPF), which describes the physical, chemical, and radiological characteristics of a waste and the generating process. The questionnaire was reviewed by the disposal facility managers and the LANL waste management program office before the pilot program was implemented.

Target Audience

LANL operates using a facility management model. Therefore, the facility managers were identified as the target audience for the questionnaire because they are responsible for the activities that take place within the facilities. Each LLW-generating facility will be requested to provide volume, matrix, and container type for each normal waste stream referenced by the WPF. LLW generators will be provided with previous

generation rates to assist them in determining future generation rates. Previous generation rates will be obtained from the LANL Chem-LLW Database.

Pilot Program

A pilot program was developed and implemented to evaluate the data gathered and the ease-of-use of the questionnaire. The pilot program was initiated at a major LLW generating facility, the Plutonium Facility. This facility generates approximately 400 cubic meters of LLW per fiscal year, making it the second largest LLW generator at LANL. The two primary waste streams coming from this facility are a compactible waste stream consisting of paper, plastic, and glass and a noncompactible waste stream consisting of building debris, metal, and wood. During the pilot program, representatives of the generating facility were given the opportunity to comment on the questionnaire in addition to providing data for the next fiscal year. A complete questionnaire for Fiscal Year 1996 is located in Appendix B

RESULTS

As a result of the pilot program, no major changes were made to the questionnaire. In the next revision of the questionnaire, dose rate information (i.e., greater than 200 mrem/hr) will be requested. This information will allow the disposal facility to identify waste that requires a more restrictive disposal location.

The questionnaire will be reevaluated annually to incorporate changes in reporting requirements and facility needs. User comments will also be considered during the review of the questionnaire.

CONCLUSION

The VPP was developed to collect LLW volume projection data essential to future planning at the LANL LLW disposal facility. Not only does the current economic environment and diminishing disposal space warrant this type of activity, it is also required by DOE Order 5820.2a (2). The questionnaire has been developed and evaluated; however, because of budget constraints the remainder of this project has not yet been completed. Once funds are available, an Oracle database will be developed to manage the data. This database will allow LANL's waste management organizations to access the information regarding future LLW generation. Upon completion of the database, the questionnaire will be distributed to the five largest waste generating facilities (accounting for 75 percent of the solid LLW disposed of at LANL). The LANL-wide implementation of this program is scheduled for the following fiscal year.

DISTURBANCES OF ENCLOSING AND SURROUNDING MEDIUM WHILE CONSTRUCTING AND OPERATING OF REPOSITORIES FOR RADWASTE MEASURES FOR THEIR MINIMIZATION AND LIQUIDATION

I. Yu. Shischitz
All-Russian Design and Research Institute for Production Engineering "VNIPIPromtechnologii"

ABSTRACT
Construction and operation of underground radwaste repositories are inevitably connected with disturbances of the environment, the geological media, the compact group of rocks surrounding the repository and technical effects of waste placed within them. Acceptability of technical decisions is determined by an evaluation of the disturbances, consequences of the waste impacts on the environment and measures used to minimize or to eliminate these disturbances.
To sufficiently carry out such assessments to satisfy experts and allow the public to determine the acceptability of a repository construction, it is necessary to determine:
- type and scale of environmental disturbances;
- type and scale of technogenous impact on the environment;
- measures to minimize or eliminate the disturbances.

To more fully and qualitatively carry out these assessments, general forms and characteristics of disturbances of the environment were defined in the zone surrounding the repository. These assessments include geomechanical, hydrodynamic and aerodynamic series of disturbances and contaminations.
Taking into account the importance of full disclosure of the impact of the repository on the environment, a complex classification of technogenous impacts has been developed and is being presented for discussion. It includes technological stages of construction and operation of a repository, technogenous impacts and objects of their influence, possible negative results and recommendations for their partial or full elimination. The proposed classification can serve as a methodological basis for preparation and support of technical decisions.
Construction and operation of underground facilities for radwaste disposal is inevitably connected with disturbances of the natural environment and conditions resulting from operation of different production facilities in the region. This is the reason environmental protective authorities of Russia issued regulatory requirements which it is necessary:
- To evaluate the existing condition of the environment, and the techtonic and social media in the area of construction with ecologically dangerous technology and to determine its possible reserve levels;

To define possible disturbances of the formed medium and levels of additional loads from the new production facilities and on the basis of complex long-term predictions for development of ecological situations along with the assessment of acceptability of the proposed decisions;

To predict all possible measures to minimize disturbances of the formed medium, to correct it, or at least to bring new technogenous effects to ecologically acceptable levels.

Environmental assessments are required by State regulation to assess the impact of designed facilities for use with nuclear radiation technologies.

Completion of construction is based on complex investigations concerned with disclosing technogenous effects, scale and possible consequences. The first step, while carrying out such investigations, consists of determining type and source of impact on the environment and the scale and characterization of these impacts.

At the second stage, from the scale of impact, deterioration of the ecological situation is determined.

On the basis of these activities, the technogenous impacts scale is defined and assumptions are made for methods to prevent or reduce the problem.

While constructing and operating an underground repositories for radwaste disposal, the resulting technogenous impact on the environment and the lithosphere must be taken into account.

As to technological processes being the source of geomechanical disturbances, it is necessary to:

arrange sites for drilling and other geological exploratory activities;

construct roads, communications for industrial and social purposes, buildings and constructions:

minimize drift of workings, and drilling debris from boreholes;

engineer development sites;

dig foundation pits for technological purposes and for building and construction foundations;

arrange for sewage settlement ponds;

prevent erosion of upper soil covers during sewage discharge up to the ravine formation.

The sources of hydrodynamic disturbances include activities of land development, mining and objects operation. Reference is made to:

transfer of river-beds;

drainage of surface water reservoirs;

change of level and condition of underground waters while drifting of debris through aquifers or under-working of aquifers;

depletion of aquifers over the area of an underground repository and beyond its boundaries when underground waters come in contact with mine debris with the resultant pumping out into water reservoirs.

To sources connected with radwaste placed in an underground repository, the following must be considered:

heat release connected with radioactive decay;

radioactive radiation;

chemical effect of placed matter;

Sources of aerodynamic disturbances include:

building and high structure change rate, direction and character of air flow movement;

change of relief of an engineered development on site;

ventilation of air from underground facilities;

surface evaporation of settling basins and reservoirs-accumulators.

Biomorphological sources of disturbances include engineering development of an industrial site (removal of fertile soil and its stock, site, clearing of site, removal of vegetation, etc.).

Contamination of lithosphere takes place as a result of radwaste emplacement and migration of solutions containing hazardous elements leached from them.

Sources of hydrosphere contamination refer to:

hazardous matters and radionuclides leached from waste placed in the repository which migrate into the active water exchange;

sewage discharge and water discharge from construction of underground facilities;

Run-off contaminants accumulated on site surfaces by precipitation; fall-out of contaminated precipitation and dust from the atmosphere.

Sources of atmosphere contamination include dusting of ground and rock dumps.

Biological contamination of the environment occurs when wastes from production are transferred to fertile soils and sites for housing construction.

Analysis of contamination sources from construction, operation and conservation of underground repositories is an important step for assessment of impacts of those facilities on the environment. This produces a number of important tasks:

to comprehensively inspect the construction and production facilities in the region of an underground radwaste repository;

to determine possible environmental and technogenous consequences and degree of impact resulting from construction and operation of an underground radwaste repository;

to develop measures for the improvement of ecological condition at the construction site and determine measures for barrier protection while placing waste in the repository.

Classification of impact sources and main forms of their manifestation witnesses that they present a list of indices of such manifestations allow to carry out such assessments.

Because technogenous factors disturb the ecological balance in the construction region of a repository, construction requires a complete evaluation of the impact on the natural environment, determination of possible negative results and methods for overcoming the impact for each stage of construction and operation of the underground facilities. While creating of systems for waste isolation, classification of technogenous processes and disturbances is necessary:

Flaws inherent in the classification system are:

- utilization of known reasons and their characteristics of disturbances as a basis for classification (1,2);
- scantiness of factors and stages of works (3,6).

Disposal of radwaste in geological formations is a new scientific direction in geotechnology. The characteristics of this direction consist of a widescale and complex influence of an underground repository on the area of waste emplacement beyond its boundaries. Therefore, classification must take into account:

scale and character of influences on the environment during every stage of construction and operation of a repository;

the factor that long-term existence of an ecologically dangerous repository becomes an integral interconnected element of the existing environment;

to every technological process on every stage of operation of an underground repository those or other objects of the environment correspond (earth, flora, fauna, hydrosphere, etc.).

Taking these factors into account will yield a representative model for radwaste isolation in the natural environment.

We propose a classification of technogenous impacts and disturbances of the environment which may occur during disposal of underground radwaste. The classification given below takes into account technological stages for construction and operation of repositories, factors of technogenous effects on different objects and foreseen negative results. This classification, with recommendation for minimization or elimination, can be considered guidelines for estimating repository disturbances on the environment.

ABSTRACT

Two precision weighing lysimeters were installed near the Area 5 Radioactive Waste Site (RWMS) on the Nevada Test Site to provide support for investigations of water, solute and heat fluxes in the near-surface of the soil. An outdoor facility is necessary because the moisture and thermal regimes in the upper part of the unsaturated zone in arid regions are strongly influenced by the atmospheric conditions at the soil surface. The lysimeters consist of soil tanks with a volume of 16 m3

mounted on a sensitive scale. The top of the soil tank is flush with the ground surface and access to the side of the soil tank is provided through an underground entry. During installation of the lysimeters, soil was removed in lifts, screened, and set aside for repacking. The soil lifts were repacked in order to simulate the natural stratigraphy. One lysimeter was revegetated with native shrubs whereas the other was kept bare to simulate a non-vegetated waste cover.

Data consisting of physical and hydrological properties of the lysimeter soils, thermal and moisture conditions in the lysimeters, and atmospheric boundary conditions, are being collected for calibrating and verifying computer models for simulating the flow of water and heat in the near surface of alluvium at the Area 5 RWMS. This effort will provide site-specific models for demonstration of "no migration" of constituents to the water table. Physical and hydrologic properties are being determined using standard laboratory methods on repacked soil cores. Moisture and thermal conditions are monitored daily using time domain reflectometry probes at eight depths in the lysimeters and thermocouple psychrometers at ten depths. Daily evapotranspiration is calculated from the lysimeter scales. Meteorological variables are monitored by sensors mounted on a 3-meter tower adjacent to the lysimeters. An array of soil-solution samplers to be installed through the side of the soil tank will allow studies of waste mobility under natural conditions.

Conceptual designs for closure at the RWMS are focused on using an upper layer of repacked native alluvium. However, performance of other components such as a capillary barrier can be tested by installing a scaled version in one of the lysimeter tanks.

INTRODUCTION

Weighing lysimeters are an important tool for characterizing near surface transport processes, including the measurement of evapotranspiration (1,2). Two precision weighing lysimeters were installed near the Area 5 Radioactive Waste Management Site (RWMS) on the Nevada Test Site (NTS) to provide support for investigations of water, solute, and heat fluxes in the near-surface of the soil. Data from the weighing lysimeters, physical and hydrological properties of the lysimeter soils, and atmospheric boundary conditions are being collected for calibrating and verifying computer models for simulating the flow of water and heat in the near surface of alluvium at the Area 5 RWMS. This effort will provide site-specific models for demonstration of "no migration" of constituents to the water table.

The lysimeters consist of soil tanks with a volume of 16m3 mounted on a sensitive scale. The top of the soil tank is flush with the ground surface and access to the side of the soil tank is provided through an underground entry (refer to Fig. 1) . During installation of the lysimeters, soil was removed in lifts, screened, and set aside for repacking. The soil lifts were repacked in order to simulate the natural stratigraphy. One lysimeter was revegetated with native shrubs whereas the other was kept bare to simulate a non-vegetated waste cover.

Fig. 1

SITE DESCRIPTION

The lysimeter facility is located approximately 400 m west of the Area 5 RWMS on the NTS, which is located in the northern Frenchman Flat in southern Nevada. Frenchman Flat is a closed basin. The RWMS is at an elevation of 976 m on a bajada of the Massachusetts Mountains at the intersection of three alluvial fans on a slope of about 1 (3).

The NTS lies in a region that is transitional between the Great Basin Desert and the Mohave Desert. The climate of the area is characterized by a large number of cloudless days, low precipitation, and high daily temperatures, especially in the summer. Annual average precipitation is approximately 125 mm. The majority of rain falls during two peak seasons, with a greater peak in the winter and a lesser one occurring during the summer months.

MATERIALS AND METHODS

Each of the weighing lysimeters were instrumented with eight time domain reflectometry (TDR) probes to measure volumetric soil water content (storage component of the water balance) at depths of 10, 20, 30, 50, 70, 110, 140, and 170 cm; and 10 thermocouple psychrometers (TCP's) to measure soil water potential and soil temperature at depths of 10, 20, 30, 40, 50, 70, 90, 110, 140, and 170 cm. The approximate placement of these sensors within the lysimeters is illustrated in Fig. 2. TDR and TCP data are collected daily.

Core samples were collected from the lysimeters in 10-cm increments from 0 to 2m depths for characterization of physical and hydrologic properties. The physical property analysis included dry bulk density and porosity. The hydrologic property analysis included water retention relations, saturated hydraulic conductivity, and hydraulic conductivity-saturation relations.

The boundary conditions at the ground surface are provided by collecting hourly averages of micrometeorological parameters from a 3-meter micrometeorology instrumentation stand located next to the lysimeter facility. Inputs of water from precipitation are recorded with tipping bucket rain gauges and hourly averages of evaporation and evapotranspiration are obtained from the weighing lysimeters.

Fig. 2

PRELIMINARY RESULTS

Precipitation and evaporation data have been collected for nearly two years, thus providing a clear picture of the water balance of the area for the past two years. Figure 3 illustrates monthly precipitation measured at four stations located at approximately the four corners (NW, NE, SW, and SE) of the RWMS, and monthly evaporation (measured in the bare-soil lysimeter), and evapotranspiration (measured in the vegetated lysimeter) for the period of September 1994 to August 1995.

Winter rain amounts were greater than evaporation (E) and evapotranspiration (ET) during the months of December 1994, and January 1995. Data were not available for the vegetated lysimeter in February 1995. Monthly ET totals were greater than monthly precipitation totals after February 1995, and monthly E totals were greater than monthly precipitation totals after March 1995.

The data period presented resulted in an annual precipitation total of 186 mm, which is approximately 50 percent higher than the annual average amount of 125 mm. The ET total amount was 320 mm, and the E total amount was 158 mm. These results indicate that although annual precipitation was greater than bare-soil evaporation, it was far less than annual evapotranspiration, thus illustrating that plant water use is a significant component of the water balance, and therefore that plants may prove to be an essential component in cover designs.

Fig. 3

The resulting pattern of soil water distribution from this annual cycle of wetting and drying is illustrated in Fig. 4 for the vegetated

lysimeter. The soil water content profile prior to the winter rains was consistently dry. Prior to 1995, TDR probes were not installed in the top 50 cm of the lysimeters. Following the winter rains, elevated soil water content values were found in the top meter of both lysimeters. Redistribution over the next new months resulted in increased soil water contents at depth. Later in the year, after a period of drying, the soil water content profile returned to a consistently dry state, with volumetric water content values at approximately six percent in the bare-soil lysimeter, and three percent in the vegetated lysimeter (Fig. 4). The presence of plant cover enabled considerably more soil drying than occurred with a bare-soil cover.

Fig. 4

DISCUSSION

Preliminary results indicate that actual ET rates exceed precipitation rates for this region, even though precipitation was 150 percent of normal for the test period. Weighing lysimeter data indicate that each annual input of precipitation is entirely removed by annual ET, thus indicating conditions of zero recharge, and indicating ideal conditions for location of a RWMS, and demonstration of "no migration" of constituents to the water table.

Future plans for the lysimeter facility include studies of waste mobility under natural conditions using an array of soil-solution samplers to be installed through the side of the soil tank. In addition, conceptual designs for closure at the RWMS will be tested at the lysimeter facility, because most conceptual designs are focused on using an upper layer of repacked native alluvium, as is found in the lysimeters. Performance of other conceptual designs such as a capillary barrier can also be tested by installing a scaled version in one of the lysimeter tanks.

TRANSPORTABLE VOLUME REDUCTION SYSTEM FOR SQUARE HEPA FILTERS

Paul B. Woollam
Nuclear Electric plc

John Sims
Golder Associates (UK) Ltd

ABSTRACT

There are numerous licensed nuclear sites which have a quantity of square, contaminated filter elements in store, awaiting disposal. The possible methods of treating these filter elements using a form of volume reduction are under review for the following reasons:

The UK Conditions of Acceptance for LLW disposal prohibit this form of waste without some volume reduction. The less radioactive filters can be incinerated in the UK but a proportion of them are too actively contaminated for volume reduction by this route or have been manufactured with metal frames unsuitable for incineration.

The square filters under consideration are of such a size that they are impossible to place within a standard waste drum for high force compaction, without some form of treatment

The purpose of this review was to produce a conceptual design of a Transportable Volume Reduction System (TVRS) to manage this waste stream, specifically for those filters which have metal frames or are too radioactive for incineration

OUTLINE TECHNICAL REQUIREMENTS

The developed system had to be readily transportable so that a number of sites could be visited, with a minimum of set-up or strip-down time. Careful consideration needed to be given to the requirement for and means of, decontamination prior to moving the TVRS on to public roads.

The system had to be designed so that materials other than square HEPA filters could also be volume reduced, so far as that was practical, and the products of the developed treatment had to be collected in a sealable steel drum, suitable for transfer to other on-site facilities, if required. A means of determining the volume of the contents of the collection drum had to be incorporated into the design. Overfilling of the collection drum was not acceptable.

The TVRS was to be provided with a form of containment around the treatment equipment, incorporating a ventilation plant built to the UK standard AECP 1054 - Ventilation for Radioactive Areas. Consideration had to be given to controlling larger pieces of debris which, although they might not become airborne, could escape the containment envelope. Conventional safety issues as well as radiological matters were to be addressed

The final dimensions of the TVRS were to be such that the unit could be driven into an existing building, equipped with the necessary services, i.e., radiological changeroom, electrical and compressed air outlets and a suitable discharge point for an on-board ventilation plant.

Standard, proven equipment was to be used in the design wherever possible to minimize the cost of hardware manufacture and operational maintenance. An estimate of overall costs and construction program was to be provided.

ASSUMPTIONS

The dimensions of the square HEPA filter elements were assumed to have external dimensions of 620 mm x 620 mm x 310 mm thick, with the filter frames being constructed of plywood, glassfibre or aluminum material.

It was also assumed that the waste collection drum into which the filters were to be packed were nominally of 200 liter capacity with dimensions of 572 mm internal diameter, 610 mm external diameter over the rolling hoops with an internal height of 813 mm and an external height of 863 mm. In addition, the drum would be fitted with a sealed lid and closure ring.

A condition set by the authors for acceptance of material for treatment was that it arrived sealed in heavy duty plastic bags with radiologically clean external surfaces and that the activity within the bags was of such a level that it would be eligible for disposal as Low Level Waste.

AVAILABLE PROCESSES

In reviewing the volume reduction of contaminated square filters, the authors investigated, in detail, the following processes:

Compaction ; Creasing ; Shredding ; Cutting ; Dissolution

Although the investigation was extremely thorough, only the main points of the different systems are summarized below.

Compaction was quickly dismissed on the basis that, although all UK reactor sites are equipped with in-drum compactors, as the filters will not enter the drum to permit compaction, the existing compactors cannot be utilized on the filter frames until some pre-treatment has been achieved.

A process of volume reduction, or more realistically, dimensional change to suit the collection drum, can be achieved by creasing the filter side frames to reduce one of the 620 mm dimensions. The amount of creasing, or deformation, required is a function of the diameter of the drum. Figure 1 indicates that one dimension of the filter would need to be reduced to around 437 mm to enable it to fit into the 572 mm diameter drum. The creasing operation shown taking place on two sides of the filter frame would produce a shape which would only permit one deformed unit to be placed in each drum. To improve the packing factor, the authors reviewed the possibility of putting other forms of loose waste with the filter before the final compaction process took place. Creasing was eventually dismissed as a candidate process because of the double handling aspect and the difficulty of handling a filter with a broken frame with airborne particulate being scattered between the creasing process and the collection drum.

Fig. 1

The process of shredding material by means of multiple cutting discs results in a product, the size of which is largely determined by the size of the perforations in the mesh below the cutting discs and the time allocated to the operation. Shredders which employ two rows of cutting discs rotating in opposite directions have a good reliability record when operating in dirty and neglected conditions. Normally they are provided with an ability to reverse the direction of cutter rotation when the system becomes blocked. The cutters will then resume the original direction of rotation. The products of the shredding operation continue to be recycled through the cutting discs until they are sufficiently small to pass through the mesh under the blades. Obviously, the smaller the perforations, the longer the process. The major disadvantage of the shredder system is that it produces large quantities of dust, demanding that the process would require some efficient containment enclosure. It is, however, a single handling operation.

A saw bench style cutting table was also considered, to reduce the frame of the elements into four individual components which could be placed inside the drum. The drum would, under this system, ultimately be filled with a large quantity of frame sides measuring 310 mm wide x 620 mm long. Like the shredder, this system raises a high degree of dust, demanding extensive containment and the depositing of radioactive solid waste, i.e. the filter element material, on the saw bench table. All movement of the waste into the drum would demand manipulation through the containment wall.

Although dissolution was considered as a means of producing a reduction in volume for the filter elements, it is obvious that it means employing large tanks containing acid (for the filter frames) and water (for the filter media) together with the required neutralizing tanks, dewatering equipment, pumps, valves, etc. The possibility of then transferring the solution to a site's Active Effluent Treatment Plant for ultimate

disposal of the liquid arisings is a complication that would best be avoided.

The selected process for the TVRS for the square HEPA filters was shredding for the following reasons:

- The shredding process is a single pass operation, which will result in a volume reduction ratio of at least 3
- It requires no hands-on intervention, indicating a minimum operator radiation dose uptake.
- The shredding mechanism is shrouded and can be extended to provide radiological containment
- The system has already been proven in radioactive environments on solid waste and initial trials indicate it can handle the frame of the square filter
- It is not expensive, or complex to operate
- It is rugged, practical and maintainable
- The shredder is light in weight, compared to the other processes reviewed, and has a small envelope size, important factors when considering a transportable concept.

As a result, the Concept Design discussed below has been based on the shredding process.

CONCEPT DESIGN

The Shredder

The basis of the concept is a standard, commercially available shredder, generally as shown in Figure 2, powered by a 15 kW electric motor, which drives the contra-rotating shredder blades via a robust gearbox. The shredder blades are, in fact, thick, hardened steel discs provided with cut-outs, installed on a shaft. As well as rotating in opposite directions, the shafts also turn at different speeds and are so installed that the two sets of discs intermesh with each other without coming into contact.

Fig. 2

A feature of this design of shredder is that if a blockage of the discs should occur, the motor control system reverses the direction of rotation, serving to clear the blockage. The electric motor will then be put into the normal direction of rotation to continue the shredding process. This forward/reverse motion will continue for up to 10 attempts, when a thermal overload sensor immobilizes the motor to permit it to cool sufficiently, before recommencing the process. Normally, blockages are cleared within the scheduled 10 attempts built into the control system. If however, the blockage is not cleared, it is probably due to the fact that the shredder has not been designed to handle the material loaded into the unit. For example, a 50 mm diameter steel bar would be considered too difficult to be treated by the shredder cutting discs. Equally, a blockage could occur because of a build up of much softer material such, as sheet steel, which when re-distributed by the reversing process, permits the shredder to handle it on a more progressive basis. By varying the cutter blade arrangements and fitting a suitably perforated grill beneath the discs, the particle size produced can be controlled, from fine granules to strips of predetermined length and width. As the waste material will continue to be treated in the shredder until it drops through the chosen grill size, the small particle size will take longer to produce than a more coarse shred.

A number of preliminary trials were conducted on a simulate filter frame constructed to the correct dimensions (620 x 620 x 310 mm) but fabricated

in 1.5 mm thick carbon steel for ease of construction. The trials proved that aluminum, wood and fiberglass frames should be easily processed by the shredder, all being softer material than the simulant frame. Further tests are advocated to confirm the earlier trials, particularly on the aspect of loading configuration of the filters into the throat of the shredder. The trials indicated, for example, that the frames needed loading in a particular manner to ensure complete, successful treatment and the concept design reflects that aspect.

The result of the trials has had a significant effect on the layout of the feed hopper, to ensure that the filters are loaded correctly, but the system can also accept bags of waste when required. The hopper is provided with a recessed hinged door which when within the hopper profile, would be sealed to the hopper wall. This door was needed to restrict the airborne particulate escaping from the hopper during the shredding process, when the ventilation system described later would be providing a scavenging flow across the door catching any loose dust that might escape from the closed door.

The opening of the hopper door will serve to stop the shredder from operating, diverting the ventilation flow downwards through the shredding machine, again restricting the release of particulate via the open hinged door.

Below the shredder is a delivery hopper directing the flow of shredded material into a collection drum which is sealed to the neck of the hopper by a sliding joint arrangement. The hopper is fitted with a gate valve to control the flow of material into the collection drum, aided by the small vibrator unit installed on the hopper, to ensure that the shred material does not remain stationary within the delivery system. The delivery hopper is supplied with a connection to the ventilation plant.

The sliding joint referred to above is required to provide clearance for the collection drum to be positioned below the delivery hopper, and to have a small vertical clearance to enable the operator to remove and replace the drum lid at the appropriate moment in the process. A vertical movement of 40 mm was considered sufficient for this purpose. The Process Flow Diagram of the system is provided in Fig. 3.

Fig. 3

Ventilation System

The ventilation system provided in the concept will meet the requirements of the UK standard, AECP 1054 - Ventilation for Radioactive Areas, with the capability to produce a maximum air speed across any openings in the containment envelope of 1 m/second. The unit in the concept consists of a canister with openings at each end providing access to a pre filter at one end and a HEPA filter at the other, each of which are circular and can be replaced employing the safe change principle. Each of these filter elements is of such a size that it can be placed within the 200 liter drum for subsequent compaction, or passed through the shredder, if preferred.

The fan fitted into the outlet duct from the filter canister is a centrifugal type capable of providing a flow of 600 liters per second. The ductwork associated with the ventilation system was supplied with balance and control/isolating dampers to obtain the optimum flow and pressure conditions.

The connections between the ventilation plant and the shredder system are arranged to provide the following service:

a flow across the recessed hinged cover when the cover is inside and sealed to the feed hopper, ensuring that any particulate which might escape from the shredder containment is swept into the filters in the canister. This flow was to cease when the hopper door is opened.

a second flow pulling air down through the open feed hopper door and the shredder, exhausting via a connection in the delivery hopper below the shredder box. This flow to diminish to a predetermined low flow condition while the feed hopper door is closed and a collection drum is sealed to the delivery hopper. This reduced flow condition would ensure that a minimum of shredded paper particles get pulled into the ventilation filters thus causing early blockage of the pre filter element. The full flow will be restored when the sliding seal on the collection drum is raised for fitting of the drum lid, at which time, the flow will be both downwards through the shredder as well as sideways and upwards past the open top drum.

The exhaust from the fan is fitted with ducting to a location on the installation where it could be easily fitted with a flexible hose, as part of the TVRS supply, the other end of which will be connected to the site ventilation ducting. The shredder ventilation plant is also fitted with a small auxiliary fan and 50 mm diameter hose to facilitate the ability to clean up any active particulate which may have fallen from the delivery hopper, prior to the plant leaving a site. The debris caught by this auxiliary system will be vented into the main filter canister. Figure 3 indicates the System Process Flow Arrangements.

The Trailer

The shredder assembly, that is, the shredding machine, feed hopper and hinged door, delivery hopper, gate valve and sliding joint, is mounted on a support structure built on to the trailer chassis. The trailer, which would be specifically designed and constructed for this purpose, has been provided with a cut-out in the trailer floor to permit the drum to be positioned on the ground, immediately under the delivery hopper. This keeps the overall height of the trailer to a minimum. Naturally, the shredder support structure is designed to provide the necessary clearance over the drum top rim.

The ventilation system is also mounted on the trailer and all equipment is carefully positioned to provide the required towing hitch down load of 100 kg and to observe the maximum wheel loadings. See Fig. 4 for the trailer weight distribution.

Fig. 4

The design of the trailer is based upon employing readily available steel channel or rectangular tube, all plated with a smooth steel sheet for ease of any possible future decontamination procedure. This chassis provides the fixings for the shredder assembly, the ventilation plant, the control unit and the standard double axle rubber - in - torsion suspension units, incorporating overrun operated brakes. The trailer has also been provided with a weather containment skin of glassfibre reinforced plywood (GRP) panels, which provides an easily decontaminable surface, with suitable hinged openings for access to the following

the feed hopper
the ventilation filters
the shredder control system
the collection drum loading/unloading sequence
and for regular maintenance requirements

The Control System

An important aspect of the Outline Technical Requirements for this concept is the need for a control system to limit the quantity of shredded solid material which is placed in the collection drum. As has been stated, overfilling of the drum is unacceptable, demanding a reliable means of determining an early indication of the level of waste in the drum at any time in the filling process, as well as the final chosen level. The authors investigated a number of level sensors and finally chose to specify an ultrasonic type which is capable of providing three distinct signals over the height of the collection drum. These levels will be set to indicate:

approaching required level

at required level- above set level

The electrical control system is arranged to be fully integrated. For example, it will be impossible to initiate the start up of the shredder with the hopper feed door open. It will also be impossible to start the shredding operation if the level sensor indicates there is insufficient room in the collection drum for another shredded filter. A delay is also built into the control system to ensure the feed hopper door cannot be opened until the shredder drive has come to a complete standstill. Equally, the electrical actuators holding the delivery hopper on to the collection drum will not be able to be initiated while the shredder is rotating, even if slowing. The electrical interlocks will also make it impossible to disconnect a drum until the ventilation plant is in the correct mode, that is with an in-flow of air across the top of the drum and upwards into the delivery hopper. All of the control systems terminate at the control unit positioned over the front frame of the trailer and accessible through a hinged hatch. The electrical power supply, which will be provided by the site being visited, via a heavy duty cable connected to the TVRS control box by a suitable industrial plug and socket arrangement. This cable is part of the TVRS equipment.

Overall Dimensions

The overall dimensions of the assembled Transportable Volume Reduction System are provided in Fig. 4. They are such that the TVRS will be capable of entering a building via a 3 m wide x 3 m high doorway. The estimated overall weight of 3100 kg means that, in Europe, the TVRS could be towed by a Land Rover Defender type vehicle as it meets the Road Vehicles Construction and Use Regulations (1986)

DEVELOPMENT REQUIREMENTS

Although the performance capability of the shredding process is well documented, there are a number of areas of development required before the concept could proceed with the utmost confidence. Briefly, these are:

More tests need undertaking on the shredder to determine if it would be sufficient to only produce strips of material, with an obvious advantage of reduced cycle time, or should the shredder be employed for a longer period of time, to produce a finer material, with more dust, but with an improved volume reduction factor.

As the drums of shredded material are likely to be transferred to a site based in-drum compactor for further size reduction, there would seem to be an overwhelming advantage to producing strips rather than fine particulate, although this policy would result in a higher consumption of drums and, therefore, higher cost.

Whichever shredding policy is adopted, the effect of dust arising from the shredder and settling on the window of the ultrasonic level sensor needs further investigation.

although it has been estimated that this concept should easily treat 4 filters per hour, this throughput must be checked when undertaking the above development work.

OPERATIONS AND SAFETY ISSUES

There are a number of important safety aspects which have been addressed in this design concept and in the proposed operational procedures, the principle issues being:

- the shredding process always takes place within a closed environment
- that environment is always subject to a ventilation in-flow of 1 m/sec. when there is any breach in the primary containment
- the shredding process will not be permitted to continue to operate when the feed hopper door is open, avoiding any possible injury to the operator and minimizing the release of radioactive particulate to the atmosphere.
- any loose particulate released from the shredded square filters should be captured on the pre and HEPA filters provided.
- the shredding process is a single operation which will not require any intermediate hands-on procedures, once the process begins
- any large loose debris falling from the shredder will be deposited on the pre/HEPA filter system by the small vacuum cleaner provided.
- the pre and HEPA filters fitted to the on-board ventilation plant are circular and will be bag posted out into 200 liter for compaction or shredding.

The concept has been subject to a preliminary Safety Review, the outcome of which was the following recommendations:

- although it was accepted that the shredder system could be thoroughly cleaned prior to moving off a site it is recommended that a special drum is put in place and sealed to the delivery hopper, to catch any loose debris that might be shaken loose from within the shredder body during the road journey.
- as a second means of preventing active material falling from the shredder, it is recommended that the final shredding operation prior to final shut down be undertaken with a small bag of clean combustible waste. The resultant very low level waste could then be treated in the site's incinerator.
- The contaminated circular filters from the on-board ventilation system should be bagged out and replaced with clean units prior to travelling on public roads. The spent filters should be either sent to the site's compaction plant for volume reduction or stored awaiting the next TVRS visit.

COSTS AND PROGRAM

The budgetary costs of construction of this Transportable Volume Reduction System for Square HEPA Filters was estimated at 120,000 ($185,000) at 1994 prices.

The construction program is dominated by the lead time required by the ventilation plant suppliers, that is 10 weeks. With careful planning and project management, the overall construction program should consume a period of 15 weeks.

CONCLUSION

All of the processes involved in the concept layout are readily available and well proven. They demand little development work to make them suitable for this application. The safety aspects of the concept appear to be acceptable for the levels of radioactivity involved.

The next phase of this project is to investigate the potential savings in disposal costs due to the volume reduction obtained and compare them with the overall finance required to implement this concept. A decision to proceed to construct this Transportable Volume Reduction System will depend on the outcome of that investigation.

ABSTRACT
CsTreat is a granular hexacyanoferrate-based ion exchange media suitable for use in fixed bed columns for the removal of radioactive cesium ions from nuclear waste solutions. IVO CsTreat System was put into use at IVO's Loviisa NPP (VVER-440), Finland, in 1991 for the removal of 134,137Cs from high-salt evaporator concentrates and a total of 700 m3 (185,000 gallons) has been purified using only 80 liters (2.8 cu.ft) of CsTreat media. This corresponds to an average treating capacity of 8,750 L of waste solution by 1 L of CsTreat media (66 000 gal/cu.ft) in this high-salt waste stream. Two other commercial applications have been sold. CsTreat has also been used in Paldiski, Estonia, to purify low-salt waste solutions resulting from the operation of training reactors by the ex-Soviet Navy. In this purification campaign, a total of 760 m3(200,000 gallons) of waste solution originating from different waste tanks was purified with 12 liters (0.42 cu.ft) of Cstreat media. This corresponds to treating capacity of 63,300 L/L (474,000 gal/cu.ft) of CsTreat media. Since no indication of the exhaustion of the CsTreat media was observed during the purification campaign, the actual treating capacity for this solution is even higher.
So far, full-scale operating experience has been gained in the treatment of both high-salt evaporator concentrates and low-salt solutions arising from the operation of nuclear reactors. These solutions were low-active, the activity concentration of 134,137Cs ranging from 1.5 kBq/L to 200 kBq/L (410-5 - 5.510-3 mCi/ml). Laboratory testing of the material has been carried out for other types of simulated solutions: alkaline high salt effluents from reprocessing plants, medium-salt waste from reprocessing plants and low-salt NPP effluents. Results obtained confirm the high efficiency of CsTreat also in these waste streams. Tentative

process flowsheets have been outlined for these applications. In order to support new applications, thermodynamic modelling studies are underway to predict the capacity of CsTreat in feeds containing most common interfering macro-ions (Na, K, Ca, Mg).

A comparison of the performance of CsTreat media with those of other Cs-selective ion exchange medias (zeolites, silicotitanates, Cs-selective resins), as published in open literature, shows that CsTreat has superior efficiency.

INTRODUCTION

Insoluble transition metal hexacyanoferrates are highly selective ion exchangers for cesium. These have been used as precipitants for the removal of radiocesium from nuclear waste effluents at reprocessing plants and research centers (1). In these processes, pre-formed hexacyanoferrate slurry, or pre-cursor reagents of an insoluble hexacyanoferrate, have been added to the waste solution. Using hexacyanoferrate in packed-bed columns is much more efficient, but difficulties have arisen in manufacturing hexacyanoferrates in granular forms suitable for this type of operation.

The purpose of our research and development is to produce highly selective ion exchange materials for the separation of radioactive elements from nuclear waste solutions in order to obtain high reductions in final waste volumes and in radioactive discharges into the environment. This report describes experiences with both the laboratory testing and the actual industrial use of CsTreat, and also presents the modeling of cesium ion exchange for predicting the performance of CsTreat in actual processes.

EXPERIENCE OF INDUSTRIAL-SCALE USE OF CsTreat

CsTreat is a granular hexacyanoferrate-based ion exchange media suitable for column operations. The first system utilizing this media was put into use at the Loviisa NPP, Finland, for the removal of radiocesium from high-salt evaporator concentrates (2,3). These solutions contain high concentrations of $NaNO_3$ (2-3 mol/L), KNO_3 (0.1-0.2 mol/L) and $Na_2B_4O_7$ (0.5-0.8 mol/L). $^{134,137}Cs$ are the dominating waste nuclides in the waste solution, typically containing more than 90% of the total activity in solutions stored for a few years. The activity concentration of $^{134,137}Cs$ has typically been in the range of 40-200 kBq/L (1-510-3 mCi/mL). Since 1991, 700 m^3 (185,000 gal) of evaporator concentrate has been purified using 80 L (2.8 cu.ft) of CsTreat media. In normal operation, the breakthrough capacities (1% breakthrough) have been in the range of 50-180 m^3 per one 8 L (0.28 cu.ft) column (47,000-170,000 gal/cu.ft). Decontamination factors (DF) obtained for $^{134,137}Cs$ at Loviisa have ranged from 1000 to 2000.

In Paldiski, Estonia, CsTreat has been used to purify low-salt waste waters originating from the operation of nuclear training reactors by ex-Soviet Navy. In 1995, a total of 760 m^3 (200,000 gal) of these solutions, stored in four different tanks, were purified with a single 12 L (0.42 cu.ft) column (7.5 kg of CsTreat media), and no indication of the exhaustion of the column was observed when the purification campaign was completed. The activity concentration of $^{134,137}Cs$ in these waste waters was initially in the range of 1.5 -80 kBq/L (410-5 - 2.210-3 mCi/ml) and 0.001-0.01 kBq/L (2.710-8 - 2.710-7 mCi/mL) after purification.

TESTING OF CsTREAT IN SIMULATED WASTE SOLUTIONS

Experience obtained in these large-scale operations indicates that CsTreat has potential for the treatment of a wide range of nuclear waste

solutions. Laboratory-scale testing has been carried out batch- and columnwise in various types of simulated solutions. Some results obtained in column experiments are described below.

High salt reprocessing waste

Composition: 250 g/L $NaNO_3$, pH = 10, 0.5 ppm Cs + 134Cs tracer

Results: See Fig. 1:
DF=15,000 - 30,000 (detection limit)
Breakthrough capacity: No breakthrough detected at 4,000 bed volumes when experiment stopped

Medium salt decontamination waste

Composition: Na 5 g/L, NH_3 0.05 g/L, Na-oxalate 0.05 g/L, Nitrilodiacetic acid 0.05 g/L, Na-polyphosphate 0.05 g/L, pH = 10, 134Cs tracer

Results: See Fig. 1:
DF = 1,000-3,000
Breakthrough capacity: No breakthrough detected at 4,200 bed volumes when experiment stopped

Medium salt regeneration solution

Composition: Na 6.7 g/L, K 3.3 g/L, pH 6, 134Cs tracer

Results: See Fig. 2:
DF = 6,000 - 7,000 (detection limit)
Breakthrough capacity: No breakthrough detected at 2,000 bed volumes when experiment stopped

For zeolite Zeolon 900 (mordenite) as comparison:
DF < 50
Breakthrough capacity: instant breakthrough, column exhausted at 500 bed volumes

Low-salt NPP waste water

Composition: Na 320 ppm, Ca 17 ppm, pH = 6, 134Cs tracer

Results: See Fig. 3:
DF = 2,000-20,000, average 5,000 (high bed)
2,000-15,000, average 2,500 (low bed)
Breakthrough capacity: No breakthrough detected at 30,000 bed volumes (low bed), experiment continues

In all the above tests, CsTreat showed very efficient performance. For practical reasons, most of the experiments were discontinued after a flow of 400-4,000 bed volumes of solutions. Rather high activity concentrations of 134Cs (0.01 mCi/mL) had to be used in the solutions to measure accurately the high decontamination levels. In order to avoid high build-ups of activity in the columns experiments were discontinued even though no breakthrough of 134Cs from the columns was observed.

Fig. 1

Fig. 2

Fig. 3

COMPARISON OF CsTreat WITH OTHER CESIUM-SELECTIVE MEDIA

Comparison with other commercially available ion exchanger materials (Table I) indicates that CsTreat is a superior exchanger for cesium. Distribution coefficient (for definition, see later), which is directly proportional to the column performance, is at least two orders of magnitude higher for CsTreat than for mordenite zeolite and the organic resin. Zeolites, which are used in many nuclear applications, are usually synthetic mordenite, chabazite or natural clinoptilolite. Chabazite and clinoptilolite have ion exchange properties comparable to those of

mordenite. As it can be seen from Table I, none of these materials is very effective for the removal of cesium from concentrated salt solutions. Also in more diluted solutions CsTreat works much more efficiently. For example, in a clinoptilolite column 1% breakthrough occurred even below 10,000 bed volumes when fuel pond water having 0.004 mol/L sodium ions was treated (4). In the purification of a comparable solution at the Paldiskij Base with CsTreat, no breakthrough was observed at all after the termination of the purification at 63,300 bed volumes.

Table I

A new sodium titanate impregnated zeolite (IONSIV IE-96) product has also been recently reported for the purification of high-active concentrated waste solutions (5). From a 2.1 M Na+ solution the 1% cesium breakthrough occurred at about 120 bed volumes. This is close to what one could expect for conventional zeolite based on the Kd-value presented in Table I (see also Eqs 1-3 later). Estimated from the Kd-value, the capacity of CsTreat would be about 1,000 times as high in this solution.

A new organic resorcinol formaldehyde resin has been developed at the Savannah River Laboratory (6) and is also available commercially. This exchanger is much more selective for cesium than other organic resins and exhibits a cesium removal efficiency comparable to that of zeolites. For example, the 1% breakthrough of cesium from a resorcinol formaldehyde resin column occurred at about 100 bed volumes in a high active waste simulant having 5.6 mol/L of sodium ions.

Durasil 230 is an inorganic oxide-based cation exchanger used at nuclear power plants for cesium removal from diluted waste solutions. It has a high throughput capacity (100,000 gal/cu.ft) but the decontamination factor is modest (250) compared with 1,000-10,000 obtainable with CsTreat (7).

IONSIV IE-911 is a crystalline silicotitanate product, which has a better ion exchange performance for cesium compared with plain titanates. 50% breakthrough values from two waste simulants, Hanford DSSF-5 and ORNL W-27, were 540 and 500 bed volumes (8), which are rather modest compared with those typical of CsTreat.

MODELLING OF ION EXCHANGE EQUILIBRIA

Fundamental studies of ion exchange equilibria of radioactive cesium and macro-ions commonly present in solutions (Na,K,Ca,Mg) is underway with a view to modeling the equilibria and to predicting the capacity of the CsTreat exchanger in different waste effluents. Here the results obtained in the three-component system (Cs/Na/K) are described, and corresponding selectivity data are used to predict the capacity of CsTreat in "model" solutions.

General Theory

What is of interest in the purification of nuclear waste effluents is the capacity of the ion exchanger in terms of solution volume (V liters) that can be treated with a given amount (m kg) of ion exchanger. This capacity is unambiguously given by distribution coefficient KD of the radionuclide. Distribution coefficient KD is defined as the equilibrium ratio:

Eq. 1

where [M]r and [M] are the equilibrium concentrations of ion M in the ion exchanger (mol/kg) and in the solution (mol/L), respectively. For column operation, KD gives the total column capacity in terms of L/kg (volumetric capacity). The distribution coefficient is determined by two factors: selectivity and ion exchange capacity. Taking the Cs/Na exchange

as an example, the equilibrium is determined by selectivity coefficient kCs/Na of the exchange reaction, i.e.

Eq. 2

where subscript r refers to the ions in the exchanger phase. Inserting [Na]r = Q - [Cs]r (Q = ion exchange capacity) into Eq.2 and solving for the KD of Cs gives

Eq. 3

It can be seen that when [Na]/kCs/Na >> [Cs], the volumetric capacity of the ion exchanger (in L/kg) is independent of the Cs concentration in the solution. This condition is fulfilled when radioactive Cs ions are present in the solution containing a large excess of Na. For instance, the chemical concentration of Cs in solution corresponding to the activity concentration of 1 mCi/L is 8 x 10-11 mol/L. Selectivity coefficients kCs/Na are typically on the order of 10 in common organic resins and on the order of 10-100 in zeolites. Thus, unless the Na concentration in solution is very low ([Na] << 10-8 mol/L), the KD (and volumetric capacity) of the exchanger is independent of the concentration of Cs in the solution and the familiar relationship is obtained for the KD, in the logarithmic from

In other words, the KD of the trace ion is inversely proportional to the concentration of the macro-ion in the solution. Selectivity coefficient can be assumed constant in this case as the loading of Cs in the exchanger is very low.

Selectivity of CsTreat for Cesium

Distribution coefficient KD of trace Cs in CsTreat has been determined in NaNO3 and KNO3 solutions of different concentrations for the Na- and K-forms of the exchanger, respectively. Binary selectivity coefficients for the Cs/Na and Cs/K exchanges have been determined from these measurements. The following values have been obtained:

kCs/Na = 1.56106

kCs/K = 4.8104

Selectivity coefficients usually decrease as a function of ion loading in the exchanger. Experiments carried out with higher concentrations of inactive Cs show that the selectivity coefficients remain in these high values at least up to the Cs loadings of 0.2 mmol/g. The capacity of the Na-form exchanger for Cs is 0.3 mmol/g and that of the K-form exchanger is 0.5 mmol/g. Experiments carried out in the ternary system (134Cs/Na/K) show that in the mixtures of NaNO3 and KNO3 solutions at a given constant total concentration, logKD is a linear function of the amount of exchangeable K (or Na) in the exchanger (Fig. 4). This makes it possible to estimate the KD in mixtures of Na- and K-salt solutions, when the corresponding Na and K contents of the exchanger are known, eg. from the binary Na/K exchange data.

Fig. 4

Table II shows some KD-values and volumetric capacities of CsTreat, predicted from the equilibrium data above for different model solutions and for two batches of evaporator concentrates processed at Loviisa NPP. The predicted volumetric capacities obtainable with CsTreat are very high. These values (Table II) represent total exhaustion capacities of CsTreat columns (which corresponds to the solution volume at 50% breakthrough for a symmetrical breakthrough curve). Actual breakthrough capacities are somewhat lower, depending on the kinetics of the exchange reaction and on operating conditions (solution flow rate, exchanger grain size, column depth, temperature etc.).

Table II

At Loviisa NPP, batch KD-values of 137Cs have been determined for the evaporator concentrates in each tank prior to purification campaigns to get an estimate of the column capacity. Data show (Table III) that breakthrough capacities (1% breakthrough) are about 40% of the total capacities estimated from the measured KD-value (Q(BT)/KD (obs) = 0.37-0.38) at relatively slow flow rates of 10 BV/h. In dilute salt solutions, where the exchange rate is faster, it may be possible to obtain breakthrough capacities that are about 50% of the total capacities. Table III also shows some KD-values for the evaporator concentrates, predicted from the ternary Na/K/134Cs exchange data. The model calculations yield somewhat lower values than what are measured for the evaporator concentrates. The model is being further developed., e.g. considering the ion activities in solution, instead of concentrations, since it is clear that solution phase activity correction cannot be ignored in such concentrated solutions. The aim is to develop a model that could be used to predict accurately the capacity of CsTreat in waste streams of differing chemical compositions. Other ions, e.g. H, Ca and Mg, will be added to the model at a later stage.

Table III

FLOWSHEETS FOR SPECIFIC APPLICATIONS

CsTreat can be utilized in many different systems and applications. Some possible flowsheets for applications are described in Fig. 5.

The most straightforward application is a tailored system to purify liquid from an existing waste tank (Fig. 5a). If the waste liquid is highly acidic (pH < 1) or alkaline (pH > 13), pH control as a first step may be advantageous to improve performance. As normal, particles are filtered up-stream to avoid the fouling of the CsTreat bed.

CsTreat media can also be utilized in a loop configuration, e.g. to purify fuel pond waters (Fig. 5b). High ion exchange capacity minimizes waste amounts. In addition to particle filtration and ion exchange by CsTreat, some additional treatments may be required before water is recirculated to the pool.

A typical demineralizer system at a nuclear power plant (Fig 5c) may include coarse filtration, carbon filtration (removal of organics and oils), anion, cation and/or mixed bed with organic resins and a cesium specific ion exchange bed. In this application, CsTreat can be used to replace conventional cesium-specific materials like zeolites. Use of CsTreat, which has extremely high selectivity for Cs, results in a remarkable decrease in waste amounts. In many cases, no additional construction is needed, since existing systems can be fully utilized.

For the purification of high- and medium-active liquids, a system can be constructed in a hot cell (Fig 5d). High levels of activity can be loaded into the inorganic CsTreat material. Removal of other radionuclides, like 90Sr, can be connected to the same system. Typically, such treatment would result in reclassification of a large volume of liquid waste as low-active waste. Only a very small amount of ion exchange media remains as high-active waste. This gives high cost savings in further treatments and especially in the final disposal

ABSTRACT

Melting process has been discussed to be applied to the treatment process in Low Level Radioactive Solid Waste (LLSW) in its advantage of volume reduction and stability of processed solid form. Hybrid type Melting Process (HMP), which combines induction heating with plasma torch has been developed and investigated in this study. Non-radioactive simulated waste is fed to the melting furnace to investigate the characteristic of solidified products and off-gas. It is demonstrated that HMP can melt or decompose any waste, even concrete or PVC. Plasma arc gives high temperature and agitation to assist melting and increases NOX content in off-gas.

INTRODUCTION

In Japan, final disposal of Low Level Radioactive Uniform Waste (LLUW) which is cement solidified liquid waste has already been started, and as the second stage, Low Level Radioactive miscellaneous Solid Waste (LLSW) disposal facility is being designed. In this situation, the melting

process is one of the most promising processes for the treatment of such solid waste in its advantage of volume reduction and chemical/physical stability of processed solid form.

Since the radioactive solid waste consists of various materials, a melting technique to be adopted for the waste treatment needs to have flexibility in accepting various constituents of waste from different sources. To realize the flexibility of the melter, the Hybrid type Melting Process (HMP), which combines induction heating with plasma torch, has been developed and investigated in this study. Its main advantages are:

1. applicability to various waste materials
2. high uniformity and high stability of processed solid form
3. high volume reduction ratio
4. separation of harmful nuclides for disposal
5. simplicity of pretreatment
6. high processing efficiency
7. ability to take representative samples for the measurement of radioactivity from the melted waste

LLSW contains various waste materials, such as steel, aluminum, copper, ash, concrete, PE (PolyEthylene), PVC (PolyVinyl Chloride), glass, clothing, paper and so on. The radioactive levels vary among waste container and within each container. Such differences would make the heavy burden for the final repository, and give very high cost for disposal. It is not rational for the design of final repository and it is better that the waste is uniform. Moreover high volume reduction gives the elongation of life of the disposal site, and decreases the cost of disposals. Non-radioactive simulated waste is fed to the hybrid type melting furnace to investigate the characteristics of solidified products and off-gas. Some test results are summarized in the following sections.

TEST PROCEDURE

The test facility investigated in this study is shown in Fig. 1. It has a induction heating furnace with plasma torch. The furnace has 7-litter volume, and the induction heating capacity is 100kW - 2500Hz, the plasma torch capacity is 30kW respectively. The waste element of concrete, ash, heat insulator, PVC, PE are selected to represent the typical waste contents in nuclear facilities for the tests. Each waste element of non-radioactive simulated waste is initially prepared in a 2.4-litter steel container separately. Then the steel container is directly charged into the furnace and melted separately. After that the mixture of the waste elements are put into the same steel container and melted at one time.

Fig. 1

The weight of solidified products and slag composition are investigated after melting. The temperature of some important points and the off-gas composition are monitored during the operation. The situation during the melting operation and after melting operation is observed.

TEST RESULTS

The test conditions and main test results are summarized in Table I.

Table I

1. All of the inorganic compounds except concrete can be melted easily. The coarse aggregates in concrete are very difficult to melt only by induction heating, and those can be melted by using plasma torch concurrently as a result of heating and agitation of plasma arc.

Organic compounds like PE and PVC are easily decomposed by heat from melted waste, and caused much black smoke. It indicates that organic compounds burn imperfectly.
2. Volume reduction ratio for inorganic materials is observed to be 1/6-1/10. Organic materials are almost burned out and only little residue is observed.
3. The basicity (CaO/SiO_2) of the generated slag from inorganic compounds is analyzed to be low (0.2 to 0.8).
4. Typical results of Off-Gas measurement is shown in Fig. 2.
The evolution of NOX gas is observed when plasma torch is used. Plasma arc causes NOX content increasing in off-gas.
Fig. 2

DISCUSSION

Melting of Concrete

Concrete is not uniform compound but mixture of cement and aggregate that consists of sand and gravel. The melting point of cement and mortar is low, that is about 1400 and 1450 respectively and also cement and sand are very fine particles. Because of that cement and mortar are melted easily. But the melting point of gravel is more than 1700 and the reaction surface area of coarse aggregates is small comparatively. Therefore, usual method can not melt coarse aggregates. According to the phase diagram (1), which is shown in Fig. 3, if agitation of molten phase is enough, the same content of concrete requires a temperature of more than 1600 for melting. The usual melting process can heat up to very high temperature at the center of the liquid, but at the surface the temperature is far lower than the center. It is the reason why such process cannot melt concrete. HMP gives high temperature surface and strong agitation to the liquid, and in this condition concrete can be easily melted. The coarse aggregates in concrete can be melted by using the plasma torch concurrently as a result of heating and agitation of plasma arc.
Fig. 3

DECOMPOSITION OF PVC

PVC is very difficult to be burnt because of its chlorine, but PVC can be decomposed at more than 200, and carbon particle and hydrochloride appear in off-gas, then a part of carbon particle is oxidized by air into carbon monoxide (CO). Carbon monoxide in off-gas is measured and the result is shown in Fig. 4. From this result, peak decomposition rate is observed, and it is about twice of the average rate. The temperature in off-gas system was also measured. The temperature did not increase by decomposition and burning. This proves difficulty of burning of PVC.
Fig. 4

NOX by Plasma

NOX was also measured during the melting operation, and the typical result is shown in Fig. 5. Maximum concentration of NOX is about 40 ppm at the condition of 20.8% O_2. This oxygen content is quite higher than usual incineration. Plasma heating does not make wastes burn, just only decomposed, then oxygen will not decrease by plasma. In this reason, NOX content should be appreciated.
Fig. 5

CONCLUSION

The following conclusions are provided through this investigation.
1. HMP is the superior method to melt LLSW.
2. HMP gives very high volume reduction rate for LLSW.

3. HMP can melt or decompose any LLSW, even concrete or PVC.
4. Plasma arc increases NOX concentration in off-gas.
5. The slag generated by melting of LLSW is 0.2 to 0.8 in basicity.
6. The slag is produced as a stable glass form.

Hybrid Melting Process will be the best way for processing the low level radioactive miscellaneous waste. Further investigation will be conducted to apply this technology to other types of waste treatment.

BITUMEN IMMOBILIZATION OF AQUEOUS RADWASTE BY THIN-FILM EVAPORATION

S.K. Sen Gupta
L.P. Buckley
Waste Processing Technology
Chalk River Laboratories
Chalk River, Ontario K0J 1J0

ABSTRACT

In the early 1980's, AECL, at the Chalk River Laboratory (CRL) site, built a Waste Treatment Centre (WTC) for managing low level solid and aqueous liquid wastes. The objective was to demonstrate processes for converting Canadian Deuterium Uranium (CANDU) wastes to a form suitable for disposal while meeting or exceeding current environmental regulations.

At present, two liquid waste streams are being treated at the Waste Treatment Centre. The liquid waste streams are volume reduced by a combination of continuous crossflow microfiltration (MF), spiral wound reverse osmosis (SWRO), and tubular reverse osmosis (TRO) membrane technologies (6). The concentrate produced from the TRO system and the volume-reduced MF backwash solutions are evaporated while simultaneously adding bitumen in a thin-film evaporator. A water-free product of chemical and radiochemical salts and bitumen is removed in 200 L galvanized steel drums for storage and eventual disposal in the CRL Waste Management Area.

The feed stream to the thin-film evaporator typically has a b/g activity of about 1 - 3 mCi/mL. This radioactivity would be concentrated by a factor of about 10, while simultaneously being immobilized. The radiation field of product drums on contact typically has a value of 0.5 to 3 R/h depending upon the feed concentration of radioactivity to the evaporator. The total solids content in the 200 L drum ranges from 25% to 35%. Encapsulated in the bitumen matrix are a variety of non-radiochemical salts which comprise the bulk of the total solids which are in the product drum. The drum contains less than 1% of free water, and the product passes the USNRC guidelines for a solidified wasteform.

The paper will discuss the volume reduction capability of the plant, with an emphasis on the immobilization of the aqueous waste with bitumen in a thin-film evaporator. Operations experience gained from over 200 campaigns are documented.

Samples of bituminized wasteforms from the Waste Treatment Centre have been leached in accordance with the ANS/ANSI 16.1 leach test. In this test, the wasteform is immersed under water for an extended period of time and the leachate is periodically removed and chemically analyzed.

The leachability index varied between 7 and 9 for the emulsified bitumen wasteforms produced at the Waste Treatment Centre, but could be improved significantly with the addition of protective overcoats of either Portland cement or oxidized bitumen.

INTRODUCTION

In 1975, the need for a Waste Treatment Centre (WTC) at Chalk River Laboratories (CRL) was identified. The WTC was built to demonstrate systems capable of converting liquid wastes to a stable and leach-resistant form. Current operations in the facility involve the treatment of the low-level CRL liquid waste using a 3-stage membrane plant to accomplish most of the volume reduction (comprised of microfiltration, spiral wound reverse osmosis, and tubular reverse osmosis unit operations). Further volume reduction is achieved with a thin-film evaporator (without bitumen addition), and another thin-film evaporator whose primary function is for bitumen immobilization.

Fig. 1

Figure 1 shows a flowsheet and volumetric balance for the primary unit operations at the WTC. For a basis of 100 units of liquid waste (or 100# in the figure), the quantities of liquid at various points in the plant are indicated. A total volume of 93.5# is released by the 2-stage reverse osmosis plant (per 100# treated), while a combined 99.9# is released from both the reverse osmosis and thin-film evaporator operations. A total volume of 0.4# (including emulsified bitumen volume) is the secondary waste product from the thin-film evaporator used for bituminizing (TFE-1). This results in an overall volume reduction factor of 250 for the plant, based on feed liquid volume to immobilized secondary waste volume, in the product drum (that is, 100 0.4).

The TFE-1 unit is used to immobilize liquid waste concentrates with bitumen. The other (TFE-2) is used to volume reduce microfiltration backwash concentrates and tubular reverse osmosis retentate prior to immobilization. The bituminized product from TFE-1 is collected in 55 US gallon (210L) galvanized steel drums. A full drum weighs approximately 240 kg. The drums are capped, transferred to a shielded container and then shipped to the site waste management area for storage and eventual disposal. The evaporation/immobilization process is carried out remotely in a shielded facility that is designed to handle product drums with contact gamma radiation fields as high as 10R/h. In practice, however, the radiation fields are maintained below 5 R/h.

At present, two radioactive CRL liquid waste streams are being processed by the thin-film evaporator used for bitumen immobilization (TFE-1). One stream originates from the central Decontamination Centre (DC). The other, an Active Drain (AD) stream, is produced from a large and diverse number of research laboratories and radioisotope production facilities. The two waste streams, totaling about 3000 m3 per year are volume reduced by a factor of 80 prior to immobilization by three membrane systems and thin-film evaporation. The performance of the thin-film evaporation process used for bitumen immobilization, and the characteristics of the wasteform after standard leach tests (using the ANS/ANSI 16.1 protocol), represent the focus of this paper.

Not much data is presently available on the performance characteristics of the current wasteform being produced at the WTC. The early work on leaching was on phosphate-based wastes encapsulated in oxidized bitumen. The reason for this is that experiments carried out about a decade ago on waste product simulants indicated that there was little difference

between the leaching properties of distilled (soft), versus oxidized (hard) bitumen. There are currently about 200 product drums of secondary immobilized secondary waste which have their own blend of contaminants and solids, and the performance of this product is currently being evaluated.

The leaching work reported here is the first step in the evaluation of the waste product currently being produced at the WTC. The ANS/ANSI 16.1 leach test (1) is an aggressive procedure that reflects unrealistically poor conditions for disposal in the unsaturated zone. For the tests carried out here, bitumen samples were unconfined and subjected to immersion and frequent leachate replenishment. The results of these leach tests will be a lower bound for the performance of the bitumen waste product in an unsaturated environment. Further work under more realistic conditions will provide a better estimate for the performance of the bitumen waste product in an unsaturated environment.

TECHNOLOGY DESCRIPTION

Membrane Plant

A flowsheet of the integrated plant for volume reduction and immobilization of aqueous radwaste is shown in Fig. 1. Liquid waste feed to the WTC is sampled and analyzed for pH, conductivity, a and gross b/g activity, tritium (3H), turbidity, total solids, gamma-emitting radionuclides, and various non-radioactive chemical species at the source tanks. Waste is then sent to a 45 m3 feed tank in the WTC and it is pH adjusted to the alkaline region (8 - 10); an adequate conditioning time of 12 hours is allowed to maximize precipitation of metals, prior to treatment with MF for the removal of suspended solids.

During microfiltration (MF), concentrate is recycled; filtrate is continually removed from each bank of filtration modules at about 25 L/min, and is directed to the spiral wound reverse osmosis (SWRO) feed tanks. When the backwash (concentrate) solution exceeds 10 g/L, it is sent to the volume reduction evaporator, TFE-2. The MF filtrate, free of suspended solids, enters the SWRO feed tank at a rate equal to the permeation rate of the SWRO. The concentrate from the SWRO membrane process is bled to the TRO feed tanks.

The TRO membrane system operates in a batch process mode, where the final tank volume is reduced to approximately 10 to 15% of the initial feed volume. The concentrate, containing about 50 to 80 g/L of dissolved solids, is transferred to one of three 7100 L tanks in the active tank room, to await further volume reduction by evaporation with TFE-2.

Liquid Waste Immobilization Process Description

The evaporator has a 10.8 ft2 (1 m2) heated surface, with superheated steam at about 100 psig (720 kPa) applied to the jacket. Waste feed containing between 5-15% total solids is introduced at a rate of about 2 ft3/h (1 L/min), along with bitumen emulsion flowing at about 0.6-1 ft3/h (0.3-0.5 L/min). The emulsified bitumen and the waste are introduced via a distribution ring to the top of the evaporator and fall along the heated surface. The evaporator has internal rotating blades, which sweep within 1 mm of the vertical heated surface. The blades in TFE-1 rotate at 900 rpm.

The evaporator does not operate full of product; the liquid or slurry forms a thin film or annular ring of product from the feed nozzle to the product outlet nozzle. Holdup or liquid inventory in a thin-film evaporator is very low, typically about 5 kg of material per square meter (0.5 pound per square foot) (3). A thin-film evaporator, which is an

inherently low-pressure-drop device, has mechanical turbulence and, therefore, good heat transfer properties over a wide range of viscosities.

DESCRIPTION OF BITUMEN USED FOR IMMOBILIZATION

Bitumen Feed

Bitumen is the name given to a wide range of hydrocarbons with high molecular weight that are commercially available as a residue of petroleum or coal-tar refining. Its two major components are asphaltene compounds, which give bitumen colloidal properties, and malthene compounds, which impart viscous liquid properties. Most bitumen is obtained during the distillation of crude oil and is called "direct distilled" bitumen. This bitumen has a high viscosity and must be heated to make it suitable for mixing. The bitumen used in the evaporator has been emulsified in water (contains 45% H_2O) and can be added directly to the evaporator without being heated. Table I shows the properties of typical bitumen used in the Liquid Waste Immobilization System.

Table I

Rationale for Selection of Bitumen Matrix

Solidification of wastes in bitumen has been tested extensively in Europe, and has been applied more recently at Virginia Power in the United States (5) . Experience has demonstrated that bitumen is also suited to most streams generated by nuclear power plants and by industry (4). The stability of bitumen with respect to radiation is a property of primary importance when bitumen is considered as a waste matrix material. The main factors influencing the radiation stability of bitumen are the dose-rate and the total absorbed dose. A total absorbed dose limit of 108 to 109 rad is commonly reported for the radiation resistance of bitumen-waste forms (4).

Bitumen generally provides superior leach resistance in comparison with cement, which could be important for certain species and disposal scenarios. One of the potentially more significant advantages provided by bituminization processes is volumetric efficiency, which is particularly important if waste must be stored for extended periods before disposal. Cement solidification can result in as much as a 100% increase in volume, whereas, depending on waste stream concentrations and the type of equipment used, bituminization can provide volume reduction factors of 5 or more, because associated water is driven off during the solidification process.

OPERATIONS PERFORMANCE OF TFE-1

Effect of Rotor Change

Data have been collected from TFE-1 after a new rotor was installed and operated at higher speeds. Table II summarizes the performance of TFE-1 before and after the rotor change. The new rotor operates at a speed of 900 rpm, compared to 600 rpm prior to its installation. A total volume of 26.9 m^3 was immobilized with TFE-1 in 1994 with a volume reduction factor (VRF) of 2.92. A volume reduction factor (VRF) is defined by Eq. (1).

Eq. 1

Prior to the installation of the new rotor a total volume of 13.2 m^3 of liquid had been processed with a VRF of 2.67. After the installation of the new rotor a total volume of 13.7 m^3 was processed with a VRF of 3.21. The cleaning frequency was reduced by a factor of three after the installation of the rotor operating at higher rpm. The higher VRF after the rotor change boosted the average volume of waste concentrate immobilized per drum from 535 L to 642 L. Over the duration of the year

(including data for both rotors) an average volume of 585 L of waste concentrate was immobilized per drum. This represents an overall VRF of 2.92. On average over the duration of the year, there was about 64.2 kg of waste solids immobilized in each drum. The drums contained approximately 30.3% solids by weight. Inert solids (associated with grit and suspended matter removed by microfiltration in the backwash stream) represent about 4 to 5% of the weight of the product drum. The immobilized waste solids are comprised primarily of sodium nitrate, sodium phosphate, sodium sulphate, and sodium carbonate. The average concentrations of the primary radioactive and chemical contaminants immobilized in the product drums are given in Table III. The data are expressed as a quantity of contaminant per unit mass of immobilized secondary waste, from TFE-1.

Table II

Chemical characterizations of the ammonium hydroxide and citric acid-based cleaning solutions used for TFE-1 (prior to the installation of the new rotor), have shown that there is severe scaling of the evaporator by phosphate- and sulphate-based salts. About 6 kg of sodium phosphate and 1 kg of sodium sulphate were deposited on the 1 m2 of evaporator surface area. Significant quantities of calcium, magnesium, iron, and silica were also detected in the ammonium citrate-based cleaning solution. Visual observations indicated that large deposits of hardened scale were present on the heat transfer surfaces, particularly within about 25 cm of the feed inlet. These observations indicated that all of the water associated with the waste solids was flashed off within approximately 0.3 m of the TFE-1 feed inlet. The length of the heated surface is 1.5 m.

Crusty deposits of scalable species are thought to be responsible for the reduction of the heat transfer area, and lower product temperatures prior to the installation of the new rotor. Product temperatures were recorded at one hour intervals during a processing campaign, which typically lasted approximately 14 hours. At the start of a campaign a process temperature of 155 oC was attainable but could not be maintained at this level for the duration of the run, due to the chemical scaling.

The chronic fouling observed prior to the rotor change has now been minimized. The frequency of chemical cleaning has been reduced by a factor of three after installation of the new rotor and this has minimized down time. It is now possible to maintain an outlet product temperature of between 135 - 145 oC for the duration of a 4000 L campaign. This ensures that there is no residual liquid in the product drum. There is less than 1% free water in a product drum based on mass balance.

For operations with the old rotor, the average combined distillate rate (evaporated from the waste and the bitumen) varied between 0.4 and 1.0 L/min. When the new rotor was initially installed the distillate rate increased to about 1.5 L/min, before subsequently decreasing back to an average of 1.0 L/min. However, the present distillate rate of 1.0 L/min can be maintained at an average product temperature of about 135oC over the duration of a 14 hour run.

Decontamination Factor of Radionuclides Treated by TFE-1

The removal efficiency of a radionuclide or other chemical contaminant in an evaporator is usually expressed as a decontamination factor (DF), which is defined by Eq. (2).

Eq. 2

Figure 2 shows the evaporator performance for the removal of the most abundant isotopes present in the feed stream to the evaporator. The data were compiled from about two years and more than 50 operational runs. The first bar of each histogram represents the total radioactivity of the specified radionuclide in the feed stream in curies. The second bar is the total radioactivity of the radionuclide in the distillate stream, also in curies. Finally the line plot, which refers to the right ordinate, is the decontamination factor for each radionuclide.
Fig. 2
The first set of two bars shows the evaporator performance for the removal of 60Co. Over an operating period of about 500 days, about 10 Ci of 60Co was introduced into the solidification plant. Of this, less than 0.002 Ci was released, representing a DF of about 6000 in the thin-film evaporator. If the fraction of suspended particles to the evaporator for a given batch of waste is high it is probable that a large removal of 60Co will be achieved, since a large fraction of this radionuclide is adsorbed to the surfaces of suspended particles.
The most problematic radionuclides from a decontamination perspective are 137Cs and 134Cs. About 80% of the cesium is present as 137Cs, but both isotopes are equally difficult to remove upstream of the evaporators in the membrane plant, due to their low valence. The cesium isotopes are rejected at about 98% by the membrane plant, compared with 99.5% for the other b/g emitters (6). The bulk of the cesium is soluble and is not retained by the suspended solids in the backwash concentrate stream. The decontamination factors for 137Cs and 134Cs are 4000 and 800 respectively.
The decontamination factors for the two cerium isotopes (141Ce and 144Ce) are 105 and 2 x 104 respectively. The large DF for these two isotopes is partially attributed to the fact that the bulk of the cerium is adsorbed on suspended solids removed by the MF system. Since the retention of suspended solids in the evaporators is very high, it follows that there is very efficient removal of the cerium isotopes.
The lower DF for the two cesium isotopes may be related to the fraction of total cesium that is dissolved. By comparison with 141Ce and 144Ce, where the decontamination factors are greater than 20 000, and 60Co (DF 6000), most of the cesium is dissolved. About 60% of the cobalt isotopes and 75% of the cerium isotopes are associated with the suspended solid phase. These adsorbed radionuclides are subsequently removed by the MF membranes as backwash concentrate. The results suggest that the removal efficiency of the evaporators for radioactivity decreases when the dissolved fraction of the isotope increases. It is known from operating experience at CRL that, of the radionuclides discussed here, the cerium isotopes are the least soluble, and the cesium isotopes are the most soluble.
Organic Carryover in Evaporator Distillate
Although the effluent quality from the evaporator meets all discharge criteria for radioactivity, there is some carryover of organics in the distillate. The source of these organics is primarily the distillation of lighter components in the emulsified bitumen in TFE-1, which is used for immobilization of the mixed aqueous waste concentrate. The concentration of dissolved organic carbon (DOC) in the distillate can vary between 1 and 300 mg/L, while the concentration of phenolics in the distillate stream ranges from 0.02 to 2 mg/L. The oil and grease concentration in

the distillate stream (T-13) is usually less than the 15 mg/L Federal Discharge target (2), but has exceeded 100 mg/L on occasion.

It has been observed that a titanium dioxide photocatalytic reactor is capable of reducing both EPA 624 (volatile) and EPA 625 (extractable) priority contaminants present in the evaporator distillate to below the method detection limits of the GC/MS analytical equipment (7). Dissolved oxygen was sufficient to remove the color associated with organics from the wastewater, even though not all of the organic carbon was removed. A concentration of 500 mg/L of hydrogen peroxide was found to be sufficient for the removal of the organics present in the evaporator distillate stream. Phenolics were effectively reduced to well below the Canadian Federal Discharge limit of 20 mg/L with the technology, and oil and grease was reduced to below the 15 mg/L imposed guideline for Federal Establishments (2). Other aromatic compounds, including naphthalene and methyl-substituted naphthalene derivatives, were removed or converted to other less toxic constituents. The dissolved organic carbon was not all converted to carbon dioxide in the catalytic reactor; some intermediate oxidation products were formed, which included organic acids.

Product Drum Radiation Field

The radiation field on the product drums is a function of the concentrations and distributions of the specific b/g emitters immobilized in it. The contact field on a product drum varied between 100 and 1000 mR/h for the first 100 drums produced at the WTC, during which time the weight per cent solids in the product drum was maintained below 25%. Thereafter, with more radioactive waste introduced into the WTC, and by maintaining the weight per cent solids at about 35%, the average contact radiation field increased significantly. There have been two runs to date where 5 R/h (contact) drums were produced. The new rotor operating at the higher speed of 900 rpm has increased the volume reduction potential of the evaporator (Table II). This is because there is better heat transfer through the vessel wall.

Fig. 3

A semi-empirical correlation was employed which allows the radiation field to be computed if the concentration of gamma emitters in the feed tank is known. Figure 3 shows the correlation between the radiation field (as measured on contact on the side of the drum), and the estimated radiation field. The correlation is accurate to within 7% on average, assuming that the radiation field on contact with the drum exceeds 500 mR/h. The correlation is accurate enough to allow fine tuning of the liquid and bitumen emulsion flowrates. This ensures that the radiation field on any drum does not exceed about 3 R/h on contact.

The estimated radiation dose to the bitumen was computed over its lifetime. The gross beta/gamma loading per kg of product varied between 5 x 107 and 5 x 108 Bq/kg. This resulted in an estimated dose to the bitumen ranging between 1 x 106 to 1 x 108 rads over its lifetime. This was well within the maximum allowable dose of about 5 x 108 rads per drum (4).

Fig. 4

The estimated dose to the bitumen (from the known beta/gamma emitters) for the 40 product drums generated in 1994, is shown in Fig. 4 on the left ordinate. A large fraction of the dose to the bitumen is due to Co-60 radioactivity (shown on the right ordinate in mCi/drum).

Radiological and Chemical Characteristics of Product Drum

The total inventory of radioactivity and salt loading immobilized in the 40 product drums was computed. These totals were divided by the total mass of immobilized secondary bitumen waste produced from the WTC in 1994. Table III shows the distribution of radiological and chemical contaminants expressed in the units of mCi/mL (of immobilized product) and mg/kg (of immobilized product), respectively. Of the b/g emitters immobilized in the product drums, the most abundant were: Ce-144 (0.91 mCi/mL), Co-60 (0.44 mCi/mL), Cs-137 (0.90 mCi/mL), and Cs-134 (0.94 mCi/mL). On average, there was a total of 0.023 mCi/mL of gross a present, about half of which could be accounted for by the two radionuclides: Am-241 (0.0072 mCi/mL) and Pu-239 (0.0033 mCi/mL). The gross a accounts for about 1% of the total radioactivity in the product drum.

Table III

Five chemicals have been identified as contributing towards the majority of the reactive solids loading in the product drum. These include the sodium-based salts of nitrate (92 g/kg), phosphate (36.5 g/kg), sulphate (18.4 g/kg), chloride (11.2 g/kg), and carbonate (10.1 g/kg). Concentrations of sodium, iron, and calcium are also given in Table III.

LEACH RESISTANCE OF EMULSIFIED BITUMEN WASTEFORM

The emulsified bitumen wasteform from the WTC was evaluated with the ANS/ANSI 16.1 test. In this standard procedure the wasteform is immersed under water for an extended period of time and the leachate is periodically removed and chemically analyzed. The test protocol is aggressive and not indicative of disposal conditions. The test is meant to be used as a relative indication of product quality.

Leach resistance of a wasteform can be expressed in terms of a leachability index (LI) as follows:

Eq. 3

The units of LI are dimensionless, while those of D (diffusivity) are cm2/s. A high value of LI implies a slow leaching rate (and a low effective diffusivity). A minimum LI of six is required by the USNRC, and a value of 10 is considered to be excellent.

The leachability index using the ANS/ANSI 16.1 standard test varied between 7 and 9 for the various salts present in the WTC wasteform. Subsequent tests have shown that the LI of the emulsified bitumen wasteform is relatively independent of the processing conditions used at the WTC. Step changes in process temperature did not have any significant effect on the results obtained.

To determine if the leach resistance of the emulsified bitumen wasteform product from the WTC could be improved, a series of experiments have been carried out using a simulated waste (prepared in the laboratory), immobilized in emulsified bitumen. The bitumen wasteform created in this fashion was itself further encapsulated in other binding agents including oxidized bitumen (used for liquid waste immobilization at the Surrey Radwaste Facility in Virginia), and ordinary Portland cement. Both encapsulating materials surrounding the bitumen core were evaluated at three wall thicknesses: 0.25 cm, 0.50 cm, and 0.75 cm. Each sample, prior to leach testing, had a diameter of 3.5 cm and a height of 7.0 cm. This sample size was maintained to provide the same surface area to volume for all encapsulated and unencapsulated samples. In addition, three different salt loadings were investigated. Only results for the maximum loading are reported in this paper.

Fig. 5

Some of the data is shown in Fig. 5, where the leachability index (from the ANS/ANSI 16.1 test) is plotted for the uncoated emulsified bitumen wasteform (zero wall thickness), and at the other three wall thicknesses. The data are plotted for both the cement and oxidized bitumen encapsulations of the emulsified bitumen wasteform. Phosphate is among the most abundant chemicals present in the WTC emulsified bitumen wasteform (Table III). The leachability index is shown as a function of the wall thickness for both the cement (open symbols) and the oxidized bitumen (solid symbols) encapsulations. For chloride with cement encapsulation, the LI increases from about 8.6 for the pure emulsified bitumen product (without additional protective coatings), to about 11.5 at a cement wall thickness of 0.75 cm. By comparison, for the oxidized bitumen overcoat, the LI for chloride increases from 8.6 (with no overcoat), to 13 for an oxidized bitumen wall thickness of 0.25 cm. No further increase of LI with a wall thickness greater than 0.25 cm is observed.

For phosphate, the LI increases from about 9.2 to 12.5 (at a wall thickness of 0.25 cm) for both the cement and the oxidized bitumen protective overcoats (Fig. 5). There does not seem to be much improvement of the LI for wall thicknesses greater than 0.25 cm, for either the cement or the oxidized bitumen encapsulations.

Fig. 6

Figure 6 shows the leach resistance of the two encapsulation matrices for cesium and strontium. The leachability index for the emulsified bitumen wasteform (without protective overcoats) is about 8.4, and increases to about 9 with coatings of cement or oxidized bitumen. For strontium the LI without any overcoat is about 11. For the cement overcoat the LI increases to about 11.8 at a wall thickness of 0.25 cm, but shows no further increase with higher wall thicknesses. This could be due to the fact that natural strontium was also being leached from the cement matrix itself, which might bias the results. For the oxidized bitumen overcoat, the LI increases from 11 (for emulsified bitumen wasteform), to about 15 for a wall thickness of 0.25 cm.

The results from Figs. 5 and 6 show that the addition of protective overcoats of either cement or oxidized bitumen can significantly improve the leach resistance of the emulsified bitumen wasteform. In general, the oxidized bitumen encapsulation was superior to the cement encapsulation for most of the chemical and radiological contaminants that were evaluated. The cesium leachability was about the same for both encapsulation materials at all wall thicknesses.

CONCLUSIONS

Product drums from the thin-film evaporator facility at the CRL Waste Treatment Centre have an on-contact radiation field of between 500 mR/h and 3000 mR/h, depending upon the radiological and chemical characteristics of the feed. The dominant b/g emitters in the product drum include 137Cs, 134Cs, 144Ce, 141Ce, and 60Co. On average, there is a gross / loading of 2.6 mCi/mL in the immobilized bitumen product. The concentration of a emitters constitutes about 1% of the total radioactivity, and the principal isotope is 241Am. The radiation dose to the bitumen varies between 106 and 108 rads per product drum (over its lifetime), which is less than 20% of the maximum allowable dose for the matrix.

The decontamination factor of the thin-film evaporator varies with the radionuclide. It is about 20 000 for 144Ce, 6000 for 60Co, and about 4000

for 137Cs. Those radionuclides more strongly adsorbed to the inert solids associated with the MF backwash solids are more efficiently removed in the evaporator.

Installation of a new rotor, and increasing its speed from 600 rpm to 900 rpm, has significantly improved the operation of the thin-film evaporator. The cleaning frequency of the unit has been reduced by a factor of three, and the solids loading has been boosted from about 25% to 35%. The volume reduction factor increased from 2.67 to 3.21 after the installation of the new rotor operating at 900 rpm.

There is some distillation of the organic fraction from the emulsified bitumen used for immobilization of the mixed waste concentrate. Photocatalytic oxidation can effectively remove the organics volatilized in the distillate.

The addition of protective overcoats of cement or oxidized bitumen can significantly improve the leach resistance of the emulsified bitumen wasteform. Based on the ANS/ANSI 16.1 test it was shown that the diffusivity of many of the chemical and radiological species can be reduced by up to three orders of magnitude with protective layers of these encapsulating agents. The oxidized bitumen matrix was superior to the cement encapsulation of the emulsified bitumen wasteforms.

ACKNOWLEDGEMENTS

Partial funding for the experimental program was provided through the CANDU Owners Group Low-Level Radioactive Waste Working Party 49. The authors express their gratitude to process operators in the Waste Treatment Centre for their efforts in operating the equipment and collecting data.

DEVELOPMENT OF THE BORIC ACID RECYCLE SYSTEM BY REVERSE OSMOSIS

ABSTRACT
MHI has developed the Boric Acid Recycle System which can recycle the boric acid in the liquid wastes by using reverse osmosis and then can reduce the volume of concentrated liquid wastes. This system can enable to reduce the capacity and cost of the volume reduction/solidification system of the concentrated liquid wastes.
The current PWRs in Japan use the evaporators to process the liquid wastes which contain the boric acid and use the large capacity solidification system to reduce the volume and to solidify the concentrated liquid wastes. The reverse osmosis in the Boric Acid Recycle System can recycle 85% of the boric acid in the liquid wastes. Then this system can reduce the volume of the concentrated wastes by the factor of about 7.

PURPOSE
To reduce produced amount of waste, various types of volume reduction equipment have been introduced and great results have been obtained so far. However, there is a tendency that the scale of the facility is getting larger. Here is a study which simplifies the treatment facilities not by reducing the produced volume of waste but by reducing the amount produced at the production source.
Currently, the number of drums produced by concentrating and solidifying waste liquid from PWR type nuclear power plants depends on the boron content contained in the waste liquid. Thus, simplification of the volume reduction equipment, solidification equipment, etc., are performed by recovering only boron in advance and effectively concentrating the waste liquid.
[Purpose] Reduction of waste by boron recovery
Simplification of treatment facilities
Fig. 1
PRINCIPLE
When waste liquid (drain) containing boron, radionuclides, etc. is supplied to the high pressure side of reversible osmosis membrane (RO membrane), the boron moves to the recovered liquid side by permeating through pores of the RO membrane, as boron exists in molecular status and its molecule diameter is small.
On the other hand, since radioactive materials (Co, Cs, etc.) and sodium (Na) exist as hydrates after ionization and they cannot permeate through pores of RO membrane as the diameters of hydrates become larger, they remain on the waste liquid side.
As a result, the boron can be recovered by separating it from the other materials.
Fig. 2
FACILITY
Figure 3 shows the relation between the PWR plant and the boron recovery system. As universally known, the boron is circulated in the cycle of Boric Acid Tank (BAT), RCS Coolant Holdup Tank (HT), Boric Acid Evaporator (EVAP) and is reused, and a part of it is contained in the drains from various sections of the plant and collected in the waste liquid holdup tank (WHT) of the WDS. The boron recovery system recovers

selectively only the boron from the liquid in this WHT, sends it to CVCS to reuse the boron, and, simultaneously, this system reduces the boron amount in the waste liquid, thus reducing the produced amount of the waste.

Fig. 3

Figure 4 shows the abstract system configuration of the boron recovery system. After removal of the impurities in particle state of the waste liquid from WHT by the pretreatment filter, the waste liquid is transferred by pressure to the reversible osmosis membrane (RO). The borated water which has permeated through the first stage RO is transferred to CVCS and reused.

Though the boric acid is contained in the liquid on the non-permeable side, the concentration of impurities rises. For this reason, the impurity concentration in the recovered borated water rises also, if the boric acid is recovered from this liquid. To avoid this, the borated water which impurity concentration is reduced is returned to the circulation tank, and is transferred by pressure to the first stage RO again, and in this way, the improvement of boric acid recovery rate is attained.

On the other hand, the waste liquid on the non-permeable side of the third stage RO, which impurities are concentrated, is cement-solidified after it is concentrated up to the concentration limit by the evaporator.

Fig. 4

Figure 5 shows an example of the boric acid recovery features of the system shown in Fig. 4. Only the boron can selectively permeate through the RO membrane, and a little impurities (SiO_2, etc.) can permeate through it. Therefore, the limit appears to the recovery rate of boric acid, by the limitation of the impurity concentration in the recovered boric acid.

Fig. 5

In the example of Fig. 5, the recovery rate of boric acid is approximately 90%, if the concentration limit of SiO_2 is 0.5 ppm. If the recovery rate of boric acid is 90%, the produced amount of waste becomes 1/10 in comparison with the case without boron recovery system, as the remaining 10% of boron is contained in the waste liquid side. Similarly, if the boron recovery rate is 80%, the waste amount becomes 1/5.

EFFECT

The comparison of facility scale (number of components and installation space), number of produced drums and maintainability was made between the following two methods:

Case A . . . Conventional Method

Concentration + Volume reduction + Solidification (EVAP) (cementation equipment with high volume reduction rate)

Case B . . . Method combining boron recovery and simple solidifying equipment (vacuum injection type cementation)

Boron recovery + Solidification

(RO) (vacuum injection type cementation)

The following is a summary of comparisons between both cases :

1. It can be said that the effect of facility simplification of case B is rather high, though the number of drums is slightly more.

2. While case A has lot of high temperature components and, further, consists of components for powder handling, case B has less high temperature components and consists only of liquid system processes.

Therefore, it can be said that case B has excellent operability and maintainability.
As above-mentioned, it is supposed that the introduction of boron recovery may contribute to the rationalization of the total system including the range from the treatment in power plant.
The following is the features of boron recovery:

- Reduction of produced amount, by tracing back to upstream
- Simple facility configuration /reduction of installation space
- Easy operation and maintenance
- Less dynamic component
- No high temperature component
- No powder handling component

DEVELOPMENT SCHEDULE
The development of boron recovery system has a long history, and this system was developed using tubular type modules which are of slightly old type RO, in 1977 and 1978, and even the site test was carried out at that time.
After that, the RO technology made great progress, and the spiral type RO module has become mainstream, which contributes to planning of size down and reliability enhancement of the device.
During the period from 1984 up to now, the boron recovery were actually carried out 13 times in total for the waste liquid from decontamination of S/G water chamber as an object, and excellent results were obtained every time. Thus, the reliability of this technology has been confirmed and, at the same time, the technology has been accumulated.
Based on this experience, the system study and various kinds of test have been conducted for the introduction of the full-scale boron recovery system since 1990 and a positive prospect for the practical use was obtained.
In 1992, the tests of long term durability was performed. Now, it is planned to apply to the Japanese APWR.

ABSTRACT

In Japanese PWR plants, radioactive spent ion exchange resins have been stored in tanks in their sites, since they have a relatively high level radioactivity and there had been no way to treat appropriately for the final disposal. Therefore, an effective treatment technique had been desired, which converted the spent resin into a stable form suitable for the final disposal.

We have performed many research and development works on the spent resin treatment technique, and finally we have successfully developed a new type of spent resin treatment system which is suitable for the final disposal.

The system removes radioactivity by eluting radioactive substances from resins.

H_2SO_4 is used for an eluant. The eluant is recovered by diffusion dialyzer for reusing. The resultant inactivated resins are incinerated. The ashes and eluted radioactive substances are solidified with inorganic matrix.

In 1994, the system has been installed in the Ohi Nuclear Power Plant No. 1, 2 of the Kansai Electric Power Co., Inc. Further the system is planned to apply to some other plants.

DEVELOPMENT OF RADIOACTIVE SPENT ION EXCHANGE RESIN TREATMENT SYSTEM

System Concept

The basic system concept is illustrated in Fig. 1. The elution process is the main part of the system where radionuclides are removed from the spent resins by the use of $2N\text{-}H_2SO_4$ as an eluting solution(this is termed eluant). The resulting low activity resins are incinerated to produce the inorganic ashes, while the effluents containing the eluted radionuclides are led to the diffusion dialyzer. The diffusion dialyzer recovers more than 90% of H_2SO_4 as eluant. The unrecovered eluants containing a major part of the eluted radionuclides are solidified by cementation with the inorganic material. Thus, the organic spent resins are converted to the inorganic forms suitable for the final disposal.

Fig. 1

Major Nuclides In Spent Resin

Knowledge of the type and quantity of radionuclides absorbed in spent resins is indispensable to develop the spent resin treatment system. Spent resins stored in spent resin storage tanks over a period of 4 to 8 years were sampled and analyzed to determine the constituents of the absorbed radionuclides. The result is that the major constituents are Co-60, Ni-63 and Cs-137 as shown in Fig. 2.

Fig. 2

Elution

Ion exchange resins used in Japanese PWR plants consist of cation exchange resins with sulfonic acid radicals as substituents and anion exchange resins with ammonium radicals as substituents. The major radionuclides absorbed in spent resins are cations such as Co^{2+}, Ni^{+} and Cs^{+}. These cations are absorbed in cation exchange resins.

The cations in the resins can be replaced with hydrogen ions in contact with the sulfuric acid solution as follows:

$$R\text{-}(SO_3^-)_2Co^{2+} + 2H^+ \quad R\text{-}(SO_3^-)_2(H^+)_2 + Co^{2+}$$

This process is termed elution.

Elution characteristics of Co and Cs were tested in relation to the concentration of the sulfuric acid solution. The result was that $2N\text{-}H_2SO_4$ could elute more than 99.9% of Co and 99% of Cs by passing through the resins with about a 20 times volume of the resins as shown in Fig. 3.

Fig. 3
Recover Of Eluant
The concept of the recover of the eluant with the diffusion dialyzer is shown as Fig. 4. The diffusion dialyzer is provided with an anion exchange membrane and is divided into two chambers by the membrane. The eluant with the eluted radionuclides is introduced to the left chamber in the upward flow and the pure water is fed to the right chamber in the downward flow. While the eluant is passing trough the chamber, SO42- and H+ move from the left chamber to the right chamber through the membrane. However, major radionuclides such as Co2+, Ni+ and Cs+,which are cations, flow out of the chamber without moving to the right chamber due to the characteristics of the anion exchange membrane. Accordingly, the eluant(sulfuric acid) is separated from the radionuclides.
Fig. 4
The test was done to examine the characteristics of the diffusion dialyzer with 2N-H2SO4 containing Cs and Co. The relationship between the eluant recovery rate and the radionuclides leakage rate is shown in Fig. 5. The eluant recovery rate has a relation to the area of the membrane. We have decided that the design eluant recovery rate is 90%.
Fig. 5
Demonstration
A pilot plant was constructed and tested to demonstrate the system performance. The plant has a capacity of 0.05 m resins per batch which is a fifth scale capacity of the practical plant. A schematic flow diagram of the pilot plant is shown in Fig. 6.
Fig. 6
In the test, a batch of simulated spent resins were transferred from the spent resin receiving tank to the measuring tank by a slurry pump until an ultrasonic level sensor detected the predetermined level. The elution column received the resins from the measuring tank by gravity ,and dumped them to the eluted resin receiving tank after the elution. All operations including handling of resin and conditioning of eluant were performed automatically.
The radionuclide concentration at the outlet of the diffusion dialyzer is shown in Fig. 7.
Fig. 7
PRACTICAL USE OF SPENT RESIN TREATMENT SYSTEM
The developed spent resin treatment system has been applied to the Ohi Nuclear Power Plant No. 1/2 of the Kansai Electric Power Co., Inc. in 1994 at first in Japan.
The system flow diagram is shown in Fig. 8.
Fig. 8
Design Base
a. Processing design capacity
The processing design capacity is 6 m3/year, which is over the averaged generation rate in the Ohi Nuclear Power Plant No. 1/2. The operation way of the system is batchwise manner and one batch is to be processed in one week. One batch processing capacity is 0.25 m3 so that the system operational availability is below 50%.
b. Design decontamination The design decontamination (DF) is 1000 for 60Co and 100 for 137Cs under the design activity level of each nuclides as bellows.
60Co : 3.7 X 1013/ 6 m3
137Cs : 1.8 X 1013/ 6 m3

The above activity level is based on the analysis of the sampled spent resin activity.

Design Features

a. The existing incinerator and solidification system can be used.
b. The system is operated automatically.
c. The system scale is compact. (easy to apply to the existing plant.)
d. The amount of secondary waste is minimized.
e. The running cost is low.

CONCLUSIONS

The spent resin treatment system employing a radionuclide elution technique coupled with an eluant recovery by diffusion dialysis has proved adequate for practical application.

This system is suitable for the final disposal, since the organic spent resins can be converted to the inorganic materials.

ABSTRACT

During reprocessing of spent nuclear fuel, intermediate level liquid waste (ILW) along with other type of wastes like high level waste (HLW), zircalloy hulls etc. are generated. ILW streams are basically concentrated condensates and are alkaline on account of neutralization step prior to storage in carbon steel tanks . The specific radioactivity varies from 2 to 100 mCi/l due to Cs137/Sr90 besides traces of Ru106. The waste also contains unrecovered traces of uranium and other actinides. A new process has been developed which employs alkali precipitation for removal of uranium and other actinides, ion exchange for Cs137/Sr90 removal followed by treatment for decontamination with respect to Ru106. The ion exchange matrix employed is resorcinol formaldehyde (RF) condensation polymer with imino-diacetic acid chelating group. This resin has been synthesized and studied in detail at BARC laboratories in India for its application for treatment of ILW. The resin is found to be highly selective for both Cs137/Sr90 even in presence of high concentration of salts (about 25% $NaNO_3$) under alkaline pH condition.

In this process, as a first step, the uranium and other actinides are precipitated after carbonate elimination. The carbonates are present in the waste since these are used for neutralization before the storage. The supernatant is then passed through the RF resin column for cesium and strontium removal. The effluent from the resin column which essentially contains Ru106 and trace amount of Cs137/Sr90 is treated further by effluent polishing. Ru106 is removed by using zinc activated charcoal

system after pH adjustment, whereas Cs137/Sr90 are removed by standard chemical treatment processes involving precipitation by barium sulfate and copper ferrocyanide, before discharge.

The salient features of this process are as follows:

1) During precipitation step, as the quantities of uranium and actinides are small, sludge is not withdrawn after each batch of operation. The sludge concentration is allowed to be built up leading to more effective decontamination and is withdrawn only after 12-15 batch precipitation operations. This concept of multiple precipitation has helped significantly in low volume of sludge generation.

2) The loaded RF resin columns are regenerated using dilute nitric acid and, in this process, Cs137/Sr90 get stripped. The regenerant solution is concentrated and passed through an ammonium-molybdo-phosphate (AMP) capsule for cesium recovery which can be used in medical and irradiation applications.

3) The resin is conditioned with alkali and is used in subsequent operations. Hence, the total amount of radioactive solid waste is very significantly reduced and an overall volume reduction factor of about 40 is achieved taking into consideration the volume of conditioned RF resin column and conditioned chemical sludge in cement matrix.

An industrial scale plant based on above process is in operation at Waste Immobilization Plant (WIP), Tarapur, India. The main ILW treatment plant consists of 1) a process cell housing process equipment and vessels, liquid sampling system and various remotization gadgets and viewing aids; 2) vessel off-gas system for treatment of process off-gases by scrubbing and filtration; and 3) chemical additive and services systems. Various processing steps and remote maintenance works are done using master slave manipulators, in- cell crane and pneumatic wrenches with the help of viewing aids like shielding windows, mirrors and closed circuit television.

The successful treatment of alkaline radioactive liquid waste on industrial scale has demonstrated the usefulness of this process. The process not only helps in separation of Cs137 and Sr90 radionuclides but also helps in decontamination with respect to Ru106.

INTRODUCTION

Intermediate level liquid waste (ILW) is generated during reprocessing of spent fuel as a second cycle raffinate, evaporator condensate and during concentration of low level waste (LLW) from nuclear power plants (1). As a practice, this category of waste is being neutralized using alkali for storage in carbon steel tanks. Sodium carbonate is used for neutralization to keep the traces of uranium and actinides, if present, in dissolved form. The specific activity of ILW ranges from 2 - 100 millicurries per liter which is predominantly due to Cs137/Sr90 with traces of Ru106. The treatment of ILW involves use of various matrices like cement, polymer or bitumen. Among these, cement is the most cost effective matrix. Polymer based processes are comparatively costlier though the product has higher leach resistance. Bitumen is another matrix used for immobilization of ILW. It is low in cost and processing temperatures are moderate. In the process developed by BARC, India, emphasis is on separation of Pu, U, Cs and Sr resulting in high volume reduction factors. In this process, the uranium and actinides are first removed by alkali precipitation after carbonate elimination. Subsequently, for removal of Cs137/Sr90, the supernatant is passed through an ion exchange column filled with resorcinol formaldehyde

condensation polymer having imino-diacetic acid chelating type of side chain (2). The effluent from the IX column, which essentially contains Ru106 and traces of Cs137/Sr90, is further polished by passing through second set of RF resin columns. Ru106 is removed using zinc-activated charcoal system after pH adjustment (3), whereas Cs137/Sr90 are removed by standard chemical treatment using barium sulfate and copper ferrocyanide before discharge.

PROCESSING SCHEMATIC

The process is broadly divided into three stages which are preconditioning, ion exchange processing, post treatment and conditioning. The other steps involved are, disposal of spent IX columns and separation of Cs137 from regenerant solution. The detailed engineering flow diagram is given in Fig. 1.

Fig. 1

Pre-conditioning

The pre-conditioning of waste in this process involves carbonate elimination and alkali precipitation. The details are given below:

Carbonate Elimination

Intermediate level wastes generally contain traces of unrecovered uranium and actinides. In order to keep these in dissolved state, neutralization (pH-9) is carried out with sodium carbonate. In order to obtain good decontamination factors (DFs) with respect to alpha, carbonates are eliminated by acidification using nitric acid.

Precipitation/ Sludge Separation

After carbonate elimination, ILW is transferred to the precipitation tank, (Tk-10). This is a conical bottomed tank with 3 drain lines located at different elevation for draining of supernatant. Sodium hydroxide is added to the waste and the resultant precipitate is allowed to settle for a period of 8 to 10 hours and drained. Once the clear supernatant is obtained, it is passed through the RF resin column.

Ion-exchange Processing

The supernatant solution is passed through the RF resin column from top to bottom. The effluent coming out of the column is monitored for specific activity. Once the specific activity of LLW reaches a pre-set value, the next column is taken on line and the loaded column is shifted to a location where it is regenerated.

Post Treatment and Conditioning

Zinc-activated charcoal (ZAC) treatment process (3) is found to be effective for ruthenium removal. The LLW is acidified to a pH of 2 and passed through the ZAC column. Finally, the waste is subjected to chemical treatment process involving precipitation with barium sulfate and copper ferrocyanide.

RESORCINOL FORMALDEHYDE BASED CHELATING RESIN

The synthesis, characterization and successful testing of a resorcinol-formaldehyde polycondensate resin for selective removal of radiocesium from alkaline salt-loaded waste solutions has already been reported (2,4). These studies also established the chemical, thermal and radiation stability of the resin. The resin contains phenolic -OH groups which ionize under alkaline conditions and serve as cation exchange sites that have high selectivity for cesium even in the presence of large concentration of sodium ions. Incorporation of imino-diacetic acid functional groups into a resorcinol-formaldehyde polymer matrix has been reported to give it the additional capability of strontium sorption by chelating mechanism (5). Based on these earlier developments,

investigations were carried out which finally resulted in the successful bulk synthesis of a suitable resin containing cesium-selective phenolic - OH and strontium-selective imino-diacetic acid groups in the required proportion. Laboratory and bench-scale tests with this resin using actual waste solutions gave encouraging results (6). This was followed by engineering scale evaluation to study the phenomena of channeling and finalization of procedures for remotized handling of loaded IX columns and disposal aspects of spent IX columns.

OPERATIONAL EXPERIENCE

This process has been adopted on industrial scale for treatment of alkaline liquid wastes at Waste Immobilization Plant (WIP), Tarapur. The engineering flow diagram is shown in Fig. 1. All process equipments are installed inside a concrete shielded cell of about 4 M X 4 M X 10 M high with an in-cell crane, shielded viewing window, master slave manipulators and other remotization gadgets. The waste feed and other process solution transfer pumps as well as off-gas handling equipments are housed separately in areas having restricted access. Instrumentation is provided to monitor various process parameters like pressure, level, density, flow rate and temperature to facilitate process and inventory control.

The facility described above has been used for conditioning of different streams of ILW having specific activity in the range of 2-15 millicurie per liter of gross beta-gamma activity. The pH of the waste was in the range of 9 to 12.5 due to presence of - OH- and CO3-- ions. The salt content varied from 190 to 280 grams per liter which is essentially due to sodium nitrate. The salient features of the process operations are as follows:

Addition of dilute nitric acid was controlled in such a manner that excessive foaming and pressurization during carbonate elimination was completely avoided.

In place of withdrawal of sludge after each precipitation operation, withdrawal after multiple precipitation operation helped in reduction of over-all sludge generation. The average decontamination factors (DFs) with respect to alpha during precipitation was of the order of 250.

The processing rate through ion-exchange column ranged from 3 to 5 bed volumes per hour (BV/H) for acceptable column performance. The DFs achieved for gross beta-gamma activity were in the range of 200 to 600. The volume of processed waste varied from 500 to 850 bed volumes between two successive regenerations for 1% breakthrough.

The zinc-charcoal system was found effective for Ru106 removal giving DF in the range of 10-30.

The loaded ion-exchange resin was effectively regenerated using 25-30 bed volumes of dilute nitric acid with about 90% removal efficiency.

Ammonium molybdo phosphate supported on asbestos fibre was found to have good column characteristics and good efficiency for removal of Cs137 from acidic regenerant solution.

The spent ion-exchange columns after final wash are placed in carbon steel drums and immobilized by using cement concrete matrix prior to disposal as solid radio-active waste.

Various remotization gadgets have been used extensively for handling of ion-exchange columns, liquid sampling and disposal drums resulting in minimum exposure to O&M personnel.

As a result of safe and successful conditioning operations, over-all volume reduction factor of the order of 40 to 50 has been obtained. Due

to ambient temperature processing, the discharges through gaseous route are also very low.

CONCLUSION

This process is essentially based on separation of uranium and other actinides by chemical precipitation followed by Cs137/Sr90 separation by ion exchange method. Presence of uranium in waste helps in removal of actinides which are present in trace quantities. The RF resin, due to its high specificity for Cs and Sr in alkaline condition, was found to be effective on industrial scale for decontamination of waste containing high percentage of sodium ions. The separation of ruthenium from waste solution by zinc-activated charcoal was found to be effective. This process offers advantage of high volume reduction factor, high DF and low man-rem expenditure to O & M staff and is, therefore, very useful for conditioning waste streams of this nature.

ADVANCED CEMENT MATERIALS FOR RADIOACTIVE WASTE MANAGEMENT

Masami Matsuda
Takashi Nishi
Tatsuo Izumida

Hiroyuki Tsuchiya
Hitachi Nuclear Engineering Co., Ltd.

ABSTRACT

Improvements in cement properties have been investigated from the viewpoint of better radioactive waste management. The basic concept for realization of the improvements is the addition of small amounts of admixtures to conventional cement; small amounts ensure the cost increase is minimized. Fundamental experiments first showed that carbon fiber reinforcement enhanced long term durability of waste forms because it increased tensile and flexural strengths of the hardened cement. Secondly, addition of natural zeolite and silica powder to cement improved sorption ability for Cs-137 and C-14, respectively. Furthermore,

lithium nitrate reduced hydrogen gas generation to 1/20 of its typical value during aluminum waste solidification, because the additive functioned as a corrosion inhibitor.

Application to actual waste management was also investigated based on these results. High performance cement allowed various low level radioactive wastes to be solidified into stable waste forms by one simple facility.

INTRODUCTION

Cementitious materials are widely used for solidification of low and intermediate level radioactive wastes and construction of waste disposal sites because these materials have long term durability and good sorption ability for radioactive nuclides, and they are low cost and can be handled easily (1). Improvements of the cement properties have been investigated from the viewpoint of better radioactive waste management. The basic concept for the improvements is the addition of small amounts of admixtures to Ordinary Portland cement (OPC), so as to minimize the cost increase.

This paper first describes some results of fundamental experiments. The points studied are:

1) fiber reinforcement to ensure long term durability of waste forms;
2) enhancement of sorption ability for Cs-137 and C-14; and
3) prevention of hydrogen gas generation during aluminum waste solidification.

Application to actual waste management is investigated based on the experimental results. A high performance cement solidification system for low level radioactive waste is presented and its features are discussed.

IMPROVEMENT OF CEMENT PROPERTIES

Fiber Reinforcement

Effect of carbon fiber: Mechanical strength of hardened cement is one of the most important parameters for long term durability. Tensile and flexural strengths of the hardened cement are relatively low, while compressive strength is quite high (Table I.) Fiber reinforcement is an effective method to increase the former two strengths. Various materials such as glass, steel and carbon can be used for the reinforcing fiber. However, glass fiber tends to dissolve and deteriorate in an alkaline atmosphere (pH13) such as present in the cement. Steel fiber is not easily dispersed uniformly in the cement mortar, because its density is high (~7g/cm3) and the fiber tends to sink downwards. Therefore, carbon fiber (18mm x 3mmL) was selected for study.

Table I indicates the effect of the carbon fiber. Tensile and flexural strengths increase in proportion to the fiber content and double by adding 3wt% fiber. Carbon fiber improves durability of the hardened cement, because resistance to cracking can be enhanced.

Application to solidification of spent ion exchange resin: Spent ion exchange resin comprises a major fraction of the low level radioactive wastes generated from nuclear power plants. The resin content in a cementitious waste form is typically controlled below 25kg-dry resin/200L, because the waste form tends to swell and crack under a water immersion condition when resin content is higher (1). The deterioration mechanism is as follows. When water penetrates into the waste form, spent resin swells by absorbing the water and tensile stress is exerted on the cement matrix around the resin particles (2,3). The waste form is cracked in water, if the tensile stress is higher than the tensile strength of the cement.

Water resistance of the waste form can be improved by use of the fiber reinforced cement, so as to raise the spent resin loading. Figure 1 shows typical results. The waste form with reinforcing carbon fiber does not deteriorate even at such a high resin content as 55kg-dry resin/200L, while the conventional cement without fiber cracks in water and its compressive strength decreases to almost 0kg/cm2 within a few days.
Table I
Fig.1
Enhancement of Sorption Ability for Radioactive Nuclides
Radioactive cesium: Hardened cement absorbs various kinds of radioactive nuclides, such as C-14, Co-60 and transuranic elements, and retards their release from the disposal site into the environment. However, the sorption ability for radiocesium (Cs-137) is low, so that potential Cs adsorbents were surveyed.
Although the highly alkaline environment and coexistence of calcium ions in the cement limited the choices of Cs adsorbent, a natural zeolite, whose main constituent is clinoptilolite, has good performance (4). Batch sorption experiments indicated that the distribution coefficient for Cs-137 increases from 2 to 120mL/g by adding 5wt% adsorbent to the cement.
Radioactive carbon: Hardened cement absorbs C-14 and its distribution coefficient is on the order of 1000mL/g. Enhancement of the sorption ability for C-14 is desirable to ensure long term safety after land burial because of its long half life (5730 years). While C-14 adsorbents were surveyed first, no suitable adsorbent could be found. The fundamental aspects of the C-14 sorption mechanism by the OPC were examined for next. The following results were obtained.
1) Carbon-14, in the form of CO32-, is adsorbed by positively charged sites on the cement particle. These sites were produced during the cement hydration process due to the reaction between CaO and SiO2 contained in the cement materials.
2) The OPC does not contain enough SiO2 compared with its CaO content, to produce sufficient numbers of C-14 adsorption sites.
3) Silica powder was added to the OPC and the mixture was hydrated.
Results of batch sorption experiments for the hardened cement are plotted in Fig. 2. The C-14 distribution coefficient increases from 2,000 to 7,000mL/g by adding 20wt% silica.
Fig. 2
Prevention of hydrogen gas generation from aluminum wastes
Selection of inhibitor: Miscellaneous solid wastes include aluminum-containing materials. They generate hydrogen gas during the cement solidification process, because the aluminum is corroded under a highly alkaline condition:
Eq. 1
Possible inhibitors were investigated to prevent this corrosion. While sodium silicate is well established as an inhibitor under an alkaline condition (5), it can not be used in the cement for the following reason. Calcium ions in the cement mortar react with the sodium silicate:
Eq. 2
Therefore, calcium silicate is precipitated and the sodium hydroxide produced accelerates the aluminum corrosion.
Galvanic current measurements and alkaline corrosion experiments were performed to find inhibitors effective in the cement (6). Soluble lithium compounds were selected, with lithium nitrate as the best. Figure 3 compares the hydrogen gas generation during the cement solidification

process. Addition of 3wt% lithium nitrate to the OPC reduces hydrogen gas generation to about 1/20 regardless of aluminum waste content.
Reaction mechanism of lithium nitrate: Microscopic observations and X-ray diffraction measurements show that the aluminum surface was coated by an thin Li-Al double salt film (~5mm, LiAl(OH)3Al(OH)4xH20) as is shown by the SEM photograph in Fig. 3. The double salt was produced by reaction between lithium ions and aluminate ions:
Eq. 3
This insoluble film stopped aluminum corrosion and hydrogen generation. While the function of the counter ion, namely nitrate ion, is not very clear, it probably prevents pitting corrosion.
Fig. 3
APPLICATION TO SOLIDIFICATION OF LOW LEVEL WASTES
A high performance cement (HP-cement) has been developed based on the fundamental experiments and a centralized cement solidification system was designed to solidify low-level radioactive wastes into stable waste forms. Figure 4 shows an outline of the system. It offers the following features.
1) Applicability to various wastes: Various kinds of wastes, concentrated liquid waste, spent ion exchange resin, incineration ash and miscellaneous solid waste, can be solidified into waste forms by one facility.
2) Stable waste form: The HP-cement contains carbon fiber, natural zeolite and lithium nitrate. These additives allow stable waste forms to be produced independently of the waste type.
3) Simple system: The HP-cement is supplied as a ready mixture, hence special equipment, such as a high-shear mixer, is unnecessary. That is, wastes are simply mixed with the HP-cement paste using a conventional mixer.
A full-scale pilot plant was constructed to demonstrate its industrial applicability. The treatment capacity was 2 drums/hour. Table II summarizes the test results. It was confirmed that all wastes can be solidified into stable waste forms.
Fig. 4
Table II
CONCLUSIONS
Improvements of the cement properties have been investigated from the viewpoint of better radioactive waste management. The following results were obtained.
1) Carbon fiber reinforcement is an effective method to increase tensile and flexural strengths of the hardened cement. This ensures long term durability of waste forms.
2) Addition of natural zeolite and silica powder to cement enhanced sorption ability for Cs-137 and C-14, respectively, so that their release from the disposal site into the environment could be retarded.
3) Aluminum wastes generate hydrogen gas during the cement solidification process. Addition of lithium nitrate reduced hydrogen generation to 1/20 of the usual value, because the additive functioned as a corrosion inhibitor.
4) Based on these fundamental results, a high performance cement was developed to solidify various low level wastes into stable waste forms by one simple facility. Its industrial applicability was demonstrated by full-scale pilot plant tests.

INCINERATION OF HIGHLY CONTAMINATED GRAPHITE WASTE FOR KEEPING CLEAN ENVIRONMENT

G. Shani
Ya Natanzon
S. Rozin
Ben Gurion University
Dept. of Nuclear Engineering
Beer Sheva, Israel.

ABSTRACT

Flameless incineration under laminar gas flow, was used to dispose of highly radioactive graphite from a nuclear reactor. The radioactive ashes were collected on filters, while the carbon dioxide formed, went through a freezing-sublimation process to achieve a better separation of the CO2 from aerosols, which might be carried by the off gas of the incineration. Optimization of the incineration process was sought by studying the effect of gas flow speed, oxidation temperature and furnace rotation speed. Sublimation of the frozen CO2 reduces its activity by a factor of 108.

The following conclusions were drawn from the research. The graphite was ground to particles of size 22.5 microns and specific area of 15 m2/gr. Since the rate of oxidation was constant, a parameter K(hour-1) was defined, equals to the part of graphite incinerated in one hour. The dependence of K on oxidation temperature, gas flow speed and furnace rotation speed was investigated. The results are as follows : by changing the incineration temperature from 6000C to 7000C under air flow speed of 0.034 m/sec, the oxidation time reduced from 7.5 hours to 2.5 hours. At 7000C the graphite powder ignited. The furnace rotation speed did not have a strong effect on incineration time in air. When the incineration was done under pure oxygen, ignition started at 5600C. Changing pure oxygen flow rate from 0.025 m/sec to 0.051 m/sec at temperature of 5600C, reduced the incineration time by 20%. Changing the furnace rotation speed from 0 to 4.2 rad/sec (at 5400C) reduced the incineration time from 30 to 5 hours. At the end of the process, after freezing the off gas and the CO2 sublimation, the specific activity of the CO2 was less than 4 10-16 curie/liter

INTRODUCTION

An alternative to treatment of high level radioactive waste, with the objective of decreasing its volume, is storing it in its original form,

in depositories. Treatment becomes expedient when storing cost of the nonradioactive part of the waste, exceed the cost of its treatment. Such depositories had not been built yet, so that other methods should be developed. The present work describes the development of a technique of flameless burning of highly contaminated graphite which was used as a construction material in large, water-cooled, graphite reactors - LWGR and high temperature gas cooled reactors - HTGR.

In case of disruption of fuel rod cladding in LWGR and a flaw in the coolant vessel, contamination of the inner surface of the graphite mould will result, by fuel and fission products. The contaminated graphite layer turns "spongy" and a highly radioactive powder. The fuel and the radioactive fission product might constitutes 0.1 - 1%.of the graphite. HTGR fuel element cladding disruption releases fissile and fertile materials particles, and results in a more complicated contamination of the graphite shell. In regular oxidation of high level waste, filtration of the highly radioactive aerosols is complicated because of the necessity of using a large number of filters, which increases aerodynamic resistance of the purification system by the large mass of the filtering material, which later on undergoes treatment as a contaminated material. Reduction of aerosols quantity released to the atmosphere may be obtained by partial rebound of the off gas for further oxidation. (1).

Oxidation of highly radioactive waste may be carried out in concentrated sulfuric and nitric acids (2) or in molten salt (3). An interesting method of catalytical oxidation of contaminated reactor graphite is described in ref (4). It is an alternative to converting CO_2 into $CaCO_3$. A two - stage process is used to oxidize and reduce contaminated graphite, according to the reactions :

$$C + CO_2 = 2CO \quad (1)$$

$$2CO = 2C + O_2 \quad (2)$$

A partial oxidation of CO provides a source of CO_2. It should be noted, that treatment of graphite by this process results in forming a fine dispersion of carbon in form of aerosol.

THE FLAMELESS INCINERATION METHOD

However, the techniques mentioned above do not provide the possibility of reducing the volume of high level radioactive waste in form of contaminated graphite, without contamination of the environment, since these techniques include release of at least a part of the aerosols, to the atmosphere. This release is avoided if oxidation is carried out in a closed volume, as described in the following scheme :

1) Oxidation of waste.
2) cooling off the off gas.
3) Freezing the CO_2 from the off gas.
4) continuous oxygen feed and
5) return of the gas (without CO_2) to the beginning of the process for further oxidation of waste.

The principal technological stages are 1) and 3). It should be noted that freezing - sublimation process is widely used in purifying of substances in radiochemical technology. The effectiveness of such process is known to be 108 (5). The amount of continuously fed oxygen (4) is determined by its consumption in the carbon oxidation (1).

Accumulation of the isotope 14C in the active zone of LWGR during 20 years of operation is on the average 3.5×10^{-3} Curie per kg graphite. After oxidation, the concentration of the isotope 14C in the gas amounts to 1.9×10^{-6} Curie/l, while the permissible level is 1.2×10^{-10} Curie/l

(6). Therefore after sublimation of the solid carbon dioxide, the gas must be convert into solid, i.e. thermodynamicly stable substance (7).
A system was designed and built for graphite oxidation under controlled conditions, according to a scheme, in which very small quantity of graphite powder leaves the oxidation volume. The rate of the process and its safety correspond given conditions. The system is shown in Fig. 1. It consists of a tube furnace 1 containing a stainless steel reactor 2. An aluminia crucible was installed in the reactor, it contained the graphite powder 3. The reactor was rotated by an electric motor and a gear box 4, on bearing 5 and stationary plug 6. Furnace 1, reactor 2, bearings 5 and 6 were hitched on the chassis 7 which with the aid of supporting tube 8, was fixed at an angle of 150 to the horizontal table. The air flow through the oxidation zone was at a constant rate, it was controlled by a compressor 9 (when pure oxygen was tested, an oxygen cylinder was used), manostat 10 and a flow rate meter 11. Inlet 12 and outlet 13 were used, in the fluorplastic plug 6, which serves simultaneously, as a sliding bearing for the reactor 2. Reactor graphite containing (0.11 0.04)% ash was burnt in the system. It was crumbled to particles of average dimension of 22.5 microns and specific surface 15m2/gr. The purpose of using fine powder graphite was to get good simulation of dispersity of LWGR waste. Too fine graphite powder can expose "hot" spots in the graphite (4) and therefore increase the release of radioactive powder from the furnace.
Fig. 1
RESULTS AND DISCUSSION
The kinetics of the process was studied by the time required to complete the oxidation of a given quantity of powder, (tc hours). Since the rate of oxidation was constant in time, then instead of tc , a parameter K , hour-1 = 1/tc was used , (the relative part of reacted graphite in 1 hour). Figure 2 represents the dependence of oxidation rate K - on temperature T0C. In the interval 600 to 7000C, the rate of oxidation increases more then three times. The time of complete oxidation, tc, changed from 7.5 to 2.5 hours. The ignition of the graphite powder was seen at 7000C.
Fig. 2
Graphite powder oxidation in pure oxygen, at temperatures interval 500 to 6000C with a constant flow rate of 0.034 m/sec and reactor rotation speed, with graphite powder, of 2.09 rad/sec, showed a complete cycle of oxidation time change from 25 to 3 hours. At the interval 560-6000C, ignition of separate particles of graphite powder was seen. At a constant temperature of 5400C, increasing the oxygen flow rate from 0.025 to 0.051 m/sec caused 20% acceleration of oxidation rate only. At the same temperature, increasing reactor's rotation speed from 0 to 4.2 rad/sec, decrease the complete cycle of oxidation by more then 6 times from 30 to 5 hours.
In case of graphite powder oxidation in air at temperature of 6500C and flow rate of 0.042m/sec, changing the reactor rotation speed from 0 to 3 rad/sec, essentially did not affect the rate of oxidation, as seen in Fig. 3. It is concluded therefore that the rotation of the reactor is not necessary. That facilitates keeping the system hermetical and enhances its safety.
Fig. 3
Figure 4 shows the dependence of oxidation rate K(h-1) on air flow velocity v m/sec. At velocity interval from 0 to 0.04 m/sec,

reproductibility of the results sharply deteriorates. That indicates dependence on additional factors (might be turbulence). Based on the data obtained, the following conditions for oxidation are recommended : the temperature of the graphite should not exceed 6800C; the velocity of air flow should not exceed 0.04 m/sec; stirring the graphite powder by reactor rotation is not necessary. Under such conditions the complete oxidation cycle was of the order of 5 hours.

Fig. 4

For evaluation of the extent of graphite powder release from the furnace, tests were carried out at constant rotation speed of 2.09 rad/sec and at different air flow velocities (without heating). At flow velocity of 0.042 m/sec, the amount of powder carried by the air was 0.15% per hour. This parameter depends on nozzle's distance and angle, relative to the powder surface. This small amount of graphite must be oxidized before it continues to the system's next stage namely the freezer. For more effective oxidation in that case it is desirable to use a catalyst. Separating the high level radioactive impurities from material deposited on carbon (crystalline or amorphous) , was done as follows: 1 kg of waste of activity 1.5 Curie was crumbled and fed into a stationary reactor. It was oxidized at temperature of about 6500C with air flow velocity of 0.04 m/sec. The complete oxidation cycle under these conditions was 5 hours. The activity released from the reactor with the gas flow, in form of aerosols, was 1.5 Curie x 0.0015 h-1 x 5h = 1.125 x 10-2 Curie. The products of oxidation together with the aerosols were fed into a reheating furnace at the same temperature. The extent of aerosols release after reheating was 0.15% per hour, that is: 1.125 x 10-2 Curie x 0.0015 h-1 x 5h = 8.44 x 10-5 Curie. 1.87 x 103 l, of CO2 were formed, hence the concentration of radionuclides was 4.5 x 10-8 Curie/l. The effect of the sublimation on reduction of gas activity is a factor of 108, therefore the concentration of radionuclides in the sublimated carbon dioxide gas did not exceed 4.5 x 10-16 Curie/l. This value coincides with permissible concentration of a mixture of unknown radionuclides composition 4x10-16 Curie/l (6).

The Authors wish to thank Dr. V. Tokarevsky for his technical help during the experimental work.

COST EFFECTIVE WASTE MINIMIZATION USING HEPA BAG VENTING FILTERS

Terry J. Wickland
Nuclear Filter Technology, Inc.

Terry Phillips
Westinghouse Savannah River Site

ABSTRACT

Nuclear waste volume reductions of 50-70% and more have been achieved by evacuating trapped air within PVC and polyethylene liner bags. The method is to vacuum trapped air out of plastic bags through a snap-tight high efficiency particulate air (HEPA) filter prior to placing the bag into the steel box, drum or other container. Estimates indicate that the mass of waste in each container may be doubled by removing the trapped air, thereby significantly reducing containerization, storage, transportation and disposal costs of low level, transuranic (TRU) mixed and asbestos waste. Nuclear waste volume reduction by evacuating trapped air through a high efficiency particulate air (HEPA) filter offers a cost savings of $45 to $65 per cubic foot of soft compressible waste with little additional cost or loss in productivity.

INTRODUCTION

Radioactive TRU and low level waste is placed in 8 mil, 55 gallon polyethylene bags, then placed in type B-25 containers or 55 gallon drums for storage and eventual disposal. Each bag is sealed before placing it into the container. Soft compressible low level waste such as cellulosic materials, gloves, towels etc., is stored in rigid fixed volume containers. The mass loading limit of containers that store soft compressible material is not typically reached. The limiting factor to the amount of material that is stored in the container is the restricted volume of the container. Volume reduction of the waste bags, then, allows a greater mass of waste to be stored in the container. Since storage and disposal cost are primarily dependent on volume, the challenge is to reduce volume safely and efficiently.

Air evacuation of PVC or polyethylene bags is accomplished safely because the trapped air is evacuated through a HEPA grade snap-tight filter. The geometry of the filter housing allows the nozzle of a vacuum hose to be snugly attached prior to evacuation, then easily removed once evacuation of resident air is achieved. Tape placed over the filter top once the vacuum hose is released prevents bag re-inflation.

The cost of poly-bag modification to include a HEPA grade snap-tight filter is about $7.00 per bag, material and labor included. Complete evacuation of a typical 55 gallon, 8 mil polyethylene or PVC bag is achieved in 2.5 to 5 minutes, therefore, throughput of waste processed bags is not compromised. The cost savings of doubling the mass of loading in waste boxes such as the B-25, by minimizing the volume of each bag of waste, may exceed $5000 to $6,000 per container. These savings are realized by reducing disposal costs alone; additional savings will be realized by reduced interim storage and transportation costs. Based on disposal cost of $70 per cubic foot, disposal of a 90 cubic foot B-25 container is $6,300 (1).

DESCRIPTION

Evacuating trapped air through the NucFil snap-tight HEPA filter greatly reduces the volume of stored wastes. Evacuation of air from waste bags is effective in TRU, low level, mixed, and asbestos waste minimization efforts.

Laboratory studies indicate that trapped air in storage bags accounts for as much as 50 to 75% of the total volume of stored waste. By eliminating

all possible air from each bag of TRU, low level, or asbestos waste, container loading may be increased by two to three times.
Shown below is simulated radioactive waste in a sealed 8 mil 55 gallon polyethylene bag. Notice the large volume of the bag.
Fig. 1
The simple low cost solution for evacuating trapped air from storage bags is demonstrated below. The technician simply applies a 0.5 to 3 horsepower vacuum pump to the flange extension of the NucFil snap-tight bag filter. All trapped air is safely removed within 2.5 to 5 minutes and the bag is compressed to 50% to 75% of its original volume. The NucFil snap-tight filter provides high efficiency particulate air (HEPA) grade particle removal efficiency when challenged with 0.3 to 0.7 micron DOP aerosol. This assures virtually no contamination or exposure health hazards to technicians involved in waste operations. The filter media utilizes patented carbon-bonded-carbon technology.
Fig. 2
The completely compressed bag of waste is easily deposited into a rigid storage container such as a B-25 steel waste box. Given the 90 cubic foot capacity of the B-25 container, and disposal cost estimated at $70 per cubic foot, cost savings of $5000 to $6000 per container are realized. Disposal of the waste that normally fills two B-25 containers costs $12,600. By compressing the volume of bags that normally fill two containers into one, the cost is reduced to $6,300, representing a savings of $6,300. Additional cost reductions are realized by reduced containerization, storage and transportation costs. At the Savannah River Site, engineers are presently testing 100 polyethylene bags configured with the NucFil snap-tight filter. Approval for use has been granted from SRS quality assurance and health departments.
Fig. 3
FIELD USE AT SAVANNAH RIVER SITE
Engineers at the Savannah River Site (SRS) have 100 8 mil, 55 gallon polyethylene bags that were modified with the NucFil-030 snap-tight polyethylene filter. The snap-tight filters are tested for aerosol removal efficiency and delivery capacity of 800 ml/min at 1 inch water column. SRS engineers conducted additional leak tests using Emery 3004 aerosol to verify filter and bag integrity.
About 20 bags of waste usually fit into a 90 cubic foot B-25 box. An objective of the study at Savannah River Site is to determine the increase in the number of bags that will fit into the B-25 container. It is anticipated, based on laboratory model studies, that about two to three times as many bags of waste will fit into the steel B-25 Box. Complete data will be available from the authors in Spring 1996
LONG TERM LIFE CYCLE COST SAVINGS
It is estimated that during the next 75 years, low level waste alone, from existing waste in storage, waste generated from future operations and waste generated from facility stabilization, nearly 647 million cubic feet of low level waste will be generated (3). Much of the low level waste in the DOE complex may be incinerated. Assuming that roughly 50% will not be incinerated leaves 323.5 million cubic feet of low level waste that must be disposed of in landfills. Of the 323.5 million cubic feet of non-incinerated waste, it is reasonable to assume that 50% is soft compressible waste accounting for 162 million cubic feet of low level waste that may be stored in air evacuated waste bags.

Under the present status quo, based on a disposal cost of $70.00 per cubic foot, and 90 cubic feet per container, total cost for disposal alone could approach $22 billion requiring 4 million B-25 boxes. Storage of toxic air will cost $15 billion and take up 226 million cubic feet of space. By evacuating the 50% to 70% of air trapped in bags, much volume and money will be saved for better uses. By evacuating trapped air from the 162 million cubic feet of non-incinerated, compressible low level waste, 80 million fewer cubic feet of landfill space will be required and about $10 billion will be saved.

CONCLUSION

The practice of removing trapped air from bags of TRU, low level, mixed and asbestos waste through the high efficiency particulate air filters saves up to $6000 per 90 cubic foot, B-25 box. Laboratory studies indicate that 50% to 70% of the volume of a typical waste storage bag is trapped air. Evacuation of trapped air saves $45 to $65 per cubic foot of soft compressible waste. Long term savings may approach $10 billion over the next 75 years. The Savannah River Site is presently investigating the snap-tight HEPA bag filters for use in evacuating trapped air from 55 gallon polyethylene bags and complete data from the study will be available from the authors in the Spring of 1996.

DEVELOPMENT OF A SCINTILLATION FLOW-CELL DETECTION SYSTEM FOR ENVIRONMENTAL RESTORATION AND WASTE MANAGEMENT APPLICATIONS*

T. A. DeVol
S. D. Branton
R. A. Fjeld
Clemson University
Department of Environmental Systems Engineering
Clemson, SC 29634-0919

ABSTRACT

A flow-cell detection system was developed utilizing a coincidence circuit and tested with BaF2, CaF2:Eu and scintillating glass. The coincidence detection system reduced the background from ~200 cps to ~0.5 cps. The detection efficiencies for these cells ranged from 0.38 to 0.66 for 45Ca beta particles (Emax=0.257 MeV) and from 0.45 to 0.52 for 233U alpha particles (Ea = 4.8 MeV). The minimum detectable activity was calculated for a 30 s count time and determined to be in the range of 1-2 Bq.

INTRODUCTION

The use of ion chromatography (IC) for radiochemical separations is a well established technique. IC is commonly used in routine environmental monitoring applications as well as in specialized research applications. Typical usage involves the separation of a single radionuclide from the non-radioactive constituents. During the past decade, a limited amount of research has been conducted using automated IC systems in actinide

separation applications (e.g., (1). More recently, separation procedures for common non-gamma emitting activation and fission products were developed utilizing a high performance liquid chromatography (HPLC) system (2,3) (Fig. 1). In addition, a separation procedure for six common actinides has been developed using a HPLC system (4). These latter systems used on-line flow-cell detectors for quantification of the radioactive constituents of the effluent stream. Figure 2 is an example of the actinide separation and on-line flow-cell detection of convenient activities (20-80 Bq/radionuclide) (5). In order to apply HPLC with on-line detection to environmental samples, sample preconcentration and a lower detection limit are a requisite.

Fig. 1

Fig. 2

Flow-cell scintillation detection systems have been developed over the past 30 years. Although other designs have been evaluated, the most common is a translucent tube in close proximity to two photomultiplier tubes (PMTs) coupled in coincidence. The coincidence counting system is used to reduce the background count rate. Radioactive samples come in contact with the scintillator in the flow-cell and the scintillation photons are measured by the PMTs. The flow-cell can contain either a homogeneous (liquid) scintillator or a heterogeneous (powder) scintillator. In a homogeneous detection system the sample is mixed with the liquid scintillation cocktail upstream of the flow-cell, and the mixture passes through the flow-cell for quantification. The major advantages of a homogeneous flow-cell are high probability of interaction and relatively low background count rate. Disadvantages include variable quench, relatively low luminosity, and increased complexity resulting from the additional pump and mixing apparatus. The heterogeneous flow-cell typically consists of an inert inorganic scintillator that is crushed and sieved into small (50-100m) particles. Advantages of a heterogeneous flow-cell are ease of use and relatively high luminosity. Disadvantages are higher background count rates and a high probability of self-absorption resulting in an overall detection efficiency that is lower than for a homogeneous flow-cell, particularly for low energy beta emitters.

OBJECTIVES

A project has just been initiated at Clemson University to develop a HPLC/flow-cell system for the analysis of non-gamma emitting radionuclides in environmental samples. An important component of this project is development of a low background, flow-cell detector that counts alpha particles and beta particles separately through pulse shape discrimination (PSD). The objective of the work presented here is to provide preliminary results of an evaluation of the following scintillators: CaF2:Eu, scintillating glass, and BaF2. Both CaF2:Eu and scintillating glass are common heterogeneous flow-cell detector materials. The advantage of CaF2:Eu is the higher luminosity while the advantage of the glass is its inertness. BaF2 was chosen as a new material for investigation, with potential advantages during later parts of the project.

PROJECT DESCRIPTION

Flow-Cell Detectors

CaF2:Eu and glass scintillators (GS-20: cerium activated lithium glass) were purchased from Bicron; BaF2 was purchased from Optovac, Inc. CaF2:Eu and BaF2 were purchased as rough crystals that were subsequently crushed

and sieved to a 63 to 90 mm particle size range. GS-20 scintillator was purchased as 63 to 90 mm particles. The scintillators were individually packed into 3.0 mm OD X 1.5mm ID X 120 mm polytetrafluoroethylene tubing and coiled to 1.5 turns to yield an approximate active volume of 0.08 mL.

Radioactive Sources

Slightly acidic aqueous solutions of an alpha emitter, 233U (Ea=4.8MeV), and a pure beta emitter, 45Ca (Emax = 0.257 MeV), were used to evaluate the flow-cell. 233UO2(NO3)2 solution at pH 5.5 and concentration of 475 Bq/ml was used. 45CaCl2 was dissolved in deionized water at pH 5.5 at a concentration of 670Bq/ml.

Electronic Circuit

A schematic diagram of the electronic circuit used to acquire the data is presented in Fig. 3. The electronic modules were all standard Nuclear Instrument Module electronics. The flow-cell detector resides in a bath of silicon oil positioned between two Hamamatsu R292 PMTs that were separated by 1 cm. The anodes of the PMTs were grounded through a 50 W resistor and used for timing. The timing signal, generated by the Ortec 935 constant fraction discriminator, was fed into an Ortec 567 time-to-amplitude converter (TAC). The TAC range was set to 50 ns, and the output gated the pulse height and pulse shape inputs to the analog-to-digital converter (ADC, Aptec MCA card). The pulse height signal was acquired from dynode 11 and had a 1MW load resistor. The pulse height outputs from the PMTs were connected to Ortec 113 scintillation preamplifiers which were connected to Canberra 2021 amplifiers with 3 ms shaping times. The unipolar outputs from the amplifiers were connected to an Ortec 533 sum amplifier which is output to the pulse height ADC and the data stored on a personal computer.

Fig. 3

Minimum Detectable Activity

In radiation detection applications, the traditional approach for quantifying detector sensitivity is through the lower limit of detection (LLD). LLD is defined, on the basis of statistical hypothesis testing, as the smallest amount of activity that will yield a net count for which there is a confidence at a predetermined level that activity is present (6). For 5% risks of false detection and false non-detection, LLD is given as:

Eq. 1

where CB is the background count rate and t is the residence time of the sample in the detector.

Minimum detectable activity (MDA) is a function of the theoretical LLD, count time, and detection efficiency:

Eq. 2

where e denotes detection efficiency. To lower the MDA, t and/or e could be increased, and/or CB could be reduced. For applications involving HPLC, t is limited by the resolution of the chromatographic peaks. A 30 second residence time is typical while 60 seconds would be an upper limit. For a heterogeneous flow-cell, e is limited by the particle size of the scintillator. The range of the 233U alpha particles in water is 43 mm. This range is on the order of the interstitial spacing in the flow-cell. A smaller particle size would yield smaller interstitial spacing and hence higher efficiencies resulting from less self-absorption, but is limited by increased back pressure. The remaining variable parameter affecting the MDA is CB. For this paper, coincidence detection techniques

are used to reduce the background events that are attributed to thermonic emissions of electrons from the photocathode of a PMT.

Coincidence Detection

The count rate of a coincidence detection system is related to the background rate in each detector in the following manner:

Eq. 3

where

Rcoin = the coincidence count rate,
R1, R2 = the single detector count rates, and
t = resolving time of the detection system.

As stated earlier, t was set to 50 ns. With the typical background count rate for a PMT at 500 counts per second (cps), the expected count rate of the coincidence detection system is 0.025 cps. The theoretical lower limit will be obtained only in the case when there are no electrical or magnetic interactions between the PMTs, when no optical cross-talk occurs, when the scintillator is not inherently radioactive, and when the shielding from external radiation is sufficient.

RESULTS

A typical pulse height distribution for a flow-cell detector is displayed in Fig. 4, shown here for the CaF2:Eu flow-cell. Tailing of the 233U alpha full-energy peak is due to self-absorption effects. In the cases of GS-20 and BaF2 the amplifier gains were adjusted to X3 and X2, respectively, the setting used for CaF2:Eu. Increasing the gain compensated for the reduced luminosity of the latter scintillators thus keeping the alpha peak channel approximately the same.

Fig. 4

The concept of using coincidence detection as a means to reduce the background count rate appears to have potential, but care must be taken in selecting a scintillator with a low intrinsic background. Table I summarizes the background count results for the CaF2:Eu flow-cell. Note that the measured background count rate is considerably above the theoretical background count rate (typical for the other scintillators as well), thus giving an indication of the margin for improvement. The elevated background count rates of CaF2:Eu and BaF2 were attributed to the insufficient inertness of the materials resulting in adsorption of the radionuclide onto the scintillator. Elevated background count rates of BaF2 and also GS-20 were attributed to intrinsic radioactivity of the scintillation material. By gamma-ray spectroscopy it was determined that the intrinsic background in BaF2 was due, at least in part, to radium contamination. The elevated background of GS-20 was attributed to thorium, which is a common contaminant of glass.

Table I

Flow-cell detector volumes were determined by a conductivity measurement using a NaCl solution that filled the detector. The detector volumes were all determined to be nominally 0.08 ml. Acidic 233U solution (233UO2(NO3)2, pH 1) at a concentration of 130 Bq/ml was used to determine the efficiency of the flow-cells. An acidic solution was necessary to ensure minimal adsorption of the radionuclide onto the scintillator. The CaF2:Eu and GS-20 flow-cells had a detection efficiency of 0.54 for 233U. The GS-20 and BaF2 flow-cells had detection efficiencies of 0.38 and 0.66, respectively, for 45Ca. But since the uranium in the aqueous solution interacted with the BaF2 and the 45Ca interacted with the CaF2:Eu, the efficiency could not be directly measured. Table II summarizes these results. The MDA was calculated using

the experimentally determined background count rate (Table I) and detection efficiency, and a 30 second count time.

Table II

APPLICATION

Based on the results obtained in this study, coincidence detection should be used to reduce the electronic noise associated with the photomultiplier tubes. The reduction in the background count rate was several orders of magnitude (from a single PMT rate of 200 cps to a background count rate of 0.5 cps). Despite the relatively high background count rates, the minimum detectable activities calculated for these flow-cells were 1 Bq for CaF2:Eu and BaF2, and ~1-2 Bq for GS-20.

FUTURE ACTIVITIES

Presented here were preliminary results of the first task of the project. Additional work on this task includes the evaluation of additional scintillators and the addition of pulse shape discrimination, active shielding, and passive shielding to the detection system. Other tasks include the identification of sample interferences in the chromatographic portion of the apparatus, the development of sample processing protocols, and laboratory testing of the entire system using surrogate environmental and waste samples.

ACKNOWLEDGMENTS

The authors wish to thank David D. Brown for his assistance in preparing the radioactive solutions as well as measuring the detector volumes, Dr. John D. Leyba for assisting in the intrinsic radioactivity analysis of the scintillators, and Jagdish L. Malhotra, METC Contracting Officer's Representative.

ABSTRACT
At Ontario Hydro's Darlington Nuclear Generating Station (DNGS), the Darlington Likely Clean Waste Management Program qualifies bagged solid wastes for free release. As part of Likely Clean waste processing, the wastes are monitored for total gamma emitters in a bag monitor and hand-frisked with gas proportional instruments to detect alpha and beta-gamma contamination. Neither of these methods of contamination monitoring is appropriate for the detection of tritium oxide (hereafter referred to as tritium), because it is a low-energy beta emitter. A system of multiple checks and balances has been established to minimize the risk of free release of tritiated wastes. The system involves the exclusion of areas that are likely to generate tritiated wastes from the Likely Clean Program. As well, bagged Likely Clean wastes are evaluated for the presence of tritium by storing them for 24 hours after collection to allow any tritium in the waste to reach an equilibrium concentration in the waste bag air. The waste bag air tritium concentration is then measured. If the waste bag air contains less than 0.5 MPC(a) tritium (1.85 x 105 Bq/m3), the waste bag is eligible for opening and the hand-frisking of each individual piece of waste. Wastes that contain no detectable radioactive contamination are eligible for free release.
A series of experiments was conducted to test the appropriateness of the tritium detection protocol. The conclusions of the experiments were:
1) The safety of workers performing hand-frisking of the wastes is assured by using the maximum bag air tritium concentration of 0.5 MPC(a). However, bag air tritium concentration does not provide a quantitative evaluation of the tritium present in the bagged wastes.
2) 24 hours of storage prior to tritium sampling was sufficient time for establishing an equilibrium bag air tritium concentration for non-absorbent materials at room temperature, but was not sufficient time for absorbent materials.
INTRODUCTION
The Darlington Likely Clean Waste Management Program has been in operation in Zone 3 of the Darlington Nuclear Generating Station (DNGS) since the fall of 1992. Zone 3 of DNGS, which consists of all areas that contain radioactive systems and material, is divided into areas eligible for Likely Clean waste collection and those excluded from the Likely Clean program. This division was made on the basis of radioactive source term investigation. Excluded areas include the areas where tritiated wastes are likely to be generated.In the eligible areas of Zone 3, waste generators segregate solid wastes into either "Active" or "Likely Clean" waste cans. Likely Clean waste bags are sealed at collection and, if they contain no visible free liquid, are stored at room temperature for 24 hours to allow any tritium in the waste to reach an equilibrium concentration in the waste bag air. After 24 hours, the Likely Clean waste bag air is sampled with a Triton III tritium monitor, and waste bags with a tritium air concentration of less that 0.5 MPC(a) are classified as eligible for further processing as Likely Clean waste. At Ontario Hydro, 1 MPC(a) for tritium is defined as 3.7 x 105 Bq/m3. The choice of 0.5 MPC(a) as the eligibility level for hand frisking was based on two factors:

1) The Ontario Hydro requirement for respiratory protection applies for air tritium concentrations above 1.0 MPC(a). Therefore, workers performing the hand frisking step would not be required to wear respirators, and
2) 0.5 MPC(a) was felt to be the lowest level of air tritium concentration that could be measured with confidence using the Triton III.

Further processing begins with a gross gamma reading of each Likely Clean waste bag in a waste bag monitor. If the waste bag meets the program's criterion for gross gamma, it is eligible for hand-frisking. The waste bag contents are placed onto a HEPA-ventilated sorting table, with a 944 L/s airflow established across the sorting table. Each piece of waste is hand frisked with a gas-proportional instrument to measure the levels of alpha and beta-gamma contamination. If no radioactive contamination above the Minimum Detectable Activity (MDA) for the instrument is detected, the wastes are "free released" (1). Free release of these wastes makes them eligible for recycling or disposal at any landfill, and puts no restriction on the end use or destination of the material.

In 1994, the Darlington Likely Clean Waste Management Program requested that a series of experiments be conducted to determine:

1) whether 0.5 MPC(a) is an appropriate maximum bag air tritium concentration to determine the eligibility of the wastes for hand frisking.
2) whether 24 hours was sufficient time for an equilibrium bag air tritium concentration to be reached at room temperature. If not, what percentage of the equilibrium concentration was reached after 24 hours.
3) whether the degree of absorbency of the waste had an effect on the rate of establishment of the equilibrium bag air tritium concentration.

PHASE 1

The objective of Phase 1 was to determine whether tritium air concentration inside empty waste bags is dependent on the specific activity of tritium in the water inside the bag, or on the total tritium activity in water inside the bag. This would indicate whether bag air tritium concentration values in MPC(a) can be used to estimate the tritium inventory of bagged solid waste.

Two tritium solutions were prepared by adding tritium to distilled water. Solution 1 contained 3.7 x 107 Bq/l tritium, and Solution 10 contained 3.7 x 108 Bq/l tritium. A schematic drawing of the equipment setup for all phases is provided in Fig. 1. In all phases, baseline tritium air concentration and ambient gamma doserate measurements were performed, and fumehood air temperature was recorded. The volume of a typically-full Likely Clean waste bag was estimated at about 59 liters by pumping a known volume of air into an empty waste bag. Using the assumption that about 2% of the empty bag volume will be water vapor at room temperature, 1 ml of Spike Solution should have provided enough water vapor to saturate the air contained in an empty Likely Clean Waste bag.

Fig. 1

One bag was labelled as Waste Bag Empty-1, and the other as Waste Bag Empty-10. A 1.5 liter glass beaker was installed in the bottom of each bag. Five milliliters of Solution 10 were added to the beaker inside Bag Empty-10. The tritium air concentration in the bag air was recorded upon addition and every 15 minutes thereafter (Fig. 2). Further additions of 10 ml, 20 ml, 30 ml and 60 ml, 125 ml, 250 ml and 500 ml were made. Time

was allowed between each addition for a stable air concentration reading to be established and recorded.

Fig. 2

The same injection protocol was followed for Waste Bag Empty-1, using Solution 1. The waste bags were left overnight with the tritium monitor's pump circulating bag air. Bag air tritium concentration was observed and recorded the following morning.

From Fig. 2, after the injection of 35 ml of Solution 1, and 3 hours and 15 minutes after the start of the experiment, a stable tritium air concentration of 1.4 MPC(a) was reached and maintained throughout the addition of a further 965 ml of Solution 1, with a final reading of 1.2 MPC(a). After the addition of 35 ml of Solution 10, a stable bag air tritium concentration was reached, this time at 11 MPC(a). The bag air tritium concentration was still at 11 MPC(a) the next day with 1 liter of Solution 10 in the bag.

Once the air inside the empty Likely Clean waste bags became saturated with tritiated water vapor, one would expect that the saturation water vapor content of the bag would remain constant at constant temperature and pressure regardless of how much water was added to the bag. Thus, for a given Spike Solution tritium concentration, one would predict that the concentration of tritium in the bag air would reach a stable MPC(a) value at water vapor saturation and remain at that value for all further volume additions of tritium solution. Given sufficient time, only 1 ml of tritium solution was sufficient to saturate the Likely Clean waste bag air with water vapor. Thus, it is not surprising that the bag air tritium concentration reached a stable value that did not change regardless of the addition of further tritium solution volumes. This phase of the experiment was conducted to illustrate the fact that the stable bag air tritium concentration was dependent of the specific activity (Bq/l) of tritium in the tritium solution but not on the total activity (Bq) of tritium present in the bag. This result has significant implications for tritium detection in bagged waste, as it indicates that sampling bag air would be an indication of the specific activity of tritium in liquid absorbed in solid waste, but would not indicate the total tritium activity present in the waste bag. Thus, using the Darlington Likely Clean Waste Management tritium detection protocol, it is not possible to quantify the total tritium inventory contained in a bag of Likely Clean waste. If unconditional release were based on the IAEA Unconditional Release levels (Bq/g), as is the case for other Clearance programs in Canada, sampling the bag air would not give the necessary quantitative information about the total tritium content of the waste.

PHASE 2

The objective of Phase 2 was to compare the time taken for waste bag air tritium concentrations to reach equilibrium inside bags of absorbent material (paper towelling) and in bags of non-absorbent material (plastic) by adding a known quantity of tritium to new material. A second objective was to determine what percentage of the anticipated bag air tritium concentration was reached after 24 hours, based on Phase 1 results.

Two large rolls (2.5 kg) of paper towel were torn into individual sheets, and 2.5 kg of paper towel were placed in each of two Likely Clean waste bags. An injection line was taped into the center of the paper towel as it was emplaced. This allowed for the injection of tritium solution into

a "worst-case" location at the center of the waste bag. The two bags were labelled Waste Bag Paper-10 and Waste Bag Paper-1.

An addition of 15 ml of Solution 10 was calculated for Waste Bag Paper-10. This 15 ml addition would result in a specific activity of 2.22 x 103 Bq/g in the waste, and the IAEA (2) unconditional release criterion for tritium in solid materials is 3 x 103 Bq/g for tritium. Although slightly less than the release criterion, 15 ml of tritium solution were added because its behavior in an empty waste bag had been studied in Phase I. For Waste Bag Paper-1, 200 ml of Solution 1 were added, which equals a tritium specific activity of 3 x 103 Bq/g of solid material. The experiment ran for over 6 days.

In the second part of Phase 2, two bags of Likely Clean waste containing mostly plastic were selected. The bags had been evaluated for tritium using the Likely Clean program's protocol, and had <0.5 MPC(a). The first waste bag, which weighed 3 kg, was labelled Waste Bag Plastic-10. The second waste bag, which weighed 4.5 kg, was labelled Waste Bag Plastic-1. Ten milliliters of Solution 10 were injected into Waste Bag Plastic-10. Thirty-five milliliters of Solution 1 were injected into Waste Bag Plastic-1, and the bag was examined for the presence of liquid. When none was observed, an additional 90 ml of Solution 1 was injected into the bag. At this point, free liquid was observed in the waste bag. Since the presence of free liquid in a Likely Clean waste bag makes it ineligible for Likely Clean processing, no more tritium solution was added. The bags were left overnight with bag air circulating through the tritium monitors.

The data from Phase 2 are shown in Fig. 3. In the bags of paper towelling, a detectable rise in bag air tritium concentration did not occur within 24 hours of the injection of the tritium solutions. For Waste Bag Paper-1, the bag air tritium concentration took 5 days to rise to 0.4 MPC(a), which is below the tritium criterion used at DNGS for the rejection of Likely Clean waste for hand-frisking. This level of tritium contamination in absorbent waste would not likely pose an occupational risk to personnel performing hand frisking, as offgassing concentrations are low and the ventilated sorting tables have good airflow. However, the paper towel was spiked near or at the IAEA (2) Unconditional Release Levels, so using 0.5 MPC(a)as the only tritium release criterion for release-level based waste segregation programs would not be advisable. Based on Phase 1 results, one would expect the maximum bag air concentration that could be reached in Waste Bag Paper-1 would be 1.4 MPC(a). Water present in the bag due to the natural water content of the paper towelling would have exchanged with the tritium solution water and vapor, resulting in the dilution of the specific activity of tritium in the waste bag. It is not likely that the maximum bag air tritium concentration for an empty bag (from Phase I) would ever have been reached.

Fig. 3

The bag air tritium concentration in Waste Bag Paper-10 took 5 days to rise to 0.5 MPC(a) above baseline. The saturated bag air tritium concentration in the equivalent empty bag in Phase 1 rose to about 11 MPC(a). These results indicate that paper towelling, and likely any other absorbent material, requires a considerable length of time in a closed bag at room temperature to yield enough tritiated water vapor to exceed the DNGS Likely Clean Program's tritium criterion of 0.5 MPC(a). Either a longer laydown period (greater than 24 hours) prior to tritium

monitoring, or some method of enhancing the offgassing of tritium from the absorbent waste prior to waste bag air sampling would be advisable. Figure 3 indicates that tritium solutions added to bagged plastics reached levels in excess of 0.5 MPC(a) within 24 hours of the addition. Since the plastics contain little or no water, there was no dilution of the tritiated water in the bag. The bag air tritium concentration inside Waste Bag Plastic-1 reached the level predicted by Phase 1 of 1 MPC(a) within the 24 hours. The bag air tritium concentration inside Waste Bag Plastic-10 rose to 6 MPC(a) within 24 hours, as compared to a predicted value of 10 MPC(a). The reason for the lower-than-predicted reading may have been the presence of a small amount of absorptive material, as a cotton glove was observed in the bag. These results indicate that the 24 hour laydown prior to sampling the bag air for plastics, and likely any other non-absorbent material, is sufficient.

PHASE 3

The objective of Phase 3 was to confirm Phase 2 results by performing Phase 2 in reverse order. Tritium solution was poured into a plastic glove bag and allowed to reach a stable bag air tritium concentration. The tritium solution was then soaked up using known quantities of paper towel and Tyvek to demonstrate any effect on bag air tritium concentration.

Two plastic glove bags were labelled Waste Bag Paper-1 and Waste Bag Tyvek-1. A sealed plastic vial containing 15 ml of Solution 1 was placed in each glove bag. For Waste Bag Paper-1, 210 g of new paper towelling was sealed into a zippered plastic bag and then placed into the glove bag. The 15 ml of Solution 1 would spike this amount of paper towel to a level of 2646 Bq/g, which is slightly below the IAEA (2) unconditional release level of 3,000 Bq/g. For glove bag Tyvek-1, a tyvek disposable suit was cut into pieces, each of which was weighed and labelled, and then the tyvek material was put in another plastic zipper bag and installed in the glove bag. The tyvek material was spiked to a level of 2282 Bq/g, which is also slightly less that the IAEA (2) unconditional release level.

The vials were opened using the gloves, and Solution 1 was poured into the glove bags. The next morning, the gloves were used to open the zipper bag containing the paper towelling inside Waste Bag Paper-1, and the tritium solution was absorbed using the paper towelling. The procedure was repeated in Waste Bag Tyvek-1, using a known weight of Tyvek material to soak up the solution, and then emptying the rest of the Tyvek into the bag. Tritium bag air concentration for both bags was recorded continuously on the chart recorder.

The volume of an empty glove bag was measured at about 120 liters.Using the same assumptions as in Phase 1 for the saturation of bag air with water vapor, and 2 ml of tritium solution would provide enough water to saturate the air in an empty glove bag.

The results of Phase 3 are shown on Fig. 4. Tritium bag air concentrations in the empty glove bags rose to the values predicted by Phase 1, about 1 MPC(a), before the tritium solution was absorbed into the paper towel and Tyvek material. Absorbing the Spike Solution into the paper towel resulted in a drop in tritium bag air concentration to 0.1 MPC (a) within 2 hours. Absorbing the tritium solution into Tyvek material did not result in any decrease in bag air concentration. The slight rise in bag air MPC(a) values after the addition of Tyvek material was likely due to the observed beading of the tritium solution over a

large surface area of material, making evaporation of the tritium solution more efficient. These results confirm the Phase 2 conclusion that the presence of absorbent material in bags of waste does decrease the anticipated tritium equilibrium concentration in the bag air. Therefore, enhanced sampling methods are required to ensure that a significant percentage of the tritium present in the absorbent waste is detectable in the waste bag air within 24 hours.

Fig. 4

CONCLUSIONS

There are two bases upon which the appropriateness of using a bag air tritium concentration of 0.5 MPC(a) to determine the eligibility of Likely Clean wastes for hand-frisking must be evaluated. They are:

i) The assurance of a low probability of the free release of tritiated wastes must be established. Assurance of the low probability of free release of tritiated wastes is achieved by the combination of the exclusion of areas of Zone 3 that would generate tritiated wastes, and by the utilization of 0.5 MPC(a) tritium in waste bag air as a pass/fail criterion for further processing of the waste as Likely Clean. As a result, no changes are required for the tritium detection protocol for the Darlington Likely Clean Waste Management program. However, the results of these experiments clearly illustrate that bag air tritium concentration is dependent on the type of waste material and the specific activity of the tritium solution. The bag air tritium concentration does not provide a quantitative evaluation of the tritium present in the bagged wastes.

ii) A consideration of the safety of personnel performing waste segregation. Ontario Hydro policy does not require the use of respiratory protection for tritium at air concentrations below 1.0 MPC(a), so the choice of the setpoint for bag air tritium concentration of 0.5 MPC(a) is appropriate. Additional worker safety is assured because adequate airflow is established across the ventilated sorting tables where the hand-frisking of the waste occurs.

With respect to whether the 24 hour storage period prior to tritium monitoring of the bagged wastes, 24 hours was sufficient time for establishing an equilibrium bag air tritium concentration for non-absorbent materials at room temperature. However, 24 hours was not sufficient time for establishing an equilibrium bag air concentration for absorbent materials at room temperature. The percentage of equilibrium concentration reached after 24 hours for paper towelling was not sufficient to estimate the equilibrium bag air concentration with confidence.

REAL-TIME ALPHA MONITORING OF A RADIOACTIVE LIQUID WASTE STREAM AT LOS ALAMOS NATIONAL LABORATORY

Charles R. Whitley
John D. Johnson
Mohini Rawool-Sullivan
Los Alamos National Laboratory

ABSTRACT

This paper discusses the development, installation, and testing of a real-time radioactive liquid waste monitor at Los Alamos National Laboratory (LANL). This detector system was designed for the LANL Radioactive Liquid Waste Treatment Facility (RLWTF) as a means of real-time monitoring of influent to the plant. By knowing the activity of the influent, the plant operators can better monitor the treatment process, potentially segregate waste better, and monitor the regulatory compliance of users of the LANL Radioactive Liquid Waste Collection System.

This detector system uses long-range alpha detection (LRAD) technology, which is a non-intrusive method of characterization that determines alpha activity on the liquid surface by measuring the ionization of ambient air above the surface. Extensive testing has been performed to ensure long-term reliability with a minimum amount of maintenance. The final design is a simple cost-effective alpha monitor that can be modified for monitoring waste streams at various points in the LANL Radioactive Liquid Waste Collection System. The detector system has been used to monitor low-level waste streams at LANL. Typical activities of influent measured at the RLWTF are tens of nCi/l due to alpha-emitting contaminants.

INTRODUCTION

Design and installation of a working prototype was begun in 1994 to meet the needs of the RLWTF at LANL for monitoring alpha contamination in their influent stream. The detector is based on the long-range alpha detection sample monitor design and monitors the airborne ionization created by alpha radiation (1).

The normal activity level for the alpha component of radioactive liquid waste at the RLWTF is tens of nCi/l. The goal of this project was to install a real-time monitor at the point where the influent enters the treatment facility so that spikes in activity could be detected. The LANL waste acceptance criteria for the main RLWTF plant is 500 nCi/l for alpha contamination. Therefore a real-time alpha monitor would alarm for large changes in activity and allow the operators to closely monitor daily fluctuations in influent activity. This could lead to a better understanding of waste disposal at LANL and perhaps lead to segregation of waste before treatment. Current regulations mandate that both influent and effluent be monitored to determine the overall effectiveness of the treatment process. Traditional methods require up to a day and a half for analysis.

Benchtop tests were made in 1994, and the detector was able to monitor liquid at the 100 pCi/l level. Modifications were made to the detector and it was installed in the pH balancing tank in mid-1995. The detector system was mounted in a non-intrusive manner on the lid of the tank, several inches above the liquid surface. The pH balancing tank is equipped with a mixer that ensures the liquid is homogeneous and a baffle that provides a calm surface of liquid for monitoring. Recent tests with an inline detector system have shown sensitivity at the several nCi/l range. The LRAD-based system is therefore a factor of 10-100 times more sensitive than the alarm limit of 500 nCi/l. This technique should save both time and money, and could be applied to effluent monitoring before discharge into the environment.

DESIGN

Traditional alpha detectors monitor the alpha particles directly, requiring that the detectors be close to the object being monitored. It is difficult to design a detector to do this because of the changing levels of the liquid stream, humidity, and other engineering concerns. The radioactive liquid waste monitor being developed by LANL is not subject to these constraints because it monitors the airborne ionization created by alpha particles generated on the liquid surface. Tests at LANL have shown that this ionization can be transported via an electrostatic field or by airflow up to distances in excess of several meters, depending on the application. Each 5-MeV alpha particle can create approximately 150,000 ion pairs, and this technology has proven to be highly sensitive for monitoring alpha contamination (2).

The Radioactive Liquid Waste Monitor (RLWM) design is based on the electrostatic long-range alpha detector (3). Initial tests were made by inserting trays of radioactive influent into the LRAD Sample Monitor. This simple electrostatic design consists of a metal enclosure and a high-voltage signal plane. The signal plane is a metal plate maintained at 300 V DC, and a highly sensitive electrometer is used to detect changes in current to the plate. The box is maintained at ground potential, and so the ions produced by alpha contamination are collected on the plate and box, according to their polarity. By using standard alpha sources for calibration, the resulting current in the system can be linearly scaled to give surface activity. The calibration was made using a set of National Institute of Standards and Technology (NIST) traceable Pu-239 sources with strengths ranging from 100 to 1100 dpm-alpha. For this prototype, the conversion for dry samples is 1 mV = 59 dpm, and the monitor is able to discriminate dry samples with an activity less than 100 dpm-alpha.

In the first design for the RLWM, a signal plane and guard plane were suspended above a stainless steel sink. Because the radioactive liquid was shown to contaminate the sink, a stainless steel insert was used to hold the liquid. Therefore a background could be taken between samples without concern for cross-contamination. This benchtop model was able to monitor changes in volume activity of the liquid and the measurements were compared to the gross alpha measurements taken by drying 10 ml samples and monitoring them in a traditional alpha detector.

The next design (see Fig. 1) was built to fit into an opening in the pH balancing tank at the RLWTF. This model had a smaller surface area than the benchtop model. A preliminary calibration showed that it had a good linear response for the dry Pu-239 source set. However, because of background ionization in the pH balancing tank, the sensitivity of the detector was greatly reduced. It is believed that this background was primarily caused by contamination on the sides of the tank and the charging of the Lexan lid. In addition, the guard plane proved inadequate for shielding the signal plane from large variations in current that were not directly related to the activity of the influent.

Fig. 1

In mid-1995 the RLWM was removed from the pH balancing tank to implement and test modifications. The final design, shown in Fig. 2, had several important changes over the original design, and it was tested in a benchtop configuration with a stainless steel sink. The guard plane was shaped so that the acceptance of the signal plane was reduced, causing the signal on the signal plane to come primarily from the surface beneath

the detector and not from the Lexan lid or the sides of the tank. Another important modification was the use of additional insulated standoffs between the signal and guard planes. By increasing the path lengths over surfaces between the ground, guard, and signal planes, leakage current was reduced and the detector was less sensitive to humidity in benchtop tests. During tests in which high-activity sources were placed in various geometries with respect to the detector, it was found that the signal wire, running from the battery to the signal plane, could collect large amounts of ionization. The resulting contribution to the signal current was reduced significantly by shielding the signal wire with an insulator; however, the signal remained noisy due to fields induced by charging of the insulating material. This noise was eliminated by adding a stainless steel mesh shield around the insulator and connecting the mesh to the guard plane.

The RLWM was re-installed in the pH balancing tank in November 1995. The detector initially showed a very poor correlation to liquid activity measured by taking grab samples near the detector. The current from the signal plane was correlated strongly with liquid level, most likely due to heavy contamination of the tank walls. As the liquid level rose, covering more of the wall surface, the signal would drop proportionally. The level is monitored continuously by the treatment facility, and it is possible to record this data simultaneously with our detector signals. By subtracting the effect of change in the liquid level, the correlation between the detector signal and the grab sample activity increased dramatically. Periodic fluctuations on the order of seconds in the signal current, induced by the motion of the liquid, were also encountered. These were damped by placing a suitably chosen capacitor across the electrometer to form a low-pass filter.

Fig. 2

RESULTS

Figure 3 shows the corrected RLWM signal over a 24-hour period. The baseline obtained with the conversion remains constant over the several weeks in which data was obtained. Figure 4 shows the data points obtained from the corrected signals plotted against the activities of grab samples in counts per minute, with the bold line giving a linear fit to the corrected signals. The raw signals decrease with activity, due to the rise of liquid levels associated with a contaminated influent. By including a level correction, the correlation is much improved.

The grab samples were filtered to remove particulate matter that contributes little to the RLWM signal because of wetting of the particle surface. The maximum values for activity obtained correspond to 100 nCi/l, while the non-filtered values ranged from 120% to 150% of the filtered values. The range of activity shown is only 20% of the action level of 500 nCi/l, and further data at higher activity levels would be useful for obtaining better calibration of the signal correction factors.

Fig. 3

Fig. 4

CONCLUSIONS

The results of monitoring influent at the RLWTF at LANL show that the RLWM is sensitive to changes in alpha activity in the influent liquid stream at the 10 nCi/l level. There is a great deal of uncertainty remaining because of the procedures used for drawing off grab samples. The calibration for LRAD applications, such as this, is always difficult when the range of samples is not great. A much improved calibration could

be made by including data for high-activity samples; however, this sort of calibration will have to be made over time by drawing off samples when the detector alarms. Therefore, over time, a much more sensitive calibration could be made. Even with a less-sensitive calibration, the detector has been shown to have a stable baseline over time and large changes in activity can clearly be measured, giving the operators at the RLWTF important information. Further development with standard liquid sources would allow improvements to be made to this detector design, resulting in a much more sensitive alpha monitoring system for liquids. Continuing development of this detector could lead to a sensitive monitor for treated effluent streams as well. This sort of application would be very useful for monitoring low-level radioactive liquid streams before discharge into the environment. A more sensitive design could ensure regulatory compliance and be used to monitor samples in the field: saving time and money over other sampling methods.

MIGRATION OF SR-90, CS-137, AND PU-239/240 IN A CANYON BELOW A LOS ALAMOS OUTFALL*

Jennifer M. Murphy
Caroline F.V. Mason
Jeremy M. Boak
Patrick A. Longmire
Los Alamos National Laboratory

ABSTRACT

Technical Area-21 (TA-21) of Los Alamos National Laboratory (LANL) is on a mesa bordered by two canyons; DP Canyon and Los Alamos (LA) Canyon. DP Canyon is a small semi-arid watershed with a well defined channel system where the stream flow is ephemeral. TA-21 has had a complex history of waste disposal as research to determine the chemical and metallurgical properties of nuclear materials occurred here from 1945-1978. Due to these operations, the TA-21 mesa top and bordering canyons have been monitored and characterized by the LANL Surveillance and Environmental Restoration Program. Results identify radionuclide activities at a clay pipe outfall identified as Solid Waste Management Unit (SWMU) 21-011(k) which exceed Screening Action Levels, and at locations along DP Canyon which exceed regional background levels.

The radioactive contaminants considered in this study are strontium-90, cesium-137, and plutonium-239/240. This paper examines sediment transport

and contaminant migration from the source at SWMU 21-011(k), which is located on a slope above DP Canyon. Three dimensional surface plots of data from 1977-1994 are used to portray the transport and redistribution of radioactive contaminants in an alluvial stream channel. Contaminant activity has decreased since 1983, in part due to more stringent laboratory controls, and also due to the removal of the main plutonium-processing laboratories to another site.

INTRODUCTION

Technical Area-21 (TA-21) of Los Alamos National Laboratory (LANL) lies on the northern section of the Laboratory, at an elevation of 7140 ft. It is located on the Pajarito Plateau,midway between the steep slopes of the Jemez mountains to the west and the Rio Grande river to the east. TA-21 lies on DP Mesa, immediately east-southeast of the Los Alamos town site. TA-21 was the plutonium processing facility for nuclear weapons research and development from 1945 to 1978. After 1978, operations were scaled back dramatically but not stopped completely. Liquid radioactive waste was treated at a site treatment plant from 1969 to 1995. TA-21 is currently being decontaminated and decommissioned.

The Liquid Radioactive Waste Treatment Plant processed aqueous effluent from TA-21 chemical laboratories. The effluent included the isotopes plutonium-239/240, cesium-137, and strontium-90, among other radionuclides. After processing, the effluent was discharged into DP Canyon via an outfall now referred to as SWMU 21-011(k). A map of TA-21 and DP canyon is shown in Fig. 1. DP Canyon is the small east-west oriented canyon which flanks TA-21 on the north. The walls of the canyon are steep and rocky. The stream channel on the floor of the canyon receives ephemeral flow from precipitation and runoff (summer storms and winter snowmelt). Sediments in the stream channel consist of sand and illitic clay. DP Canyon joins Los Alamos Canyon approximately 1.5 km downstream from SWMU 21-011(k).

Fig. 1

SWMU 21-011(k) received processed waste effluent streams from 1969 until 1978. From 1978 until 1984, it received chemical waste containing various radionuclides. A 400 L aqueous spill of untreated effluent probably containing various contaminants, occurred at the outfall in 1991 (1). The clay pipe at 21-011(k) released effluent into a precipitous rock strewn slope with minimal soil depth.

Sediment Sampling Technique

This investigation examined temporal trends in available data for radionuclides at sediment sampling stations in DP Canyon. The sampling locations included the SWMU site, two locations (DPS-1 and DPS-4) in DP Canyon, and the site of well LAO-3, near the confluence of DP and Los Alamos Canyons (See Fig. 1). The first site was sampled in the summers of 1992 and 1993 (2). The last three sites have been sampled repeatedly by the Environmental Protection Group (3).

Stream bed samples were taken from sampling stations along DP Canyon shown on Fig. 1. A consistent sampling procedure for the sediments was repeated annually to ensure comparability of the results. Samples from the bed of DP stream were collected by digging a line of uniform depth in an undisturbed area across the main channel (4). Using a trowel, 500 ml of sediment was collected at a depth of one-half to three-fourths inch. Soil from SMWU 21-011(k), in contrast with sediment, samples were taken at a depth of one to six inches and six to eighteen inches in the soil. Care was taken to collect the clay-rich fraction with which the

radionuclides are commonly associated (5). The sediment sample is mixed prior to analysis and analyzed at the LANL Environmental Measurements Lab and each year the field samples were taken within a period from late April through May (5).

The Environmental Chemistry Group at LANL used a documented Quality Assurance and Sampling Procedure for the sample analysis and data verification. The analyses of radioactive constituent concentrations were determined by gamma-ray spectrometry.

Table I portrays the regional background concentration, the Screening Action Level (SAL), and half life of the three elements.

Table I

A SAL is set on potential contaminants in various media based on conservative calculations of human health risk. Soil SALs for radionuclides are calculated using a residential scenario at an annual dose limit of 10 millirem (10 mrem/a) above regional background.

Plutonium-239 decays by alpha- and gamma-emission with a half life of 24,100 years (a). Plutonium-240 is also an alpha- and gamma-emitter, with a half-life of 6560 a. Cesium decays by beta-and gamma-emission, with a half life of 30.17 a. Strontium decays by beta-emission, with a half-life of 28a.

Clay minerals are very effective at retaining these radionuclides. As a monovalent alkali cation, cesium readily exchanges with potassium, and is commonly strongly bound to surface and interlayer sites of clay particles (6). Thus, contaminant cesium is expected to be associated with the finer fractions (especially the <0.053 mm fraction) in soils and sediments (7). Transport of cesium commonly occurs in association with soil and sediment erosion (7). There is evidence of substantial drainage erosion from the SWMU 21-011(k) clay pipe down the slope to DP stream in the form of two drainage channels.

Strontium is a divalent alkali earth cation which readily substitutes for calcium in mineral lattices and on surface sites. Although transport of strontium will also be largely through sediment transport, sorption on mineral grains is generally less strong for strontium, and hence, transport in runoff may also be significant.

Because of their similarity to potassium and calcium, respectively, cesium and strontium are also bioactive (readily absorbed by plants, soil microbes, and animals). Plants and microbes whose growth is limited by calcium and/or potassium will tend to take up larger amounts of strontium and/or cesium (8).

RESULTS AND DISCUSSION

This section discusses the present concentrations in soil and sediment at SWMU 21-011(k), and the variations with time of radionuclide activities at the sediment sampling stations downstream. The three radionuclides discussed are Pu-239/240, Sr-90, and Cs-137. (Note that the standard measurements for plutonium do not distinguish the two isotopes, so the value reported is for the sum). At the source [SWMU 21-011(k)], Pu-239/240 activities range from 7.2 to 46,000 pCi/g,

Cs-137 activities ranged from 8.23 to 2675 pCi/g, and Sr-90 activities ranged from 1.96 to 1800 pCi/g. Figs. 2,3, and 4 show the variations in activities as a function of time and location in DP Canyon. Table II summarizes the data on radionuclides activities in DP Canyon.

The plutonium chart (Fig. 2) portrays the maximum activities occurring at DPS-1, with values at DPS-4 and LAO-3 consistently below 1.0 pCi/g. After 1986, the DPS-1 activities are likewise below 1.0 pCi/g. The outfall

clearly displayed high activities (1900 times the soil SAL) after the decline in levels at DPS-1, so it would appear that transport of plutonium was facilitated by the effluent from the outfall. Without the continued effluent, relatively small degrees of transport occurred to the stream channel, and the remaining contamination at DPS-1 was moved downstream and mixed with less contaminated soil by runoff.
Table II
Fig. 2
Plutonium does not appear to be migrating to DPS-1 or DPS-4 at levels above the SAL. Cesium historically has had high levels at DPS-1, and DPS-4 but currently the levels are well below the SAL. The strontium data is similar. There is an evident decrease in the three radionuclides downstream.
The cesium data (Fig. 3) indicate that concentrations were above the SAL at all three stations until the late 1980s, but have subsequently declined to activities at or near background levels. The high levels seen at SWMU 21-011(k) are not found in the stream channel, so dispersion and mixing of contaminated sediment appears to have diluted the concentration of cesium. In addition, the cessation of effluent release appears to have permitted contamination levels in the channel to decline through transport and/or dilution. However, the activities remained higher for cesium than for plutonium, and cesium is the predominant radionuclide contaminant in DP Canyon. This conclusion is corroborated by the EG&G aerial radiological gamma surveys in 1975 and 1982 (9). These surveys show that cesium is the dominant anthropogenic radionuclide found outside of TA-21, and that it had migrated approximately 600 meters down DP Canyon.
Fig. 3
The strontium data (Fig. 4) show a pattern similar to that for cesium, with high values at the source, values above the SAL at DPS-1 until the mid-1980s, and values below the SALs, at all stations since then. The values are lower than those for cesium, which may reflect the composition of the original effluent, but may also represent the lower sorptivity of strontium. Strontium may have been mobilized into the surface water and alluvial ground water, and transported deeper, or further downstream.
Fig. 4
Table III shows sorption coefficients for all three elements. Strontium is less strongly sorbed onto clay mineral surfaces than plutonium and cesium, but appears to have behaved in a manner similar to cesium in the sediment of DP Canyon. The pattern for plutonium appears unusual in the light of its estimated sorption coefficient, as it is expected to sorb slightly less strongly than cesium, yet it appears hardly to have been transported at all. It is conceivable that plutonium in the effluent was sorbed onto or precipitated in extremely fine colloidal particles which percolated into the soil to some depth. The cesium and strontium, which sorbed rapidly onto clay or silt particles at the surface may have been more susceptible to transport in surface runoff. Further analysis is underway to test this concept.
Table III
Strontium is less strongly sorbed onto clay mineral surfaces than plutonium and cesium, but appears to have behaved in a manner similar to plutonium in the sediment of DP Canyon. Strontium is likely to remain stored in the banks of the stream channel, but to a smaller extent (10). Strontium sorbs to the LA Canyon sediments less strongly than cesium by a

factor of 12. Batch strontium sorption experiments were conducted on 20 soil and 16 channel sediment samples collected in TA-21, and upper Los Alamos Canyon. Cesium sorption coefficients (Kd) ranged from 162.3 to 1444.3 ml/g in soil and 77.5 to 1034.1 ml/g in sediment (11). Strontium sorption coefficients ranged from 15.8 to 67.7 ml/g, with a mean of 35.7 ml/g for soils. For strontium in LA Canyon channel sediments sorption coefficients ranged from 8.8 to 41.3 ml/g, with a mean of 21.4 ml/g (11). These data suggest that strontium is a non-conservative solute that is partially removed from solution through cation exchange.

CONCLUSIONS

The outfall at SWMU 21-011(k) is a major source for radionuclide contamination in DP Canyon. Plutonium has not migrated from the source in concentrations sufficient to exceed the SAL, and activities declined very rapidly after effluent ceased to be released into the SWMU. Cesium and strontium have been transported in quantities sufficient to exceed the SALS, although only cesium activity exceeded SALS at station DPS-4 after 1977. Both declined in activity after effluent ceased to be released into the SWMU. Recent year samples have all shown activities below the SAL values. The systematic relationships among multiple contaminants are complex, involving interactions among surface and ground water hydrologic and geochemical processes, and understanding may also require detailed knowledge of the effluent discharge and surface water history.

ABSTRACT

Science and Engineering Associates, Inc. (SEA) has developed a unique and versatile method of transporting characterization tools into pipes, drain-lines, and ducts. The system, called the Pipe ExplorerTM, uses a pressurized inverting membrane to tow sensors such as radiation detectors, video cameras, and pipe locator beacons through pipes. In addition to towing characterization tools, such as a radiation detector, the membrane also lines the pipe to provide a clean conduit through which the detector travels. This protects expensive sensors by preventing removable contamination from coming into contact with them. Cross contamination is thus eliminated allowing the system to obtain a true measurement of contaminant activity as a function of distance. The system is currently capable of transporting detectors up to 250 feet in pipes 2 inches in diameter and greater. It can also negotiate multiple elbows and obstructions. The DOE Morgantown Energy Technology Center sponsored the development of this technology as a characterization tool to support the decommissioning and decontamination of DOE nuclear process facilities. Recently the system was demonstrated at a site being remediated under the DOE Formerly Utilized Sites Remedial Action Program (FUSRAP). The Pipe ExplorerTM successfully characterized a total of 8, 4-inch diameter buried drain-lines, over lengths as long as 120 feet. The interior surfaces of the drain-lines were coated with a thick oily sludge that contained residual amounts of U-238. The drain-lines were continuously characterized over the entire lengths and were found to have contamination levels ranging from below 3000 dpm/100cm2 to over 1,000,000 dpm/100cm2.

By using the Pipe ExplorerTM system the DOE FUSRAP was able to save in excess of $1,000,000 in this single demonstration. These cost savings were realized through reduction of secondary waste and by avoiding more labor intensive and less accurate survey methods. A description of the system and samples of the data obtained from the FUSRAP site are presented. In addition, data substantiating the cost savings by the DOE are included.

INTRODUCTION

The U.S. Department of Energy's nuclear facility decommissioning program needs to characterize radiological contamination inside piping systems before the pipe can be recycled, remediated, or disposed. Historically, this has been attempted using hand held survey instrumentation, surveying only the accessible exterior portions of pipe systems. Difficulty, or inability of measuring threshold surface contamination values, worker

exposure, and physical access constraints has limited the effectiveness of this approach. Science and Engineering Associates, Inc. under contract with the DOE Morgantown Energy Technology Center has developed and demonstrated the Pipe Explorer system, which uses an inverting membrane to transport various characterization sensors into pipes. The basic process involves inverting (turning inside out) a tubular impermeable membrane under air pressure. A characterization sensor is towed down the interior of the pipe by the membrane.

Advantages of this approach include the capability of deploying through constrictions in the pipe, around 90 bends, vertically up and down, and in slippery conditions. Because the detector is transported inside the membrane (which is inexpensive and disposable), it is protected from contamination and cross-contamination is eliminated. Characterization sensors that have been demonstrated with the system thus far include: gamma detectors, beta detectors, video cameras, and pipe locators. Alpha measurement capability is currently under development.

A remotely operable Pipe Explorer system has been developed and demonstrated for use in DOE facilities in the decommissioning stage. The system is capable of deployment in pipes as small as 2-in-diameter and up to 250 ft long. This paper describes the technology and presents measurement results of a field demonstration conducted with the Pipe Explorer system at a DOE site. These measurements identify surface activity levels of U-238 contamination as a function of location in drain lines. Cost savings to the DOE of approximately $1.5 million dollars were realized from this one demonstration.

PROBLEM

By their nature, the interiors of pipes and ducts are difficult to access. In many cases, even the exteriors are inaccessible. For example, drainlines are buried or encased in concrete and duct work is often elevated or enclosed. To access these structures for characterizations such as radiological surveys, requires significant effort and cost. These costs are further increased if the characterizations are carried out in a radiological control zone, where greater personal protective measures and support crews are required.

Furthermore, for alpha and beta emitting contaminants, such as U-238 and Pu-239, it is necessary to take unobstructed measurements of contaminated surfaces. Thus, external measurements through pipe walls are inadequate and the only way to gather data is to get an instrument inside of the pipe.

Alternative methods to the Pipe Explorer system can be used to transport detectors into pipes, such as pipe crawlers and push rods. However, these methods lead to ambiguous results if there is removable contamination present. With nothing to prevent contamination from getting on the detector there is no way to differentiate between contamination on the pipe wall and contamination on the detector. There are additional limitations associated with these alternative methods. For example, pipe crawlers are typically limited to larger diameter pipes (> 4 in). They are also cumbersome to operate around elbows and have a difficult time in pipes with slippery surfaces. Push rod methods are limited in length and are often unreliable when trying to get a detector around elbows.

SOLUTION

As a solution to this problem, SEA adapted its inverting membrane technology to transport radiation detectors and other characterization tools into pipes. The system uses an air-tight membrane configured such

that when it is pressurized it inverts into a pipe. As it inverts the pressure force on the end of the membrane is adequate to tow a detector around multiple elbows and through several hundred feet of piping. This technology not only provides an effective transportation method for detectors, but it also provides a clean conduit through which the detector can travel.

TECHNOLOGY DESCRIPTION

The primary components of the Pipe Explorer technology are illustrated in Fig. 1. The heart of the system is an air-tight membrane which is initially spooled inside of a canister. The end of the membrane protruding out of the canister is folded over and attached to a basepipe. When the canister becomes pressurized in this configuration, the air pressure on the membrane causes the membrane to be pulled from the spool. This continues until the membrane is completely off the spool. A characterization tool, such as a radiation detector, is attached to the end of the membrane and towed into the pipe as the membrane continues to invert. The detector cabling is also towed into the pipe from the spool. To retrieve the system from a pipe, the process is simply reversed, where the cabling, detector, and membrane are wound back onto the spool. The system can thus be used to move a detector freely back and forth through a pipe while the detector output and position are continuously recorded. As a result, the Pipe Explorer system provides high resolution analysis of the location of radioactive contamination in pipes.

The membrane also provides a clean conduit through which the detector travels. This protects both the detector and the workers handling it. Furthermore, measurements are inherently more reliable. A detector transported in any other fashion runs the risk of removable contamination adhering to the sensor, which can cause erroneously high or false positive readings.

The general operating procedure is to first deploy the membrane halfway into the pipe. This is the point where the detector begins to enter the pipe from the deployment canister. At this time data acquisition is initiated. In most cases the detector is deployed out relatively quickly (up to 30-ft/min). More detailed radiological measurements are taken as the detector is retrieved from the pipe at a slower rate.

As the detector is being retrieved, the tether is wound back into the deployment canister. The membrane prevents contamination from contacting the tether. However, as a precautionary measure, two sampling smears are used to swipe the entire surface of the tether and the detector. When the tether is completely retrieved the smears are surveyed with a pancake GM probe to ascertain if any contamination has potentially been transferred into the canister. To date, no contamination of the canister or tether has been noted. Once the detector has been retrieved and the survey completed (the detector can be re-deployed for additional data if needed), the detector is removed from the end of the membrane. The membrane is then fed through a diaphragm to an external reel assembly or manually fed into a disposal drum. The membrane being handled has been inverted. Therefore, the side of the membrane that has been in contact with the contaminated pipe is contained within itself (this is analogous to the way a Hazmat worker removes rubber gloves). The inexpensive membrane (about $0.03/ft) is then disposed. This secondary waste generation is minimal. Several hundred feet of membrane is easily compacted into less than a cubic foot.

Fig. 1

Capabilities Summary

The absolute maximum deployable distance of the system is currently limited by the length of cabling and canister size. The current configuration allows for 250-ft deployments. Longer distances may be achievable but no applications to date have required any longer attempts. Practical deployment lengths are limited by elbows in the lines and the diameter of the pipe. Table I lists typical results that have been achieved, in laboratory tests, and are used as general guidelines.

Table I

The Pipe Explorer system has been used to transport several different types of radiological measurement instruments. Table II lists these instruments and their descriptions.

Table II

SEA currently has two deployment systems available. The first is a fully automated system. With its motorized operation and built in deployment sensors, it allows for continual unattended pipe surveys. The second system is a smaller, manually operated system.

Additional uses of the Pipe Explorer have been identified and have either been nominally demonstrated or are being integrated with the system. These include;

- Transport of pipe locating beacons
- Transport of video cameras
- Alpha detection methodologies

RESULTS

An extensive demonstration of the Pipe Explorer was conducted for the DOE Formerly Utilized Sites Remedial Action Program (FUSRAP) at a site in Adrian Michigan. During the 1950's the Bridgeport Brass Company operated a Special Metals Extrusion Plant at the site. This was done under contract with the DOE, then the Atomic Energy Commission. The product of this operation was material for uranium fuel elements for reactors in Hanford, Washington, and the Savannah River Plant in South Carolina. Uranium handled in this operation included depleted, natural, and up to 2.1 percent enriched in U-235. The site is still an active factory where plastic automobile parts, such as door panels and dash-boards, are extruded and finished.

During production of the uranium fuel elements, waste material from the extrusion process mixed with oil from the machinery. This mixture subsequently flowed into the oil drainage system contaminating over 1000 ft of buried drain-lines with varying amounts of uranium tainted oil. In order to quantify the extent and degree of this contamination and to conduct post-remediation measurements, the DOE FUSRAP hosted a demonstration of the Pipe Explorer system.

SEA conducted surveys at the site on two separate occasions. The first occurred in April 1995 and the second in May 1995. Thirteen surveys were carried out in eight drain-lines. Several lines were surveyed more than once to confirm success of remedial actions. Two Pipe Explorer deployment systems were used with 3 different radiological sensors. The first system used during the April demonstration was a manually operated system. Deployment with this system is controlled by a hand crank. Figure 2 shows the system in operation at the site.

Fig. 2

With this system, the detector is deployed to a specified location where the position of the detector and its output are recorded by the operator. Figure 3(a) shows data from one of the surveys conducted with the

manually operated Pipe Explorer system in conjunction with a beta detector. The data was taken prior to any remedial actions. Thus, the drain-line had a substantial amount of thick oily sludge in it (about the consistency of peanut butter). The detector and its tether were successfully deployed and retrieved with none of the oily contamination coming into contact with the detector, tether, or workers. The data in Fig. 3(a) was obtained with a detector designed and calibrated by the DOE Grand Junction Projects Office Radon Laboratory (1).

For the second stage of the demonstration carried out in May 1995, the automated Pipe Explorer system was used with a higher sensitivity beta detector. The system canister includes a motorized reel and a deployment distance measurement sensor. Additional sensors in the canister such as a slack indicator, a tension meter, and pressure transducers enable the system to run with minimal operator interaction. All outputs from the sensors are displayed on a control panel. In addition, they are recorded and displayed on a laptop computer acting as a virtual instrument through a LabView program. The radiological data is also recorded on the laptop so that surface activity as a function of distance into the pipe can be monitored in real time. Figure 4 shows the automated system in use at a DOE site.

A sample of the data obtained with this system is shown in Figure 3(b). The actual drain-line begins at a distance of 27 ft. Since access to the drain-line was obtained through a deep manhole it was necessary to construct a conduit of this length to guide the membrane to the drain line entrance. The structure of this data shows the utility of a continuous survey. The data shows a small amount of contamination up to the 40-ft mark in the drain-line. At this point the line intersects another drain line which had been thoroughly cleaned. After the intersection, however, substantial contamination was encountered. The only exception was a relatively clean section between 90 and 100 ft.

Fig. 3

Fig. 4

Confirmation of the Data

Data obtained with the Pipe Explorer system at the FUSRAP site was verified with several methods. The first was purely qualitative, where the membrane was visually inspected as it was retrieved from the drain-line. This was useful in such instances as shown in Fig. 3b where the data showed significant structure. For example, a large amount of the oily sludge was noted on the portion of the membrane that had traveled 100 to 120 ft into the drain-line. The portion of the membrane around 98 ft had virtually no oil on it, but below 90 ft substantial amounts of the oily sludge were again seen on the membrane.

Another validation method used was to measure the activity of contamination adhering to the membrane as it was being retrieved. Measurements were taken with a conventional pancake GM probe. This data is shown as triangles in Fig. 3b. The distance accuracy for these measurements is substantially less than the accuracy of the Pipe Explorer data (pancake meter data accurate to approximately 2 ft, Pipe Explorer accurate to 1 in). Surface activity measured with the Pipe Explorer is consistently higher than that measured with the pancake GM probe because the Pipe Explorer system measures the contamination in the pipe and the pancake GM probe measures only the contamination that adheres to the external surface of the membrane. Furthermore measurements with the

pancake probe are not calibrated for attenuation effects of the membrane, whereas the data obtained by the Pipe Explorer system is.

Confirmation of the data was also attempted by pushing a small GM detector into the drain-line. However, contamination adhering to the GM probe assembly tended to obscure the measurement of contamination on the pipe wall.

Detector Calibration

The ideal way to confirm the Pipe Explorer system data would have been to excavate a portion of a drain line and have it analyzed. However, the motivation for using the system at the FUSRAP site was to avoid excavating drain-lines. Therefore, confidence in the data was obtained through rigorous calibration of the detector.

Detectors used with the Pipe Explorer system are specifically calibrated for each use. They are calibrated with an isotope of similar energy of the contaminants that are suspected in a pipe and calibrated in the same measurement geometry. For example, U-238 was suspected at the FUSRAP site. Therefore, Sr-90 was used as a calibration source (U-238 is not available in sufficiently high activities for calibrations). The daughter product of Sr-90 (Y-90) emits a beta particle with similar energy as the dominant U-238 daughter product, Pa-234m. The Sr-90 calibration source has a known activity traceable to the National Institute of Standards and Technologies. Using this calibration source results in slightly elevated detection efficiencies because of a lower energy beta emitted by Sr-90 (546 keV max.). This emission is more heavily attenuated by air and the membrane material than the higher energy beta from Y-90, but no effort was made to determine this difference. The significant added cost of assessing this effect on the calibrations was not deemed necessary, since the error was not considered significant (on the order of 20 percent) and results in conservative measurements.

The calibrations were carried out to best simulate the measurement conditions that would be encountered at the FUSRAP site, where the detector rests on the bottom of a 4-in pipe inside of a 4-mil polyethylene membrane. Therefore, all of the calibration measurements were made through a sample of the membrane material in 4-in pipe. The fundamental procedure used in the calibrations was to move the calibration source to various grid locations surrounding the detector and determine the probe response at each location. The response of the detector to the Sr-90/Y-90 source was integrated over all angular and axial positions to determine detector response to distributed contamination inside of 4-in pipes. The response of the detector to a check source in a fixed geometry was recorded immediately before and after the detector calibrations. The check source measurement was repeated prior to and after each drain-line survey at the FUSRAP site to verify the detector performance had not changed since the calibration.

BENEFITS

The use of the Pipe Explorer offers many technical benefits. These include;

- Video surveys
- 100% gamma and beta surveys of pipe interiors, even in buried pipes.
- 100% alpha surveys of pipe interiors (available soon)
- Detector does not become contaminated
- Removable contamination is not spread along pipe.
- Personnel exposure significantly reduced.
- Immediate results.

Technical benefits such as the ones listed above for the Pipe Explorer are usually heralded as the pay-off for a DOE investment in a new technology. However, the primary reason the DOE provides funding for development of environmental technologies is so that economic benefits will result through more expedient and cost effective methods. Substantial cost savings have already been realized from use of the Pipe Explorer system at the FUSRAP site demonstration. These cost savings to the DOE are nearly three times the amount invested in the development of the Pipe Explorer system.

The DOE FUSRAP recognized that the cost of excavating buried drain-lines at the site in Adrian, MI would be substantial. Therefore, they developed a methodology to avoid these excavation costs. The plan was to verify that activity levels of contamination in the pipes were below a criteria level of 7x105 dpm/100cm2 (averaged over the length of the drain-lines). It was determined through a hazard assessment that such levels of contamination posed no threat to the general population. Thus,the drain-lines could be left in place after filling them with grout to seal the contamination. If surface activities were found in excess of the criteria level then the drain-lines were to be flushed and cleaned prior to grouting.

The initial method used to characterize the drain lines was to insert a small geiger-mueller (GM) detector directly into the drain lines. This was soon found to be an ineffective method because of the abundance of removable contamination. The contaminated oil would adhere to the detector, making it difficult to differentiate between measurements of contamination on the pipe walls and contamination directly on the detector. In addition, only limited lengths of the drain-lines could be accessed since in many cases the detector could not be shoved around elbows.

The benefits of using the Pipe Explorer over direct insertion of a detector were readily seen in surveys of one of the drain-lines. Data initially obtained with the manually operated Pipe Explorer system from this drain line showed surface activity levels in the pipe in excess of the 7x105 dpm/100cm2 criteria level. The drain-line was then cleaned and a subsequent survey was conducted. Activity levels were found substantially reduced with the exception of a hot spot near the beginning of the drain-line. A detector manually inserted into the pipe would have come into contact with this hot spot and measurements through the rest of the drain-line would have been inaccurately high. Therefore, the Pipe Explorer system provided accurate results showing that the drain-line was within the criteria level. Similar results were obtained in the other seven drain-lines surveyed.

Had data not been available from the Pipe ExplorerTM system there would not have been an accurate way to assess activity levels in the drain-lines. Therefore, it would have been necessary to excavate them. It is estimated that the costs to excavate the drain-lines would have been on the order of $1.2 million (2). However, this estimate neglects the fact that the site is an active automotive parts factory. Therefore, costs associated with plant impacts and relocating factory operations should also be included. Factory personnel have current estimates of these costs from prior experiences of modifications to the plant. Their estimate of these costs are about $0.8 million. The cost savings were diminished somewhat by the expense of cleaning the drain-lines and disposing of the

waste generated from the cleaning. This cost is estimated at $0.5 million. Therefore, the net savings is estimated to be;
$1.2 +$0.8 -$0.5 = $1.5 million

FUTURE ACTIVITIES

The development of the basic Pipe Explorer system which includes gamma and beta detection capability is nearing completion. The final aspect of this phase of development was to demonstrate the system at another DOE site during November 1995. Video inspection capability of the system was demonstrated along with radiological surveys. Significant cost savings ($0.5 M) to the DOE were also realized from this demonstration of the system.

The Pipe ExplorerTM system is now available for service work as an inspection tool. A great deal of interest has already been expressed in using the system at;

- Rocky Flats
- Los Alamos National Laboratory
- Sandia National Laboratory
- Other FUSRAP Sites
- and Argonne National Laboratory

In July of 1995 the development of an enhancement to the system was funded by the DOE METC. This will enable the system to be used for detecting low levels of alpha emitting contaminants such as Pu-239. This will be accomplished by making the inverting membrane component of the system an alpha sensitive scintillator. A photo-detector, towed through the membrane, much the same way as gamma and beta detectors, will quantify activity levels as a function of length over 100% of the internal surface area. After this enhancement is added to the system, complete alpha/beta/gamma surveys will be possible with the Pipe Explorer system.

ACKNOWLEDGMENTS

SEA wishes to thank Mr. C. Edward Christy of METC for his diligent and enthusiastic support as COR of the Pipe Explorer system development. SEA also wishes to thank Mr. Al Tardiff of EM-50 who has helped in finding demonstration sites for the system. We also thank Mr. James D. Kopotic of the FUSRAP for agreeing to host the demonstration of the Pipe Explorer system. Finally we wish to thank Mr. Marty Keller and Mr. Gil Drexel of Bechtel along with the site crew at the FUSRAP site who were all extremely helpful in the successful demonstration of the system.

RADIOLOGICAL CHARACTERIZATION OF WASTE UNDER THE DOE WASTE MORATORIUM

S. Gibson
Benchmark Environmental Corporation
Albuquerque, New Mexico 87110

ABSTRACT

In response to the release of radioactively contaminated wastes from DOE facilities to non-licensed commercial Treatment, Storage, and Disposal (TSD) facilities, the Office of Waste Operations (EM-30) issued a

moratorium on DOE shipments of hazardous and toxic waste that had the potential for radioactive contamination. To ship waste under the moratorium each facility is required to defend their characterization and certification programs against the requirements of the EM-30 Performance Objective for the Waste Moratorium (PO) (DOE 1994b). The PO defines Radioactive Material Management Areas (RMMAs), and requires waste characterization for radiological contamination both at the surface and in volume. These actions have resulted in an increase in the volume of waste managed as radioactively contaminated.

This report presents a methodology for certifying radioactive waste characterizations in compliance with the requirements of the PO. The methodology addresses the unique definitions of radioactive and mixed waste presented in the PO as well as the logistics of establishing and managing RMMAs. Recommendations are made for using existing waste management and radiation control documentation to develop a documentation package capable of defending characterizations of "no radioactive waste present". Proper implementation of the methodology presented can significantly reduce the volume of radioactive and mixed waste generated at DOE sites.

HISTORY

In order to implement a successful program for certifying the radioactive status of wastes, it is important to understand the history behind the Department of Energy (DOE) waste moratorium and the affect it has had on the DOE complex.

What is the DOE Waste Moratorium?

The DOE Waste Moratorium (moratorium) is a one page memorandum issued on May 17, 1991, by the Office of Environmental Restoration and Waste Management, Office of Waste Operations (EM-30). This memorandum called for a freeze on shipments of hazardous waste as defined by the Resource Conservation and Recovery Act (RCRA), and toxic wastes as defined by the Toxic Substances Control Act (TSCA) which had the potential for being radiologically contaminated. The memorandum required the freeze to remain in effect until a DOE-HQ Moratorium Review Team could review and approve the site's, programs, and procedures for certifying "No Radioactive Waste Present." This approval is based on the facility being able to meet all of the criteria established in the PO. The PO is a series of requirements defining what is required to defensibly characterize and certify the radiological nature of wastes.

Why was the moratorium established?The moratorium was established as a result of the lack of "de minimis" standards (amount of radioactivity below which there is no concern for disposal) for radioactivity in waste. Because there is no de minimis standard each facility within the DOE complex was left to establish their own waste release criteria.

From 1980 to 1991, the DOE shipped hazardous waste containing low levels of radioactive materials to commercial treatment, storage, and disposal (TSD) facilities which were not licensed to receive radionuclides. This was discovered when ash from the Rollins Incinerator facility in Baton Rouge was monitored and found to be radioactive. The ash was generated from shipments of uranium-contaminated waste from the Oak Ridge and Savannah River sites. These shipments occurred due to the use by these sites of self-generated standards which defined waste containing low levels of radionuclides as non-radioactive. The self generated standards had not been formally approved by DOE. DOE acted to end this practice by imposing the moratorium on the off-site shipment of all DOE hazardous and

toxic wastes which had the potential to contain radioactive material until the programs and procedures of each field installation could be reviewed and approved of by DOE-HQ.

What have been the effects at DOE Sites?

The moratorium established a new area designation called a radioactive materials management area (RMMA). A RMMA must be established around any location which has the potential for generating radioactively contaminated waste. Most DOE sites have taken a very conservative approach in designating RMMA boundaries. All wastes from RMMAs are defined as potentially radioactively contaminated or suspect radioactive. That results in managing nonhazardous waste (e.g., paper, plastic, glass) as radioactive waste, and hazardous waste (e.g, waste lead, waste solvent, corrosives) as mixed waste. For most DOE sites the amount of mixed and low-level radioactive waste generated increased greatly after imposition of the moratorium.

The impact from the increased mixed waste volumes has been severe due to the limited capacity for mixed waste treatment and disposal. Without the ability for disposal, mixed waste volumes in storage have increased greatly. Mixed wastes are regulated by the RCRA as a Land Disposal Restricted (LDR) waste. LDR wastes can be stored for one year only. Many regulating agencies have granted extensions to DOE sites for continued storage of mixed waste beyond one year, however, these extensions are not indefinite. Regulators can elect to cancel these extensions and cite facilities with storage violations. These violations can result in fines of up to $10,000 per drum, per day.

This report provides a methodology for operating in compliance with the PO, while reducing the volume of waste managed as suspect radioactive.

PERFORMANCE OBJECTIVE REQUIREMENTS

In order to have the moratorium lifted, a site must show compliance with the requirements established in the PO. This report does not discuss all of the PO requirements, but, rather focuses on those requirements directly impacting radiological waste characterizations.

Performance Objective Definitions

The PO has redefined several terms commonly used within the waste management industry and added several new concepts for managing radioactivity in waste. The following definitions are now applicable at DOE sites and all procedures using these terms must utilize the PO definitions.

The PO definition of radioactive waste defines two aspects of contamination that must be addressed for all radioactive waste determinations. A radioactive waste is any waste managed for its radioactive content, which is not otherwise regulated for that content (e.g., emissions regulated by the Clean Air Act, and effluents regulated by the Clean Water Act). If nonradioactive material is used in a process, the resulting waste is not radioactive as long as no measurable increase in radioactivity is found above background in volume or bulk (at a statistically defined confidence interval); and the waste contains no surface radioactivity above limits established in DOE Orders or guidance. It is important to note that the surface criteria has not changed, it is only the definition of contamination in volume that presents a new challenge.

A mixed waste under the PO is a radioactive waste as defined above which is also regulated by either RCRA or TSCA. Radioactive TSCA waste, although not a mixed waste by regulation, is defined as such by the PO.

Most DOE sites have taken this concept one step farther, by managing all wastes and materials in accordance with PO criteria.

A RMMA is an area in which the potential exists for contamination due to the presence of unencapsulated or unconfined radioactive material or exposure to high energy beams or particles (neutrons, protons, etc.) capable of causing activation.

Unrestricted release (i.e., free release) is a release of property (e.g., waste), based on a formal, documented decision reflecting risk-based standards, licensing considerations, and associated implementing procedures, that the property may be utilized, treated, or disposed of by any party without concern for radioactive content. The PO definition has specified treatment and disposal for unrestricted release due to the potential for concentrating radionuclides during these processes. This definition arose from the incident at the Rollins incinerator.

Basic Principle of the Performance Objective

The PO is a lengthy and complex document, but, it can be reduced to one basic principle. This principle is that mixed waste, as defined above, is not to be shipped off-site to a facility unless that facility is specifically licensed for the receipt of the radioactive component of the waste.

Three Cases of the Performance Objective

To ensure that the basic principle of the PO is met, three cases (i.e., waste management scenarios) have been defined for the management of wastes. In the first case the waste is determined to be a non-radioactive hazardous waste and is shipped off-site for treatment and disposal. If the waste is determined to be a mixed waste it can be managed, treated, and disposed of at DOE sites as a second case. If no capacity exists within the DOE for the treatment and disposal of mixed waste, the third case allows the waste to be shipped to a licensed off-site commercial facility for treatment; then the residual is disposed of in a licensed and/or permitted commercial disposal facility or returned to DOE for treatment/disposal. If the third case is selected the site securing the vendor must obtain an approved DOE Order 5820.2A, Radioactive Waste Management (DOE 1988), exemption for use of the facility.

Determining the Radioactive Status of Waste

In order to select a case to operate under the site must determine the radioactive status of their waste. This characterization can be made through process knowledge or survey, sampling, and analysis. Survey techniques are widely used for determining surface contamination, however, their application for characterizing volume contamination can be impractical, especially for heterogenous wastes. Process knowledge is often the only method available or practical for characterizing volume contamination. If process knowledge is selected as the characterization method it must be accomplished in accordance with PO requirements. These requirements have been established to ensure that the quality of process knowledge is adequate to certify that no radioactive waste is present.

Process Knowledge

A generator must show knowledge of three critical elements in order to use process knowledge for radioactive waste determinations under the PO. These critical elements are knowledge of waste origin, use, and potential for exposure.

Critical Elements

Knowledge of waste origin is defining the radioactive nature of the materials involved with waste generation. Were the materials used to

generate the waste radioactively contaminated? Knowledge of use goes one step farther to evaluate the waste generating process. If radioactive materials are present in an operation, does the process contaminate the wastes generated? Finally knowledge of potential for exposure involves defining the areas where the waste is generated and stored. Was the waste generated or stored in an area where a potential for contamination existed (i.e., in a RMMA)?

A REALISTIC METHODOLOGY FOR PROCESS KNOWLEDGE

Now that we have an understanding of the moratorium and the PO we will present a waste characterization program addressing PO criteria while supporting efficient operations. The program utilizes the waste management and radiological control practices routinely used at DOE sites to provide the process knowledge and documentation necessary to certify the radioactive status of waste.

Knowledge of Origin

The DOE Radiological Control Manual (RadCon manual) (DOE 1994a) establishes requirements for the identification and labeling of radioactive materials. These requirements are intended to maintain radiation exposure to workers and the public as-low-as-reasonably-achievable (ALARA). This control of radiation and radioactive materials forms the basis of the generator's knowledge of origin. If no radioactive materials were used in a waste generating process and the waste was not subjected to radiation of an energy capable of causing activation, the waste is not radioactive. For most routine operations knowledge of origin is already established through RadCon manual requirements for identification and labeling of radioactive materials.

Sometimes wastes are generated from materials whose origin is uncertain. Decommissioned facilities, equipment, and weapon components usually have insufficient documentation to certify the waste origin as non-radioactive. If this is the case survey and assay techniques for surface contamination can be used to show impermeable materials are non-radioactive. However, if the waste is a permeable substance or has a potential for volume contamination, a sampling and analysis approach approved by EM-30 or an approved area office is required for characterizing the waste. Although the potentially volume contaminated material requires additional analysis, survey results showing surfaces below release levels can be used to release secondary wastes (e.g., gloves, laboratory wipes) generated during management of the material.

Knowledge of Potential

Knowledge of Potential can be established simply by identifying the RMMA status of waste generation and storage locations. Remember, a RMMA is defined as an area where the potential for radiological contamination exists. If a waste can be generated and managed outside of RMMAs it has never had the potential for being contaminated and can be declared a non-radioactive waste. It is therefore, beneficial to reduce the size of RMMAs as far as practical. Many DOE sites have established extremely conservative RMMA boundaries, some extending around entire facilities. The large size of many RMMA boundaries is often due to complicated and onerous programs developed for establishing and maintaining these areas.

Knowledge of Use

Information from radiological control and characterization programs and the RMMA status of waste management locations can be used in conjunction with procedural evaluations to establish knowledge of use. To properly apply knowledge of use, generators must understand the behavior of the

radionuclides involved in their processes. For example, tritium, a radioactive form of hydrogen, is capable of contaminating hydrogenous materials, via molecular exchange, without noticeable physical contact. To ensure generator understanding, an approval process for waste generators should be established providing instruction on the PO requirements. Once trained, approved generators, should be able to defend their knowledge of use.

A REALISTIC APPROACH TO RMMA MANAGEMENT

Establishing RMMAs

A formal program should be developed for establishing RMMAs. The radiation control group for a site is usually best prepared to establish RMMA boundaries. The process used for establishing RMMAs should be simple and support RMMA boundary changes as needed.

In order to determine whether a RMMA will be necessary for a given location, two questions must be answered. The first question is, does this location have the potential for activating waste? This question can be answered in a two step approach by first asking the generator if the location generates photons in energy above 7 millielectron-volts (MeV), has a neutron source, or has a particle accelerator present. If the generator responds positively to these questions, then the location and operations should be reviewed by a health physicist to evaluate the source and potential targets for activation potential. The second question is, are there any unencapsulated or unconfined radioactive materials present at the location? This question can be easily answered by a trained generator. If an activation potential exists or there is unconfined radioactive materials present, a RMMA is required. If the area was previously a RMMA, but no longer meets the RMMA criteria, area surveys can be used to release the location. If surveys show that the area is free of contamination above DOE Order 5400.5, Radiation Protection of the Public and the Environment (DOE 1993), release limits then it can be determined that no potential exists to contaminate waste. By making the RMMA determination criteria easy for generators to understand, RMMA boundaries can be established appropriate for the operation. Area surveys in conjunction with documented answers to the questions presented above are adequate to release a location from RMMA status. This approach is more efficient than complex management plans that require extensive paperwork on the part of the generator. With smaller and more realistic RMMA boundaries the volume of radioactive waste generated can be greatly reduced.

Posting RMMAs

The posting used for a RMMA identifies the area as one where the potential exists for radiological contamination of waste according to the PO definition. The posting should not be interpreted as a warning for personnel exposure. As stated earlier, there is no de-minimis quantity for radioactivity in waste. The RMMA is established for levels of potential contamination well below the level where personnel risk is an issue. Radiologically controlled areas defined by the RadCon manual are established to control exposures to personnel. RMMAs are established to minimize the amount of waste managed as radioactive. For this reason postings established for RMMAs should contrast visually from RadCon manual control area postings.

Operating in RMMAs

In order to perform work in a RMMA, a generator should be trained on the requirements of the PO and waste minimization planning. Because the RMMA

has the potential for contaminating waste, it is important to minimize the amount of expendable material taken into the area. Anything that has entered into a RMMA must be managed as radiologically contaminated unless a justification can be made that the item is clean. Developing defendable justifications takes time and resources therefore, it is more advantages to reduce the volume of waste generated in a RMMA.

Release of Materials/Wastes from RMMAs

In order to release material from a RMMA as "Not Radioactively Contaminated" a justification must be documented and readily retrievable. The justification for process knowledge determinations must demonstrate knowledge of origin, use, and potential for exposure.

Release of material from one RMMA to another is not considered an unrestricted release and therefore surveys are not required. Likewise when moving a material from a Non-RMMA to a RMMA no survey is required. However, when bringing material into a RMMA previous determinations that the material was not contaminated are placed in doubt.

Surveys can be used to release non-permeable items that have no potential for volume contamination. If items are moved across RMMA boundaries routinely, survey data can be accumulated and used to release the process. For example, a tool is used for the same operation and is moved across the RMMA boundary, if survey data is sufficient to statistically show that the item does not become contaminated in the process, the tool can be moved across the boundary without survey. Verification surveys (i.e.,surveys conducted on a scheduled basis) should be used to validate previous process characterizations. Verification survey frequency can be chronological (e.g., weekly, monthly) or process based (e.g., one survey for every 20 processes).

Waste Disposal

The moratorium was established to ensure that no mixed waste is sent to an off-site TSD facility unless that facility is specifically licensed to manage the radionuclides present in the waste. At DOE sites a few general rules of thumb will ensure that this criteria is met. All wastes generated inside of a RMMA should be disposed of in containers located within the RMMA and wastes generated outside of a RMMA should be disposed of in containers located outside the RMMA. Waste containers should be labeled to identify the RMMA status of the location and wastes should be removed from a location before RMMA boundaries are modified.

DOCUMENTATION

Proper documentation of process knowledge is critical for securing certification that wastes are not radioactive. The following forms are routinely used at DOE sites and can be modified to meet the criteria of the PO.

Origination Label

An origination label should be used to identify whether the material has been in a RMMA. This label identifies the materials point of origin as either a RMMA or a Non-RMMA. The label should be attached to all items coming from RMMAs unless another form of container documentation provides this information. For Non-RMMAs the label can be used to certify materials as not radioactively contaminated. The origination label can be issued by anyone with authority over the waste.

Radiation Survey Form

In order to free release a waste it must be shown to have no radioactive contamination on the surface and in volume. The surface can be defended as clean through surveys. These surveys must be recorded on a form to

document the determination. Proof that wastes are not contaminated in volume must also be documented. The generator should record and certify process knowledge on the survey form, (e.g., a container of hazardous solvent was not opened in the RMMA). Now the information necessary to make the determination that the material is "Not Radioactively Contaminated" is present in one document. The waste container number should be included on the radiation survey form to facilitate retrieval.

Free Release Label

A free release label is a certification that accompanies waste determined to be non-radioactive. The label can be issued when survey results show that surface contamination is below DOE Order 5400.5 release levels and justification is given that the volume is free of contamination. The label is an essential piece of documentation and should be protected. A free release label should only be issued by the group responsible for offsite certification. An origination label certifying that the waste was generated outside of a RMMA can be used in stead of a free release label to certify that the waste is not radioactive.

Surface Release Label

A surface release label is used to identify wastes which meet DOE Order 5400.5 surface release criteria, but have the potential for volume contamination. The surface release label allows a waste to be moved onsite for controlled release. The surface release label cannot be used to release a material offsite or for intrusive processing. Only the radiation control group should issue surface release labels.

Radioactive Material Label

The radioactive material label is used to identify equipment, components, and items that are radioactive, potentially radioactive or have been exposed to radioactive contamination or activation sources. They are also required for sealed and unsealed radioactive sources or associated storage containers. The radioactive material label must meet the RADCON labeling requirements to ensure that items are not accidentally released or processed as non-radioactive. The radioactive material label should be issued by anyone with authority over the item.

Container Inventory Form

Many DOE sites use a container inventory form to document the contents of a waste package. The inventory, in addition to providing adequate information on the make up of the waste, should identify the RMMA status of the waste generation location. In fact the RMMA status for the location of the container should be completed before any waste is placed in the container. The RMMA status on the inventory ensures that radiological characterizations are adequately documented for each waste container.

Waste Disposal Form

Many DOE sites also use waste disposal forms to provide communication between waste generators and waste management personnel. The waste disposal form usually identifies the labeling requirements for the waste package and provides a place for the generator to certify that the waste placed in the drum was approved for that container. This form like the inventory sheet should identify the RMMA status of the generation location. A disposal form is usually completed for each waste container shipped offsite for disposal. Many times wastes are compiled into one drum from several other containers. That is why it is necessary to identify the RMMA status on the container inventory sheet. From the

container inventory sheets, personnel responsible for drum disposal can accurately determine the RMMA status of the disposal drum.

Waste Shipment Checklist

A waste shipment checklist should be used to identify the containers sent under a given manifest, ensure that certification criteria are met, and verify that certification documentation has been compiled. The checklist provides a vital link between the information sent with a waste shipment and the supporting documentation maintained at the site. If the checklist is constructed properly, certification documentation can be maintained by different groups at different locations within a site and still be easily retrieved. The checklist should confirm that all non-radioactive waste packages have documentation showing the waste was generated outside of a RMMA or justifying the non-radioactive determination based on knowledge of waste origin, use, and potential for exposure. If the waste is radioactive the checklist should reference the radiological characterization data showing the waste is within offsite TSD facility license restrictions.

Traceability of Rationales

The PO requires traceability of each waste container certification to the documented rationale for the decision that no radioactive waste is present. Traceability can be accomplished through the compilation of a shipment file. The shipment file should include all paperwork specific for a waste shipment, such as a copy of the manifest, waste shipment checklist, waste disposal forms, waste container inventories, origination labels, and free release labels. The waste shipment checklist provides a listing of all containers shipped under a specific manifest. For each container, a file of all container inventories, disposal forms, and labels should be compiled. The container inventories will identify the RMMA status of the location where the waste was generated. All free release labels associated with the container provide certification of "No Radioactive Contamination" and radiation survey forms provide the rationale used to free release containers generated in RMMAs.

In a scenario where a single drum is in question, such as a drum found off-site, or a TSD facility radiation alarm is set off, certification personnel can retrieve survey data, process knowledge rationales, and certifications generated throughout the waste management process defending the radiological characterization.

CONCLUSION

The basic methodologies presented here, when properly implemented, can greatly reduce the volume of suspect radioactive waste generated and can provide a mechanism for better controlling the radiological status of materials. The approach utilizes standard conventions used throughout the DOE to provide the documentation necessary to defend radiological characterizations. This approach cannot be used for all wastes and some survey sampling and analysis will be required for non-routine waste, however, the majority of process waste can be effectively managed under this methodology.

U. S. DEPARTMENT OF ENERGY NEVADA OPERATIONS OFFICE (DOE/NV) LOW-LEVEL WASTE (LLW) DISPOSAL COST ANALYSIS

Steve D. Karney
Max R. Dolenc
Kirk D. Lachman
USDOE - Nevada Operations Office

ABSTRACT

The Nevada Test Site (NTS) is a major waste disposal site for low-level radioactive waste generated by DOE installations. Approximately 22,300 cubic meters (796,625 ft3) per year of LLW have been disposed at the NTS in the last four years, placing it among the waste volume leaders for radioactive waste disposed in the United States. The waste disposal costs at the NTS are significantly lower than the other DOE and commercial disposal sites around the United States.

A waste generator fee for disposal of LLW at the NTS has been used since 1978. However, the generator fee does not provide a full cost recovery for all functions of LLW disposal at the NTS. Additional funding is obtained from DOE/Headquarters (HQs). This paper addresses the costs associated with LLW disposal at the NTS and the factors that keep the costs minimal. Some of the factors that will be discussed are operations efficiency and productivity savings. The factors do not hinder the state regulator views or the safe operation of the disposal site. The DOE/NV costs to dispose of waste at the NTS include all activities (i.e., performance assessment, site monitoring, site characterization, waste acceptance program, etc.) associated with complying with DOE Order 5820.2A, "Radioactive Waste Management," in addition to the actual waste disposal operations.

INTRODUCTION

The DOE/NV has two LLW disposal sites at the NTS: the Area 5 Radioactive Waste Management Site (RWMS) and the Area 3 RWMS. The Area 5 RWMS is located approximately 22 km (13 mi) north of the NTS entrance to Mercury in Frenchman Flat, an enclosed geological basin. The Area 5 RWMS consists of 296 hectares (732 acres), 37 hectares (92 acres) of which are being utilized for disposal of LLW. At the current rate of land utilization and a disposal rate of 11,552 cubic meters (407,901 ft3) of LLW per year, the facility can be expected to provide disposal capacity for 10,884,440 cubic meters (388,733,000 ft3) and will have a life expectancy of more than 900 years. Pits and trenches are used for shallow land burial at the Area 5 RWMS.

Fig. 1

The Area 3 RWMS occupies an area of approximately 50 hectares (125 acres) and is approximately 38 km (23 mi) north of Mercury and 17 km (10 mi) north of the Area 5 RWMS. Adjacent subsidence created from underground nuclear weapons tests conducted at depths well above the groundwater table are used as waste disposal cells for shallow land burial. The active disposal cell, U3ah/at, has an available volume capacity of

approximately 169,901 cubic meters(6,000,000 ft3). The remaining disposal capacity for the Area 3 RWMS, which includes three additional subsidence craters, is 1,745,767 cubic meters (62,348,832 ft3). The average disposal volume for the Area 3 RWMS is 11,694 cubic meters (412,906 ft3) and a life expectancy of 151 years.

Fig. 2

Fig. 3

SITE CHARACTERIZATION

The RWMSs are located in closed basins which receive the lowest precipitation of any LLW disposal site in the country. The disposal sites have the thickest unsaturated zones (deepest water tables) of all sites and are located in the most remote sites with respect to nearby population. The water table at the Area 5 RWMS is approximately 240 m (770 ft) below the surface. The Area 3 RWMS is located on an alluvial plain, and the water table is approximately 500 m (1600 ft) below the land surface.

COST ANALYSIS

Costs Associated With LLW Disposal

In order to determine the incurred and estimated costs for disposal, costs were categorized. The categories consist of: Programmatic costs (DOE regulatory activities, permits, other outside agencies, and required monitoring); Operational costs (direct activities of putting waste in the ground such as pit design and construction, maintenance of facilities, and security); and Program Support costs (program management, infrastructure).

Programmatic Costs

Costs to dispose of LLW at the NTS include all activities associated with DOE Order 5820.2A, "Radioactive Waste Management," which "establishes polices, guidelines, and minimum requirements by which DOE manages its radioactive and mixed waste contaminated facilities." Waste management activities associated with this order include the following:

Provide characterization and engineering data for the systematic analysis of the potential risks posed by the waste management site to the public and the environment (i.e., Performance Assessments);

Establish waste acceptance criteria and audit any waste generating organization that ships waste to the NTS;

Assure that quality assurance activities are established and implemented for all waste management activities; and

Establish and maintain an integrated database program for all types of waste under DOE/NV purview.

Other activities which are part of programmatic costs include the LLW portion of the DOE/NV Site-Wide Environmental Impact Statement and site monitoring. State regulator involvement in LLW disposal is very proactive. The Nevada Division of Environmental Protection (NDEP) is actively involved in assuring that no mixed waste enters the state for disposal. The NDEP is confident that the LLW disposed at the NTS is free of hazardous constituents due to the strict and rigorous DOE/NV Radioactive Waste Acceptance Program.

Operational Costs

Activities related to the actual cost of burying waste consist of the following:

Engineering, design, and construction of new pits and trenches in the Area 5 RWMS and modifications to the subsidence craters in the Area 3 RWMS;

Waste handling capabilities for the Area 3 and Area 5 RWMS;
Health physics support for the facilities;
Purchasing equipment and supplies for RWMS operations;
Maintenance of existing facilities and roads;
Engineering, design, and construction of support facilities; and
Provision for specific user fees which include feeding, housing, janitorial, fire protection, and electrical power.

Program Support Costs

Activities which provide support for the actual burial of the waste include the following:

Overseeing budget responsibilities for disposing of waste and establishing a fee to recover the costs of disposal;
Generating budget requirements and reports for DOE/HQs; and
Preparing updates of waste management plans and procedures.

Generator Fees

A waste generator fee was established in order to recover incremental costs (disposal-dependent) associated with waste disposal at the NTS. The waste generators are required to provide to DOE/NV a "Three-Year Waste Shipment Forecast"; this forecast is updated on a quarterly basis. The generator issues a purchase order to the disposal contractor based on an estimate of the amount of waste expected to be shipped. In previous years, the generator fee only paid for the direct disposal of the LLW. In Fiscal Year 1995, DOE/NV received permission from DOE/HQs to add to the fee structure, a broader range of activities associated with complying with DOE Order 5820.2A.

COST COMPARISON

Attempts have been made in the past (Salomon, 1993) to compare the costs of LLW disposal facilities. This is not an easy task since all disposal facilities are designed differently, serve different functions, and are located in different geologic environments. Salomon attempted to compare proposed facilities located in two distinctively different environments: one facility was proposed as a earth mounded above grade vault in a humid site with a projected high volume capacity; the other facility was a below grade concrete canister technology in an arid site with much lower volume capacity. Life cycle costs varied by a factor of three, and unit costs were nearly 20 percent different. He found similar results for foreign LLW facilities. His conclusions were that significant differences in costs exist because of the variable environments in which the sites are located and the different designs which were planned.

Comparison With DOE Disposal Facilities

Similar differences exist when comparing costs of the NTS sites to other DOE and commercial facilities. A cost comparison study was initiated by DOE/HQ in FY 1995; this study compared LLW disposal costs at major DOE disposal facilities. The comparison study consisted of collecting FY 1994 and projected FY 1995 standard operational costs at six DOE disposal sites. The standard costs compared were: putting waste in the ground, routine maintenance, required monitoring, regulatory permits and other outside regulatory activities, DOE regulatory activities, Field Office program control and oversight, waste acceptance criteria activities, and overhead "taxes." The standard costs were compared to annual LLW disposal volumes and disposal fees. Out of the six disposal sites, the NTS ranked the highest in volume disposed by 313 percent and had the lowest cost per volume by 74 percent.

Table I shows total costs for LLW disposal operations at the major DOE disposal facilities.

Table I

One of the main differences noted in the study was the use of different disposal systems at the DOE sites. Savannah River disposes of LLW in an aboveground concrete vault, and Oakridge disposes of LLW in a tumulus. These engineered structures are more expensive than excavating a pit in the alluvium of the NTS or emplacing waste in a subsidence crater developed from an underground nuclear test. Idaho National Engineering Laboratory, Los Alamos National Laboratory, and the Hanford-Richland sites utilize unlined shallow land disposal for LLW. The primary difference in unit costs compared with the sites that use shallow land burial is the volume of waste disposed. The total cost per cubic meter decreases as the volume increases.

Comparison With Commercial Disposal Facilities

The cost of NTS disposal facilities compare well with the Barnwell facility, a commercial site located in South Carolina, which annually disposes approximately the same volume as the NTS. The comparison confirms that larger waste volumes result in a decreasing cost per unit volume since costs for labor can be spread over these larger volumes. The comparison becomes difficult when the cost per cubic meter is compared to the NTS because Barnwell costs depend on surcharges made on certain shipments of LLW.

OTHER FACTORS

Some of the other factors that keep the NTS costs favorable are controlling the manpower base and performing non-routine tasks with subcontractors. History has proven that as many as 38 shipments (truckloads) of waste can be inspected and off-loaded in one day. An analysis performed at the NTS indicated that an additional 50 percent of LLW can be disposed before it would be necessary to increase the labor force at the RWMS facilities.

CONCLUSION

The LLW disposal costs at the NTS are significantly lower when compared with other DOE sites and commercial facilities. The largest cost inhibitors are the geologic location of the NTS RWMS facilities, the type of LLW disposal utilized at the NTS, and the annual volume disposed. Another cost inhibitor is controlling the manpower base for LLW disposal operations.

EXPERIENCES FROM "POST-DRYING" OF SUPERCOMPACTED WASTE FROM THE INTERIM STORAGE BUILDING OF THE NUCLEAR POWER PLANT BRUNSBTTEL, GERMANY

Michael Szukala

Kai Tscheschlok
Hansa Projekt Anlagentechnik GmbH
Germany

William Behrens
NPP Brunsbttel GmbH
Germany

ABSTRACT
In the drum stores of different NPPs, several drums turned out to be bulged at their top and bottom regions due to the occurrence of drum-internal gas formation. Investigations have shown that, within a storage period of several years, the internal drum pressure can rise up to a value of 4 bar. Apart from nitrogen, mainly hydrogen is contained in the gas. The drums principally affected by these occurrences contain low level radioactive waste (LAW) in a super-compacted form (1).
The repository specifications in Germany stipulate that suitable waste conditioning measures be taken in order to prevent the waste in an effective way from producing gas (2).
In the following, the causes of gas formation in super-compacted mixed waste packages are going to be dealt with. It will clearly be shown that further gas formation can safely be avoided by drying such waste. Following an introduction on the drying process, the experience gained in the drying campaign presently being carried out at the Nuclear Power Plant of Brunsbttel (KKB) will be presented.

INTRODUCTION
Low level radioactive mixed waste from nuclear power plants contains a wide variety of substances, such things as cleaning rags, safety gloves, plastic sheets, insulating material, rubble. The waste often is interspersed with cleaners (water, cleaning alcohol, chlorinated hydrocarbons, etc.). Due to this, a small portion of residual moisture is contained in it.
In order to achieve a waste package suitably conditioned for the repository, this type of waste usually is super-compacted. As the initial waste volume can be reduced up to a ratio of 10 to 1 by that, a considerable reduction of the transport and storage costs is obtained at the same time. The waste, partly preclassified in advance, is filled into steel cartridges, is capped, and subsequently super-compacted. The pellets resulting from this process are then introduced in overpacks (drums of 200 liters or containers) and sealed for transport and storage or repository purposes.
While storing the waste packages that had previously been conditioned this way, gas formation often occurs in the enclosed waste. The affected waste drums show then clearly recognizable bulges at their lids and bottoms. Table I provides information on the drum-internal pressure values and the principal elements which the drum atmosphere consists of.
Table I
It is obvious that the oxygen content of the air enclosed in the drums is being consumed while, at the same time, a large amount of hydrogen is developing.
Inspecting the waste composition inside the drums, it was revealed that the containing matter was damp and there was a penetrating smell of organic solvents.

SOLUTION OF THE PROBLEM

It is the aim to avoid gas formation in the drums and containers filled with super-compacted waste. For this purpose, further investigations have been carried out which, as a first step, were intended to work out the causes of the gas formation phenomenon and, as a second step, were aimed at finding out proper measures to prevent gas formation. The following results have been achieved:

After the drums filled with damp mixed waste had been sealed, first a pressure decrease took place in the drums due to oxygen consumption (oxidative corrosion of metal). Subsequently, a pressure increase could be observed which was due to the formation of hydrogen gas.

Hydrogen gas formation occurs when metals exist in an environment that contains residual moisture. A considerable gas formation rate results when different metals exist, e.g. iron and aluminum, together with small amounts of water and chlorinated hydrocarbons. The mere presence of residual moisture vapors provokes a perceptible formation of gas. The cause of hydrogen formation is the occurrence of electrochemical metal corrosion. The chlorinated hydrocarbons have an accelerating effect on this process.

Oxidative as well as electrochemical corrosion can to a great extent be prevented by drying the waste (i.e. separating the electrolyte). This statement was proved to be correct by the results of the above mentioned tests.

Hydrogen gas formation in the drums is to a satisfactory extent prevented by drying the waste appropriately.

Based on this provable fact, inter alia, the super-compacted waste stored on the grounds of the Nuclear Power Plant of Brunsbttel (KKB) has been subjected to drying procedures since January 1995, which in the following will be reported about.

OPERATING EXPERIENCE

In the interim storage building of the Nuclear Power Plant of Brunsbttel (KKB), a number of drums of 200 liters loaded with super-compacted waste of 10 to 15 years of age are kept in storage for being subjected to a drying procedure. This is due to the fact that some drums are showing bulges caused by internal pressure increase.

The drying procedure is being carried out in batch quantities in a multi-drum dryer. In 1995, thirty waste batches of 30 drums each (a total of 900 drums) have been dried in accordance with the drying procedure described in the following, so that the repository requirements are satisfied. The principals of this procedure are shown in Fig. 1. A summary of plant data as well as some information concerning consumption of energy and service media are given in Table II.

After the lids have been lifted, the drums are brought to the drying chamber. The dryer loading device as presented in Fig. 2 has shown good results in operation. Loading is effected row by row (2x3 drums per row stacked in two tiers). Spacers are placed between the stacked drums. The drying chamber can this way be loaded to a total of 30 drums (Fig. 3).

Table II

Fig. 1

Fig. 2

Fig. 3

Once closed the loaded drying chamber, the drying procedure is started. The recirculation fans force the air enclosed in the drying chamber to undergo a powerful recirculation. Upon starting up the thermal oil system, the air is heated up to a temperature between 100 and 130C.

With the evaporation of moisture-causing substances, the drying process already starts during the heating-up phase. Heat transfer to the waste is mainly effected through convection (direct contact with the carrier gas) and thermal conduction via the drum's shell which is exposed to the flow of heated air. As a result of this, quite short drying periods of 8 to 12 days per batch are achieved. For transferring the evaporated waste components out of the drying process, a part flow of the recirculating air is continuously extracted from the drying chamber and lead via a vapor condenser. This causes the temperature of the previously evaporated waste elements to fall below the dew point. The resulting condensate, after having been subjected to a volumetrical measurement, is lead via a drip collector to a condensate collecting tank. From there it is turned over to the NPP. The dried air is then fed back into the drying chamber. The drying process is controlled by a continuously operating, fully automated monitoring system. For process documentation purposes, all the operating parameters with process relevance are documented by means of a multi-channel recorder.

As far as safety aspects are concerned, the concentration levels of inflammable organic substances as well as of carbon monoxide (CO) in the recirculating air are measured and monitored. It is thus ensured that the drying process is run with a high safety standard.

If the limiting value for inflammable organic substances is exceeded, the plant changes its mode into cooling operation. The electrical heat supply to the thermal oil system is then immediately cut off, while the cooling process for the recirculating air remains active.

Monitoring the CO concentration level is important with respect to detecting a fire caused by spontaneous combustion. If a steady increase in CO concentration is registered, first the inlet temperature of the thermal oil heating circuit will gradually be reduced. If this trend continues to exist, the plant changes its mode into cooling operation. In case that a further increase in CO concentration occurs, an inert atmosphere will be provided for by injecting CO2 as an additional measure.

In Fig. 4, a typical drying history is presented. Shortly after the heating-up phase, an increase in CO concentration takes place in the loaded drying chamber due to the presence of organic mixed waste. As a consequence, the temperature of the thermal oil is reduced. Evaporation of water starts with a certain delay relative to the formation of CO. This can be recognized through the time history of condensate formation. The evaporation of water causes the waste surface to become inert (decrease in oxygen concentration). This leads simultaneously to a decrease in CO concentration. The thermal oil temperature is once again being increased during this drying phase. This accelerates the drying effect. The drying procedure is finally indicated to be concluded when the cutoff criterion has been reached (under 0.5 liters of condensate formation within four hours). This can provoke the formation of some CO at the same time (reduced inert effect). The evaporation rate can be determined from the time course of condensate formation, which in the main drying phase amounts to a value between 1 and 2 liters per hour. The drying procedure is concluded when less than 0.5 liters of condensate arise within a period of four hours.

Fig. 4

SUMMARY

In the past, gas formation phenomena have been observed in connection with the intermediate storage of super-compacted, low-level radioactive waste packed in gas-tight drums. This is due to corrosion processes which are triggered by the complexity of the waste composition associated with the presence of residual moisture.
Investigations revealed that this gas formation can be prevented by eliminating the residual moisture in a drying procedure. Based on this discovery, the super-compacted mixed waste stored In the interim storage building of the Nuclear Power Plant of Brunsbttel (KKB) is being dried in accordance with the repository requirements, employing a compartment drier which is operated with recirculating air.
In 1995, a total of thirty batches, each batch consisting of 30 drums (=900 drums), was conditioned this way in accordance with the repository requirements. Drying periods between 8 and 12 days were reached. The average condensate volume per drum ranges between 4 and 10 liters. When the drying chamber has been loaded, the drying process is being controlled by a fully automated system and permanently monitored with respect to plant safety. The batch record, which is drawn up by means of a multi-channel recorder in the on-line mode, contains the operating parameters with process relevance.

DURABILITY ASPECTS OF HIGH-PERFORMANCE CONCRETES FOR A WASTE REPOSITORY
Ken E. Philipose
Atomic Energy of Canada
Chalk River, Ontario, Canada, K0J 1J0
ABSTRACT
A waste repository for the disposal of low-level radioactive waste is planned at the Chalk River Nuclear Laboratories, Chalk River, Ontario, Canada. It relies greatly on the durability of concrete for the required 500 years of service life. A research program based on laboratory testing to design a durable concrete and assess its long-term behavior was initiated in 1988, and is still in progress. This paper discusses the methodology to assess the long-term behavior of concrete, and some initial observations. Longevity predictions for concrete formulations based on diffusion testing are also presented.
INTRODUCTION
The disposal concept of the low-level radioactive waste repository, planned at Chalk River, relies on the durability of concrete to isolate the waste from the human environment for a minimum of 500 years. The durability of concrete and the corrosion of reinforcements have been studied for some time. Most of the principal factors that reduce the long-term integrity of reinforced concrete elements are well understood (1). Unfortunately, few studies can help predict the longevity of reinforced concrete structures over hundreds of years. Very little information in the literature is helpful in relating in a quantitative way the rate of degradation of concretes subjected to the principal

characteristics of the environment. For these reasons, a research program on concrete durability was initiated by AECL Research in 1987 as part of the licensing support for the repository. The objective of the research program was to assess the durability of a wide variety of concrete types and qualities subjected to different environmental exposure conditions and to develop a high-performance concrete for the waste repository. The program is jointly conducted by AECL Research and the Institute for Research in Construction of the National Research Council (NRC), Ottawa.

METHODOLOGY

Traditionally, concrete durability has been assessed by measuring either the strength or length change of specimens subjected to a corrosive agent. Usually, the corrosive agent is applied at the external boundary of the specimen, but sometimes it may be included within the mix as an internal agent. Results from these types of tests are not applicable to lifetime predictions and are not sensitive to the design geometry of structural members. Tests for sulphate resistance for cements,for example, which involve measuring the expansion of specimens in which sulphates have been integrally included, yield information on whether the cement is suitable for use. These tests give no information on the rate of deterioration. The same criticism can be made of tests of standard laboratory-size specimens exposed externally to a corrosive agent, where failure is indicated by a given loss of strength or a given expansion. The measure of durability in these cases would be strictly relative and insensitive to geometry (2).

The service life of concrete is dependent on a slow rate of deterioration and is influenced by the quality of concrete and the service environment. Factors such as cement type, cement content and water-to-cement ratio can affect the diffusion rate of ionic species into concretes. In addition, service life will depend on the size of specimens and failure criteria adopted. After examining the major failure mechanisms for the repository concrete, corrosion of reinforcement was selected as the mechanism for the failure of the waste repository structure. Chloride ions in the presence of oxygen can initiate corrosion of reinforcement and failure of the reinforced concrete components (3). The failure criteria chosen for the concrete was the time taken for the aggressive ions to reach the reinforcing steel by diffusion through the concrete cover (75mm thick). Based on these criteria, the rates of deterioration and hence an assessment of the longevity of concrete can be made (4 to 7).

The rate of penetration of aggressive ions into the concrete was evaluated by determining the reaction zone front with time of exposure in the solution baths. Prediction of long-term concrete behavior involves the extrapolation of current data, based on the assumption that long-term processes (not currently identified) will not invalidate the extrapolation. The durability prediction chosen for the study was based on the time-dependent depth of penetration of chloride and sulphate ions into the test concretes. Concretes were selected so that the effect of cement blends containing silica fume or blast furnace slag on the diffusion rate of chloride or sulphates in concrete could be investigated and compared with the diffusion in Type 10 cement concrete.

During a post-closure period of hundreds of years, the repository structure will be subjected to various aggressive elements in the environment. For example, the environment inside the repository will be influenced by the chemicals leaching out of the waste, or generated by the waste, whereas the external environment will be influenced by the

changes in the anion and cation content of the precipitation, due to the changes in acid rain and the addition of road salt. On the basis of an analysis of the repository service environment, the following major degradation parameters were selected for laboratory testing of concrete specimens:

- sulphate ions,
- chloride ions,
- leaching of calcium hydroxide by water,
- carbon dioxide reactions, and
- several agents in combination.

EXPERIMENTAL

1. Binders: Portland cement Type 10 and 50, silica fume and blast furnace slag were used for the three concrete systems described in this paper. The nomenclature and composition of cement systems are listed in Table I.

2. Aggregates: An unblended sand consisting mainly of quartz and feldspar was used. The following tests were carried out: an accelerated mortar bar test for alkali aggregate reactivity where samples are placed in 1M NaOH solution at 80 C, a magnesium sulphate soundness test, freeze-thaw cycling and petrographic evaluation. All testing indicated that the sand was satisfactory.

A limestone coarse aggregate of somewhat variable composition was used. Tests conducted were similar to those for the fine aggregate and the results were satisfactory.

3. Concrete: Three concrete systems (S1, S2, S5) were each prepared at Four different water-cement ratios: 0.35, 0.42, 0.5 and 0.60, denoted as mix 1, 2, 3 and 4 (M1, M2, M3, M4).

The cement contents for S1, S2 and S5 are as follows: S1 (M (1-4)): 485, 370, 335 and 280kg/m3. S2 (M (1-4)): 383, 338, 338 and 275kg/m3; S5(M(1-4)): 437, 359, 325, and 259kg/m3. A target slump of 125-150 mm was maintained for all mixes.

Table I

Concrete Specimens

Two concrete prisms, 75 x 75 x 280 mm, were cast for each mix and each exposure condition. S1, S2 and S5 were moist cured for 7, 14 and 28 days, respectively. Prior to immersion in the test solutions, the prisms were coated with wax on all sides but one, to allow a unidirectional ingress of chloride or sulphate ions.

Solution Baths:

Of the 25 baths used in this study, the worst-case scenario for the repository concrete was simulated in the laboratory in baths containing the following aggressive ions and ionic combinations:

NaCl (g/L):	5
Na2SO4 (g/L):	22
CO2:	1 Atmospheric
Temperature:	22oC and 45oC

Methods

1. Sample preparation: Specimens for Energy Dispersive X-ray Analysis (EDXA) were prepared according to the following procedure. A 12.5 mm slice was cut from the concrete prism taken from the test solution. This slice was further cut about 25mm from the exposed surface and then immediately surface dried.

2. Depth-of-Penetration, Profiles determination - C1- and SO4:

a. A Cambridge Stereoscan S-250 was used for the examination and a Tracor Northern TN 5500 Energy Dispersive X-ray Analyser was used for the

quantitative analysis. Calibrations were performed with an obsidian standard containing 0.36% Cl. EDXA analysis on several pieces gave 0.38%, a difference of 5.5%. Analyses were performed in 0.5mm steps, and three profiles for each concrete sample were determined. A value of 0.3% Cl was used to determine the position of the reaction front.

b. Profiles were also determined by slicing concrete specimens approximately 1-3 mm thick and in 1.5 x 1.5 cm cross section. Kerosene was used as the lubricant. The concrete was powdered, the anion was extracted by nitric acid and quantitative evaluation was made by titration.

3. Characterization of concrete:

a. Pore-size distribution: Pore-size data were obtained on mortars extracted from the concretes. An Autoscan 33 Quantachrome mercury intrusion porosimeter was used at pressures up to 227 MPa.

b. Non-evaporable water and Ca(OH)2 content: These determinations were made using the mortar phase. Non-evaporable water was taken as the weight loss on heating between 100-55C, assuming the weight loss between 550-1000C to be negligible. Calcium hydroxide content was determined by estimating the weight loss associated with its decomposition at around 450C.

4. Diffusivity measurements: The two-compartment diffusion cell used for these measurements is similar to that used in other research works (11, 12, 13). The data was recorded over 200 days in order to determine the effective diffusivity of chloride ions at 21C. Steady-state conditions were achieved after that time.

RESULTS AND OBSERVATIONS

Durability Aspects

Diffusivity:

Even though properties such as compressive strength, Young's modulus of elasticity and the porosity of hardened cement paste, mortar and concrete are indirectly related to durability, the transport properties of diffusivity and permeability are probably the most important factors relating to durability (8).

Table II lists the values obtained for the diffusivity of the mortars of Systems 1, 2 and 5. Data to calculate diffusivity (D) were obtained using diffusion cell techniques after exposure to NaCl solution for 75 to 175 days. Generally, diffusivity increases with an increase in total porosity and with cement systems S5<S2<S1. Thus the cement systems rank similarly for the properties such as median pore diameter, resistivity and diffusivity. This is similar to the ranking for Ca(OH)2 content; the higher the Ca(OH)2 content, the lower the resistivity. System 5 concrete has the lowest diffusivity coefficient, as it has the lowest total porosity percentage.

Table II

These measurements indicate that median pore diameter and Ca(OH)2 content are ranked in the same order for the three cement systems, and that they are similar to the electrical conductivity and diffusivity. The data obtained from the SEM indicate that concrete System 5 ranks the lowest with respect to permeability, and provides maximum resistance to chloride attack. On the basis of the physical test results and the diffusion test data, System 5 mix 2 was selected as the candidate high-performance concrete for the repository construction.

Ionic ingress:

Results of the influence of concrete quality on ionic ingress are shown in Fig. 1. Depth of chloride ion penetration is plotted as a function of the square root of time of exposure. The figure shows that supplementary materials provide enhanced performance with respect to ionic ingress. The reference OPC concrete, System 1, has the least resistance to chloride ingress. System 2 with Type 50 cement and 10% silica fume provides better resistance. This is expected, since the addition of silica fume makes the concrete less permeable for ionic ingress, due to the pozzolanic reaction between Ca(OH)2 and the silica fume. System 5 concrete, with 75% slag and 3% silica fume replacing Type 50 cement, provides the most resistance to the chemical ingress. This illustrates the superior quality of the blended cement with regard to permeability, and hence resistance to deterioration (6, 7). This trend is also true for all water-to-cement ratios from M1 to M4 (from 0.35 to 0.6), and for all salt concentrations from 0.99 to 49.95 g/L of NaCl.

Fig. 1

Figure 2 shows the depth-of-penetration of chlorides into System 1, 2 and 5 concretes with different water-to-cement ratios. Water-to-cement ratios of 0.35 and 0.42 are clearly superior ratios of 0.5 and 0.6, in terms of resistance to the penetration of chloride ions.

Fig. 2

Figure 3 shows the synergistic effects due to chloride, sulphates and CO2 bubbling through the solution, for an exposure period of 34 months. The chloride ions penetrate the concrete more when it acts alone than when combined with sulphate or sulphate and CO2. This phenomena can be due to the precipitation of solid reaction products such as calcium sulphates and sulpho-aluminates into the pores, making the concrete denser, and thereby less permeable to the chloride ions.

Fig. 3

Service life predictions:

The service life of reinforced concrete structures exposed to sufficient chloride ions to initiate the corrosion of embedded reinforcement is largely controlled by the rate at which the chloride ions penetrate the concrete. Figure 4 shows the depth-of-penetration of chloride ions into Systems 1, 2 and 5 concrete specimens as a function of square root of time of exposure in Bath 13. Even with the scatter in the data, the System 5 concrete shows a remarkably lower rate of chloride ion penetration. Regression lines are also drawn for the concrete systems. Table III lists the time in years required for the chloride ions to penetrate a depth of 75mm into the concrete Systems 1, 2 and 5, based on the assumption of constant diffusivity during that period of time. The correlation coefficient of 0.8 or above in the Table provides higher confidence in the analysis results. Unlike the laboratory test specimens, the repository concrete will undergo microcracking or cracking due to imposed mechanical loads and other effects. The influence of cracks in concrete on the rate of ionic ingress has to be taken into consideration for the final assessment (3).

Fig. 4

Table III

DISCUSSION

The median pore diameter and Ca(OH)2 content are ranked in the same order for the three cement systems, and are similar to the electrical conductivity (inverse of resistivity) and diffusivity. Generally, the diffusivity increases with cement systems S5<S2<S1. Comparison of these

diffusivity coefficients with those obtained by previous workers (13, 14, 15) can only be general, because the cements and curing times are not exactly the same and the values of the previous workers are for pastes. Values for Type 10 cement at water/cement ratios of 0.4, 0.5, and 0.6 were found to be 260, 447, and 1235x10-10cm2s-1, respectively, for diffusivity (D), compared to 247, 418, and 581x10-10 cm2s-1, respectively, obtained in this work. Curing times were longer for the latter set. These results confirm that hydrated blended cement bodies have significantly lower diffusivities than normal hydrated Portland cement bodies, and that the lowest diffusivities were obtained with the 75% blast furnace slag, 3% silica fume blend.

Ionic profiles and depth-of-penetration measurements (determined by EDXA) in concrete show that reasonably accurate results can be obtained and predictions of ionic ingress made. There is some scatter in the experimental results, because of the difficulty of locating the reaction front in concrete test specimens, due to the tortuous path of ionic ingress through dense concrete. In addition, the rate of movement of the front can be speeded up by the rapid diffusion of ions in interfacial regions and in cracks. However, there is enough consistency and redundancy in the system to obtain fairly accurate results. The procedure following the diffusion path around the fine and coarse aggregate particles, using the scanning electron microscope and electron microprobe for analysis, has been successful.

CONCLUSIONS

The following can be concluded from the experimental test data:

1. Hydrated blended cements mortars have diffusivities up to 25 times lower than equivalent Type 10 hydrated Portland cement mortars. A 75% slag system generally yields the lowest values of diffusivity among the blends.
2. Median pore diameter and Ca(OH)2 content are ranked in the same order for the three cement systems (S5<S2<S1), and are similar to the ranking for electrical conductivity and diffusivity.
3. Lower water-to-cement ratios in concrete systems decrease the diffusion rate of ions, and sulphate ions inhibit the rate-of-penetration of chloride ions.
4. On the basis of experimental studies to-date, the System 5 concretes rank the lowest with respect to permeability, and provide maximum resistance to chemical attack.

ABSTRACT

The effectiveness of engineered barriers on long term performance of disposal facilities is linked to effects of variations in infiltration and of rock-water interactions. This work investigates the effects of nonsteady flow on reactive contaminant migration in a radioactive waste disposal facility, using a new computer code, DYNATRAN. This code differs from conventional models in two aspects: a) use of DYNATRAN can eliminate the need to use an overly conservative infiltration rate; and b) this code can take into account rock-water interactions which can significantly enhance waste confinement in a disposal facility. Use of DYNATRAN therefore, has the potential to demonstrate environmental compliance with less effort and higher reliability than conventional approaches. This study considers a hypothetical near-surface disposal facility that involves engineered low-permeability earthen covers, concrete canisters, and backfill. A numerical investigation is conducted in a phased manner to evaluate the combined impacts of infiltration and

geochemical reactions, with a focus on the performance of engineered features in the confinement of waste materials.

INTRODUCTION

In analyzing the confinement of contaminants by engineered barriers in waste disposal facilities, a critical concern is with the infiltration that may come into contact with waste canisters since the process will gradually dissolve the contaminants as they are exposed. In fact, an accurate and reasonably conservative estimate of infiltration rate is perhaps more important than any other factor in predicting radiation dose via groundwater pathways in a radioactive waste disposal facility. An important question is then raised about the impacts of variations in the infiltration rate on the long-term performance of engineered features in the facility, and specifically, on their ability to confine radionuclides. In addition, the performance analysis is complicated by various soil/rock-water interactions such as chemical precipitation and sorption. The purpose of this work is to develop a new technique for investigating the effects of variable infiltration on containment of radionuclides and other types of reactive chemicals in such environments. For this purpose, DYNATRAN, a general-purpose numerical code for groundwater flow and reactive contaminant transport, has been developed (1, 2). The code has the potential to demonstrate enhanced waste confinement due to two advantages over conventional models: a) DYNATRAN simulates variable infiltration under realistic field conditions, thus avoiding the use of an overly conservative infiltration rate; and b) the code considers rock-water interactions such as precipitation and sorption which have been found to significantly retard the movement of contaminants in cases studied (1, 2).

As an application to radioactive waste management, DYNATRAN is used in the present work to simulate infiltration in a hypothetical LLRW disposal facility. This work focuses on the performance of engineered features in confining radionuclides of concern. Numerical simulations are carried out in a phased manner. First, unsaturated flow within the facility resulting from steady infiltration is studied. Next, the impacts of variations in infiltration on flow will be examined. Following that, the release of radionuclides from the facility will be simulated by considering the full problem of infiltration, chemical reactions, and transport. Comparison will be made between the steady and nonsteady infiltration conditions. Progress so far and plans for future activities are presented in this paper.

NUMERICAL MODEL DYNATRAN

For application to this and similar problems, a generic numerical model, DYNATRAN, was recently developed to simultaneously handle transient saturated-unsaturated flow, multicomponent transport, and solid-liquid interactions in the subsurface (1, 2). DYNATRAN can be run in three modes: a) subsurface flow, b) geochemical equilibration, and c) subsurface transport under steady or transient flow conditions. In equilibration and transport simulations, DYNATRAN can handle liquid or liquid-solid systems. In transport simulations, it can handle either single or multiple species that are subject to reactions such as ion pairing, precipitation-dissolution, sorption-desorption, and reduction-oxidation. The code is capable of handling heterogeneous and anisotropic media in up to three dimensions with irregular geometry and time-dependent boundaries.

DYNATRAN has been verified extensively against analytical solutions and numerical models for several cases that involve flow, geochemical equilibration, and transport under steady flow (1, 2). One of the verification cases considered simultaneous transport of 14 chemical components, 78 additional aqueous complexes, and 9 minerals with highly contrasting alkalinity and redox conditions. The code has also been used in two studies to model migration of single- and multiple chemical components subject to various types of rock-water interactions in a dynamic flow field. The first application involved the impacts of seasonal infiltration/evaporation on contaminant leaching in a landfill. The second case involved a detailed geochemical evolution of an irrigated soil column, that included 16 components, 93 additional aqueous species, and 10 minerals.

DYNATRAN differs from conventional flow and transport models in the following two aspects:

1. The incorporation of transient flow allows for simulation of infiltration fluctuations, thus eliminating the need to use overly conservative estimates of the infiltration rate. The reduction in infiltration rate will strongly reduce contaminant concentration and environmental risk resulting from leaching.
2. The incorporation of detailed chemical reactions allows for simulation of precipitation, sorption, and reduction/oxidation reactions. In a study of acidic mine drainage at Pinal Creek, Arizona, the migration rate characterized by the fronts of pH and heavy metal concentrations, was reduced by a factor of 5 when precipitation was taken into account. Similar retardation due to rock-water interactions was also observed in other cases investigated.

Therefore, use of DYNATRAN in evaluations of waste confinement provides realistic simulations of field conditions that can potentially result in significant reduction in the licensing, design, and operation costs of waste containment facilities. Due to its generic formulation, DYNATRAN can also be applied to other cases that involve subsurface processes such as the remediation of contaminated groundwater and soil.

STUDY OF CONFINEMENT WITHIN A DISPOSAL FACILITY

Conceptual Model

This study considers a hypothetical disposal facility for low- and intermediate-level radioactive waste (LLRW). The facility is based on the concept of below-ground concrete vault and involves engineered low-permeability earthen covers, concrete canisters containing waste packages, and backfill (Fig. 1). To minimize infiltration into the vault, multiple layers of low-permeability natural clay and engineered high-density polyethylene liners will cover the vault. Void space between waste canisters will be filled with sandy materials to maintain structural integrity and divert infiltration away from the waste. Material and site hydrogeochemical data representative of the facility is collected from literature reviews of site characterization studies at several facilities in the U.S. and abroad, on which a conceptual hydrogeologic model has been developed.

Fig. 1

The model is designed to represent a general near-surface disposal facility, and can be easily modified to accommodate site-specific data. The design includes waste canisters placed within several disposal units. In each disposal unit, fifteen 80"80"80" waste canisters will be uniformly placed in three levels of loading (Fig. 2). Each waste canister

is made of an outer fiber-reinforced concrete shell with an inner polyethylene container. The horizontal space between two neighboring canisters is 2", which will be filled with a cohesionless material such as pea gravel. The fill will be selected according to NRC guidance (3). The top and two sides of each disposal unit are filled with 8" thick gravel, and the bottom with 4" thick gravel.

Fig. 2

This model considers the distribution of infiltration within the disposal unit after it reaches the top pervious layer overlying waste canisters. The loading configuration of waste canisters in one disposal unit is illustrated in a typical cross section (Fig. 2), which is considered in this study. Lateral flow in the third dimension was not simulated because this flow component was not anticipated to be significant in comparison with infiltration. By symmetry, only half of the cross section is modeled. The cross section was discretized into a computational grid of 612 nodes. To ensure reasonable accuracy in the simulated results of the partially saturated flow case, the grid was made finer at the top of the disposal unit where infiltration occurs and around the fills where higher flow fluxes are expected.

Flow under Steady Infiltration

Numerical simulations are carried out in a phased manner. First, a preliminary analysis was conducted to investigate the subsurface flow under the influence of steady infiltration within the disposal facility. Specifically, we used an overall infiltration rate independently estimated with HELP3 (4), and representative material properties as input. Then we simulated the dynamic infiltration into a typical disposal unit under unsaturated conditions, and examined the relative amount of flow through the canisters and through the fill materials during a period of 300 years following significant degradation of the concrete canisters.

The flow analysis was based on the following assumptions:

1. Degraded waste canisters were used so that their properties would ensure conservatism in the calculations.
2. The initial conditions were assumed to be hydrostatic such that the water level was at the bottom of the infiltration collection system.
3. The infiltration, after percolating through the earthen cover, reaches the top of waste disposal unit at a constant and uniform rate. The infiltration will flow through either the waste containers or the space in between the waste containers that is filled with the fill materials.
4. The left and right sides of the model were treated as no flow boundaries. The bottom boundary was assumed to be such that the infiltration collection drain remains dry during the time period of interest.

The infiltration rate reaching the top of the disposal unit was independently assessed using the HELP3 model. To be conservative, the maximum rate obtained, 3 inches/year, was used in a steady infiltration case. Variations in the infiltration rate will be taken into account in a more realistic study of transient flow. Steady infiltration was treated as a constant flux in the simulations.

Both fully saturated and partially saturated conditions were considered. The flow problem is highly nonlinear due to the strong dependence of hydraulic conductivity on pressure head in the fill and the contrast in hydraulic conductivity between the concrete and the fill. Important factors in the infiltration study are the hydraulic characteristics of the concrete and fill materials. Backfills were considered to be

consistent with NRC recommendations. Based on these specifications, the hydraulic conductivity of the backfill was estimated using the Fair and Hatch formula (5) and data from Maidement (6). Material properties of degraded concrete were derived from measured fresh concrete and conservative assumptions about degradation (7). The hydraulic conductivity and saturation characteristics of the waste canisters and the fill were both developed using the van Genuchten model (8) (Fig. 3).

Fig. 3

Several cases were carried out to test the sensitivity of infiltration-induced flow to key model assumptions and input parameters (Table I). Case I was chosen as the base case. Additional cases were studied considering variations in hydraulic conductivity of degraded waste containers and backfilling materials. Relative amount of flow through the waste-containing concrete canisters and that through the backfills were calculated for the time period of interest, which provides a more realistic estimate of the amount of leachate generated than the often too-conservative approach traditionally adopted in performance assessment.

Table I

For the particular configuration and material properties assumed, it was estimated, based on a simple water balance, that when the disposal unit is fully saturated and a uniform hydraulic gradient exists over the top of the disposal unit, more than 99% of the total infiltration that reaches the top of the disposal unit will flow through the filling materials and will not come into contact with the waste.

Numerical simulations suggest that the ratio of flow bypassing the waste canisters would decrease when the fills are partially saturated (Table I). In addition, the results showed that the waste containers would remain at full saturation even when the fill materials are under very dry conditions, which is consistent with the observation of Walton and Seitz (9). Partially saturated flow, therefore, is significant only in the fills. It was noted that in the multi-layer system, the bypass ratio is dependent on the location of waste containers. Around waste containers closer to the infiltration collection drain, the fills tend to become more saturated and will withdraw more fluid away from the neighboring waste containers. Infiltration is also a time-dependent phenomenon in the disposal facility; the ratio is dependent on how long infiltration has taken place after the waste canisters are degraded. For the specific combinations of parameters (Table I), the bypass ratio was found to be at least 60% (Fig. 4). Therefore, under similar site conditions the source term methodologies that assume that all the infiltration will come into contact with waste can be considered conservative. The results also suggest that design features of the facility will continue to divert a significant amount of the water away from contact with the waste after degradation of canisters has occurred.

Fig. 4

Future Work

In the next phase of this study, we will consider transient flow within the facility caused by fluctuations in infiltration. Incorporation of variations in infiltration will allow simulations of realistic field conditions, thus avoiding the need to use a conservative infiltration rate throughout the time period of interest. Appropriate boundary conditions are being developed to handle variable infiltration. As in the steady infiltration case, relative flow through the waste canisters

(i.e., leaching), will be calculated as a percent of total infiltration that reaches the top of the disposal unit.

The final phase will utilize DYNATRAN's provision for integrating flow and transport to simulate the long-term performance of a disposal unit for confining radionuclides under realistic infiltration conditions. Amount of leachate and radionuclide concentrations in the leachate will be calculated as a function of time and location within the disposal facility. This will help to identify locations within the facility that are weak to resist infiltration, and thus may assist in refining the design regarding the placement of waste canisters. When geochemical characteristics of the infiltrating water and the facility are available, geochemical reactions among radionuclides and other chemicals will also be considered. It may be noted that the current practice of disposal assessment usually ignores or oversimplifies such chemical interactions. It will therefore be of particular interest to examine the system behavior when the coupled flow-transport-reaction processes are taken into account in the full problem.

SUMMARY

A new technique and the associated numerical code (DYNATRAN) have been developed for studying the combined effects of variable infiltration and rock-water interactions on the confinement of residual materials in disposal facilities. This approach has the potential to demonstrate environmental compliance through realistic confinement evaluation due to its inherent advantages over the conventional methods: a) use of DYNATRAN can avoid the need to use an overly conservative infiltration rate; and b) DYNATRAN takes into account of rock-water interactions such as precipitation and sorption, which can significantly enhance waste confinement. In an application to radioactive waste management, DYNATRAN is used to investigate the confinement of radionuclides and other reactive chemicals within a disposal facility. Preliminary results of the analysis of infiltration-induced flow show that the majority of infiltrating water will be diverted by the fill in between concrete canisters, even after the canisters are degraded. The amount of diverted flow will be impacted by hydraulic properties of the canisters and fill, as well as the configuration of the disposal unit. To provide further insights into the confinement assessment, detailed evaluation of nonsteady infiltration and contaminant transport is under way.

Session 39 -- MARKET DRIVEN RECYCLING
Co-chair: Michael J. Gresalfi, ORNL

39-1
COMPREHENSIVE APPROACH TO RECYCLING RADIOACTIVE SCRAP METAL

Michael A. Rollor
James N. Taylor
ALARON Corporation

ABSTRACT
A market-driven trend toward integrating the four major disposal and recycling options for radioactive scrap metal (RSM) into a single, comprehensive approach is described. Each of the four currently-available disposal/reuse options and the respective roles of RSM generators and processors are described as background for discussing shortcomings of traditional approaches to RSM disposition. Poor characterization and "bundling" of RSM into heterogeneous "lots" often result in critical errors in the selection of a single option for RSM disposal or reuse. A specific example of disadvantages associated with this "specialized" processing approach is provided. As a direct result of these problems and other important market forces, RSM processors have "diversified" their individual disposal/reuse processes to minimize risks associated with RSM recycling. A comprehensive approach integrating individual disposal/reuse options into a single, flexible scheme is described. Unlike the traditional methods, this comprehensive approach emphasizes up-front segregation of metal components into categories best-suited for specific technologies. An example of the new approach is provided.

INTRODUCTION

Generators of radioactive scrap metal (RSM) typically must choose one of four basic options for the final disposal and/or reuse of their material:
1. Direct Burial whereby RSM is packaged in boxes or drums and deposited in a licensed radioactive material landfill; alternatively, some landfills do not require prepackaging of RSM and the material is deposited directly into the landfill "cells".
2. Volume Reduction whereby RSM is physically modified to reduce its "packaged" or spatial volume prior to burial. Volume reduction is achieved in one of two ways:
a) Mechanical Volume Reduction in which RSM is cut and/or compressed using standard mechanical techniques including saws, torch-cutting equipment, plasma-arc and metal compactors.
b) Metal Melt in which RSM is transformed into a volumetrically-contaminated metal block at close to the ideal mass density of the original material (e.g., close to 495 lbs/ft3 for stainless steels).
Volume reductions (VRs) typically must exceed 80% (i.e., for every 100 ft3 of RSM volume reduced, less than 20 ft3 of resulting material is sent to a burial site for final disposal) to be cost-effective. It is

important to note that volume reduction affects only the volume of RSM buried and not the mass. Therefore, volume reduction is best thought of as a density change -- packing more material into less space.

3) Metal Melting/Beneficial Reuse whereby radioactive contamination is volumetrically dispersed throughout an homogeneous molten metal mixture and, subsequently, formed into ideal density blocks, ingots or other forms of internally-contaminated metal. Subsequently, this material can be formed into products for restricted use in the nuclear industry. Typical applications include shielding, waste boxes and drums, casks and canisters. Secondary waste resulting from melt operations can vary from 5 - 25% by volume of incoming material (as received at 20 - 35 lb/ft3 bulk densities).

4) Surface Decontamination/Recycling whereby radioactive contamination is removed from the external surfaces of RSM for proper handling and burial; concomitantly, the decontaminated or treated bulk metal objects are surveyed and, where specific criteria are met, released for unrestricted use in private-sector scrap metal markets. Secondary waste resulting from decontamination activities is typically limited to 1 - 10% by volume of incoming material (as received at 20 - 35 lb/ft3 bulk densities).

Over the last several years, RSM generators and private sector "processors" have learned that no single option (discussed above) is best-suited for all types of RSM. Technical, economic and political factors continue to drive processors toward "comprehensive" services which integrate the four (4) basic options into a single, systematic approach for RSM handling, recycling and disposition. This, in turn, means that the RSM must be properly characterized and sorted in terms of important physical, chemical and radiological parameters and, subsequently, properly assigned to the best available technical option for that specific type of RSM -- direct burial, volume reduction, metal melt or surface decontamination.

APPLICABILITY OF OPTIONS -- A SIMPLISTIC VIEW

The task of identifying and choosing the best disposition/reuse option from the four (4) presented above is made relatively simple by assuming that all of the RSM under consideration has already been sorted and collected into homogeneous "lots". In this case, homogeneity is defined as a close similarity among the individual RSM objects in a single "lot" in terms of the characteristics listed in Table I. Since empirical evidence confirms that, in general, RSM is notoriously heterogeneous in nature, the preceding assumption dictates that these homogeneous "lots" of RSM vary significantly in character from one "lot" to the next. In other words, the RSM exhibits homogeneity within "lots" and heterogeneity between "lots". Under this scenario, the two overriding factors affecting selection of an option are:

1) Technical feasibility of the option or process for the specific type and form of RSM contained in the "lot" under consideration. The specific characteristics of individual RSM material is the key to matching each "lot" to one of the four (4) disposal/reuse options. As the information provided in Table I clearly indicates, the number of pertinent evaluation criteria increases dramatically from direct disposal to volume reduction to metal melting to surface decontamination. In other words, as the disposal/reuse option moves from less "green" to more "green" in terms of true recycling, the selection criteria for RSM material becomes significantly more restrictive.

The diversity and breadth of evaluation criteria provides some insight into the complex nature of sorting RSM for treatment/disposal. Further, certain evaluation criteria such as "percent inaccessible surface" indicate opportunities for further processing decisions. In this particular case, a processor may determine that, although the amount of surface accessible to decontamination and survey is initially low, the RSM under consideration may be easily modified (mechanically) to expose most or all of the surfaces at little cost to the processor. Once these surfaces are properly exposed, the material qualifies for cost-effective treatment by surface decontamination.

2) Economic feasibility of applying a given option to a specific RSM "lot". In the absence of government- or industry-imposed incentives (i.e., recycling "rebates" or "credits"), economic feasibility continues to be largely dependent upon direct burial rates. This dependence on burial rates is due to the following:

a) All technical options for RSM disposal/recycle produce waste(s) -- primary, secondary or a combination of both primary and secondary wastes.

b) Waste volumes generated per unit RSM treated tend to decrease with greater restrictions on the physical, chemical and radiological characteristics (listed in Table I) of the material under consideration. However, the economic feasibility of a disposal/recycle option for a given RSM "lot" may also be heavily dependent upon other factors. For example, processing costs may increase with tighter restrictions on input material. In this case, any potential waste volume savings may be offset by these increases in processing costs.

Table I

In summary, the task of selecting the best disposal/reuse option is relatively straight-forward for any single, homogeneous "lot" of RSM. This selection is dependent entirely upon the relative technical and economic feasibility of each option for the specific RSM "lot" under consideration.

DETERMINING THE BEST APPROACH -- A REAL-WORLD PERSPECTIVE

Unfortunately, the preceding assumption that RSM is classified and sorted into "lots" of similar material prior to selecting a treatment option is a significant oversimplification of actual market practices. In fact, generators have always and, in most cases, continue to "bundle" RSM for direct disposal or further treatment as an heterogeneous mix. Although interested in the overall costs of treatment and extent of reuse achieved by processors, RSM generators are more heavily influenced by other factors:

1) Schedule and Critical Path Issues: For commercial utilities, RSM is often generated during power station "outages" and, consequently, greater emphasis is placed on speed and critical path issues than on sorting material into various "lots" just to promote the reuse of a few thousand cubic feet of RSM.

2) Demolition Costs: The decontamination and decommissioning (D&D) of commercial and government facilities generally involves the removal of large equipment, structures and buildings. Obviously, demolition and random "bundling" of the resulting RSM (in containers) represents the least-expensive method for achieving the demolition objectives. Although not clearly defined to date, the decommissioning costs associated with systematically dismantling structures so as to optimize RSM treatment processes are, intuitively, higher than those associated with traditional demolition techniques. However, potential economic savings from

optimization of RSM treatment processes (e.g., avoided transportation and disposal costs) have also not yet been fully defined and made available in the marketplace.

3) Direct Disposal Rates: In the case of government facilities generating RSM, perceived disposal rates less than $100 per cubic foot and, in some instances, as low as $10 - $20 per cubic foot have virtually eliminated reuse/recycling options from consideration. In these cases, classification and sorting of material prior to placement in containers for direct disposal is of no technical or economic value and, therefore, ignored in the D&D process.

4) Partitioned D&D Responsibilities: In most D&D applications, specific responsibilities for demolition and waste disposition/reuse, respectively, are "decoupled" -- assigning two different managers with specific tasks that are not considered to be related except in terms of project scheduling and which, in many ways, conflict with one another. The manager in charge of demolition is concerned only with removing the equipment or structure at least-cost and on- schedule while the waste-minimization manager is concerned with optimizing the RSM disposal/reuse process. In effect, the two (or more) managers are "partitioned" from one another -- each with specific responsibilities which, in most cases, are never integrated into one overall plan that may minimize the cost of the overall D&D effort. Until recycling/reuse is adopted as an integral part of D&D planning, it will be difficult to "couple" these activities into a single least-cost option.

Given these and other influences, RSM generators continue to "bundle" material for treatment as a heterogeneous mix of metal types, configurations, densities, shapes, geometries, sizes and other characteristics. Despite this practice by the RSM generators, the processors have, until recently, been providing relatively "specialized" services. One or two processors have emerged as metal melting specialists while others have focused their efforts on volume reduction and surface decontamination. Even within the various option categories, processors have developed and maintained specific areas of specialization. Although most processors have always claimed to offer a broad range of services, all have practiced some level of specialization over the last 5 or 6 years.

At first glance, this "specialization" by processors is somewhat confusing. Given the way in which generators "bundle" RSM and the greater restrictions on acceptable RSM forms for the "greener" options such as metal melting and surface decontamination, it only makes sense that each processor would want to provide all four (4) of the disposal/reuse options. However, large capital investment requirements and regulatory hurdles have precluded most from this approach -- forcing each processor to carve out a unique niche based on his/her respective financial and technical resources. With the exception of volume reduction, the less "green" options require greater financial resources and investment capital (e.g., metal melt equipment is typically more expensive than surface decontamination equipment). On the other hand, the less "green" options (including volume reduction) can accept a greater range of RSM (see Table I). Therefore, it makes sense that processors with the financial wherewithal would choose options that inherently offer a broader range of RSM treatment capability.

Unfortunately, this "specialization" by processors has placed the burden of the disposal/reuse decision squarely on the shoulders of the

generators themselves. Although the "greener" options are available, the fact that RSM is still "bundled" as an heterogeneous mix often precludes generators from optimizing the disposal/reuse of their material. Further, once the metal is mixed and containerized for shipment, the arduous task of characterizing and sorting the material represents an additional cost which, despite avoided disposal costs achieved through improved reuse/recycle, may still be cost-prohibitive. Consequently, the generator must make some assessment of the character of his/her RSM and, based on claims and prices from the processors, make a decision regarding the ultimate fate of the material. In most cases, generators shift most of the risk associated with the decision to the processors by requiring firm fixed price contracts and guaranteed recycling or volume reduction efficiencies.

The down-side risk for the RSM generators and processors associated with the selection of a "greener" option can be enormous. Figure 1 provides a visual representation of the decision faced by RSM generators in a market characterized by specialized processors. The generator, based on his/her own internal information, must decide the treatment path. Although surface decontamination and metal melt may offer economic benefits by means of avoided burial costs, an error in judgement at the outset can result in significant unforeseen costs. For example, assuming the generator believes that his/her RSM is well-suited for surface decontamination, it is reasonable to expect avoided disposal costs which will more than offset the cost of processing. However, if the material received by the processor is improperly characterized by the generator, the specialized processor (with no other technical option available) has no choice but to "re-characterize" the material and sort out the RSM unacceptable for surface decontamination. This unacceptable material, set aside as primary waste in Fig. 1, must then be placed back into acceptable containers and either returned to the generator or shipped directly to a burial site. In any event, the additional costs associated with transportation, containers and material handling can lead to a final cost well above that for direct disposal of the entire volume initially considered. Therefore, without some economic incentive (e.g., high burial rates, recycling credits), most RSM generators are motivated to choose the broader, less "green" options -- especially direct disposal. In a market characterized by low or ambiguous burial rates, it is difficult to justify any amount of true recycling for RSM.

Fig. 1

A REAL-WORLD EXAMPLE: FERMCO STRUCTURAL STEEL

In December 1994, ALARON Corporation was engaged by the Fernald Environmental Restoration Management Corporation (FERMCO) to participate in a feasibility study evaluating surface decontamination as a cost-effective option for the reuse/recycle of structural steel. The decontamination project was designed by FERMCO as an integral part of the D&D of the Fernald Plant 7 building. Therefore, following the initial implosion of the six (6) story building, the structural steel was to have been removed by cutting and shearing to produce material acceptable for surface decontamination. The structural steel consisted of a variety of painted I-beams, deck-plate, channel iron, angle iron, piping and bridge-crane steel. In almost all cases, the steel had been painted a number of times with lead- and latex-based paints. The lead-based paint was used originally to prepare the surfaces prior to use of the building and to "fix" contamination over the years of building use, while the latex paint

was used by FERMCO to "fix" any remaining contamination just prior to building implosion. A relatively small amount of non-metal material was, by design, to have been delivered with the steel. This material included wooden pallets and super-absorbent sheets used for shipping purposes. Based on design drawings and information provided by FERMCO, ALARON's technical staff determined that grit blasting represented the best general method for decontamination of this particular metal. Although some amount of sorting, further characterization and specialty decontamination (i.e., chemical decontamination of some components) was anticipated, the original characterization and assessment of the material indicated that the vast majority of the material would be easily decontaminated by grit-blasting. ALARON's basic approach, based on experience with similar materials, assumed that free-release criteria could be met by simply removing the paint from the metal surface. Although paint as thick as 8 mils was expected on some surfaces, preliminary testing with grit-blast equipment confirmed that the coatings could be effectively removed.

Figure 2 provides a flow-diagram summarizing the anticipated material flow for the structural steel and other materials shipped to ALARON's facility in Wampum, Pennsylvania. Note that the general form of Fig. 2 agrees with the "Specialized Processing Services" scenario provided in Fig. 1. As the RSM generator, FERMCO was faced with the decision of how best to dispose/reuse the Plant 7 structural steel. After assessing their own material and proposals submitted by various "specialty" processors, FERMCO chose surface decontamination as proposed by ALARON Corporation. The non-bracketed numbers provided in Fig. 2 indicate the originally anticipated quantities (tons) of material for receipt and processing per ALARON's plan. Note that, of the total 725 tons expected, approximately 700 tons were earmarked for surface decontamination. Some minimal amount of sorting and surface preparation prior to surface decontamination was accounted for in the original plan. Based on assumptions regarding material characterization and processing efficiencies, ALARON believed that a total of 693 tons of structural steel could have been free-released to scrap dealers for recycling. This represented, by weight, a 95% recycling efficiency based on the total material received (including non-metals) and a 99% recycling efficiency based on the structural steel selected for surface decontamination. Total primary and secondary waste anticipated was approximately 82 tons, with material unacceptable for decontamination accounting for 30% (by weight) of the waste generated.

Fig. 2

Despite the planned approach, extensive preparation for recycling of the structural steel, and FERMCO's commendably high level of understanding of the criteria for cost-effective decontamination, unforeseen circumstances negatively impacted the recycling process. The initial implosion of Building 7 was not successful. Consequently, in order to meet schedule and budget requirements, further demolition efforts were required to prepare the building for dismantlement. Unfortunately, these unanticipated demolition activities and tight schedule for removal of the building resulted in a departure from the originally-planned dismantlement procedures. The overall approach shifted from systematic dismantlement to a "brute-force" demolition in which material was sheared, ripped, bent, and otherwise modified without regard for any subsequent impact on the planned decontamination process. A clear indication of the twisting, bending and poor treatment of the material

from a decontamination perspective was provided by the material bulk densities achieved prior to shipment to ALARON's facility. Under the original assumption of systematic dismantlement, bulk densities of 24-30 pounds per cubic foot were anticipated and, in fact, achieved for the bridge-crane and other material unaffected by the modified dismantlement approach. By comparison, the bulk densities achieved for structural steel resulting from the demolition were typically less than 20 pounds per cubic foot -- with some as low as 16 pounds per cubic foot.

In contrast to the originally anticipated material flow, the tons of material actually received and processed (bracketed numbers provided in Fig. 2) reflect the strong, negative influence of the demolition method on recycling efficiency. The additional 36 tons of material received (761 tons actual versus 725 tons originally anticipated) was, for the most part, due to reasonable error in estimating the structural steel weight prior to demolition. However, the division of material by sorting into metal suitable and unacceptable, respectively, for decontamination clearly illustrates the detrimental impact on recycling. Of the 761 tons of material actually received, only 448 tons (59% by weight) were characterized by ALARON as "acceptable" for surface decontamination. It is important to note that the material identified as "acceptable" by ALARON also possessed the general characteristics of the RSM specified in FERMCO's original Request for Proposal. The remaining 313 tons of material, mostly steel, were generally characterized by a high percentage of inaccessible surface area. This inaccessibility would have not only been detrimental to the grit-blast operation, but also would have prevented survey instrumentation from the access required to confirm that free-release criteria had been met.

The final results indicate that, overall, 445 tons or 58% (by weight) of the received 761 tons of material were actually decontaminated and free-released as "clean" scrap. However, it is important to note that, of the 448 tons characterized by ALARON as "acceptable" for decontamination, the originally-anticipated goal of 99% recycle (by weight) was achieved. Total primary and secondary waste was close to 350 tons, but material unacceptable for decontamination accounted for 90% (by weight) of the waste generated. These results serve to illustrate the previous argument regarding the level of risk taken by RSM generators in determining the best option for RSM disposal/reuse -- especially in a specialized-processor environment. In this particular case, the generator probably made the correct decision based on initial assumptions and original plans for dismantlement of Building 7. However, the shift in approach toward a demolition-based technique resulted in a significant difference in the final form and characteristics of the structural steel. In turn, this difference in the characteristics of the RSM precluded a large portion of the material from cost-effective decontamination.

A CHANGING LANDSCAPE -- MARKET FORCES AT WORK

Despite the preceding explanation and example of risks faced by RSM generators in recent years, the market for RSM disposition/reuse is evolving in such a way as to place significantly more risk and financial burden directly on the RSM processors. Market opportunities, direct disposal rates, and the level and nature of competition have all changed drastically over the last five or six years, forcing RSM processors to improve and broaden their capabilities and contract terms.

At the outset of the 1990's, the marketplace was relatively "simple" for RSM processors -- with commercial nuclear power station opportunities

dominating the market, unambiguous and firm burial rates and relatively limited competition. Most RSM was generated during power station "outages" and, as mentioned earlier in this paper, the generators themselves were more concerned with on-site critical path issues than the disposition/recycling of RSM -- especially when the worst case scenario was direct disposal at $35 per cubic foot. In order to compete, processors had to offer off-site (from the utility itself) processing, firm fixed-price contracts and guaranteed volume reductions. As shown previously, the RSM generators were required to decide which option represented the best approach for disposal/reuse of their metal wastes. Once that decision was made, the only other responsibility of the generators was to place the RSM in certified containers for shipment to the processing facility. Since the primary emphasis was usually on speed to prevent outage critical path conflicts, little or no thought was given to the condition, characterization or sorting of RSM prior to demolition, removal and shipment to the processor. Consequently, any required characterization, sorting and metal preparation was performed by the processor and, with burial rates so low and volume reduction the predominant option, these activities were relatively negligible in terms of cost to the generator.

Today the market can be characterized as significantly more "complex". Government opportunities have emerged and, with the promise of thousands of tons of RSM for disposition/recycle over the next 20 - 30 years, have caused an influx of competitors and technical alternatives. The number of competing companies has more than doubled since 1990 and new ideas and practices -- including RSM export to foreign countries, long-term storage and improved waste-minimization techniques -- have broadened the choices for generators of RSM. Although commercial burial rates have soared to more than $300 per cubic foot for non-southeast compact generators (forcing many utilities to invoke plans for long-term storage and other alternatives), government burial rates have yet to be clearly stated and supported by true life-cycle cost determinations. This ambiguity, together with the fiercely competitive nature of new companies struggling to "get in" the RSM recycle market, has served to erode RSM processors' margins and has forced processors to shoulder increasingly more financial risk. Processors have, over the last several years, invested millions of dollars in high-tech equipment and processes to meet the predicted demands of the Department of Energy and nuclear utilities. However, prices charged by processors today are not significantly higher than those charged at the outset of the 1990's. Further, even with all the private-sector capital at risk, processors continue to provide firm fixed-price contracts and guaranteed waste volume reductions without any real change in the way in which RSM is characterized, prepared and bundled by the RSM generators themselves.

A COMPREHENSIVE APPROACH

In order to effectively compete in this new and changing environment, many RSM processors have broadened their capabilities -- through capital investment and/or teaming with other processors -- to provide all four of the basic disposition/reuse options previously identified in this paper. These broadened capabilities provide the technical and economic diversification required to minimize their own risk in processing and disposing or recycling inherently-heterogeneous RSM. In other words, asystematic, comprehensive approach -- integrating all the available

options together to provide an optimal outcome -- is now available to meet the demands and restrictions of today's nuclear marketplace.

The comprehensive approach adopted by ALARON Corporation -- in conjunction and through a formal teaming relationship with Carolina Metals, Inc. (a subsidiary of Nuclear Metals, Inc.) -- is summarized in Fig. 3. The figure illustrates a flow scheme in which heterogeneous RSM is received, evaluated, characterized, sorted and prepared for disposition/recycle by each of the available options. In this way, RSM best-suited for metal melt is prepared specifically for and processed by the metal melt facility at Carolina Metals, Inc. in Barnwell, SC. Similarly, RSM best-suited for direct burial, mechanical volume reduction or surface decontamination is identified, prepared and processed by the corresponding technology.

Fig. 3

The development of comprehensive services is, in effect, a necessity for RSM processors in today's marketplace. Increased competition for RSM disposal and/or reuse has made it possible for generators to make more demands on the RSM processors. The generators still demand firm fixed price contracts and performance guarantees without any significant change in the way they "bundle" RSM as a heterogeneous mix. Consequently, the risk associated with the decision as to which option or set of options is best-suited for a specific "lot" of RSM is transferred completely to the generator. In order to minimize this risk, the processors must have at their fingertips the capability to handle any and all types of RSM. The challenge for processors is now to become highly efficient in characterizing and sorting RSM so as to optimize the overall process by ensuring that each piece of metal is matched to the best possible disposal/reuse option. The processors must "pay" for the additional handling and processing costs incurred by avoiding direct disposal charges.

COMPREHENSIVE APPROACH EXAMPLE: QUAD CITIES RWCU

In mid-1995, ALARON Corporation and Carolina Metals, Inc. (CMI) proposed a comprehensive approach to Commonwealth Edison Company (CECO) for disposal/reuse of retired reactor water cleanup unit (RWCU) components from the Quad Cities Nuclear Power Plant. The planned approach integrated direct disposal, volume reduction, metal melting and surface decontamination into a single-best overall option for the RWCU material. ALARON Corporation and CMI were selected by CECO for treatment of the RWCU material through a competitive bidding process.

The RWCU material originally described by CECO exhibited typical RSM characteristics. Metal varied significantly in terms of treatment selection criteria previously identified in Table I. However, based on the specific characteristics of the RSM, five (5) specific categories were established and evaluated for treatment -- "small" valves (< 2" o.d.), "large" valves (> 2" o.d.), piping, heat-exchanger tubing, and heat-exchanger "shell" material. Technical information provided by CECO indicated that all the RSM associated with this project was stainless steel. The heat-exchangers were regenerative and non-regenerative units typical of a boiling water reactor (BWR) system. Based on the initial characterizations provided by CECO, ALARON determined that the "small" valves and heat-exchanger tubing were best suited for metal melting. The "large" valves, piping and heat-exchanger shell materials were selected for surface decontamination -- due in large part to their relatively low

surface area to mass ratios and the accessibility of surfaces to treatment and survey.

Figure 4 provides a flow-diagram summarizing the anticipated flow for the RWCU steel accepted by ALARON Corporation. The non-bracketed numbers represent the tons of material expected to flow through each process based on initial RSM-characterizations provided by CECO. Of the roughly 32 tons expected for receipt, 10 tons (31% by weight) were slated for metal melt and 22 tons (69% by weight) for surface decontamination. Based on the initial characterization and plan, 9.8 tons of material were to be converted to ingots for beneficial reuse and 21.3 tons were to be recycled as clean scrap. The total waste volume was expected to be approximately 1.3 tons.

Fig. 4

The condition and characteristics of the RSM received by ALARON differed from the anticipated material in quantity, the presence of non-metal components, and activity level. Approximately 42 tons of RSM were actually received from Quad Cities compared to the 32 tons originally expected. Whereas the original plan was established for RSM exhibiting general field dose rates less than < 50 mR/hr (average), portions of the heat-exchangers and piping actually exhibited values exceeding 200 mR/hr (average) with a few hot spots as high as 1-3 R/hr. In addition, a small quantity of asbestos insulation was associated with the RSM received. This asbestos accounted for roughly 2.4% or 1 ton of the total 42 tons received. These differences further illustrate the difficulty in accurately characterizing RSM prior to dismantlement. In this case, restricted access prior to removal of each component prevented the generator from developing an improved picture of this material for disposal/reuse. However, the RSM characterizations provided by CECO were relatively accurate and quite useful in planning the processing activities.

The bracketed numbers provided in Fig. 4 indicate the tons of RSM actually received by ALARON. Of the 42 tons received, only 1 ton (asbestos) was classified as primary waste. The remaining 41 tons are presently being processed for reuse -- 14 tons by metal melt and 27 tons by surface decontamination. Based on preliminary results, 97-98% reuse/recycle efficiencies are anticipated for both metal melt and surface decontamination efforts. Of the total 42 tons actually received, only 2.7 tons of waste are expected -- with the asbestos (non-metal) material accounting for 37% of the total waste generated. Although the Quad Cities RWCU processing is still underway, available information strongly suggests that at least 95% of the RSM received will be processed for reuse. The resulting 26.1 tons of "clean" metal will be sold as scrap and the 13.7 tons of ingots from metal melt operations will be returned to Quad Cities for storage or on-site use as shielding material. Options for converting the ingots into other products are currently under evaluation.

Although the relative proportions of RSM slated for metal melt and surface decontamination are, in this particular case, very close to those originally anticipated, most estimates based on the characterization of RSM prior to dismantlement are not nearly as accurate. However, the availability of a comprehensive approach allows ALARON to bid and pursue market opportunities with a built-in degree of confidence and flexibility. Unlike the "specialized" processor scenario described in Fig. 1 and 2, ALARON is now able to "shift" material from one

disposal/reuse option to another in order to accommodate differences between initial and final characterization of the RSM under consideration. The preliminary results provided by the Quad Cities RWCU project (Fig. 4) indicate that, despite differences in key characteristics of the RSM originally anticipated versus that actually received, availability of comprehensive services allows ALARON to optimize the overall treatment scheme and, consequently, maximize recycling and minimize final waste volumes.

CASTING AN EYE TOWARD THE FUTURE

With the advent of comprehensive processing services, improved performance is likely to convince many generators that reuse and recycle represent cost-effective options. In turn, significant volumes of RSM are expected to be made available for processing over the next several years. Despite these changes in the RSM marketplace, potential for greater improvements in reuse/recycle may yet to be realized. As discussed earlier, present-day demolition practices continue to negatively impact RSM recycling options. This is due in large part to the fact that dismantling efforts do not incorporate recycling/reuse considerations and requirements into the up-front planning stage of the process. The two areas of the dismantlement process that offer the greatest opportunities for improved, cost-effective reuse/recycling are RSM characterization prior to demolition and, based on the results of characterization, sorting of material as an integral part of the demolition process. Based on the inherent heterogeneity of RSM, the four (4) disposal/reuse options are all critical components of an optimal solution. The potential savings in material handling, transportation and waste disposal costs made available by simply integrating recycle/reuse considerations into the dismantlement planning process are significant and, as such, should motivate RSM processors and generators to cooperate in the development of new dismantlement procedures.

ABSTRACT

The future size of the radioactive scrap metals (RSM) recycling industry hinges on major policy decisions by the Department of Energy (DOE) and the implementation of a regulatory framework by the US Environmental Protection Agency (EPA) and Nuclear Regulatory Commission (NRC). If the industry meets its aggressive forecasts, over 50,000 tons from government and 20,000 tons from commercial, radioactively-contaminated scrap metal will be processed and recycled in the year 2000. Alternatively, without these key changes by the federal agencies listed above, the current industry will remain essentially flat consisting primarily of commercially generated waste at an annual rate of 15 to 20 thousand tons/year.

This paper forecasts a moderate view of metals recycling in the year 2000 - processing approximately 30-40,000 tons of radioactive scrap per year with 45% from DOE/Department of Defense (DOD) and 50% from commercial

generators. This segment of the nuclear industry will have annual revenues of approximately $200 million per year spread over a half dozen or more competitors. Services provided will primarily be decontamination for free release, melting for fabrication of containers or industrial items and melting for burial.

This paper presents a detailed discussion of the market and RSM industrial processing capacity, the policy and regulatory drivers, and the financial projections.

THE MARKET

What will the market for metals recycling be in the year 2000? By characterizing the market in the first six years of the 1990's and making assumption of the major market drivers, a reasonable projection of the market as we enter the 22nd Century are possible. The market is defined by two components, the generators and the processors.

PROCESSING EXPERIENCE

In the six-year period of 1990 to 1995, an estimated 100,000 tons of RSM from commercial and government generators was sent to processors for "recycling or burial." The introduction of commercial metal melting services in 1993 increased RSM processing by about 10,000 ton per year due to the large savings over burial or decontamination. Of the material that was not directly buried, roughly half was decontaminated and half melted into shield blocks for the DOE/DOD high energy physics program. Table I - RSM Processing and Technologies '90-'95 shows that in 1995, the block melting process consumed half of the total, with direct disposal less than 5%. Decontamination share remained about half the total.

Table I

Disposal costs have increased by a factor of more than three during 1990-1995 for both commercial and government disposal services. This factor of three or more increase has made metal decontamination and recycling via melting more economical than burial. Commercial use of technologies which have been made more cost effective due to the high cost of direct disposal, include metal melting and recycling, and extensive use of new chemical decontamination technologies for metal cleaning.

Fig. 1

MARKET FORCES -- 2000

How much metal will be available in the market? The answer to this question is dependent on the amount produced, the technologies and cost and the decisions and policies that will be made by the DOE and to a lesser extent, the NRC-NEPA.

Technology Available

Over the next five years, repackaging and direct disposal of metals is expected to take a minimal share of the overall metals market. Repackaging, however, will be technologically enhanced by the utilization of metal melting to produce optimum waste density prior to burial. Companies currently in the metal melting business are Manufacturing Sciences, SEG, Nuclear Metals and Aerojet who have existing metal melting capacity. Of these, all will have commercially-available operations by early 1996.

Commercial Production of RSM

Commercial waste generation from 1996 to 2000 will remain essentially flat as compared to the previous six years. Metals from commercial sources will continue to consist of piping, structural items, and decommissioned buildings with a sporadic input of decommissioning wastes from nuclear power plants or industrial facilities. The commercial market

is expected to remain flat with approximately 20,000 tons per year including the large scale decommissioning wastes. Not included in this volume estimate are large components such as steam generators or reactor vessels which are expected to be handled as direct disposal items.

Government Production of RSM

Government metal volumes, while large in inventory, may be relatively small in annual availability due to funding constraints and policy decisions from both the DOE and EPA/NRC. The DOE is developing a policy for metals recycling that is consistent with public safety and cost effectiveness. If approved and implemented, this could result in a annual metals volume that exceeds 50,000 tons per year. Initiatives for metals mining of gaseous diffusion plants and nuclear weapons production facilities may drive high-value metals into the market, providing significant sources of RSM.

In subsequent sections of this paper, the factors that will effect the volume of DOE metals entering the marketplace are examined.

METAL RECYCLING INTO PRODUCTS

Metal recycling to date has been limited to either decontamination and unrestricted release of metals into the scrap metal market or production of shielding blocks for the high-energy physics program. Over the next five years, a market will be developed for high-quality containers manufactured from radioactively-contaminated steel alloys. These containers will be primarily of stainless steel due to the availability of nickel for the stainless alloy and the high market cost of clean stainless. A smaller percentage of the containers will be manufactured out of carbon steel, but due to the higher cost of radioactive container fabrication versus clean containers, only specialized applications of these carbon steel containers will be utilized.

Table II -- DOE Metal Container Consumption Forecast for 2000 shows the annual requirements of the DOE for both stainless and carbon steel in the year 2000. DOE is likely to be the sole customer for radioactively-contaminated steel containers. These containers will be utilized primarily for low-level waste disposal containers. In some cases, specialized uses of stainless steel containers, i.e., for TRU waste will be piloted on a demonstration basis during the time period. Large scale utilization of vitrification, storage or transportation casks or other large consumer markets for radioactive steel recycling will not materialize until after the year 2000, due to the developmental lag time in these demanding applications.

Table II

Due to cost constraints, radioactively-contaminated container manufacturing is expected to occupy approximately 1/5 to 1/3 of DOE's annual radioactive waste containerized waste requirements. This will be produced from RSM removed from DOE decommissioning sites that cannot be economically cleaned for unrestricted use.

UNRESTRICTED USE MATERIAL

Standards and limits are in place now allowing for unrestricted use of materials into the commercial metal recycling market. Criteria for release of materials for recycling in an unrestricted manner, e.g., conventional scrap metal recycling, have been based on criteria established by the Nuclear Regulatory Commission in the mid 1970's. These criteria are the same as Reg. Guide 1.86, criteria for unrestrictive release of facilities. The same criteria have been used to apply to release of materials from recycling operations. Functionally, this

criteria equals to 100 counts per minute above background with a thin window g-m detector. For alpha contamination, this translates to a rate of approximately 2 cpm above background using a alpha probe. In 1995, approximately 10,000 tons of metal was recycled from the industrial processors providing this service. An additional 2,000 tons was released directly by commercial generators.

Over the next five years, the amount of material released is expected to remain essentially constant. Unless standards are changed (see below), there will not be any new developments in technology that significantly change the amount of material that would be released.

RISK BASED UNITS

Table III, Numeric and Risk Based Limits, compares the existing and future standards for contamination on and in recycled metals. Over the next five years, individual states, and possibly the Federal Government, will adopt standards that are not based on numerical limits like Reg. Guide 1.86, but based on dose to man or risk-based limits. Tennessee, by virtue of its pre-eminent position in regulating the radioactive waste processing industry, is leading other states (with the exception of possibly Texas) in the development of risk based limits. By the year 2000, it is likely that Federal guidance on this issue will be forthcoming. This will help the development of large scale RSM container recycling for restricted use within the radioactive waste industry. States such as Tennessee will adopt risk based limits that allow limited release of radioactive contamination on metal but produce insignificant doses to the public, e.g., less than 1 mR/year to the maximally-exposed individual. This action by individual states will promote full scale metals recycling industries.

Table III

In the worst case, the standards will remain the same which would preclude widespread recycling of metals into container feed stocks.

If the Federal Government acts quickly and establishes risk based limits before the year 2000, the impact on the metals recycling industry would be large. A standard on the order of two pico curies/gram could increase the available processing capability of the industry significantly by providing an outlet for low-cost, high-quality RSM.

COST FOR DECONTAMINATION OR PROCESSING

The cost of decontamination or recycling of metals varies widely depending on the material type, contaminant and physical configuration of the metal itself. Surface contaminated items composed of large carbon steel or similar materials with a large mass to surface area ratio can be decontaminated and surveyed for unrestricted use for less than $1/lb., excluding disposal of reject wastes. Typical materials composed construction materials, stairways, cabinets, piping and similar items with a medium surface to weight ratio cost approximately $1.50/lb. for decontamination and free release. Complex items such as small diameter piping, cabling, thin gauge steel cost $1.85/lb or more. Heavily contaminated items, items which have ingrained contamination and require aggressive surface removal, chemical cleaning or sectioning, frequently have a decontamination cost of $2.00-$2.50/lb. including survey.

All of these figures are offset somewhat by the scrap value of the material. The various classes of decontamination costs and scrap values are shown in Tables IV and V, respectively. Table IV, Processing Cost Projections and Market Pricing 1995, shows the class of material and its

approximate decontamination cost. Table V, Scrap Values, shows the current market scrap value for various material types.
Table IV
Table V
In the year 2000, these costs are expected to be about the same as in 1995. It is assumed that the rate of inflation will remain very low during this period and that the value of the scrap metals will remain essentially flat. Costs which are increasing, such as labor and disposal, will be offset by production efficiency gains resulting in a net annual cost increase of less than 5%.
Melting and disposal or recycling costs are currently in the $1.70 to $2.50/lb. range. The low end represents low activity materials which are already cut into sizes which fit the existing furnace dimensions. The high end represents heavily contaminated austenitic steels which must be decontaminated, cut and blended into the melt to meet the specifications. To date, the only significant recycling activity has been the production of shield blocks for the DOE. In the future, radioactive waste containers will become a significant portion of the market on an economic basis while comprising a somewhat smaller share on a mass basis.
DOE POLICY
The DOE has a fundamental policy decision to make regarding the recycling of radioactive metals. If the DOE adopts a recycle policy, including the disposal of most, if not all radioactive metals, the market for radioactive metals recycling will be very large. Conversely, if the Department bases all recycling decisions on economics alone in terms of current cash cost, it is unlikely that any significant volume of metals recycling into useable products will occur.
It is likely that the DOE will adopt a policy for RSM recycling to the extent that it can be accomplished for a cost which is within 10% of all available alternatives. This will result in some products being manufactured from radioactive metals but probably not more than 20% of the metals currently available for recycling. The production and utilization of low-cost items, made from carbon steel, is probably not feasible based on economic cost models developed by The Association for Radioactive Metals Recycling (ARMR). Where a high value component is needed, such as stainless steel drums, the economics associated with recycling and utilization of these containers is more favorable as compared to the straight option of burial and procurement of new, nonradioactive containers.
MARKET FORECAST -- 2000
With the adoption of a DOE policy for recycling and issuance of a risk-based standard for metals recycling, the government sector of the RSM market would be able to produce 50,000 to 100,000 tons of metal per year for recycling. This forecast projects that only about half of this would actually be available, due to economic and technical constraints. Figure 2 - RSM Production Forecast with Policy and Regulations-- 1996-2000, shows the result of these projections.
Fig. 2
The processing technologies that will make up this industry will still largely rely on conventional means, e.g., decontamination or melting for volume reduction and burial. The government's policy on recycling of RSM containers will drive only the high-value, stainless steel containers to be economical.

Figure 3, RSM Processing Share Forecast with Policy and Regulations, shows large share of government origin decon and smelting business that grows significantly between 1997 and 1999.
Fig. 3
FINANCIAL PROJECTIONS
Using the pricing and assumptions listed above, the 1996 RSM market (excluding direct disposal costs) is a $90 million dollar per year industry. The growth, due to a favorable DOE policy and risk-based regulations, to the year 2000 would increase this industry by roughly $100 million or by the year 2000, a RSM industry would generate $200 million per year in revenues.
Employment in the RSM industry in 1995 is estimated to be about 450, using an average of $200K of revenue per employee. The growth in this industry will result in an industry employment of 1000, a doubling in size by the year 2000. Table VI, Revenue Projection for RSM Processing -- 1996-2000 shows the components of revenue and the dramatic impact of government processing on the total. In the year 2000, government processing will account for about 60% of the industry's revenue.
Table VI
CONCLUSION
The RSM industry in the year 2000 will be between $100 and $200 million per year with an employment of 500 to 1000 people directly involved in processing RSM. The factor of two variation is dependent on the outcome of federal government action to establish RSM recycling policy and standards. The industry has poised itself to respond to the large, potential demand. Based on current technology and experience, the possibility of a $200 million per year industry is realistic and achievable.

RECYCLING FOR PROFIT THROUGH QUANTUM-CEPTM
Andrew H. Gorin
M4 Environmental L.P.
1000 Clearview Court
Oak Ridge, TN 37830
ABSTRACT
M4 Environmental L.P. provides the DOE a unique opportunity to commercially recycle mixed waste or convert depleted uranium hexafluoride (UF6) while simultaneously purifying radioactive scrap metal (RSM). No other Low-Level mixed low-level (LLMW), or RSM processing technology offers this unique recycling/conversion solution to the multiple waste challenges faced by DOE. The dissociation and partitioning capabilities

inherent to Quantum-CEP allow the creation of useful products from the elemental constituents of a multitude of wastes. This co-processing approach will allow safe, economical disposition of the majority of DOE wastes. The life cycle costs associated with co-processing RSM, LLMW, and depleted UF6 utilizing the Quantum-CEP technology are anticipated to be significantly lower than individually processing these wastes/materials through separate, standard industrial processes.

Potential RSM feedstocks for co-processing LLMW and depleted UF6 include: 1) approximately 200,000 tons of contaminated ferrous and non-ferrous metals in the current national DOE inventory (1); 2) barrier nickel in the intact buildings that house the gaseous diffusion operations; 3) PCB-contaminated ductwork, copper instrument tubing and copper wire (with and without insulating encasement) present in the still-intact gaseous diffusion plants; 4) aluminum from compressors and other process equipment in the still-intact gaseous diffusion plants; and 5) ferrous alloys present in the still-intact gaseous diffusion plants.

LLMW streams such as inorganic sludges, organic sludges and liquids, soils, scintillation fluids, inorganic debris, batteries, laboratory packs and reactive metals can be co-processed with the RSM. Products from the co-processing of LLMW include a synthesis fuel that can be used as either a fuel or a chemical feedstock; ingots of RSM for 1) feed material for the fabrication of radioactive waste containers; 2) shield blocks for DOE operations; or 3) free-release into the European Community or other areas that have existing release standards; and a stable ceramic phase that contains most of the radioactive contaminants from the LLMW and RSM, which can either be reused within the DOE or disposed of at a site such as Envirocare's facility in Utah.

Review of DOE's inventory of depleted UF6 indicates approximately 50,000 cylinders containing more than 1.2 billion pounds of material that can be co-processed with radioactive scrap nickel, copper, aluminum or ferrous alloys. Products generated from the Quantum-CEP conversion of the depleted UF6 include anhydrous hydrogen fluoride (AHF), aluminum fluoride, a reusable uranium oxide ceramic, a reusable uranium-iron alloy for feedstock to the Atomic Vapor Laser Isotope Separation (AVLIS) uranium enrichment process, and purified ingots of the RSM.

M4 ENVIRONMENTAL L.P.

M4 Environmental Management L.P. (M4), formed in August 1994, is a limited partnership between Lockheed Martin Corporation and Molten Metal Technology, Inc. (MMT). The company has the exclusive license to provide Mat's proprietary CEP and Quantum-CEP technologies to the U.S. Department of Energy, the U.S. Department of Defense, and the United States Enrichment Corporation for processing hazardous, radioactive, and mixed wastes into useful products. Quantum-CEP refers to CEP technology when applied to radioactive material.

M4 recently announced the commissioning of its second Quantum-CEP system, a commercial system which processed DOE LLMW in December 1995. M4 activated its first system to process depleted uranium hexafluoride at the M4 Technology Center in October 1995. The completed Technology Center will have required an approximately $40 million capital investment and will house several CEP and Quantum-CEP systems that have a range of nominal molten metal capacities from 20 to 3000 lb. The company also was recently selected as one of three finalists, out of 23 competitors, for the U.S. Army's Alternative Technology Chemical Demilitarization Program.

OVERVIEW OF CEP/QUANTUM-CEPTM

Quantum-CEP is an adaptation of CEP technology for radioactive and mixed waste streams. Quantum CEP allows both destruction of hazardous components and controlled partitioning of radionuclides. This leads to decontamination and recycling of a large portion of the waste components to commercial products as well as volume reduction and concentration of radionuclides for final disposal.

At the core of both CEP and Quantum-CEP technology is a molten metal bath that acts as a catalyst and solvent in the dissociation of the feed, the synthesis of products and/or the concentration of radionuclides in the desired phase. Upon introduction to the bath, feeds dissociate into their constituent elements and go into metal solution. The critical criteria for evaluation of feeds for processing, therefore, lie not in their molecular structure, but rather in their elemental makeup, since most materials will be dissolved through an elemental intermediate regardless of molecular structure at introduction. Once in this dissolved elemental state, the addition of co-reactants enables reformation and partitioning of desired products by either remaining in the molten metal phase, moving to the ceramic phase directly above the metal, or exiting the reactor in the gas phase. The partitioning control afforded by co-reactant addition is a distinguishing feature of CEP and Quantum-CEP.

The versatility of the CEP process is attributed to the 'singular' dissolved elemental intermediate through which reactions proceed. For example, the metal bath ensures that in the dissociation of an organic feed, dissolved carbon (C) is the only carbon intermediate. This is in contrast to open flame systems, in which multiple free radical intermediates can be formed, leading to hard-to -control side reactions. While a traditional non-catalytic technology (e.g. incineration) operates in a strongly oxidizing atmosphere and hence produces large quantities of carbon dioxide and water vapor, the strongly reducing atmosphere of CEP produces carbon monoxide and hydrogen gas, with a CO:CO2 ratio on the order of 10,000:1.

Given the key role of the metal bath as a solvent, the thermodynamic forces governing the solubility of elements in liquid metal baths are important in understanding how the operating conditions of the CEP system can be manipulated to synthesize desired products of commercial value. The reducing strength of dissolved carbon is an important factor in CEP's flexible recycling ability. Specifically, CEP provides the flexibility to recycle organics to synthesis gas, recover metals and inorganics, such as halides, sulfur and phosphorus, and separate and concentrate compounds of the actinide elements. The dissolution of carbon in the liquid iron solvent ensures a homogeneous reducing environment and, hence, robust control of product composition and quality.

MELT PURIFICATION OF RSM

CEP radioactive waste processing and recycling has been studied extensively by MMT under a DOE-sponsored Program Research & Development Award. This $38 million research program was designed to investigate the "Recycle of Contaminated Scrap Metal." One of the program focus areas was radionuclide partitioning, for which 152 tests were performed, consuming 1,390 hours of hot metal time on the bench-scale, pilot-scale and demonstration-scale CEP systems in the Fall River, Massachusetts facility. Hafnium was used as a surrogate for the actinides in these studies, which involved partitioning in both molten iron and nickel. In iron, the lower detection limit (LDL) for hafnium is 0.2 ppm; in nickel it is 1.74 ppm. Results consistently showed residual radionuclide

surrogate concentrations in the matrix metal that were below the LDL with no radial or axial gradients identified. Additional partitioning tests were performed with similar success on the bench scale at Scientific Ecology Group's Quantum-CEP facility, using both cerium and uranium as contaminants.

DOE national laboratories have extensively researched the decontamination of metals using melt refining/slagging ("passive partitioning"). The documentation of these experiments indicates that among all of the ceramic phase compositions tried, the best results occurred with the use of the borosilicate and high silica. For instance, decontamination factors (DFs) between 600 and 1,100 were achieved for the removal of uranium dioxide (UO2) and (PuO2) from nickel with these ceramic phases (1). Note that here DF is defined as the initial weight fraction of contaminant in the as-received RSM divided by the final weight fraction of contaminant in the purified RSM. Quantum-CEP enhances decontamination through continuous processing, selective reactant addition, superior mass transfer characteristics, unique reactor configurations, and alternate materials selection ("active partitioning"). Therefore, higher DFs than those benchmarked from the previous DOE "passive partitioning" work are anticipated.

A thermodynamic analysis of melt purification can be used to approximate the magnitude of the maximum theoretical separation under equilibrium conditions where the partitioning of the contaminants is to an oxide-based ceramic phase. A favorable theoretical separation is a "green light" to proceed, but the calculated result will not likely be achieved in practice because of system nonidealities. The Quantum-CEP system under consideration consists of a molten metal bath, an oxide-based ceramic phase floating on the molten metal, and a head space of oxygen. These phases are assumed to be in equilibrium. The equilibrium state of a closed system is that state for which the total Gibbs energy (G) is a minimum with respect to all possible changes at the given temperature and pressure. This means that at equilibrium, the change in the Gibbs energy (DG) is zero. For a given chemical reaction aA + bB = cC + dD, the expression for the change in the Gibbs energy is given as:

Eq. 1

where

1. DGo is the standard Gibbs energy of formation at a given temperature
2. ai is the activity of the chemical species = gixi.
3. R = 8.314 J mol-1 K-1.
4. T = temperature.

The two reactions (for RSM with one contaminant) that are at equilibrium in this system are (matrix metal = Mm; contaminant metal = Cm)

Eq. 2

Eq. 3

Because DG1 = DG2 = 0 at equilibrium,

Eq. 4

To determine the maximum theoretical DF, rearrange the above equation to obtain an expression for aCm. Then, use the following set of assumptions to simplify:

1. aCm = gCmxCm (where gCm is the thermodynamic activity coefficient for the contaminant metal in the matrix metal, and gCm is the mole fraction of contaminant metal remaining in the matrix metal after melt purification).

2. aCmxO2y and aMmxO2y in the ceramic phase are approximated by xCmxO2y and xMmxO2y, their respective mole fractions.
3. aMm may be approximated as unity.
4. T is the temperature of the system.

Solve for xCm, and convert to the appropriate weight fraction using the appropriate molecular weights. Finally, an assumption must be made as to the value of gCm.

M4 TECHNOLOGY CENTER

Overview

M4's state-of-the-art Technology Center is located in a light industrial/commerce park in Oak Ridge, TN. The three-story facility has more than 75,000 ft2 of factory floor space and 25,000 ft2 of office space. Quantum-CEP systems in the M4 Technology Center are designated as Radioactive Processing Units (RPUs). The following provides a description of each of the systems that have been installed or are being installed in the facility.

Description of LLMW Facilities

RPU-2

RPU-2 provides a bench-scale facility for research and development and treatability studies. Each unit is constructed with feed preparation equipment (excess water removal, etc.), two replicate Quantum-CEP test units, a common gas mixing system and three redundant gas handling trains (GHTs).

The gas delivery set-up is capable of mixing three reagent gases and an inert gas for submerged lance injection into a molten metal or metal and ceramic phase system. The gas composition is controlled using individual flowmeters and a gas mixing chamber, and can be directed to either test unit via a three-way valve at the exit of the gas mixing chamber.

On-line analysis of the process gas stream during waste injection is performed with, for example, a Total Hydrocarbon Analyzer (THC) mass spectrometer, CO/CO2 analyzer, etc. The on-line analysis allows quantification of the gas phase product quality for comparison to larger Q-CEP systems. Additionally, metal and ceramic phase samples can be taken during operation. Post-run elemental analysis is performed on metal, ceramic, containment, head space, etc., for material balances.

RPU-3

RPU-3 is a refractory-lined Catalytic Processing Unit (CPU) which can be fed either through a submerged lance, a lock hopper or a bottom tuyere. A tuyere is a concentric pipe mounted from the bottom of the reactor where flowable feed with a small nominal particle size (i.e., < 1 mm) and co-feeds are injected into the reactor. The submerged lance and lock hopper are typically used for adding bulk solids to the CPU. A sludge/ slurry injection system is under development to enhance the capability of RPU-3 to process a wide range of materials. The RPU-3 has a nominal molten metal capacity of 800 lb. A prototype ceramic and metal tapping assembly has been developed for the RPU-3. This system allows for continuous removal of the two phases from the CPU on a continuous basis. Throughput for RSM may be up to 60 lb/hr in this system.

Thermocouples (for measuring gas and/or metal temperature), off-gas plumbing and reactor relief stations are installed at the top of the reactor. A containment monitoring system is also installed. An angled sample port is provided for intermittent contact measurement of temperature as well as withdrawal of ceramic and metal samples. Product gases are withdrawn from the reactor through a gas handling train (GHT).

RPU-4

RPU-4 is rated for the largest waste throughput of any processing unit in the Technology Center. The CPU is an inductively heated, refractory-lined steel pressure vessel with a nominal molten metal capacity of 3,000 lb. The unit is equipped with ceramic and metal tapping capabilities that allow up to 1,400 lb/hr of RSM to be decontaminated.

A gas handling train will allow off-gas cooling and collection of dust including volatile heavy metals and metal halides. The ability to separate alkali halides from the lead, zinc, and other volatile heavy metals will be accomplished through as dual-stage cooling and filtration train. A small purge stream containing the volatile heavy metals is required for the system. Appropriate polishing steps, such as carbon bed absorption and caustic scrubbing, are utilized to ensure off-gas quality prior to being sent to storage or flare system. The carbon bed is fully recyclable to the CEP system after saturation.

Planned melt purification work to be done in these three CEP systems in 1996 includes co-processing commercial mixed waste (chlorinated and/or fluorinated organic liquids) and nickel with 2.1 wt. % ThO2. Other potential RSM feedstocks for co-processing LLMW in 1996 and out years include: 1) approximately 200,000 tons of contaminated ferrous and non-ferrous metals in the current national DOE inventory; 2) barrier nickel in the intact buildings that house the gaseous diffusion operations; and 3) ferrous alloys present in the still-intact gaseous diffusion plants. It is expected that the Quantum CEP Technology will be economical for the processing of mixed wastes in comparison with other available technologies; by using RSM in the processing, the economics will be in hand.

UF6 Program Background

In May 1995, M4 signed a one-year contract with the USEC to demonstrate the applicability of Quantum-CEP to convert UF6 process tails to a stable uranium form (i.e., UO2/U3O8 or bulk uranium metal) with reuse of the fluorine. A successful technology demonstration and a decision to proceed would lead to the construction of one or more production facilities to convert USEC's stored and newly generated tails. This would provide a solid experience base for pursuing the DOE market, reported to be 556,000 metric tons of UF6, as well as the international market.

The experimental plan has been constructed with three process flowsheet options. In the baseline approach, the uranium content of the UF6 is converted to either UO2 or U3O8, and the fluorine content is recovered as anhydrous hydrogen fluoride (AHF). A general representation for this process is:

Option 1 (Baseline): UF6 + H2O + CO2 = UOx + AHF + CO + H2

In Option 2, a metal oxide and a carbon source are co-fed to the CPU to produce either UO2 or U3O8, the fluoride of the metal that was fed as an oxide, and synthesis gas (CO + H2). The option differs from the baseline in two respects: it feeds a solid material (such as CaO, MgO, or Al2O3) and it does not need the elaborate gas recovery system required for AHF since the fluorine values are recovered as a salt (CaF2, MgF2, or AlF3). This option is expected to have less attractive economics than the baseline approach, which is the focus of planned development and demonstration activities. A general representation for this process is:

Option 2 : UF6 + MOy = UOx + MFz + CO + H2

Finally, as a third option, a reactive metal (Al, Mg, or Ca) can be fed into the process as a reductant, producing a uranium alloy with the bath

metal (i.e., iron) and the fluoride of the reactive metal. A general representation for this process is:

Option 3: $UF_6 + M = U + MF_x$

The dense, stable storable uranium oxide produced in the first two process options can either be sent to a disposal site or made into products for shielding. The uranium alloy produced in Option 3 could be used for such things as AVLIS metal feed or shielding. The bath metal for Options 1 & 2 may be copper, nickel or iron, which can be provided from RSM in DOE inventories; the preferred bath metals for option 3 are iron or carbon steel, which can yield an alloy that melts significantly lower than either iron or uranium alone. Option 3 is unique in that it would allow the use of radioactive scrap aluminum from idle gaseous diffusion plant equipment (such as compressors) as feedstock for conversion to AlF_3. The aluminum fluoride could be collected from the gas phase so that, with proper filtration, it is free of radioactivity and is of very high purity (i.e., 99% minimum). Currently, AlF_3 is available commercially in purities of 92% and 97% and has a value of around $0.50/lb. Also, in a production plant designed to convert the DOE UF_6, the UF_6 cylinders will provide significant metal input and up to 70,000 tons of steel product for resale from Quantum-CEP operations. By feeding excess bath metal to the process, Quantum-CEP purified RSM can be cast and made available for additional reuse.

Specific RSM feed being lined up for RPU-1 includes: 1) copper contaminated with depleted uranium from the H-1 Foundry at the Oak Ridge Y-12 Plant; 2) a 180-lb Monel UF_6 cylinder from the K-25 Site in Oak Ridge; 3) aluminum compressor blades contaminated with slightly enriched uranium also from the K-25 Site; and 4) barrier nickel from the gaseous diffusion plants (either part or all of a 100-lb ingot or "cornflakes." The cost of Quantum CEP conversion of depleted UF_6 are expected to be in lined with quoted competitive conversion process cost (two dollars to eight dollars/kg of UF_6); RSM addition to the process will further lower conversion costs.

Description of UF_6 Demonstration Facility

RPU-1

The M4 RPU-1 experimental facility incorporates the general capability to feed gaseous UF_6 and various reactants (co-feeds) necessary for the chemical conversion of UF_6 (e.g., H_2O, H_2, O_2, CaO, and CH_4) at prescribed rates, temperatures, and pressures to a CPU and analyze the resulting off-gas in near real time. HF generated by the conversion process is chemically reacted with chemical sorbents for disposal. The capability to sample the metal melt and ceramic phase is available, but bulk removal is not. The design allows quantitative operation of the CPU at pre-established process conditions for sufficient periods of time (e.g., one to six hours) to achieve steady state and collect meaningful process performance and material balance information. The overall design allows quick turnaround of the experimental equipment to accommodated two test periods per week. Each test period can determine the steady state results for several values of an experimental variable.

RPU-1 consists of six major components: 1) Feed System, 2) CPU, 3) Off-Gas System, 4) Purge System, 5) Analytical and Control Instrumentation, and 6) Containment. A summary description of the facility is given below.

The Feed System consists of an electrically-heated environmental enclosure for generating a UF_6 vapor feed, gas manifolds for various gaseous components, steam generator, and solid feeder. Solid co-feeds

(e.g., Ca, UO3, CaO, Al, and CaF2) may be batch charged to the CPU (along with the initial metal charge) as well as lance fed to the CPU in a continuous mode from a feed hopper.

The CPU is a crucible-based reactor designed by MMT specifically for UF6 service. The unit will operate with a variety of molten metals, including iron, nickel and copper. The nominal temperature range is 1000o to 1700o C. The crucible design will accommodate a nominal 45 kg of metal and will allow the collection of sufficient ceramic product to support a six-hour experimental campaign. Multiple tests may be performed for each experimental campaign. The CPU can be operated under a broad range of processing conditions to enable parametric mapping of process performance for the assumed reaction scenarios. The CPU operates at essentially atmospheric pressure. Metal and ceramic phase tapping is not provided although the design allows metal and ceramic phase sampling.

The Off-Gas System consists of a ceramic process filter to remove entrained metal and ceramic particulates from the CPU, chemical traps to quantitatively react the CPU-generated HF and residual UF6, and HEPA filters for final particulate removal.

The Purge System consists of a cold trap, chemical traps, and HEPA filter to remove bulk process gas from the experimental system after completion of an experimental campaign.

The Analytical and Control System consists of near real time, on-line instruments for the quantitative analysis of process gas for process control and process performance determination. Off-line analytical equipment is provided for analysis of the ceramic and metal phases. In this case, the crucible will be removed from the CPU after completion of an experimental campaign and bisected for quantitative analysis. X-ray fluorescence or energy dispersive x-ray will be used to provide quantitative elemental distributions in the crucible, metal and ceramic (as well as any interface). Scanning electron microscopy (SEM) will be utilized to identify any distinct phase regions of interest in the crucible, metal, ceramic and any interfaces. Electron probe microanalysis (EPMA) will be used to determine the chemical identity of the distinct phases identified by the SEM.

The Containment System provides multiple physical barriers to double and triple contain radioactive gas and solids, as well as flammable and toxic process components, at the source in the event of a primary process breach. The Feed System, CPU, Off-Gas System, and Purge System are located in separated, independently ventilated, secondary containment structures. The CPU will be readily removable from the containment structure for post-mortem examination. A hooded work area is also provided for disassembly of the crucible after a test. All components of the facility are located in a third containment structure for ultimate environmental isolation and protection of workers. HF, H2, and CO monitors with alarm circuits are provided in the various containment structures to alert the operator to process leaks.

ABSTRACT

The Westinghouse Savannah River Company (WSRC) is partnering with a number of commercial nuclear power plants in order to directly implement utility best practices as a means of improved treatment, storage and disposal of low-level radioactive waste. Initial focus has been on development and implementation of an aggressive pollution prevention/waste minimization program. Through a series of benchmarking visits and technical exchanges, WSRC has identified and begun implementation of a series of changes to work practices and material/product specifications that are expected to result in substantial cost savings and extension in the life of on-site disposal facilities. The utility participants in this partnership have been exposed to a number of technologies with significant applicability to current and planned operations at commercial nuclear plants. This partnership is consistent with the Department of Energy's (DOE) initiative to utilize commercial technologies/practices to an increased degree and the U. S. electrical industry's continuing practice of cost reduction and economic competitiveness.

INTRODUCTION

The Savannah River Site (SRS) is a key DOE facility focusing on national security work, environmental and waste management activities, and economic development and technology transfer initiatives. Owned by the DOE and operated under contract by the Westinghouse Savannah River Company (WSRC), the complex covers 310 square miles near Aiken, South Carolina.

From its construction and initial operation in the 1950s until the early 1990s, SRS operated in a manner consistent with its national defense mission. There was minimal contact with the commercial world, with all process-related research and development performed on site. Production goals, and employee and public health and safety were paramount. Cost effectiveness was secondary. The situation was similar at the other sites in the DOE Weapons Complex.

With the fall of the Soviet Union in the early 1990s, the DOE complex began a transition period with an often traumatic effect on its mode of operations. Site missions changed from production to environmental management, plans were made to completely shut down some facilities, budgets were cut as the Federal Government struggled with an increasing budget deficit, and thousands of workers were laid off as funding for

their projects vanished. DOE and its contractors quickly recognized that a basic change in operating culture was required both for basic survival and to complete remaining missions within available budgets. This change in operating culture involved, among others:

- privatization
- outsourcing
- use of commercial best in class technologies
- change in basic structure of operating contracts

The cost effectiveness/savings initiatives undertaken by DOE and its contractors mirror the efforts begun by the U.S. electrical utilities with commercial nuclear plants in the early 1980s. Specifically in the area of low-level radioactive waste management, the commercial power plants were faced with spiraling costs for waste disposal. Burial costs were increasing steadily from a few dollars per cubic foot in the late 1970s to several hundred dollars per cubic foot today. This problem was compounded by the formation of regional compacts which presented the possibility that the majority of generators would be denied access to available disposal capacity.

As the cost of disposal of low-level radioactive waste became an increasing part of the nuclear plant's operating budget, this portion of the operation came under increased scrutiny as the utility endeavored to reduce costs and improve its situation in what was quickly becoming a highly competitive electrical generation and distribution industry. Strategies were developed and implemented to:

- reduce waste generation at the source improve the packaging of waste that is generated
- decontaminate material where practical
- volume reduce waste volumes to the maximum extent
- develop storage concepts where required

IMPLEMENTING A COST REDUCTION CULTURE AT SRS

The Solid Waste Management Department (SWMD) at SRS is responsible for the treatment, storage, and disposal of all solid waste streams generated at SRS with the exception of high-level waste stored in underground tank farms. The disposition of these waste streams are as follows:

- hazardous waste is shipped off site for incineration at a commercial facility
- mixed waste is stored on site awaiting operation of the Consolidated Incinerator Facility
- transuranic waste is stored on site awaiting opening of the Waste Isolation Pilot Plant
- sanitary waste is disposed of at an off-site commercial landfill
- low-level radioactive waste is disposed of in on site engineered disposal vaults

As part of its program to reduce the cost for treatment, storage and disposal of the site's solid waste, SWMD has pursued some of the more traditional approaches including:

- privatization of sanitary waste disposal
- development of needed technologies under the Vendor Forum Program
- awarding of a contract for off-site volume reduction of low-level radioactive waste
- utilization of subcontracts with commercial vendors for selected tasks

In addition to these initiatives, it was recognized that there was a significant source of proven, world-class best practices within easy grasp of SRS; the 100 or so commercial nuclear plants. These plants

readily share their best practices among themselves without regard to utility ownership. Discussions with several of these plants found them willing and eager to share their best practices with SRS as well.

The SWMD at SRS therefore formed an informal Waste Management Partnership with a number of commercial nuclear plants. The objective of the partnership was to identify and directly incorporate as many utility best practices as possible at SRS that would assist our cost reduction initiative. To ensure effectiveness of this partnership, certain classical paradigms had to be overcome at SRS:

What we've done for the past 40 years has worked and is safe. Why change now?

Utility practices are not as technically rigorous as we require.

We have a lot of alpha contamination which invalidates many utility practices.

We've got to study it some more.

The areas in which SRS could benefit from the partnership are:

waste minimization/source reduction strategies and practices

decontamination strategies/practices

volume reduction techniques

container selection and design

waste storage

treatment, storage and disposal of greater than Class C waste

filtration, demineralization and other treatment of dilute liquid radioactive waste streams

hazardous chemical control programs

waste characterization and certification programs

reuse/recycle of radioactive scrap

Although the cost of low-level radioactive waste disposal at SRS does not provide the same hard economic driver as exists in the commercial nuclear industry, radiological performance requirements for low-level radioactive waste disposal facilities have resulted in an almost doubling of unit disposal costs. This results from a 1995 change from shallow- land burial to disposal in engineered vaults. The need for a new focus on pollution prevention/waste minimization at SRS resulted in this area becoming the initial focus of the Waste Management Partnership. SRS benchmarking teams therefore visited the following commercial nuclear plants:

Susquehanna Steam Electric Station near Berwick, Pa.

Beaver Valley Nuclear Station near Pittsburgh, Pa.

McGuire Nuclear Station near Huntersville, N.C.

Plant Vogtle near Waynesboro, Ga.

V.C. Summer Nuclear Station near Jenkinsville, S.C.

These plants are but a few of the plants with demonstrated track records of significant reduction in the volume of low- level radioactive waste generated and disposed of over the past ten years. During the benchmarking visits, plant personnel openly discussed their programs, what had worked (and what hadn't worked), the need for senior management commitment and support, employee education and motivation, and opportunity identification and assessment. Plant walk downs were key ingredients of the visits as most of the members of the benchmarking team were representatives of SRS' larger waste generators.

WHAT THE PARTNERSHIP HAS MEANT TO SRS

The Waste Management Partnership has been the cornerstone for the successful development and implementation of SRS' pollution prevention/waste minimization program. The Partnership will also

represent the engine for continuous improvement of the program. Whereas a typical commercial nuclear plant has only a handful of individual waste generators, a DOE site the size and complexity of SRS has approximately 55 individual waste generators. The development and implementation of a site-wide pollution prevention/waste minimization program is therefore faced with a number of unique hurdles and barriers.

The Partnership provided SRS' SWMD with a litany of utility success stories that were crucial in receiving senior management buy in and commitment. The information gained from the Partnership was used to develop a brochure entitled "Savannah River Site, The Commercial Connection" that was targeted at the site's division vice presidents. The brochure described the successes and cost reductions achieved by the utilities and described the techniques and work practices that, when applied at SRS, would result in an overall reduction in SRS' radwaste budget. The utility success stories also provided operating experience to overcome skepticism that implementation of common sense changes to operating practices could have a significant impact on radwaste volumes and disposal costs. The Partnership clearly allowed SRS to immediately benefit from 10 years of utility field work.

Following the example of the commercial nuclear industry, SRS has formed a Solid Waste User's Advisory Board to represent the focus of site-wide implementation of pollution prevention/waste minimization initiatives. As a result of the Waste Management Partnership, the following initiatives are being pursued (both on a pilot and across the board basis) at SRS facilities:

- Segregation of Radiation Buffer Area (RBA) Waste - Green is Clean program
- Segregation of all waste types at point of generation
- Elimination/reduction of throw away items (especially plastic and tape)
- Maximize use of launderable items; e.g., waste bags, rags, etc.
- Select materials of construction consistent with incineration in the Consolidated Incinerator Facility
- Designation of contaminated tool cribs
- Clearance of tools in regulated areas with an automated tool frisker
- Decontamination of tools
- Elimination of double bagging of LLW

Once fully implemented, it is estimated that these programs have the potential to reduce waste generation volumes by 30% and reduce annual disposal costs at SRS by $2-3 million. These efforts will also extend the life of the site's engineered disposal vaults, thereby delaying the need for scarce capital project funding.

In addition, as SRS and other DOE facilities intensify their recycling efforts, the utilities represent a potential end user of the "products" manufactured from the recycled materials.

WHAT'S IN IT FOR THE UTILITIES?

A reasonable question is, what can the commercial nuclear plants learn as part of this Waste Management Partnership? The answer is quite simple and straightforward: additional opportunities for cost effectiveness/reduction. Although the mission of a commercial nuclear plant and a facility at SRS or other DOE site differ, the tail end of the nuclear fuel cycle offer numerous areas of commonality as discussed earlier in this paper. The lifting of the veil of secrecy at SRS and other DOE sites offers the utilities the opportunity to investigate those best practices in these areas of commonality. In addition, nuclear plant

personnel frequently become involved in issues such as off-site incineration and design and operation of regional disposal facilities that directly affect the operation of their plants. The exchange of design and operating information on SRS facilities such as the low level radioactive waste disposal vaults and the Consolidated Incinerator Facility will assist nuclear plant personnel perform this part of their responsibilities.

In the case of Susquehanna Steam Electric Station, sufficient interest was generated during the SRS benchmarking trip in May 1995 that two utility personnel visited SRS in August 1995. The utility personnel were interested in learning more about SRS' solid waste operation with specific emphasis on disposal vault design and design and operation of the SRS Consolidated Incinerator Facility. The utility representatives' visit to SRS was also used to allow them to walk down two of the site's larger generators and critique their waste minimization practices. Once again, by working together, the DOE facility and the electric utility were able to develop a win-win situation.

PARTNERING BEYOND THE SAVANNAH RIVER SITE

There are geographically convenient commercial nuclear plants available to most DOE facilities. These commercial plants offer numerous opportunities to the DOE facilities for partnering on day-to-day operations issues as well as, one- time events such as decommissioning. With many DOE facilities actively undertaking D&D programs, the potential for exchange of world class practices and techniques do exist.

Another partnership that has developed at a Westinghouse operated DOE facility is the one between the waste management organizations at the Hanford DOE site and the commercial nuclear plant operated by the Washington Public Power Supply System (WNP) on the Hanford reservation. WNP personnel had initially participated in the annual Westinghouse GOCO Waste Management Operations Workshop at Hanford in November 1994. This relationship has now grown into one that has proven beneficial to both organizations. WNP personnel actively participate in Westinghouse Hanford Company's monthly pollution prevention meetings. WNP personnel have learned from the DOE pollution prevention program and is implementing many of the philosophies, such as pollution prevention opportunity assessments, recycling/reuse and materials substitution to minimize waste generation. Additional Westinghouse Hanford has provided WNP assistance in development of procedures and programs for control of chemicals and management of hazardous waste.

In return, WNP has shared their initiatives on radioactive waste minimization with Westinghouse Hanford. The use of anti-contamination clothing designed to eliminate waste generation are being considered both at Hanford and West Valley. The use of launderable tarps to replace herculite and other plastic sheeting is also being pursued.

The partnership between WNP and Westinghouse Hanford has and will continue to provide opportunities for exchange of information with mutual benefit. The partnership has provided the key vehicle -- an open line of communications.

CONCLUSION

Yes Virginia, DOE facilities can learn from commercial nuclear plants and commercial plants can learn from DOE facilities. Once the NIH (not invented here) factor is overcome, partnering between DOE facilities and commercial nuclear plants provides a powerful vehicle for exchanging best practices as both cultures strive for improved cost competitiveness.

Partnering between the SWMD at SRS and waste management organizations at a number of commercial nuclear plants has provided the impetus for the SRS pollution prevention/waste minimization program that is expected to result in significant cost savings. The partnering commercial plants have gained information and knowledge needed to further make their operations cost effective. This partnering can be expanded to any DOE/utility pair as shown by the Hanford/WNP experience.

As we all look to make our operations more cost effective and competitive, remember, put the NIH monkey back in its cage and look beyond your culture for opportunities for continuous improvement.

AN INDUSTRY RESPONSE TO RECYCLE 2000

ABSTRACT

The United States Department of Energy (DOE) is expected to issue a policy early this year articulating DOE's position on the recycle of DOE radioactive scrap metal. In anticipation of this "Recycle 2000" initiative, the nuclear industry has formed a new trade association called the Association of Radioactive Metal Recyclers (ARMR). This article describes the Recycle 2000 initiative, provides some background on ARMR and its membership, and identifies industry views on the actions to be taken and issues to be resolved if Recycle 2000 is to become a reality.

RECYCLE 2000

The U.S. Department of Energy (DOE) has a huge volume of radioactive scrap metal (RSM) in inventory at sites across the DOE complex. In March 1995, an inventory report prepared for the Office of Technology Development documented the existence of 157,501 tons of contaminated carbon steel at thirteen (13) sites (1). Others have estimated that, when metal generated during the future dismantlement of contaminated DOE facilities is included, the total volume of DOE RSM could reach 3 million tons!

In December 1994, the "Recycle 2000" concept was articulated by DOE at a meeting in Denver in conjunction with a diverse group of stakeholders including citizens groups, environmental organizations, unions, industry and various government organizations. The overall objective was to determine stakeholder support for DOE to remove RSM from the waste disposal stream and "beneficially reuse" the DOE metal in applications where its small radioactivity content would not be a detriment. Specifically, DOE proposed that, by the year 2000, at least 50 percent of the low-level waste disposal containers (B-25 boxes) used by DOE would be fabricated from DOE-generated radiologically contaminated carbon steel defined as RSM. Such a proposal would recycle natural resources (metal)

and vastly reduce the DOE disposal volume that would otherwise be required if the radioactive scrap metal was buried.

Since this successful Recycle 2000 concept introduction, other meetings have been conducted by DOE in Salt Lake City and Knoxville with considerable emphasis placed on, 1) developing a cost model comparing the cost of recycling RSM into waste containers to the cost of burial, and 2) evaluating the dose received (risk) by industry workers and the general public if the Recycle 2000 concept was implemented.

There appears to be considerable support for recycling not only in industry but throughout DOE and EPA. Consider the following:

USDOE Assistant Secretary for Environmental Management, Thomas P. Grumbly, has stated that, "It is our policy to reuse or recycle these scrap metals to the maximum practical extent" (2).

USDOE Director of Environmental Restoration, James Owendoff, expressed in a Weapons Complex Monitor interview a preference to use waste disposal containers fabricated from recycled DOE metal as opposed to containers made from virgin steel, even at a large cost premium (3).

USDOE Director of the Office of Eastern Area Programs, Jim Fiore, has stated, "Pollution prevention and waste minimization activities such as scrap metal recycling are supported and encouraged by Headquarters" (4).

USDOE Director of the Waste Minimization Division, J. Kent Hancock, estimated that between $28 to $43 billion could be saved within the complex over the next 75 years by implementing pollution prevention programs including recycling (5).

The USEPA has established pollution prevention as a "national objective" requiring that pollution be prevented or eliminated at the source wherever feasible, recycled when prevention is not feasible, and disposed of only as a last resort.

Presidential Executive Order #12780 requires that DOE "promote cost-effective waste reduction and recycling of usable materials from waste generated by Federal Government activities," and that DOE "integrate these programs to assist in addressing the nation's solid waste disposal problems."

Because of the strong support for recycling both within industry and government, the industry consensus is that the Recycle 2000 Policy will be adopted by DOE and promulgated in early 1996.

ASSOCIATION OF RADIOACTIVE METAL RECYCLERS (ARMR)

In 1995, strong industry interest in the beneficial reuse concept and in DOE's Recycle 2000 initiative spawned the formation of a new trade association called the Association of Radioactive Metal Recyclers (ARMR), headquartered at the University of Tennessee in Knoxville.

ARMR is a trade organization of the holders, decontamination processors, metal fabricators and end users of recycled radioactive scrap metal. Through the activities of the Association, the Members seek to stimulate and support the movement of radioactive scrap metal to useful products with the following specific objectives:

Coordinate the exchange of information among the Members regarding Radioactive Scrap Metal (RSM).

Foster the identification of reuse products, including the free release of decontaminated metals.

Support the development of the industry infrastructure to permit the beneficial reuse of RSM.

Encourage research into cost-effective recycle of RSM.

Advocate regulatory practices and national standards supportive of RSM recycle.

Promote the recycle of RSM as an environmentally favorable and cost effective alternative to disposal.

Hold or participate in industrial society meetings to promote the recycle of RSM.

Provide information to the interested public and speak with the single voice of a trade association.

Advance other activities supportive of the purpose of the Association.

Since its formation, ARMR has worked closely with DOE in refining the Recycle 2000 policy. In an October 13, 1995 letter to ARMR, Tom Grumbly, DOE Assistant Secretary for Environmental Management, stated that "We welcome your (ARMR) thoughts on how to implement that decision (Recycle 2000) efficiently and quickly. We also encourage you to share your ideas on how the National Recycle Program might be expanded in the future." Although ARMR has a strong focus on DOE, the organization will also address material generated by the commercial nuclear power industry and the fabrication of many different products in addition to low-level waste containers.

A current list of ARMR organizational members include:

- Advanced Recovery Systems
- Alaron
- Allied Erecting and Dismantling
- American Technologies, Inc.
- Brandenburg Industrial Service Co.
- CDM Federal Programs
- Carolina Metals
- Corpex Technologies
- Fernald Environmental Restoration Management Corporation (FERMCO)
- Hake Associates
- Lockheed Martin Energy Systems, Inc.
- MSE Western Environmental Technology Offices
- M4 Environmental Management, Inc.
- Manufacturing Sciences Corporation
- Molten Metal Technology
- Princeton Plasma Physics Lab
- Scientific Ecology Group
- University of Tennessee
- U.S. Ecology
- Westinghouse Savannah River Company

The formation of ARMR and the list of organizational members should leave no doubt in anyone's mind that industry is ready to support the DOE Recycle 2000 effort!

INDUSTRY IS READY!

Recycling options available today for radioactive scrap metal include both decontamination/free release of metal and metal melting/beneficial reuse.

Decontamination/Free Release Capability

The nuclear services industry not only strongly supports the Recycle 2000 concept but has already made considerable capital investment in preparing to respond to DOE for policy implementation. In fact, nuclear industry emphasis on waste volume reduction beginning in 1980 has spawned a number of companies that specialize in removing contaminated material, including contaminated metal, from the waste disposal stream. These companies are

typically licensed by agreement states, states authorized by the Nuclear Regulatory Commission to issue radioactive material licenses, and permitted to receive radiologically contaminated metal for subsequent decontamination, survey, and free release in accordance with NRC Regulatory Guide 1.86 and DOE Order 5400.5.

A list of companies currently operating commercial facilities offering decontamination and free-release service is as follows:

ALARON	Pittsburgh, PA
ATG	Richland, Washington
Hake Associates	Memphis, TN
Manufacturing Sciences Corporation	Oak Ridge, TN
SEG	Oak Ridge, TN
US Ecology	Oak Ridge, TN

The metal most suitable for cost-effective decontamination and free-release normally has a high mass to surface area ratio with easily accessible surfaces for decontamination and survey. Following metal decontamination and free release, the metal is typically sold to commercial scrap metal dealers.

Metal Melting/Beneficial Reuse Capability

In direct support of the Recycle 2000 initiative, industry has recently expanded its metal recycling capability going beyond simple decontamination/free release. Specifically, a number of companies now offer metal melting services for that metal that cannot be easily decontaminated -- a capability required to support Recycle 2000. In fact, a true niche marketplace has developed with considerable competition.

SEG

In 1990, SEG was the first company to offer commercial metal melting services to process metal not suitable for economic decontamination, that is, metal with low mass to surface areas, inaccessible surfaces or otherwise difficult or impossible to decontaminate.

The melting process reduces the bulked volume of radiologically contaminated scrap metal by a factor of approximately 15. The process also concentrates most of the RSM's radioactivity in the "slag" which is removed for burial. Since the resulting metal product still retains a small amount of volumetric radioactivity, the product cannot be "free released" under current regulations in the United States. SEG has contracted with Los Alamos to provide shield blocks fabricated from this metal - an application where the slight volumetric contamination of the metal was not a detriment to the products intended use - shielding (6). SEG currently has the capacity to melt and process more than 15,000 tons per year.

In addition to its metal melt facilities in Oak Ridge, SEG has acquired and now operates a container fabrication facility in Carlsbad, New Mexico.

SEG's effort has been followed up and expanded by other companies in an attempt to anticipate the commercial opportunities growing out of the Recycle 2000 concept.

MANUFACTURING SCIENCES CORPORATION (MSC)

MSC, in a joint venture with British Nuclear Fuels Limited (BNFL), recently completed construction of a new, 115,000 square foot metal recycling facility in Oak Ridge. The facility features automated indoor storage of all incoming contaminated scrap metal, remotely operated material handling, semi-automated mechanical and chemical decontamination processes and vacuum induction melting. The new plant will operate in

conjunction with MSC's existing metal rolling and fabrication facility. Estimated plant capacity for complete metal recycle is 10,000 tons per year.

MSC is ideally positioned to respond to Recycle 2000 in the short-term since the company possesses not only the capability to melt RSM into ingots but also to roll the ingots into metal sheet and fabricate waste containers.

MSC also has a contract with DOE to convert four buildings at Rocky Flats to commercial use for RSM recycling. These buildings collectively contain nine vacuum induction melting furnaces and two rolling mills. This so-called National Conversion Pilot Project, when completed in 1997, will be offered by DOE to commercial enterprises and be available to support DOE Recycle 2000 efforts.

CAROLINA METALS

Carolina Metals operates a metals processing facility in Barnwell, SC which is licensed to handle radioactive materials. In 1995, the company worked with MSC in a demonstration to fabricate stainless steel containers for Westinghouse Savannah River Company using 20 tons of volumetrically contaminated heat exchangers, cooling water piping, and slug buckets from activities at SRS. The company has an estimated capacity to melt 1,000 tons of RSM annually.

Carolina Metals currently does not provide any decontamination services but has teamed with Alaron to melt materials which they have generated in their decontamination activities.

RECOMMENDED ACTION

With industry infrastructure in place, it's now time for DOE to consider the privatization of DOE recycling efforts. Privatization would enable commercial companies to recycle DOE metal operations under NRC or Agreement State rules - and not be bound by DOE Orders which frequently increase cost. The concept has many advantages:

Speed - DOE recycling efforts can move forward quickly if DOE will fund large recycling projects by commercial companies, essentially privatizing the function in support of Recycle 2000 objectives.

Cost Reduction - A large-scale privatization effort will provide significant manufacturing "economies-of-scale" resulting in reduced DOE costs. In addition, DOE contractor labor costs now incurred in fragmented recycling efforts and in the custodianship of existing RSM piles would be reduced.

Backlog Reduction/Contaminant Migration Mitigation - The huge DOE scrap metal backlog could be eliminated quickly, reducing storage costs and the continued migration of contaminants into the environment from numerous DOE scrap metal piles.

Visible Cleanup Progress - Real cleanup progress will be visible at a time when visible progress is very important.

The strongest argument for action is very pragmatic. Many of DOE's scrap metal piles have been in existence for well over a decade. For example, the Oak Ridge Scrap Metal Program was established in 1986, but the scrap metal piles are still there, in outdoor uncovered storage, with the metal corroding and with small amounts of radionuclides escaping into the environment. DOE has the ability to recycle this material now! The RFP issued in November

1995 by Lockheed-Martin Energy Systems in Oak Ridge for the recycling of approximately 710 tons of RSM is a small first step supporting DOE recycling efforts. A national procurement contract should be considered

so that all sites can participate in the achievement of Recycle 2000 objectives. Features of a national procurement contract could include: 1) standardization of terms and conditions. 2) specification of the new family of standard DOE waste disposal containers, and 3) definition of secondary waste disposition responsibility.

KEY ISSUES

Despite broad support within government and industry for the Recycle 2000 effort and industry readiness to support DOE, there are a number of issues that appear to be impeding DOE recycling efforts.

Funding

Current federal budget realities in general and DOE budget cuts in particular put recycling efforts in competition with other cleanup activities for limited dollars. With funding limited, the decision is frequently made to let RSM piles grow in size and deal with them later. If funding for recycling is not provided, it will be difficult or impossible for the Recycle 2000 policy to succeed.

Recycle Cost Premiums

Budget constraints are related to the "recycle cost premium". In many cases, it costs more to recycle metal than to simply bury it. The problem is particularly acute for those DOE sites planning on-site disposal cells where the recycle cost premium can be especially significant. Sometimes the issue is whether to recycle or take what appears to be fiscally expedient action, at least in the short-term.

Life Cycle Costs

The size of the "recycle cost premium" depends heavily on the true life cycle cost of waste disposal. A recent study performed by the Oak Ridge National Laboratory's Center for Risk Management for the DOE's EM Waste Management organization stated that the total annual cost of waste disposal at DOE sites is, in most cases, considerably higher than the burial charge used in most recycle vs. disposal cost comparisons. For example, the full-cost of disposal at the Nevada Test Site in FY-95 was determined to be $24 per cubic foot, double the published disposal price (7). In fact, the weighted average DOE disposal price in FY95 was calculated to be $38.50 per cubic foot. By understating real disposal costs, economic analyses comparing recycle to disposal will almost always favor disposal.

Decentralization of DOE Recycling Efforts

DOE recycling efforts are underway at a number of sites across the complex including Oak Ridge, Savannah River, Rocky Flats, INEL and Fernald. Due to the nature of DOE management and operation (M&O) contracts, these positive M&O efforts are often uncoordinated, overlapping and thus unable to take advantage of the substantial "economies of scale" that would result from large-scale DOE procurements to rid the complex of unwanted RSM inventories. It is recommended that DOE centralize recycling activities, utilizing a National Procurement Contract to assure Recycle 2000 policy implementation.

CONCLUSION

The DOE Recycle 2000 Policy has wide support, both in industry and government. Industry has invested millions of dollars in the infrastructure required to support DOE recycling efforts. Now is the time for DOE to move ahead to eliminate the Department's huge backlog of radioactive scrap metal.

INCENTIVES FOR RECYCLING IN THE U.S. DEPARTMENT OF ENERGY

ABSTRACT

A 1994 change in public law (P.L. 103-329, Section 608) enables Federal agencies to receive and use funds from the sale of materials recovered through recycling or waste prevention programs. The law states that these funds must be used for specified environmental programs or other authorized employee programs. Numerous recycling programs exist across the complex; however, revenues generated from these programs are either not captured or managed, are being used to fund unrelated programs (e.g., employee incentive programs), or are being donated to charities. This change in public law provides a valuable incentive for agencies to maximize the recycling of wastes otherwise bound for disposal, especially in light of recent and projected Federal budget cuts. This paper discusses the provisions of the public law, the Department of Energy (DOE) recycling progress, and incentives for recycling within DOE.

PUBLIC LAW 103-329, SECTION 608

The change in public law occurred in 103rd session of Congress and was reauthorized by the 104th Congress. (P.L. 104-52 was signed by President Clinton on November 19, 1995). The law states that, in addition to other funds provided to agencies, Federal agencies can receive and use funds from the sale of materials recovered through recycling or waste prevention programs for three specific purposes:

1. Acquisition, waste reduction and prevention, and recycling programs as described by Executive Order 12873, "Federal Acquisition, Recycling, and Waste Prevention," including any such programs adopted prior to the effective date of the Executive Order (October 20, 1993).
2. Other Federal agency environmental management programs, including but not limited to, the development and implementation of hazardous waste management and pollution prevention programs.
3. Other employee programs as authorized by law or as deemed appropriate by the head of the Federal agency.

DOE RECYCLING REVENUE

Based on recycling information contained in the draft 1993 "Annual Report on Waste Generation and Waste Minimization Progress," DOE facilities recycled 60,717 metric tons sanitary waste (33 percent of the sanitary waste stream). Recyclable materials were grouped into four main categories: precious metals, scrap metals, paper, and other (aluminum cans, glass, plastic, Polystyrene, toner cartridges, batteries, engine oil, wood, tires, food waste, and concrete).

The amount of material diverted for recycling in 1993 increased 248 percent compared to 1991. This increase can be attributed to an increase in recycling activity, improved tracking systems, and an increase in the number of materials being tracked. Using current market conditions for scrap metal, paper, and other recyclables, these materials could generate over one million dollars if sold on the open market to local recycling processors. This revenue could be as much as two to three times higher if DOE facilities market directly to recycling mills, rather than going through intermediate recycling processors.

An informal survey of DOE facilities showed that waste recycling revenue often goes into a general overhead account at the facility where it is difficult, if not impossible, to track how it is spent. A few sites reported that revenue is returned to the U.S. Treasury. In some cases, the revenue is used to pay for the cost of the recycling program or offset future purchasing costs. Most sites reported that revenue from the sale of aluminum cans is used by employees (i.e., donated to charity). Previously, all revenue from Federal recycling programs administered by the General Services Administration (GSA) was donated to day care centers operated for the Federal employees. Decisions regarding the use of recycling revenue are currently made at the discretion of the sites.

INVESTMENT IN RECYCLING

The Department of Energy is continually searching for ways to minimize the wastes and prevent wastes from being generated in the first place. The "1995 Baseline Environmental Management Report" showed that the eventual costs of dealing with the wastes generated across the DOE complex over the last 40 years will be hundreds of billions of dollars unless certain things are done to reduce the waste streams from routine operations and dismantlement activities. Recycling is one means to reduce the volume of DOE waste and typically represents activities that are "doable" for the near term.

High Return on Investment Projects

In 1994, the DOE Pollution Prevention Executive Board approved funding for 17 pollution prevention projects that were identified as providing a high Return on Investment (ROI) to the Department. Of these 17 initial (Round I) projects, five were eventually funded through other mechanisms or rescoped, and 12 have gone on to implementation. The expected net present value savings to the Department (ten years after project completion) are more than $28 million.

The ROI approach has proven to be a successful mechanism for fostering pollution prevention activities within the Department. In 1995, the Office of Pollution Prevention solicited proposals from the field for a second round (Round II) of ROI proposals. The Environmental Management organization has approved 22 projects for funding with an anticipated net present value savings of about $109 million. Table I provides a project summary and the projected ROI, costs and net present value savings for the six high ROI projects that involve recycling.

Table I

SUMMARY

Executive Order 12873 defines recycling as "the series of activities, including collection, separation, and processing, by which products or other materials are recovered from the solid waste stream for use in the form of raw materials in the manufacture of new products other than fuel for producing heat or power by combustion." In the past, recycling activities relied almost totally on the extra effort by a few champions who wanted to save resources and "do the right thing" environmentally. There were few, if any, resources available from upper management to make the programs work cost-effectively. Recent management emphasis on self-supporting program activities has given "new life" to the Department's recycling efforts.

Within DOE, the Office of Pollution Prevention (EM-77), is responsible for coordinating implementation of Executive Order 12873. Waste Minimization/Pollution Prevention coordinators at the field office level are responsible for incorporating recycling into their facilities' operations. Recent budget cuts have resulted in a substantial reduction in the Office of Pollution Prevention's overall budget in FY 1996. The opportunity to obtain additional revenue from previously unavailable sources is a powerful incentive for the Department to maximize the efficacy of its recycling programs.

ABSTRACT

A new class of inorganic ion exchangers called crystalline silicotitanates (CST), invented by researchers at Sandia National Laboratories and Texas A&M University, has been commercialized in a joint Sandia-UOP effort. The original developmental materials exhibited high selectivity for the ion exchange of cesium, strontium, and several other radionuclides from highly alkaline solutions containing molar concentrations of Na+. The materials also showed excellent chemical and radiation stability. Together, the high selectivity and stability of the CSTs made them excellent candidates for treatment of solutions such as the Hanford tank supernates and other DOE radwastes.

Sandia National Laboratories and UOP have teamed under a Cooperative Research and Development Agreement (CRADA) to develop CSTs in the powdered form and in an engineered form suitable for column ion exchange use. A continuous-flow, column ion exchange process is expected to be used to remove Cs and other radionuclides from the Hanford supernatant. The powder material invented by the Sandia and Texas A&M team consists of submicron-size particles. It is not designed for column ion exchange but may be used in other applications.

IONSIV IE-910 CST powder has been manufactured by UOP in commercial quantities and tested under a wide range of conditions. Cesium distribution coefficients (Kd) of up to 1,000 mL/g are measured in DSSF-5 simulant, a Hanford waste that is 5M in Na, and 0.5M in K and has high concentrations of OH-, NO-3, NO-2, and other ionic species. The engineered form of IONSIV IE-911 CST has been prepared by UOP under commercial manufacturing conditions and tested for cesium Kd in batch and kinetic tests. Tests with Hanford DSSF-5 and related simulants resulted in a 50% breakthrough of Cs of about 550 column volumes (CV) at a flow rate of 3.75 CV/hr. A column test on IONSIV IE-911 using an ORNL Melton Valley Tank W-27 simulant also resulted in a 50% breakthrough of 500 CV at a flow rate of 3 CV/hr. Column tests on INEL groundwater simulant with a flow rate of 10 CV/hr showed no Cs breakthrough to 4500 CV and excellent performance for removing Sr.

The experimental results have been integrated with an effort at Texas A&M University to model the CST's equilibrium and kinetic behavior. For the

IONSIV IE-910 exchanger, the removal of Cs and Sr from solution can be estimated to within about 10% for a variety of solutions ranging from 2M acid to 6 M hydroxide. The model also predicts the effect of high concentrations of potassium, sodium, and rubidium on the selectivity for Cs. Kinetic models have been developed that accurately estimate the breakthrough curve through the 50% breakthrough point for IONSIV IE-911 as conditions are varied.

Data are also presented confirming the excellent stability of the commercial CSTs over a broad pH range and the high radiation stability of IONSIV IE-910 and IE-911 exchangers. In addition, data are provided that demonstrate the high physical strength and attrition resistance of IONSIV IE-911, critical properties for column ion exchange applications.

INTRODUCTION

A new class of inorganic ion exchangers, invented by researchers at Texas A&M University and Sandia National Laboratories, has been successfully commercialized by UOP. The materials, crystalline silicotitanates (CSTs), demonstrate high cesium distribution coefficients in acidic, alkaline, and neutral, solutions despite the presence of high concentrations of competitive ions such as Na+ and K+ (1,2). The affinity for Sr++ in neutral and alkaline wastes is also found to be high (2). The CST is stable in Hanford tank waste simulants for long time periods and to exposure to at least 109 rads (2).

UOP and Sandia teamed under a Cooperative Research and Development Agreement (CRADA) to develop commercial CST materials. UOP commercially-synthesized IONSIV IE-910 CST powder demonstrates high capacity and selectivity for Cs+ and Sr++ over a wide range of pH conditions and competitive ion concentrations. In simulated and actual waste tests, Cs+ distribution coefficients are high over a pH range of 0 to 14 in the presence of varying concentrations of Na+ and K+. Distribution coefficients for Sr++ are also high at neutral and alkaline pH. The chemical stability of the IONSIV IE-910 exchanger is also demonstrated at pH from 0-14, and no effect on performance is noted after radiation exposure to 109 rads.

The UOP-Sandia CRADA was targeted toward the development of a commercial engineered form of the CST (beads, pellets, or granules) to meet the requirements anticipated for the removal of Cs, Sr, and other radionuclides from the Hanford alkaline tank waste supernates. These requirements included high selectivity and capacity for Cs+ and Sr++ from highly alkaline, high-sodium waste solutions, that have good radiation and chemical stability. The column ion exchange process likely to be used at Hanford for radionuclide removal also requires an ion exchanger that can be easily loaded and unloaded from the columns and that provides rapid ion exchange kinetics with acceptably low pressure drop and good mechanical strength characteristics. A final critical requirement was that the ion exchanger needed to be compatible with final waste forms, such as borosilicate glass, that are likely to be used at Hanford. An ion exchanger meeting all the above requirements has the potential to offer significant waste-treatment cost savings. Because other DOE sites also have a need for radionuclide removal, the product developed under the CRADA was to be as broadly applicable as possible. Work is presented that shows that UOP IONSIV IE-911 ion exchanger has met these criteria in a wide range of test conditions.

Application Conditions; High pH, High Salt, Low Cs

The principal target use for the CST ion exchanger is in the remediation of liquid wastes containing radioactive Cs from DOE operations. UOP has developed this material into commercial products: the CST powder is IONSIV IE-910 ion exchanger, and the engineered form is the IONSIV IE-911 ion exchanger.

The primary waste-treatment application is at Hanford, Washington, where 177 tanks containing highly radioactive waste are currently stored. Most of the gamma radiation results from 137Cs. A significant amount of radiation is also due to the presence of 90Sr. The liquid portion of this waste has a wide range of compositions, but all of it can be characterized as high pH (typically pH 11.5 to 2 M OH-) with high dissolved salt concentrations and a low molar concentration of Cs. The concentrated salt solution contains several cationic metals (mostly sodium and potassium), which compete with Cs for ion exchange sites and can affect both the selectivity and the ultimate capacity of the exchanger for cesium. The waste also contains significant concentrations of anions including NO-3, NO-2 and Al(OH)-4.

Three typical waste liquids; Double Shell Slurry Feed (DSSF), Neutralized Current Acid Waste (NCAW), and Complexant Concentrate (CC). are highly concentrated sodium salts (mostly nitrate and nitrite) with low concentrations (at the parts per million level) of Cs. The NCAW tends to have a relatively high concentration of 137Cs but comparatively low potassium concentration. The DSSF has relatively high potassium concentration, while CC tends to have more residual organic material, including some original complexing agents combined with their hydrolytic and radiolytic by-products.

The overall objective of the remediation project is to reduce the volume of High Level Waste (HLW) for disposal. The approach to be used is to extract the Cs from the concentrated salt solution by selective ion exchange and, thereby, convert the treated solution to Low-Level Waste (LLW) for easier disposal. The concentrated 137Cs along with the other Cs isotopes would then be vitrified and placed into long-term storage as HLW.

Product Requirements: Capacity/Selectivity, Stability; IE-911

The need to produce a minimum volume of concentrated 137Cs from a dilute Cs solution, in the presence of high concentrations of competing metal cations, sets severe demands on the capacity and selectivity of the ion exchanger chosen. In addition, the ion exchanger needs to operate in the high pH environment without loss of its high capacity and selectivity and physical integrity. Finally, the exchanger needs to operate without loss of performance resulting from the effects of prolonged exposure to high levels of radiation.

These requirements are all taxing. Nevertheless, the CST invented by Sandia and Texas A&M University (TAMU) and commercialized by UOP as the IONSIV IE-910 and IE-911 ion exchangers has these characteristics and can deliver the performance needed to ensure the successful decontamination of the Hanford waste.

A standard method of exchanger evaluation involves determination of the equilibrium distribution coefficient, or Kd value. The Cs Kd is dependent on test conditions such as pH, ion concentration, and relative abundance of competing ions. The Maintenance of a high Kd value in the operating environment is critical to achieving the maximum reduction in waste volume. As will be illustrated later, the IONSIV IE-910 and IE-911

products maintain high Cs Kd values across a broad range of conditions spanning the expected range at Hanford.
The distribution coefficient, Kd, is calculated using the equation:
Eq. 1
Kd: distribution coefficient
Cs: equilibrium activity in the ion exchanger solid
Cl: equilibrium activity in the liquid
Ci: initial concentration of the ion of interest in the liquid
Cf: final concentration of the ion of interest in the liquid after the period of contact V: solution volume
M: mass of ion exchanger used, as received basis
F: F-factor = ratio of (mass of dry exchanger) to (mass of as-received exchanger)
Figure 1 shows the effect of pH on the Cs distribution coefficient (3). The Kd value decreases noticeably as pH becomes increasingly alkaline. However, even at the highest pH, CST maintains a high coefficient. The high selectivity for Cs at low pH enables it to resist acid leaching.
Although the principal focus of the IE-910 and IE-911 development was the selective removal of radioactive Cs, (Fig. 2), the CST is also effective for Sr exchange at alkaline pH (3). This capability was also highlighted in later studies with simulated Hanford ground water, neutral ground water (INEL simulant), Oak Ridge waste, West Valley waste, and also in DSSF actual waste at PNL (4).
Fig. 1
Fig. 2
The abundance of Na+ present in the Hanford solutions would be expected to compete with Cs+ for the ion exchange sites within the CST. Increases in both (Na+) and Na:Cs ratio are expected to influence the ion exchange selectivity for Cs+. This effect is illustrated in Figs. 3 and 4 for both the IE-910 CST powder and the IE-911 (engineered form) (3). The actual solutions at Hanford have high Na:Cs ratios and tend to have high molar concentrations of Na+. An important feature of CST is that it maintains a high selectivity even under these extreme conditions. All of the data in this paper have been obtained with representative simulants at room temperature.
Another significant, or competing, cation present in the Hanford waste is potassium. Potassium would be expected to have an ion exchange affinity more similar to that of Cs and, therefore, a more competitive influence on Cs+ selectivity (distribution coefficient). This effect is illustrated in Fig. 5 for the IE-910 powder (3). In this comparison, the (Na+) in the DSSF simulant is at a typical concentration representative of much of the Hanford waste, and the (Cs+) and (K+) are varied across the typical ranges expected. As expected, the presence of potassium reduces the Cs Kd values. The effect is most pronounced at low (K+), but further increases in (K+) don't appear to have much additional impact on selectivity. As noted previously with the effect of both pH and Na:Cs ratio, the IONSIV ion exchanger maintains a high selectivity in the presence of realistic concentrations of competing potassium that is representative of actual wastes.
Fig. 3
Fig. 4
Fig. 5
Because of the wide range of solution compositions and the competing effects standardized tests were established for use during ion exchanger

development: Batch and Column tests. These tests allowed rapid, accurate comparison of relative exchanger selectivities, capacities, and ion exchange kinetics.

Batch Ion Exchange tests were used to evaluate comparative equilibrium Cs Kd values at various times. The test consists of contacting a small amount of ion exchanger (typically about 0.1g) with a fixed amount of waste simulant (typically about 10mL), such as DSSF, and then vigorously shaking or swirling the mixture. Experiments are established for several time durations to evaluate the rate of approach to equilibrium. The simulant composition is prepared in the laboratory to be representative of its respective waste type. Results of this testing are expressed as Cs Kd values vs. time. Comparisons between materials can be made using their equilibrium values (data > 24 hr). The Kd values obtained are expressed on an exchanger weight basis (mL solution per gram exchanger). This method can provide a crude estimation of large differences in mass transfer efficiency. However, if small differences in physical properties exist between ion exchanger samples or subtle differences in mass transfer rates occur, then the Column Ion Exchange test is more representative of performance.

Comparisons can be made between materials of widely differing physical properties. For example, if the density of an exchanger is known, then a volumetric distribution coefficient can be estimated. This "Cs-lambda" (units: mL of solution per mL) value is derived by simply multiplying the exchanger density by its respective Cs Kd value. Comparison on this basis can estimate the relative waste-volume reduction achievable by each ion exchanger being evaluated, a key factor for consideration. However, a value for the exchanger density must be representative of its density in the waste solution. Many organic resins change density depending on their degree of hydration and solution pH. The IONSIV IE-911 does not change density with hydration or solution pH.

Performance of IE-910 and IE-911 Ion Exchangers

Several different ion exchangers (Table I) have been under evaluation for this application. Each was tested using the standard Batch Ion Exchange method.

The results are summarized in Fig. 6 (4). The figure shows Cs-lambda values, which provide a relative volumetric capacity for the ion exchangers listed. The key features to note are the values at 24 to 72 hours, where all materials have achieved equilibrium (note that the Cs-lambda values are shown on a log scale). A comparison of equilibrium Cs-lambda values shows that both IONSIV IE-910 and IE-911 ion exchangers achieve similar high distribution coefficients compared with all of the other candidates evaluated. Comparison of IONSIV IE-911 with the parent IE-910 powder shows that it has a slightly lower value because of the presence of the inert binder acting as a diluent.

Fig. 6

At test times much less than 24 hours, an obvious difference shows in the apparent Cs-lambda value for the IE-910 powder and the IE-911 30x60 mesh material. This apparent difference in performance is almost entirely due to differences in mass transfer efficiency caused by the particle size. The IE-910 powder particles are approximately 0.2 microns in size. The size for the 30x60 mesh IE-911 material is a nominal 250 to 600 microns. Evaluation of ion exchangers is usually reported on a weight basis (as is the data in this paper). The UOP IE-910 and 911 ion exchangers outperform all of the other candidates. The SuperLig 644 is the next best performer.

However, in the type of column ion exchange system envisioned for Hanford, the low density of the SuperLig is a detriment. This candidate would require additional column volume (therefore, capital cost) because of the low density.

Comparisons of how regenerable organic and nonregenerable inorganic ion exchangers are integrated into radwaste processing are a complex issue. The regeneration of organic ion exchangers will generate large volumes of acidic waste that must be concentrated and processed for vitrification. This waste may require interim storage. Disposal of the resins is another consideration. The present flow sheet calls for the spent organic ion exchanger to be decontaminated and sent to the low level glass plant. There it must be integrated into the redox chemistry of the wastes being fed to the LLW glass melter.

In contrast, the IONSIV IE-910 and 911 CST materials are not designed for regeneration and will permit the design and operation of a much-simpler facility. Studies to-date show that the IE-911 composition is compatible with high-level waste vitrification. This inorganic exchanger also seems compatible with extended lag storage options.

In addition to Batch Ion Exchange evaluations, the second type of test uses a small-scale simulation of the column ion exchange process. This Column Ion Exchange test also uses simulated waste liquids as a feed (actual waste has been used but is less typical). Multiple columns are sometimes used in series to simulate the large-scale process.

Figures 7 and 8 illustrate the performance of a sample of IE-911 exchanger (3,5). The feed compositions in each of the illustrations are representative of the different waste streams. The figures show the relative effluent Cs+ concentration for a nominal 10 ppm Cs in the simulant feed plotted against the cumulative amount of feed processed expressed in relative Column Volumes (CV). Exchanger capacity is estimated by observing the point at which the relative effluent concentration reaches 50% of the feed concentration. Assuming that the breakthrough curve is approximately symmetrical, the 50% breakthrough point gives an estimate of the amount of feed solution that can be treated at equilibrium saturation of the exchanger.

In both illustrations, with DSSF or Melton Valley simulants, the example shows that a preliminary development sample of IE-911 exchanger has the capacity to treat more than 500 CV of waste (at 10 ppm Cs) before becoming saturated. Testing at Oak Ridge with actual Melton Valley waste confirmed good, though somewhat lower, performance with 350 CV treated to 50% breakthrough in W-27. Retesting at Sandia National Labs has confirmed that the difference between Melton Valley simulant and actual waste data resulted from a higher sodium concentration and higher pH in the W-27 waste. This performance has been further improved to 660 CV capacity in DSSF with an improved material (Fig. 9). This high capacity coupled with high selectivity demonstrates a level of performance sufficient to allow use without regeneration or further concentration. Eliminating the need for regeneration or elution offers significant cost savings in the construction of the large-scale unit.

Fig. 7

Fig. 8

Fig. 9

Figure 7 also includes predictions of column ion exchange performance from the model developed at Texas A&M University (5). The experimental

results closely match the prediction and demonstrate the utility of the model of Zheng , Anthony, et. al..

Samples of IE-911 exchanger have also been evaluated with lower pH West Valley waste and with contaminated ground water. Although still alkaline, both of these applications are at significantly lower pH, than the Hanford type wastes. The lower pH would be expected to further improve the performance of IE-910 and IE-911 beyond that already discussed because of the large increase in Cs Kd values that accompany decreases in pH. A test at West Valley with actual waste (pH 11.5) demonstrated more than 400 CV capacity without breakthrough to give a Cs decontamination factor of 105-106 (3). Tests with Neutral Ground Water simulant (pH 8 to 9) also demonstrated decontamination factors of more than 500 even though the Cs+ feed concentration was only 50 ppb.

In addition to the high Cs decontamination factors, significant Sr removal occurred in both the West Valley actual waste and Neutral Ground Water studies. The Neutral Ground Water study saw a slight breakthrough of Sr with a decontamination factor more than 1800. Testing with the actual West Valley waste gave a decontamination factor of 104. A modest removal of uranium and plutonium cations, represented by a decontamination factor of about 100, also occurred.

Kinetics and Particle Size

In addition to selectivity and capacity, a number of other considerations need to be taken into account when designing an ion exchange column. As noted previously, smaller particles give improved mass transfer rates. Therefore, using the smallest practical particle size is to the designer's advantage. However, as average particle size decreases, flow resistance (pressure drop) through a packed bed of particles increases sharply.

The commercial development effort behind the IE-911 exchanger focused on achieving the optimal mass transfer efficiency from the optimal particle size. The 30x60 mesh particle size for the standard IE-911 exchanger represents a balance of ion exchange kinetics and design engineering requirements. Although the 30x60 mesh product represents an engineering optimum, other size ranges, both larger and smaller (for example, 20x50 or 60x100), could be made available on request.

Early in the development of the CST engineered form, researchers recognized that an understanding of the ion exchange kinetics would be useful to optimize the design of the ion exchange plant. An effort was undertaken, under the direction of R.G. Anthony (coinventor of CST) at the Kinetics, Catalysis and Chemical Reaction Engineering Laboratory of Texas A&M University, to model Cs ion exchange. This work was done in parallel with the commercial development of IE-911 exchanger. The model developed by R.G. Anthony, and others, has clearly demonstrated its utility as a predictive tool. It can be used to predict the effects of variations in waste chemistry and column ion exchange design parameters. Readers are referred to published papers by R.G. Anthony for further details (5).

Physical Properties of IE-910 and IE-911 Ion Exchangers

UOP IONSIV IE-95 and IE-96 and TIE-96 ion exchangers are zeolite-based ion exchangers developed, and used successfully, for earlier wastewater and ground water remediation. The IE-911 exchanger was engineered to match the strength and attrition characteristics of these earlier successful products.

Both the IE-910 CST and the inert binder used to make the IE-911 exchanger are highly resistant to chemical attack. Thus, the exchanger can maintain its physical integrity under virtually all pH conditions. Samples of IE-911 have been tested for seven days in contact with extremely high pH DSSF-5 simulant to determine whether there might be a loss of strength typical of the Hanford type wastes, might occur during exposure (3). Strength after exposure was, by the standard UOP ion exchange attrition test, comparable to material not exposed to DSSF-5. The results were within the acceptable range for successful commercial nuclear ion exchange materials such as IONSIV IE-95 exchanger. Additional long-term tests that include the effects of time and temperature are currently underway.

The Cs loaded CST powder could not be significantly eluted using 3M nitric or 3M formic acids. Neither could Cs-CST be eluted with 8M NH4NO3, 2M Ca(NO3)2, 1.5M Pb(NO3)2 or 2M Mg(NO3)2 (4). This experience correlates with the extremely high distribution coefficient observed at low pH. This property, combined with its high capacity, makes IE-910 powder and IE-911 exchanger an ideal, single-use materials. Their inorganic composition makes them compatible with direct vitrification.

The CST has also been evaluated to determine the effects of thermal exposure. Dry heating of Cs-loaded CST to several hundred degrees should not cause any loss in the retention of Cs. The CST shows no loss in performance or structural integrity during exposure to ambient temperatures in alkaline solution. However, temperatures should be maintained at less than 60C when CST is exposed to concentrated acids or extremely alkaline solutions for extended times. Long-term exposure to concentrated nitric acid (> 6M) results in leaching of some Ti (4).

The IE-910 and IE-911 materials have rigid inorganic structures that resist significant swelling or shrinkage with changes in temperature, pH, and ion exchange levels. This resistance to physical changes sets it apart from the organic ion exchange resins. Organic ion exchange materials shrink and swell with variations in pH, temperature, and salt concentration. These variations cause deterioration in organic IX beads, that leads to flow maldistribution, bed plugging, and other problems. The bulk density of IE-911 exchanger is approximately 1 g/cc (62.4 lb/ft3). Typical water contents determined by loss on ignition (LOI) are about 12wt-% for the IE-910 powder and about 20 w-t% for the IE-911 engineered-form exchanger.

Samples of IE-910 powder have also been exposed to high levels of radiation (109 Rads) in various solutions and showed no loss of structure or performance. This resistance to performance degradation was not seen for the organic ion exchange resins (6,7). Testing of the IE-911 engineered-form exchanger, is currently in progress.

SUMMARY

Commercial-grade CSTs in the powdered form (IONSIV IE-910) and the engineered form (IONSIV IE-911) have been developed and manufactured by UOP. Both materials have been tested under a wide range of conditions in simulants and actual waste solutions. The IE-910 and IE-911 materials exhibit the high radionuclide selectivity and capacity and the chemical and radiation stability of the CST developed by Sandia and Texas A&M. A comparison of equilibrium cesium lambda values shows that both IONSIV IE-910 and IE-911 materials achieve high distribution coefficients compared with all of the other candidates evaluated. In addition, the IONSIV IE-

911 ion exchanger exhibits physical strength and attrition resistance equivalent to the best inorganic ion exchangers manufactured by UOP. The commercial CST products are not intended for regeneration. Thus, the design of a cost-effective, safe, and reliable cesium ion exchange process does not require the capital or operating expenses of a regeneration system. The commercial CST products are also compatible with the batch ion exchange processes or with backfill barrier applications not involving a column ion exchange process. The cesium radionuclide-exchanged CST appears to meet the requirements for long-term storage and for incorporation into final waste form, such as glass and concrete. IONSIV IE-910 and IE-911 ion exchangers provide high capacity, high selectivity, high decontamination factors, physical strength, and resistance to chemical and radiolytic attack. These properties make the IONSIV IE-910 and IE-911 products ideal for treating a wide range of wastes across the U.S. DOE complex and in commercial applications.

REDOX POTENTIAL MONITORING IN GLASS: FERROUS-FERRIC RATIO DETERMINATION WITH ADAPTATION FOR IN-CELL USE

T. Borek
West Valley Nuclear Services Co., Inc.
P.O. Box 191
10282 Rock Springs Road
West Valley, NY 14171

ABSTRACT

The ferrous-ferric (Fe^{2+}/Fe^{3+}) ratio in glass may be determined using an ammonium acetate buffer/1,10-phenanthroline reagent scheme similar to Standard Method 3500-Fe D following dissolution of glass in a hydrofluoric acid (HF) and sulfuric acid (H_2SO_4) mixture. This method is within the 95% confidence level for t-test comparison with the method of Schreiber. This method has been adapted for remote use in shielded cells for determination of waste and vitrified waste redox potential.

INTRODUCTION

It has been shown that the control of the oxidation-reduction potential in ceramic glass melters, for high-level nuclear waste vitrification, effects glass product quality and may extend the melter's useful life (1-5). The ratio of ferrous ion (Fe^{2+}) to ferric ion (Fe^{3+}) is one indication of the overall redox conditions in the melter and is readily determined in the laboratory. A review of the current iron ratio methods suggests that a spectrophotometric method may be the one most readily adaptable to hot cell use (6).

A simple colorimetric method for ferrous-ferric (Fe^{2+}/Fe^{3+}) ratio determination developed by Jones (7) was suggested for monitoring the redox conditions in crucible- and pilot plant-vitrification. Developed for the commercial glass industry, this method, as modified by Schreiber (8) (Fig. 1), involves dissolution of a glass in an HF/H_2SO_4 mixture, reagent addition, and then pH adjustment with HCl or NH_3 to a pH of 3.3 to 3.5. Reduction of the ferric ion is accomplished with the addition of hydroquinone followed by a 30 minute reaction period. The resulting orange-red solution is analyzed spectrometrically at 510 nm.

Fig. 1

A West Valley Demonstration Project (WVDP) adaptation of this method was attempted In-cell and was not readily performed. It was difficult and time consuming to perform the pH adjustment step In-cell with dropwise addition of acid or base, particularly for large batches of samples that include blank and quality control samples.

A review of the literature for a more adaptable method that would produce acceptable results suggested that Standard Method 3500-Fe D, Phenanthroline Method (9), would be a useful starting point. This is because of the minimum number of reagents required for complete analysis and the acceptable sensitivity of the method in the range desired. The addition of excess buffer to establish an acceptable solution pH instead of acid/base addition for pH adjustment is readily accomplished In-cell. The method calls for the use of an ammonium acetate/acetic acid buffer, which has a pH ~4.0.

Method development was performed in the laboratory before use in hot cells. A laboratory comparison was then conducted between the WVDP iron

ratio method and that of Schreiber. The spectrophotometers used were Perkin-Elmer Lambda 1A for bench-top analysis and a Hewlett Packard HP8452A equipped with Custom Sensors & Technology fiber optics and a dip probe for remote, In-cell analysis.

METHOD

Required reagents:

1. Ammonium acetate-acetic acid buffer: Dissolve 250 grams of ammonium acetate ($NH_4C_2H_3O_2$) in type II water. Add 700 ml of glacial acetic acid and stir.
2. 0.1% 1,10-phenanthroline solution: Dissolve 100 mg of 1,10-phenanthroline monohydrate in 100 ml of type II water. A couple of drops of HCl will hasten dissolution.
3. Hydroxylamine hydrochloride (NH_2OHHCl), reagent grade.
4. Concentrated hydrofluoric acid (HF).
5. Concentrated sulfuric acid (H_2SO_4).

The WVDP method is summarized in Fig. 2. A finely ground glass sample weighing 50 to 80 mg was placed in a 125 ml disposable beaker or 125 ml poly bottle. One milliliter of conc. HF was added and allowed to react. One milliliter of conc. H_2SO_4 was then added and allowed to react. Approx. 100 ml of type II water was added. Approximately 2 ml of this dissolution is transferred to a 60 ml analysis bottle that contains 15 ml of reagent water, 10 ml of ammonium acetate-acetic acid buffer and 5 ml of 0.1% 1,10-phenanthroline solution. The solution is diluted to 50 ml with Type II water.

Fig. 2

After 10 minutes, each solution is analyzed spectrophoto-metrically at 510 nm for Fe^{2+}. Approximately 0.1 to 0.2 grams of solid hydroxylamine hydrochloride (NH_2OHHCl) is added to each solution and heated to a gentle boiling in a microwave oven. After a 15 minute cooling period, each solution is again analyzed spectrophotometrically at 510 nm for total Fe^{2+}. Ferric ions are determined by the difference, and the Fe^{2+}/Fe^{3+} ratio is computed.

DISCUSSION

A single ground glass sample that is used as a reference material at WVDP was analyzed by the bench-top method and by the In-cell modification. Fifty Fe^{2+}/Fe^{3+} data points (Fig. 3) were collected: the bench-top data average was 0.343 0.048 and the In-cell average was 0.310 0.066.

Fig. 3

The bench-top method was then compared with the iron ratio method of Schreiber. Twenty data points for each method were collected (Fig. 2). The WVDP method average was 0.600 0.053 and the Schreiber method average was 0.627 0.079 (Fig. 4). A t-test comparison of the data points indicates that the means for the two methods are similar to a 95% confidence level.

Fig. 4

For the In-cell method, the analytical device is a fiber optic dipping probe connected to the spectrophotometer located outside the shielded cells. The dip probe was found to be much easier to use and maintain In-cell than a flow-cell. A "C"-shaped stainless steel fixture is used as a sight guide In-cell for the 50 ml dilution prior to analysis; this fixture is sized to fit 60 ml poly bottles. During method development, all reagents were dispensed In-cell. It is current WVDP practice to prepare dissolution and analysis bottles Ex-cell. The only reagents added In-cell are water and hydroxylamine hydrochloride. Pre-weighed

hydroxylamine hydrochloride is introduced in scintillation vials for each analysis. The WVDP is investigating forming pellets with this reagent for ease of handling.

SUMMARY

WVDP has developed a method based on Standard Method 3500-D which is readily adapted for In-cell use and found to produce comparable results to the widely cited method for Fe2+/Fe3+ determination. Results may be obtained in less than one hour from the time of sample grinding.

ACKNOWLEDGEMENT

The author would like to thank the members of the Analytical & Process Chemistry Staff for performing the analyses during method development.

GLASS DURABILITY RESULTS FROM THE DWPF STARTUP TEST PROGRAM

M. K. Andrews
C. A. Cicero
Westinghouse Savannah River Company
Aiken, SC 29808

ABSTRACT

The Defense Waste Processing Facility (DWPF) at the Savannah River Site (SRS) produced seventy-one canistered waste forms containing simulated waste glass during the Startup Test Program. Glass from these canisters, along with glass samples taken during filling of the canisters, was characterized as part of a continuing effort to demonstrate compliance with the Waste Acceptance Product Specifications (WAPS).

Each of the glass samples taken during the Startup Test Program was subjected to the Product Consistency Test (PCT). The PCT is an ASTM crushed glass leach test that measures the releases of several elements over a period of seven days. The acceptance requirement related to this testing states that the PCT results of all of the glass samples analyzed

must be at least two standard deviations below the mean PCT results of the Environmental Assessment (EA) glass. The acceptance requirement was met for each of the three hundred and ninety-two glass samples characterized which demonstrated readiness of the DWPF to transition to Radioactive Operations.

INTRODUCTION

High-level radioactive waste at the Savannah River Site (SRS) will be immobilized in a durable borosilicate glass and poured into stainless steel canisters in the Defense Waste Processing Facility (DWPF). The canistered waste form will then be sent to a geologic repository for final disposal. The Department of Energy's Office of Civilian Radioactive Waste Management, which is responsible for the design and operation of the repository, has defined requirements which the canistered waste forms must meet to be acceptable for disposal in the repository. These requirements are the Waste Acceptance Product Specifications (WAPS).(1) To demonstrate compliance with the WAPS and to ensure that the DWPF was prepared for Radioactive Operations, the DWPF developed a Startup Test Program. As part of the Startup Test Program, the DWPF performed five non-radioactive melter runs which were designed to simulate the process expected during Radioactive Operations. Four of the simulated melter runs, the Qualification Runs, were used to obtain the data required for waste qualification.

A brief description of each of the five melter campaigns during the Startup Test Program is shown in Table I. The first run (FA-13) was not part of the Qualification Runs, but was used to flush the startup frit from the melter and achieve stable operation. In WP-14, the first campaign of the Qualification Runs, neodymium was added to the feed to study the mixing behavior of the melter. The WP-15 and WP-16 campaigns were used to simulate extreme changes in feed composition, and the WP-17 run was used to return to a baseline composition and to introduce noble metals to the DWPF.

Table I

The compositions used for the simulated feeds were based on the projections of various high-level wastes at SRS. While the high iron and high aluminum feeds were designed to test the extreme cases, the composite feed was based on an overall blend of the existing waste. To ensure that DWPF could consistently produce a durable waste form independent of the feed type, the Savannah River Technology Center (SRTC) designed an extensive program to sample the glass from the canistered waste forms.

GLASS SAMPLING

During filling of the majority of the canisters in the DWPF, samples were taken from the glass pour stream using a specially designed sampler. The samples were removed from the sampler by DWPF personnel and sent to the Savannah River Technology Center (SRTC) for characterization. Sixty-two of the seventy-one canisters were sampled by this method during filling. Samples of glass from the canisters were also characterized. The canisters were prepared for glass sampling by two methods: sectioning with a bandsaw and wall removal using arc-air cutting. Sectioning allowed three entire cross sections of the canister to be glass sampled. Wall removal only allowed the glass near the canister wall to be sampled. Generally, the first three canisters filled during a campaign (the period of the maximum change in composition) and the last three canisters filled (the period of closest approach to steady state), were cut at three

levels which separated the canister into four sections. For each of these canisters, samples were taken at each level. For each level, samples were taken as a function of radial position in the canister. A minimum of twelve samples were removed from each sectioned canister. A total of 295 samples were removed from the sectioned canisters.

A window at least twelve inches wide and twelve inches high was removed from the canister wall for all other canisters scheduled to be sampled. Wall removal allowed the canister to be available for glass sampling much quicker than by sectioning, but only one glass sample was taken from the wall removal canisters. Thirty-five samples were analyzed from the canisters with a wall removed.

Table II provides an overview of the number of canisters sampled, along with the total number of glass samples characterized during each melter run. Only six canisters were sampled during FA-13 because the data was not used for waste acceptance purposes. The sampling and characterization methods were tested during FA-13 to ensure readiness for the Qualification Runs. The last three canisters of WP-17 were not sectioned since the material at steady state was the composite feed that was characterized during WP-14.

Table II

A total of 392 glass samples were removed from the canisters during the DWPF Startup Test Program. Each sample taken was characterized by determining its composition and its durability. The results discussed below concentrate on the durability testing.

GLASS TESTING AND RESULTS

The durability of the glass was assessed by leaching it according to the Product Consistency Test (PCT) protocol.(2) The PCT is a crushed glass leach test that measures the releases of boron, sodium and lithium from the glass at 90C in ASTM Type I water over a period of 7 days.

The PCT was performed on all of the glass samples taken during each melter campaign. The tests were performed in triplicate and each test included the appropriate blanks and standards. The results of the standards indicated that the tests were within an acceptable range.

For each sample, the measured PCT responses for boron, sodium and lithium were normalized by the weight fraction of that element present in the glass. The normalized releases were compared to the Environmental Assessment (EA) glass (3) to determine the effectiveness of the Glass Product Control Program (GPCP).(4) The acceptance criterion of the GPCP states that the glass produced by the DWPF must have PCT results which are at least two standard deviations better than the PCT results of the EA glass.(5)

The average normalized boron release and the associated standard deviation for each campaign can be found in Table III along with the boron release of the EA glass. Tables IV and V show the same information for sodium and lithium, respectively. These results show that the glass produced by DWPF during the Startup Test Program was significantly more durable than the EA glass. Therefore, the acceptance criterion of the GPCP was met.

Table III

Table IV

Table V

The composite feed contained higher concentrations of silicon and aluminum than the high iron feed, WP-15. Since silicon and aluminum have a positive effect on the glass durability, it was not unexpected that the

glass from the composite feed was more durable than the glass from the WP-15 high iron feed. Figure 1 graphically depicts the changes in the boron release during WP-15 and WP-16. The results for each canister were averaged and were plotted in the order of canister filling. Although there is some scatter, the general trends can be observed. Even at the maximum value, the boron release for the DWPF glass is significantly below the EA glass.

Fig. 1

CONCLUSIONS

The characterization of the glass taken from the canisters produced during the DWPF Startup Test Program showed that the DWPF can produce a durable glass even with extreme changes in feed types. Nearly four hundred glass samples were removed from the canisters and subjected to the Product Consistency Test to measure the chemical durability of the glass. The PCT results indicated that all of the samples tested met the acceptance requirement when compared to the PCT results for the EA glass. The DWPF was therefore able to demonstrate readiness of the DWPF to transition to radioactive operations.

VITRIFICATION OF HIGH LEVEL NUCLEAR WASTE INSIDE AMBIENT TEMPERATURE DISPOSAL CONTAINERS USING INDUCTIVE HEATING: THE SMILE SYSTEM*

James Powell
Morris Reich
Robert Barletta
Department of Advanced Technology
Brookhaven National Laboratory
Upton, NY 11973

ABSTRACT

A new approach, termed SMILE (Small Module Inductively Loaded Energy), for the vitrification of high level nuclear wastes (HLW) is described. Present vitrification systems liquefy the HLW solids and associated frit material in large high temperature melters. The molten mix is then poured into small (~1 m3) disposal canisters, where it solidifies and cools. SMILE eliminates the separate, large high temperature melter. Instead, the HLW solids and frit melt inside the final disposal containers, using

inductive heating. The contents then solidify and cool in place. The SMILE modules and the inductive heating process are designed so that the outer stainless can of the module remains at near ambient temperature during the process cycle.

Module dimensions are similar to those of present disposal containers. The can is thermally insulated from the high temperature inner container by a thin layer of refractory alumina firebricks. The inner container is a graphite crucible lined with a dense alumina refractory that holds the HLW and frit materials. After the SMILE module is loaded with a slurry of HLW and frit solids, an external multi-turn coil is energized with 30-cycle AC current. The enclosing external coil is the primary of a power transformer, with the graphite crucible acting as a single turn "secondary." The induced current in the "secondary" heats the graphite, which in turn heats the HLW and frit materials. The first stage of the heating process is carried out at an intermediate temperature to drive off remnant liquid water and water of hydration, which takes about 1 day. The small fill/vent tube to the module is then sealed off and the interior temperature raised to the vitrification range, i.e., ~1200C. Material volatized (e.g., small amounts of cesium) during the liquefaction process is retained by an internal lower temperature "cold trap" inside the module. Liquefaction is complete after approximately 1 day. The inductive heating then ceases and the module slowly loses heat to the environment, allowing the molten material to solidify and cool down to ambient temperature.

The process cycle requires approximately one week, with most (60%) of the time used for cool-down. During the process cycle, the outer steel can is maintained at near ambient temperature by air cooling to remove heat generated by parasitic induced currents and conductive heat transfer through the insulating firebrick layer. These parasitic effects increase the amount and cost of energy required to process module; however, the cost is still very low. For example, a SMILE module containing 1.25 m3 of vitrified HLW, (equivalent to the baseline HLW disposal module for the Hanford TWRS program) will require approximately 10 mWh. At a cost of 10 cents per kWh, this corresponds to only $1200, which is negligible compared to the repository fee of several hundred thousand dollars per module. Heat transfer analyses for the SMILE process are described, together with projected glass compositions based on Hanford HLW feeds. Using appropriate frit materials, the composition of SMILE-Hanford HLW glass can be made very similar to that projected for Savannah River waste. Because of its modularity and the elimination of long-term material problems, there do not appear to be major technical issues for the SMILE concept.

DESCRIPTION OF THE SMILE CONCEPT

The present vitrification approach is based on large, high cost, centralized high temperature glass vitrification facilities that melt the solid waste in large furnaces and then pour the molten glass into the final steel disposal containers. In SMILE, the waste solids would be vitrified in-situ inside closed, individual containers that serve as the final geologic disposal containers. The outer SMILE container is maintained at a relatively low temperature while its inner contents are heated to high temperature by an external low frequency (e.g., hertz) inductive heating coil. Thermal insulation between the inner contents and outer container minimizes heat leakage from the hot interior. The SMILE concept appears to offer substantial cost savings over the baseline

approach. It also appears to be more reliable and maintainable, is much less demanding on materials, and essentially eliminates the problems of radioactive emissions from hot melters. Besides its advantages of lower costs and simpler operation, SMILE has the unique capability that the vitrified waste inside disposal containers can be reheated to high temperature without degrading canister containment. If long-term radiation damage to the vitrified waste were to prove unacceptable, the inner contents of SMILE containers could be annealed when necessary.
Figure 1 shows the proposed SMILE concept. The empty container consists of a graphite cylinder with an inner alumina liner. The graphite is inductively heated to high temperature by an outer solenoidal coil that is connected to an external power source. The solenoidal coil operates at a low frequency (e.g., 30 hertz), and acts as the primary of a transformer, with the secondary being the graphite cylinder. The graphite cylinder is enclosed in a stainless steel jacket (not shown) with a layer of thermally insulating refractory ceramic, e.g., alumina fire brick (also not shown), between them. The graphite can operate at high temperature, e.g., 1200C or higher, while the enclosing steel jacket is maintained at a relatively low temperature [200C, for example] by auxiliary air cooling. The stainless steel jacket completely enclosed the graphite cylinder and its contents except at the top of the container, where the fill/vent tube is initially open.
Fig. 1
The SMILE version in Fig. 1 uses graphite as the conducting scepter that is heated by the inductive heating coil. Other versions are possible. For example, the graphite cylinder could be replaced by an iron container, which would couple even better to the inductive coil, making the heating process more efficient. The iron scepter version of SMILE would have a somewhat lower temperature capability but would still be high enough (i.e., ~1150C) to vitrify HLW into borosilicate glass. It also is possible to have multiple tubes or cylinders (graphite or steel) at several points in the HLW solids to enable faster and more uniform heating. Here, however, we only analyze SMILE designs with a single graphite scepter that contains all of the HLW solids to be vitrified.
The external fill/vent tube at the top of the container allows the waste slurry (solids plus water) to be introduced and also allows the gases from the drying phase (e.g., steam) to leave. The central internal porous ceramic vent tube collects the gases generated inside the annular porous bed which then allows them to flow to the external vent. The steam travels at most about 12 inches (average about 6 inches) through the porous solid zone to reach the central vent tube, compared to a distance of 15 feet if there were no tube.
Figure 1A illustrates the drying operation. The container is filled with a wet slurry of HLW solids and frit material. Excess water is pumped out through the central vent and external fill/vent tube, leaving behind a settled bed of wet solids. The contents are then sequentially inductively heated to a sufficiently high final temperature (e.g., ~800C) to first drive off all liquid water, then the water of hydration, and finally any residual decomposition gases. The remaining solids then contain only dry refractory waste oxides and frit.
The external vent/fill tube is then sealed off and the contents inductively heated to a higher temperature (i.e., ~1200C) to vitrify the HLW (Fig. 1B). No radioactive gases, e.g., volatized cesium, are released during vitrification, since the fill/vent tube has been sealed. This

minimizes radioactive release and contamination of the vitrification facility. After the HLW solids have been vitrified inside the sealed container, it cools to near ambient temperature, and is discharged to a temporary storage facility. Eventually it would be shipped to an off-site geologic repository.

If an additional protective barrier is desired, the container can be overpacked with an outer steel container. The process is illustrated in Fig. 2A. The open outer steel container would be positioned below the inner container and inductive heating coil during the drying and vitrification phase of the process.

Fig. 2

After vitrification is complete and the inner container has cooled to near ambient temperature, the outer container is raised to enclose the inner container (The outer container fits inside the heating coil). The outer container would then be lowered with the enclosed inner container, and removed through an exit transfer lock at the bottom of the pit. At the beginning of the sequence, both the inner and outer steel container come in through an entrance transfer lock at the bottom of the pit. The inner container enters first, is raised up by the hydraulic lift and then held in place by the center and adjustable side supports. The hydraulic lift is then lowered and the outer container brought in through the transfer lock. The treatment sequence is then initiated. The inner container is filled with wet HLW solids (#1); the water is removed by moderate heating (#2); the vent/fill tube of the inner container sealed (#3); and the HLW solids vitrified at high temperature (#4). In contrast to previous HLW vitrification processes, the SMILE process will not result in any significant release of radioactive volatiles. In the drying step (#2), the only volatiles are steam and decomposition gases (e.g., from residual nitrates) which are trapped externally; in the vitrification step (#4) all volatiles are fully retained inside the inner container.

After the heated, sealed inner container cools to near ambient temperature, the hydraulic lift raises the outer steel container around it (Step #5). The outer/inner container combination is then lowered to the bottom of the process pit and removed through the exit transfer lock. The open top of the outer steel container is then covered with a lid, and a welded seal made remotely, completely sealing off the vitrified waste inside a double barrier container (Step #6). The completed inner/outer container combination is shown in Fig. 2B. The finished container would be temporarily stored and then sent to an off-site geological repository. The projected time line for processing SMILE containers is given in Table I. A more detailed description of the SMILE concept is given in the BNL report, "SMILE - A New Approach for the Vitrification of High Level Wastes," by J. Powell, et al (1).

Table I

ANALYSIS OF THE SMILE CYCLE

Dimensions for a typical SMILE container are given below. These values are based on an initial study of the SMILE concept, and may change somewhat after further, more detailed studies. Outer radius of central vent tube = 5 cm; outer radius of HLW glass region = 32.5 cm; outer radius of alumina cylinder = 33.5 cm; outer radius of graphite cylinder = 41.0 cm; outer radius of thermal insulator = 46.0 cm; outer radius of stainless steel jacket = 47.5 cm; length of canister = 450 cm.

The drying of the wet HLW/frit solids involves a complex conductive/convective transient heat transfer process. Exact analysis of the process is beyond the scope of this paper. However, the transient behavior can be approximately determined from analytic solutions given by Schneider (2) in the Handbook of Heat Transfer. The following thermophysical properties are taken for the bed of HLW/frit solids: k = 1x10-2 watts/cmK, 70% solids volume fraction in bed, rCp = 2 Joules/cm3K [per cm3 of bed], with a corresponding thermal diffusivity of a = k/rCp = 5x10-3 cm2/sec. At the beginning of the drying phase, the temperature of the graphite alumina cylinder is raised from its original value, To, to TG and held constant. Heat is conducted/convected radially inwards, with steam and other gases being driven off through the central vent tube. The temperature ratio, TR, relating the time dependent (Q = time) temperature at the axis of the HLW/frit bed (i.e., at the central vent tube) to the original temperature To, is a function of the Fourier number, Fo,
Eq. 1
Taking TG = 1150 K(877C) and the Fourier number = 0.5, the analytic solution given by Schneider yields a value of TR = 0.90 (center temperature = 1065K). For the condition of RB = 32.5 cm and a = 5x10-3 cm2/sec, the time required is QDRY = 29.4 hours. At the end of the drying phase, the temperature of the coolest portion of the bed (i.e., at the central ceramic vent rube) is 792C, with the average bed temperature being ~800C. The temperature of the graphite/alumina cylinder is then increased to a higher constant value, TG*, so that the HLW/frit solids can be vitrified. Fixing a precise value for TG* will require experiments but it is expected that TG* will be on the order of 1200C (1473K). Taking temperature ratio, TR*, for the vitrification phase is 0.85, the corresponding Fourier number is Fo* = 0.4. The time required for vitrification is QVIT = 23.6 hours. The bed temperature at the ceramic vent tube at the conclusion of the vitrification phase is T* (0,QVIT) = 1150C, based on values of TG = 1200C and To = 800C.

The total energy input to the bed for drying and vitrification supplied by the graphite/alumina heater is QTB = QDRY + QVIT = 1.16x109 Joules/meter, based on the change in enthalpies of the original components. Two additional energy inputs are supplied by the graphite/alumina heater: 1) energy to raise the heater from a cold state to its final operating temperature, and 2) energy lost to the cool outside steel container by conduction through the insulating alumina brick layer during the drying and vitrification phases. The first term equals 0.75x109 Joules/meter, the increase in enthalpy of the graphite cylinder and alumina liner. The second term is considerably greater, 2.42x109 Joules/meter. The temperature, TSS, of the outer steel container is maintained at a relatively low value, e.g., 500K (227C) by air cooling. The thermal conductivity of the insulation is taken as equal to that given by Marks (3) for #16 insulating brick refractory. The total energy input from the heater then equals QTOT = QDRY + QVIT + QHEATER + QINSUL = 4.33x109 Joules/meter. This corresponds to a heater energy input that is approximately 3 times greater than that required to dry and vitrify the HLW/frit solids themselves. The total energy input for a 5 meter long container is 2.16x1010 Joules or ~6000 kWh. At an electrical energy cost of 10 cents per kWh, this corresponds to a cost of ~$600 per container. The average electrical power input during the drying and vitrification phases is 113 kW(e).

There is an additional energy input and cooling load associated with parasitic I2R losses generated in the outer stainless steel container by the inductive heating coil. The SMILE container is equivalent to a single turn secondary of a transformer, with the primary being the inductive heating coil. The large size of the container, plus the low heating rate enables the use of low AC power frequencies, i.e., 30 hertz, in the inductive heating coil. The alternating magnetic field produced by the inductive heating coil will induce currents in the outer stainless steel container as well as in the graphite cylinder, however, and energy losses to the steel must be included as part of the overall energy losses. They will not affect the internal temperature distribution, but do affect the cooling load on the outer steel container. Analyses of the inductive heating process find that the parasitic currents in the steel container approximately double the required input power, from 113 kW(e) to a total of 230 kW(e).

COMPOSITION OF HLW GLASS PRODUCED BY SMILE

SMILE can be used with all processing alternatives, including enhanced sludge washing and acid dissolution (e.g., TRUEX). As an example, HLW from the TRUEX D process proposed for the Hanford TWRS program can be combined with suitable frit material to yield a final borosilicate glass composition that closely approximates Savannah River HLW glass.

Table II gives the weight percent of the various solid oxides (after heating) in the TRUEX D waste (4) and compares it to the weight percent distribution for Savannah River waste (5). There are substantial differences, and some components fall outside of the quoted possible range. However, by addition of appropriate frit material, the combination of Hanford TRUEX D waste and frit can closely match the composition of Savannah River waste glass. Table III shows the resultant composition produced by adding frit in the ratio of 3 parts frit by weight to 1 part of TRUEX D waste. The resultant composition matches that of the Savannah River glass for all components except those marked with an asterisk. For those that are different, the discrepancies are relatively small, with the principal differences being a higher amount of Al2O3 (6.9 vs. 2.8 wt.%) and a somewhat lower amount of Fe2O3 (10.1 vs. 14.5 wt.%). These differences are not expected to change glass properties significantly, however. These relatively small differences could be further reduced by minor adjustments in the concentrations of the other components.

Table II

Table III

SMILE DEVELOPMENT

There do not appear to be any major technical feasibility issues for SMILE. The inductive heating coil is low tech and thermal insulation techniques are well established. The handling and lifting equipment appears straightforward. Material behavior during the vitrification phase should be confirmed; however, it appears molten glass can be contained without problems in both alumina and graphite. Because the SMILE concept involves small modules, and it does not require the high temperature components to operate for long periods, it should be possible to readily demonstrate the concept at full scale, and show that containers can be reliably produced. Technology modifications can be made quickly and easily, since the time to process a container is only a few days. This eliminates waiting for many months to detect problems, and then waiting for many more months to see if the required modifications are successful.

Borosilicate glass can be produced in alumina, steel, or graphite containers. Issues relating to heat transfer and energy cost do not appear to be significant. The issue of how much gas is released inside a SMILE container during the vitrification phase, and whether it would result in an objectionable pressure increase, can be resolved at an early stage by laboratory tests on simulated wastes. As discussed earlier, if the release amount is considered excessive, the container could be vented during vitrification with an attached cold trap to catch whatever cesium would volatize.

There is a substantial information base on the properties of the various materials that would be used for SMILE, and the thermal and electrical designs of the SMILE container and process facility appear to be straightforward. However, SMILE will require the normal engineering development associated with any new process, which involves going from bench scale to pilot plant to full scale.

HANFORD HLW IMMOBILIZATION IN SYNROC

ABSTRACT

Current strategies for the remediation of Hanford tank wastes envisage four HLW product streams: Cs, Tc, Sr/TRU and insoluble residues. All of the Cs and Tc products can be immobilized in 27 metric tonnes of Synroc that could be produced in a plant of 2 MT p.a. capacity over the time scales envisaged for Hanford remediation. There is a possibility that further segregation of the major heat generating HLW can be achieved without significant increase in the amount of Synroc by including the Sr/TRU stream with Cs and Tc. The Synroc would require extended intermediate storage prior to geological disposal but the benefits of low heat generation and the absence of hard g from 137Cs in the major HLW stream would outweigh the costs. Results are also presented of a Synroc/glass composite with high waste loadings produced by melting. Crystalline zirconolite and perovskite, which have very stable analogue minerals in nature are the hosts for TRU in this composite wasteform.

INTRODUCTION

About 240,000 MT of process chemicals contaminated with about 250MCi of radioactive elements are currently stored at Hanford in 177 steel tanks (1). The wastes are dominated by sodium nitrate and nitrites. Recent

descriptions of the waste compositions have been given (1) but considerable uncertainty exists because the wastes are inhomogeneous, resulting from various reprocessing and subsequent chemical processing campaigns and numerous intertank transfers. Current strategies (2) for the remediation of Hanford Tank Wastes envisage prior separation of most of the Cs, Tc and Sr/TRU from the existing liquid components of the waste, including sludge washings, which are then destined for solidification as low-activity waste. The insoluble components of the sludges together with the three separated components, will thus form four separate HLW products.

Borosilicate glass is the only currently accepted high-level waste form in the US. At glass waste loadings of 25-45 wt.% as many as 30,000 standard 0.6m diameter by 3m long waste canisters will require geologic disposal. Significant incentives exist to minimize the volume of conditioned HLW because repository space is limited. High waste loadings in glass require melting temperatures significantly higher than the 1150oC currently envisaged in conventional ceramic glass melters. Waste loading in glass is subject to two constraints: product quality and ease of processing (3). High temperatures in glass making may lead to extensive loss of Cs and Tc through volatilization. Crystallization of refractory crystalline phases (4) at high waste loadings is detrimental to the operation of Joule melters, but does not affect melters with short residence time and with vigorous mixing such as high frequency induction heated cold-crucible melters.

The separation of the HLW fraction of Hanford wastes into four distinct products provides an opportunity to explore possible synergies between Synroc, a crystalline ceramic wasteform underdevelopment at ANSTO, and borosilicate glass in the context of Hanford Waste remediation. Two aspects will be discussed in this paper:

The immobilization of Cs and Tc in Synroc by ceramic process technologies to provide a stable wasteform for Cs135 and Tc99, both of which have very long half-lives and significant solubility and mobility in most geologic media.

The results of early studies in the development of a Synroc/glass composite waste form that can be produced by melting at temperatures of about 1400oC.

SYNROC

Synroc-C, a formulation developed for the immobilization of HLW from the reprocessing of commercial LWR spent fuel, consists mainly of zirconolite, $CaZrTi_2O_7$, barium hollandite, $Ba(Al,Ti)_2Ti_6O_{16}$, perovskite, $CaTiO_3$, and excess titanium oxide. A combination of the first three phases has the capacity to accept, in solid solution, most of the elements present in HLW. Under the redox conditions chosen for Synroc fabrication, a number of waste elements such as Ru, Rh, Pd, and Tc, are reduced to the metallic state and form alloys that are microencapsulated within the titanate phases. The alloys also contain Mo, Ni, Te and some Fe. Hollandite is the host for Cs, Ba and Rb; perovskite is the major host for Sr; and zirconolite and perovskite are the hosts for rare earths and actinides.

Titanium metal powder is added to calcined Synroc at the 2 wt.% level for redox control during consolidation by hot-pressing. This is an important aspect of Synroc chemistry. An excess of reduced rutile provides Synroc with the capability to maintain the desired phase assemblage (by changes in the relative abundance of the phases) even if unexpected fluctuations

occur in the HLW stream composition. This process flexibility is evidenced by the ability to use the same Synroc precursor composition for waste loadings in the range 0-30 wt.% without deleterious effects on the chemical durability. The composition and mineralogy of Synroc-C are given in Table I.

Table I

The density of Synroc-C is 4.48g/cm3, the thermal conductivity is 2.5 W/m/K and it has an incongruent melting point at about 1350oC. These properties permit the consideration of higher waste loadings than in glass with the accompanying high temperature in the wasteform.

The major phases in Synroc are analogous to titanate minerals that have successfully immobilized (5) naturally occurring radioactivity (eg. U,Th) in a wide range of geochemical/geological settings. Natural samples of zirconolite have been studied (6) which have immobilized U, Th and their decay products for periods approaching one billion years.

The data base on the aqueous chemical durability of Synroc is extensive (7, 8). Protection is afforded by hydrated films of TiO_2 which form on Synroc and the leach rate decreases rapidly with time even with frequent replacement of leachant. At long dissolution times, the normalized leach rate of Cs and Tc at 90oC is less than 1x10-4g/m2d and for the actinide elements is less than 1x10-5g/m2d in water saturated with air. Matzke (9) has shown that the dissolution rate of Synroc at 150oC is less than 0.15 nm per day. Consequently, Synroc can be considered to be an important independent barrier to the return of radioactive waste elements to the biosphere. Radiation stability of Synroc and its phases has been discussed in the recent review by Ewing et al (10).

The key parameters for Synroc processing are effectively dictated by the need for a dense, fine grained product, ie > 98% of theoretical density, and control of redox potential at all key stages of the process to eliminate the possible losses of volatile species whilst maintaining chemical control to ensure appropriate partitioning of radwaste species into targeted phases. The redox potential is controlled during rotary calcination of the Synroc precursor (Table I) and HLW solutions at 700oC by a counter-current flow of 3.5% H_2/N_2 reducing gas that prevents the formation and subsequent loss of potential volatile species such as Cs, Tc and Ru. The calcine after blending with 2 wt.% titanium powder is transferred to stainless steel bellows containers, normally containing 35 kg of Synroc, before hot pressing at 1180oC. The use of the innovative bellows containers, Fig. 1, that are eventually stacked in waste canisters for storage, transport and disposal, avoids unnecessary generation of process wastes. The bellows containers also facilitate heat transfer from Synroc to the waste canister. The metallic top and bottom plates provide a short heat conduction path to the canister, and hence high waste loadings are possible for wastes to be stored for extended periods in engineered facilities prior to disposal. Direct methods of quality control are possible through sampling of Synroc in the bellows on a statistical basis. The process technology of Synroc production by ceramic hot-pressing has been demonstrated on a non-radioactive basis at 10kg/hr scale (8) and the operating experience has provided the basis for a conceptual design of a radioactive plant.

Fig. 1

Whilst the Synroc-C formulation was specifically designed for HLW from commercial reprocessing of LWR fuels, it is flexible and has useful properties for waste partitioning strategies in commercial fuel

reprocessing (11). Applications of zirconolite-rich Synroc-C for excess plutonium disposition have been discussed recently (12, 13). Synroc-D, developed by Ringwood et al (14) for the immobilization of defence wastes at Savannah River, demonstrated the overall flexibility of the Synroc concept in adapting to different wastes. High concentrations of inert contaminants such as Na2O, SiO2 and iron oxides, coupled with relatively low levels of actinides and fission products, required a compromise for high waste loadings to be achieved. In Synroc-D, hollandite was no longer thermodynamically compatible with silicate phases. Nepheline ($NaAlSiO_4$) was introduced as the host phase for Cs, Rb and Ba. Compatible spinel phases are used in Synroc-D for the excess inert components in defence wastes to yield acceptable waste loadings with a leach resistance superior to defence waste glasses. The Synroc-D strategy employing ceramic processing is not capable at present of reaching the high production rates required for immobilization of the sodium-rich Hanford wastes.

HANFORD Cs AND Tc WASTES

About 2000kg of Cs and 1500kg of Tc are likely to be extracted from the Hanford Tank wastes. The 137Cs constitutes about 26% of the total Cs and the total decay heat from Cs is 220kW. The maximum Cs loading in Synroc can be constrained by solubility limits or by the permissible heat loading.

The maximum heat loading at the La Hague, France, vitrification plant (15) is 3kW for a container holding 400kg of glass. This is a much higher thermal loading than the Hanford specification of about 0.4kW for a similar weight of glass. The separation of 137Cs and 90Sr followed by conditioning in stable matrices (eg. borosilicate glass or Synroc) and storage for about 150 years has been advocated by Northrup et al (16) to reduce the size of geological repositories for HLW disposal. An acceptable center line maximum temperature in Synroc bellows for intermediate storage loaded in a French canister is estimated (11) to be about 650oC corresponding to 8kW/400kg Synroc.

Recent studies by Hart et al (17) indicate that the solubility of Cs in Synroc is about 10 wt.%. On the basis of 7.5 wt.% Cs (1.95 wt.% 137Cs) in Synroc from Hanford Tanks, the heat loading on 400kg of Synroc is 3.3kW which is only 10% higher than the specification at La Hague. Consequently, the separated Cs from Hanford wastes could be immobilized in about 27 MT of Synroc. This could be achieved in a small Synroc plant of less than 2 MT p.a. within the envisaged time scales for HLW solidification at Hanford.

The Tc, immobilized together with the Cs, would be in the metallic state. This Synroc with 7.5 wt.% Cs and 5.5 wt.% Tc, has the ability, if required, to immobilize significant quantities of the separated Sr/TRU product at Hanford. On a series of tests on Cs/Sr added in molar ratios of 2:1 to the standard Synroc-C precursor, Hart et al (17) observed the correct phase assemblage existed in Synroc containing 10 wt.% Cs2O and 3.4 wt.% SrO. Since this Synroc also contains perovskite and zirconolite there is the additional capacity to immobilize TRU as well. The Sr will increase the heat loading on Synroc and may require some increase in the total weight of Synroc over that for Cs and Tc immobilization. Nevertheless, the bulk of Sr and TRU and the remaining Tc in the Hanford HLW are expected to remain in the insoluble residues stream. It is premature to speculate further at this time of the amount of Synroc required to immobilize the Cs, Tc and Sr/TRU streams at Hanford until

better estimates are available of the composition and quantity of the Sr/TRU extracted from liquid phases during Hanford Tank waste remediation.

The chemical durability of Synroc has been studied extensively in MCC-1 type tests with frequent exchange of leachant. The normalized differential leach rates for Cs and Tc decrease with leaching time. In de-ionized water at 90oC, the normalized leach rates for Tc after 90 days are < 1 x 10-4g/m2/d in air saturated water, and <1x10-6g/m2/d under anoxic conditions (17). The Cs leach rates in long term tests are also<1x10-4g/m2/d (8, 13).

SYNROC/GLASS COMPOSITE WASTEFORMS

Development of a Synroc/glass composite wasteform for the sodium-rich insoluble HLW sludges at Hanford has been initiated at ANSTO and preliminary results have been published (11, 18). Our strategy has been to formulate a wasteform that retains the extensively characterized refractory phases perovskite and zirconolite of Synroc-C as hosts for the long-lived TRU elements. Developments in cold-crucible melters (19) and the demonstration that Synroc can be produced through melting (20) in cold-crucible melters suggest that the technology for high-temperature and high throughput melting of crystalline/glass composites is feasible. The initial formulation was based on hypotheses about which elements could be removed from the solids in Hanford Double Shell Tanks (DST) by washing of sludges. The composition of the simulated DST average waste chosen is shown in Table II. The TRU were simulated by rare earth oxides.

Table II

To encourage the formation of zirconolite and perovskite, CaO and TiO_2 were added in either 1:1 or 1:2 molar ratios and SiO_2 was added to increase the durability of aluminosilicate phases. Melting was carried out in Pt-5%Au or Al_2O_3 crucibles under an argon atmosphere at 1400-1500oC. The melts were cooled at 2, 5 or 20oC/min. and no significant differences were observed in their microstructures.

The microstructure of a Synroc/glass composite containing 70 wt.% of the simulated DST waste in Table II and $TiO_2/CaO/SiO_2$ of 11.9, 8.3 and 9.8 wt.%, respectively is shown in Fig. 2. The phase assemblage consists mainly of zirconolite, perovskite, spinel and glass in the ratio of 25:10:10:54. The rare earth simulants of TRU were found to be distributed between zirconolite and perovskite (18). The durability of this composite wasteform was good as indicated by the following 7-day 90oC PCT test leach rates (g/m2) : Na (0.3), K(0.3), Si(0.1). For the remaining elements the leach rates were all < 0.07g/m2. Preliminary results for simulated sludge in wastes from NCAW and NCRW tanks suggest that acceptable formulations with waste loadings higher than 50 wt.% are achievable to meet the PCT criteria (18). Similar waste loadings have been reported by Hrma and Bailey (3) on glasses with other crystalline phases.

Fig. 2

DISCUSSION AND CONCLUSIONS

Technetium and 135Cs, because of their long half-lives and ability to migrate in the environment, contribute significantly to the long-term risk associated with radioactive waste disposal. Synroc can accept waste loadings of 7.5 wt.% Cs and 5.5 wt.% Tc. About 27 MT of Synroc is sufficient to immobilize all of the Cs and Tc product streams from Hanford originating from current strategies for remediation of the tank wastes. The high 137Cs content in the Synroc will require extended

intermediate storage prior to geological disposal. However, it may well be that two half-lives of 137Cs may be required before a geological repository is available, particularly if the bulk of the remaining conditioned HLW is disposed first. A very small Synroc process plant of 2 MT p.a. would be required to immobilize the Cs and Tc over the envisaged time scales of Hanford remediation.

There are advantages in also immobilizing in Synroc the Sr/TRU fraction from Hanford waste pretreatment. The amount of extra Synroc production capacity over that required to immobilize Tc and Cs is expected to be small. Such a strategy would reduce the heat loading in the remaining fraction of HLW that could be conditioned in borosilicate glass. There would be accompanying benefits in the ease of handling the HLW glass because of the elimination of the hard g from 137Cs decay and the reduction of heat loading enables more glass blocks to be disposed early in the first geological repository in the U.S. The cost of the interim store for heat decay of the much smaller amount of Synroc would be insignificant compared with savings in the handling and disposal costs of glass.

The Synroc process technology, based on conventional ceramic processing, combined with the innovative use of bellows containers during hot pressing, generates less secondary waste compared with large glass melters that have to be disposed.

Preliminary results also indicate that high waste loadings are possible in a Synroc/glass composite waste form produced by melting of the insoluble stream of HLW products from Hanford. The TRU component in these wastes is likely to be partitioned in the crystalline Synroc phases, zirconolite and perovskite, for which very stable analogue minerals are available in nature.

USING THE 3R-STAT COMPUTER CODE TO DETERMINE THE QUANTITIES OF I-129 AND TC-99 IN LOW LEVEL WASTE
Jene N. Vance
Vance & Associates

P.O. Box 997
Ruidoso, NM 88345

ABSTRACT

This paper describes the use and application of the computer code, 3R-STAT to determine the quantities of I-129 and Tc-99 in LLW generated by operating nuclear plants. A topical report has been submitted to the U.S. NRC for review on July 20, 1993. After more than two years of review, the U.S. NRC has approved the use of 3R-STAT as an acceptably accurate method to determine the quantities of I-129 and Tc-99 generated by nuclear power plants. The NRC approved the use of 3R-STAT for LLW Disposal Site Developers, and Nuclear Utilities in their waste management programs. The paper discusses how the code is used in terms of the proper execution of the code. The paper also discusses the nature of the 3R-STAT code results and how these results are used to report the quantities of I-129 and Tc-99 shipped to disposal site operators.

INTRODUCTION

The computer code, 3R-STAT, was developed by Vance & Associates to determine, through computer modeling, the quantities of I-129 and Tc-99 in low level waste. The computer code was developed as an alternative to costly and difficult radiochemistry measurements on actual waste samples from nuclear power plants. A Topical Report was prepared and sent to the US NRC for review and approval in July of 1993 and it was approved in August of 1995. The NRC approved the use of the computer code by LLW site developers, nuclear utilities and LLW disposal facility operators.

DISCUSSION

The basic modeling developed for the 3R-STAT code was derived from the chemistry and physics of the release of the short-lived radionuclides from reactor fuel in a reactor relative to the release of the long-lived isotopes of I-129 and Tc-99. The input to the code are the measured reactor coolant concentrations of the eight (8) gamma radionuclides:

I-131	Cs-134
I-132	Cs-137
I-133	Co-60
I-134	
I-135	

From the relative concentrations of these radionuclides, the computer code determines the corresponding reactor fuel release conditions and based on these conditions determines the corresponding release rates of I-129 and Tc-99.

Typically, the reactor coolant isotopic data are analyzed on a fuel cycle basis to determine the average release rates of I-129 and Tc-99 over the fuel cycle. The computer code analyzes the isotopic data for each day that a sample of reactor coolant has been collected. The code determines the release rate of I-129 and Tc-99 for each day in units of mCi/MWD. The average release rate for a fuel cycle is simply the average of all of the days that samples were collected. For plants that sample reactor coolant daily, there could be 300 to 400 I-129 and Tc-99 release rates in the computed average for a fuel cycle. Table I displays the average fuel release rates and radionuclide conditions over a Beaver Valley fuel cycle. Figure 1 shows a graph generated by 3R-STAT displaying the activity release rate for I-129 (mCi/MWD).

Table I

Fig. 1

The code has been used to develop the inventory projections of I-129 and Tc-99 for new LLW disposal facilities in the following States:

- Nebraska
- Illinois
- Pennsylvania
- New York
- North Carolina
- Connecticut
- Texas

The inventory projections, were based on data from past fuel cycles (3 to 4 fuel cycles) from those plants planning to ship waste to the LLW facility. The unique future of 3R-STAT is that the code can be applied retroactively to fuel cycles long since completed, if the isotopic data can be retrieved. Each fuel cycle for each plant was analyzed using the computer code to yield average release rates of I-129 and Tc-99 for each fuel cycle and an average for each plant. The calculations for the inventory projections is summarized as follows:

Eq. 1

The NRC also approved the use of the computer code by nuclear utilities to determine the quantities of I-129 and Tc-99 contained in low level waste shipped from their power plants to an operating disposal facility. The method approved by the NRC for utilities would involve continuing to include MDA values on shipping manifests for I-129 and Tc-99. Then on an annual or fuel cycle basis, the utility would report the values produced by 3R-STAT for the reporting period. The calculation is as follows:

Eq. 2

In the 3R-STAT Topical Report, it was proposed that a semi-annul or annual report be provided by the reactor generators to the site operator. This report would provide the total quantities of I-129 and Tc-99 shipped in LLW for the reporting period.

An illustration of the actual calculations for several of the Beaver Valley fuel cycles is given in Table II.

Table II

The NRC also approved the use the computer code by LLW disposal site operators for the purposes of verifying the results submitted by utilities. The site operator would receive the raw unedited isotopic data from a utility for a given fuel cycle. The site operator would analyze the data using 3R-STAT and compare the results against the results submitted by the utility.

IMPACTS OF 10CFR61 SCALING FACTORS FOR UTILITY LOW-LEVEL WASTE ON WASTE FACILITY PERFORMANCE ASSESSMENT

Man-Sung Yim
North Carolina State University
Raleigh, NC 27695

ABSTRACT

Importance of accurately estimating the scaling factors for 10CFR61 radionuclides is investigated with respect to waste facility performance assessment. Scaling factors used in the analysis are estimated based on the shipping manifest information from Barnwell LLW site. Sensitivities of scaling factors of each radionuclides on the estimated dose are evaluated for a test case problem in a humid permeable site and key radionuclides and waste streams are identified. For 129I and 99Tc, the

use of scaling factors based on the lower limits of detection (LLD) values are compared with the case where more accurate scaling factors are used. Based on the test case analyses, the key radionuclides in LLW performance assessment among the 10CFR61 nuclides were found to be 14C, 129I, and 99Tc. Others that could produce non-negligible dose include 59Ni, 239Pu, 94Nb and 3H. It was found that the changes in scaling factors for key waste streams could potentially have a significant impact on performance assessment. Important waste streams were Class C and B dewatered resins, Class A unstabilized mixed DAW, Class C solid irradiated equipment, and Class C dewatered cartridge filters. It was also found that 129I and 99Tc will remain as important radionuclide in performance assessment even after more accurate non-LLD based scaling factors are used. This was due to the contributions from non-utility generators.

INTRODUCTION

The primary objective of low-level radioactive waste (LLW) characterization is to accurately assess radionuclide inventory in a waste disposal facility. In utility waste management, scaling factors are used to quantify the concentrations of difficult to measure (DTM) radionuclides within LLW. These scaling factors are known to have large variabilities depending upon the types of waste streams and radionuclides ranging several orders of magnitude. For I-129 and Tc-99, the lower limits of detection (LLD) are often reported by the laboratory analyzing the samples when these nuclides have not been detected or measured. When the LLD, rather than actual analyzed concentration, are used in the scaling factors the concentrations of these radionuclides in the wastes are over-estimated. This over-estimation of I-129 and Tc-99 inventory was found to range by factors of 10 to 10,000 (1,2). According to some of the recent performance assessments of LLW facilities, I-129 and Tc-99 are one of the major nuclides of concern. Therefore the overestimation of inventory of I-129 and Tc-99 may potentially have a significant implications in the licensing of any proposed LLW site.

The purpose of this work is first to identify the radionuclides and waste streams of importance in performance assessment and to quantitatively characterize the impact of variabilities of scaling factors of these radionuclides on the performance assessment. The implications of over-reporting I-129 and Tc-99 inventory is also investigated.

INVENTORY DISTRIBUTION OF 10 CFR 61 NUCLIDES IN LLW STREAMS

Performance assessment of a waste disposal facility is directed by the inventory of radionuclides stored in the facility. Accurately estimating the distribution of radionuclide inventory in major waste streams are thus important in performance assessment.

Table I shows this information for the 10CFR61 radionuclides associated with the use of scaling factors. This information was calculated using the radionuclide concentrations estimated by Chem-Nuclear Systems, Inc. based on shipping manifests collected at Barnwell, SC (3). Utility wastes account for the majority of inventory for all the radionuclides listed in Table I, except for Am-241 (only 6% from utilities). In fact, for many of these radionuclides, more than or close to 90% of the total activity disposed was estimated to be from the utility waste: 99.2% for Ni-59; 99.8% for Ni-63; 89.3% for Co-60; 91.3% for Sr-90; 99.4% for Nb-94; 95.8% for Pu-238; 94.3% for Pu-239; 95.1% for Pu-241; 100% for Cm-242; and 99.9% for Cm-243. For C-14, I-129, and Cs-137, about 80% of total activity disposed was estimated to be from utility generators. In the

case of Tc-99, utility waste accounted for about 66% of the total activity. The contributions from non-utility generators are separately listed in Table II.

Within the utility wastes, dewatered resins and irradiated equipment were the two major waste streams that make up the majority of inventory for the listed radionuclides except I-129 and Tc-99. The percentages of inventory accounted for by dewatered resins were: 60% for C-14; 20% for Tc-99; 37% for Ni-59; 34% for Ni-63; 78% for Sr-90; 88% for Nb-94; 78% for Cs-137; 73% for Pu-238; 80% for Pu-239; and 72% for Pu-241. The percentages of inventory accounted for by irradiated equipment were: 13% for C-14; 20% for Tc-99; 37% for Ni-59; 34% for Ni-63; 78% for Sr-90; 88% for Nb-94; 78% for Cs-137; 73% for Pu-238; 80% for Pu-239; and 72% for Pu-241.

For I-129, mixed DAW (~35%), dewatered cartridge filters (~16%), and incinerator ash (~20%) were reported to contain the majority of activity. The activity of Tc-99 was more evenly distributed within various waste streams (22% in DAW, 20% in dewatered resins, 13% in filters, 5% in incinerator ash, and 3% in equipment).

As shown in Table II, the contributions from non-utility generators to the total activity inventory were generally minor except Am-241 (94% from non-utility generators) and Tc-99 (34% from non-utility generators). Among the Tc-99 activity which was estimated to be from non-utility generators, industry produced most of this as DAW (26%) and as incinerator ash (6%). Am-241 in LLW was coming mostly from government and industry as sealed sources or dry solids.

Table I

Table II

TEST CASE PERFORMANCE ASSESSMENT FOR 10CFR61 NUCLIDES

To identify the radionuclides of importance, test case performance assessments are performed for the listed radionuclides. The test case was based on a hypothetical waste disposal facility, characterized as humid permeable site. Major input parameters used are listed in Table III. For the performance assessment, a computer model similar to SYSCPG (4) with modifications in the source inventory descriptions and the pathway/dose analysis was used (5). Results of test case analyses are given in Table IV. Many of the nuclides including Ni-63, Am-241, Co-60, Cs-137, Pu-238, Pu-241, Cm242, and Cm243 showed no or negligible contribution to the projected dose. Radionuclides found to be important include I-129, C-14, and Tc-99 followed by Ni-59 and Pu-239. For H-3, Nb-94, and Sr-90, non-negligible contributions were observed. For the three major nuclides in the assessment. i.e., I-129, C-14, and Tc-99 the peak dose was estimated to be close to 1 mrem/yr which occurred within 1,000 year time frame for the test case problem. Dose from Ni-59 and Pu-239 was estimated to be less than 0.02 mrem/yr with much longer time to the peak (6800 yr and 47600 yr, respectively).

Table III

Table IV

POTENTIAL IMPACTS OF SCALING FACTOR VARIABILITIES ON PERFORMANCE ASSESSMENT

To investigate the impacts of scaling factor changes of key radionuclides on performance assessment, sensitivity calculations were made for the waste streams of importance. The radionuclides considered for this sensitivity analysis include C-14, I-129, Tc-99, Ni-59, Pu-239, and Nb-94. Table V lists scaling factors for these radionuclides estimated in

each of the waste streams considered. These scaling factors were increased by the factor of 10 for the sensitivity analysis.

Table VI shows the results of the sensitivity analyses. Each data points in the table represent the ratio of dose estimate after the increase of scaling factor by a factor of 10 to the base case. The dose estimates were shown to increase by a factor of up to 3.5 for C-14 (Class C dewatered resins), up to 4.1 for I-129 (Class A unstabilized mixed DAW) and up to 2.4 for Tc-99 (Class C dewatered resins). For Ni-59, Pu-239, and Nb-94, the increase in the ratio was estimated to be higher: by a factor of 4.9 for the Class C solid equipment for Ni-59; by a factor of 4.9 for the Class C dewatered resins for Pu-239; and by a factor of 7.6 for the Class B dewatered resins for Nb-94. Almost all of the calculations show that the increase in the estimated peak dose was proportional to the inventory increase due to the increase in scaling factors. One exception observed was the case with Pu-239 where the solubility limit became limiting.

Table V

Table VI

IMPLICATIONS OF INVENTORY OVER-REPORTING FOR I-129 AND TC-99

It is known that the inventory of I-129 and Tc-99 in LLW is highly over-estimated due to the use of LLD in the calculation of scaling factors (1). To investigate this issue, calculations are made with different set of scaling factors for I-129 and Tc-99 based on recent findings (1,2,6,7). New scaling factors used for I-129/Cs-137 and Tc-99/Cs-137 were: (1) the existing scaling factors divided by a factor of 1000 (7), and (2) the existing scaling factors divided by a factor of 10 (1,2). The results of test case performance assessment after these changes were made are shown in Table VII. Results show that decreasing the current scaling factors by a factor of 10 was enough to significantly reduce the inventory of I-129 and Tc-99. With new scaling factors, the peak dose predicted was significantly reduced, by a factor of 3.7 and 5 for I-129 and 2.5 and 5 for Tc-99. Predicted peak dose levels, however, were still significant enough for I-129 and Tc-99 to remain important in LLW performance assessment. This was due to the contributions from non-utility generators. Non-utility generators contribute about 18% and 31% of the total activity inventory of I-129 and Tc-99, respectively, as listed in Table II.

Table VII

CONCLUSIONS/DISCUSSIONS

Based on test case analyses for a hypothetical LLW disposal facility, key radionuclides in LLW performance assessment among the 10CFR61 nuclides were found to be C-14, I-129, and Tc-99. Ni-59, Pu-239, Nb-94 and H-3 were found to be capable of producing non-negligible dose in the performance assessment. The test case analysis showed that the changes in scaling factors for key waste streams could potentially impact the performance assessment significantly. The waste streams that were identified important were Class C and Class B dewatered resins, Class A unstabilized mixed DAW, Class C solid irradiated equipment, and Class C dewatered cartridge filters. It was also found that I-129 and Tc-99 will remain important in LLW performance assessment even after the use of newly proposed, more realistic scaling factors due to the contributions from non-utility generators.

For more complete understanding of the importance of LLW characterization in performance assessment, comparative evaluations of all major parameters in performance assessment will be undertaken as the next step.

CONSOLIDATION of WASTE CORRELATION FACTORS at DIABLO CANYON

L. T. Claytor III
Enercon Services

C.C. Miller
Pacific Gas & Electric

ABSTRACT

Diablo Canyon Power plant is a two unit PWR. Solid radwaste in the form of resin and cartridge filters is generated from both unit specific and common plant systems. The number of solid waste streams is potentially large due to the various plant systems. As part of the waste classification program samples from the various waste streams are sent to off site laboratories for radionuclide analysis on an annual basis. The annual cost of these services has ranged from $60,000 to $100,000. Statistical trending of eight years of laboratory data using vendor software has enabled the number of spent cartridge filter waste streams to be reduced from seven to two. This trending examined fission and corrosion product activity across the various systems, unit fuel cycles and the two different units.

Additional data trending enabled constant correlation factors for corrosion and transuranic fission products to be derived. This derivation was accomplished with a comparison across resin, cartridge filter and dry active waste streams over various systems, fuel cycles and the two different units. This has enabled a reduction in the number of nuclides requested in an off site analysis thus, reducing the annual cost of the service. As a result of the consolidation of waste streams and the truncation of the spectrum analysis, the cost of a single analysis has been reduced by 40% and the 1995 laboratory service budget has been reduced to $50,000.

INTRODUCTION

Diablo Canyon Power Plant is located on the Pacific coast near Avila Beach, California. Pacific Gas and Electric Company (PG&E) owns and operates the two unit Westinghouse 1100 MWe PWR units. The commercial operation dates for Units 1 and 2 were May 1985 and March 1986 respectively.

A waste classification program has been established at Diablo Canyon to comply with Federal regulations. Appendix F, 10 CFR 20 indicates the requirements for manifesting, certification, control and tracking of low level waste transferred to a land disposal site. Section 61.55 of 10CFR 61 requires waste to be classified. Wastes suitable for land disposal must fall into one of three categories; Class A, B, or C.

Wastes are determined to fall into one of the three classes based upon the concentration of particular radionuclides in the waste versus the limits set forth in Table 1 and 2 of Section 61.55.

Many of the nuclides listed in 10 CFR 61 are considered difficult to measure (DTM) since they emit no gamma radiation. Such nuclides must be measured using radio chemical separations. Since lab facilities at nuclear power plants are limited to gamma and tritium detection, such nuclides must be analyzed at off site vendor laboratories. These analysis are time consuming and expensive.

The NRC's Branch Technical Position on waste classification requires that the method of radionuclide content determination be accurate to within a factor of ten. The ratio of non gamma emitting nuclides to key gamma emitting nuclides from off site analysis enables correlation or scaling factors to be derived. These factors, derived from off site analysis, can be used in concert with subsequent on site gamma analysis to determine waste container activity. These factors can also be used to determine waste streams and trend waste stream spectrums over time. The Branch Technical Position allows the use of this technique as an accurate, cost effective and timely means of compliance.

The Branch Technical Position specifies that for Class B and C waste a confirmatory analysis should be performed annually to insure accuracy to within a factor of ten. Confirmatory analysis for Class A waste should be performed at least biennially.

PLANT WASTE STREAMS

Three types of low level radioactive waste are generated at Diablo Canyon. These are spent ion exchange media, spent cartridge filters and dry active waste (DAW). Spent filters and ion exchange media are produced by several different systems within the plant. Each unit has a spent fuel pool cleanup system, a chemical and volume control system (CVCS) and a boron recycle system. Within the spent fuel pool system is a refueling water cleanup system and within the CVCS is a letdown cleanup and a seal water injection/return cleanup system. In addition, a common radwaste treatment system processes liquid waste from both units.

Spent cartridge filters are produced from each system listed above. Since there are three unit specific systems and a common radwaste system at the plant a possible total of seven spent filter waste streams exist.

Spent ion exchange media is transferred from each system to one of two spent resin storage tanks. In general, high activity resin is stored in one tank and medium activity resin in the other. High activity resin consists of letdown mixed beds and spent fuel pool beds. Medium activity resin consists of all other CVCS beds, boron recycle evaporator feed beds, and all liquid radwaste beds. Since ion exchange media is blended

within these storage tanks there is a possible total of two such waste streams per year.

In practice a waste stream is any waste product or mixture of waste products where the DTM nuclide concentrations can be inferred by use of a single set of correlation or scaling factors (1). Intuitive grouping of waste streams would lead one to suspect that all cartridge filters would likely be similar in waste spectrum. Conversely, a cartridge filter spectrum should be very different from that of ion exchange media since a filter will not remove significant quantities of soluble nuclides.

Early in plant life, Diablo Canyon obtained annual cartridge filter samples for off site analysis from each system when waste was generated. The plan was to collect data for three or four years and plot the results. It was anticipated that the results would demonstrate that the cartridge filter spectrum from various systems would be the same. Although the magnitude was known to vary greatly between systems dependent on the proximity to the fuel, the relative abundance of nuclides were expected to be similar. If the spectrum were modeled as a color, say blue, one would expect a dark blue in letdown and refueling water filters with lessor shades of blue for boron recycle and liquid radwaste.

In 1990, a comparison of the cartridge filter correlation factors from all off site analysis was performed. The results of this study showed that both Unit 1 and 2 filter waste streams possessed similar characteristics. The filters removed the same nuclides regardless of the system. Cesium was not found in significant quantities on cartridge filters. Cobalt was shown to be of no influence in cartridge filter waste classification while non gamma emitters, particularly 14C, controlled classification. The study further found that all corrosion and fission product correlation factors were well within a factor of 10, except for 14C/60Co. It was concluded that further analysis to resolve the variability of 14C should be conducted.

EPRI reviewed the 14C content in cartridge filters at Diablo Canyon in 1991. This review concluded that the variability of 14C was partially influenced by the method of off site analysis. The vendor laboratory was not determining the gamma activity of the aliquot for destructive 14C analysis for normalization to the prime sample gamma spectral analysis. The off site lab specification was revised in 1992 to correct this problem and annual samples were obtained for three additional years.

In 1994, Diablo Canyon performed another comparison of cartridge filter sample results. This time the 10CFR61 Sample Analysis Program produced by D W James and Associates was used to trend and analyze the data.

SAMPLE ANALYSIS PROGRAM

The Sample Analysis Program enables rapid trending of numerous radionuclide sample results. Correlations or scaling factors can be determined for each sample and these factors can be compared for groups of samples as requested by the user. The program produces plots of historical scaling factors, see Fig. 1. The program calculates a median scaling factor and plots the factor of ten limits above and below the median for visual comparison. Any data points beyond these factor of ten limits are noted to be outliers. The user may select and remove outlier data points and produce another plot.

Fig. 1

In addition, the program calculates the dispersion of the data to quantify the variation. In this program the dispersion is defined as the

anti log of the standard deviation calculated from the log ratios (2). The lowest variability off site laboratories can achieve for the same sample is a factor of two. Any data plot from the Sample Analysis Program with a dispersion near two indicates that there is minimal variation in the data.

CARTRIDGE FILTER WASTE STREAM CONSOLIDATION

The basic strategy for consolidating several waste streams is to compare all historical scaling factor results as a data set. This comparison encompasses different fuel cycles, different systems and different reactors. If the dispersion for each scaling factor is near 2, then a common waste stream is indicated. If the dispersion approaches 5 for any single scaling factor, it suggests that more than one waste stream exists.

In order to consolidate the various filter waste streams at Diablo Canyon, fission product and corrosion product scaling factors for all historical data were plotted. All of the scaling factors met the general dispersion of two test except 14C /60Co, see Fig. 1, and 55Fe/60Co. Individual filter waste streams were removed from the grouping to determine if a single system was the cause of the increased dispersion. In addition, unit specific plots and annual plots to depict individual fuel cycles affects were generated.

The result of this comparison was that there are two cartridge filter waste streams at Diablo Canyon. Boron recycle filters are a separate waste stream because they have a higher 55Fe content, and a 14C content which is more than an order magnitude greater than all other filters, see Fig. 2. All other filters make up the other waste stream because a single set of scaling factors meet the general dispersion of 2 test.

Fig. 2

This evaluation reduced the number of filter waste streams requiring annual sampling from seven to two. With analysis costs ranging from $3,000 to $7,000 per sample depending on the turn around time, this reduction resulted in a substantial cost savings.

CONSTANT TRANSURANIC SCALING FACTORS

Based upon the success of the filter waste stream consolidation, an evaluation was conducted to determine if constant scaling factors could be determined from historical data for all waste streams, at Diablo Canyon. Industry data suggested that individual transuranic nuclides would correlate very well with 239Pu. Data plots from all waste streams were generated for the various transuranic nuclides versus 239Pu. These plots resulted in dispersions very near the factor of two test and a set of constant scaling factors.

These transuranic scaling factors were valid for any waste, any fuel cycle and either unit at Diablo Canyon. If the 239Pu/60Co ratio is determined for any future waste, the remaining transuranic nuclides can be determined by use of the derived scaling factors.

CONSTANT CORROSION PRODUCT SCALING FACTORS

Once again, industry data suggested that constant scaling factors could be derived for corrosion products 55Fe, 59Ni, 63Ni. Unlike transuranic nuclides, constant corrosion product scaling factors were likely to be waste stream specific.

Corrosion product scaling factors for the two filter waste streams, spent ion exchange media and DAW at Diablo Canyon were compared. The results were in keeping with industry data. The Nickel scaling factors had a small dispersion and valid constant values could have been used for all

waste streams. The 55Fe scaling factors had a larger variation between waste streams. As mentioned above the 55Fe concentration was much larger in Boron Recycle filters than other filters. The 55Fe/60Co scaling factor for Boron Recycle filters was nearly 7.7 while all other filters had a value of 2.7.

The 55Fe scaling factor variation resulted in two waste streams for ion exchange media. Medium activity resin and inorganic zeolite proved to have the same set of constant corrosion product scaling factors. High activity resin had nickel scaling factors slightly lower than those of medium resin. The dispersion of 55Fe in high activity resin was too large for a constant scaling factor to be derived.

Off site analysis for 55Fe in future spent fuel pool and letdown mixed beds will be obtained. The reason for the large dispersion is due to older spent fuel pool resin results. In 1995, spent fuel pool resin from both units was generated. The 55Fe results from these beds indicate a constant scaling factor for high activity resin will be obtained with a few more data points.

DAW corrosion product data also produced a constant set of scaling factors. These factors were valid for both radioactive trash and clean trash collected in the radiological controlled area. The DAW set of factors were closer to the cartridge filter values than those for resin.

AFFECTS OF FUEL DEFECTS

In late 1994, unit 2 began its seventh fuel cycle. Early on it was noted that a fuel defect was present in this cycle. In order to determine if the fuel defect had any affect on the constant scaling factors which were just derived, a letdown filter was removed and a full spectrum off site analysis performed.

The results of this analysis indicated no variation from the transuranic or corrosion product scaling factors previously derived. The refueling outage for unit 2 is scheduled for March 1996. A full spectrum analysis of a letdown filter and resin bed is planned to verify what affect, if any, the fuel defect has had. At this time, it is expected that this fuel defect will not result in altering the scaling factors derived from historical data.

COST REDUCTION

The economic benefit of deriving site specific constant scaling factors is reducing the number of nuclides analyzed in off site samples. The cost for 55Fe, 59Ni, and 63Ni analysis range from $800 to $1,300 per sample depending on the turn around time. The cost for transuranic nuclides excluding 239Pu range from $900 to $1,400. Thus, the use of constant scaling factors for corrosion products and transuranics saves $1,700 to $2,700 per sample.

Off site sample analysis can be reduced to a gamma isotopic, 14C, 89Sr, 90Sr, 239Pu, 99Tc and 129I for each waste stream. These results coupled with the constant scaling factors derived from historical data enable accurate waste classification to be conducted at a reduced cost.

The consolidation of cartridge filter waste streams and the use of constant scaling factors has resulted in significant cost savings at Diablo Canyon. In the past, $60,000 to $100,000 would be spent annually on off site lab analysis. In 1995, off site analysis for all waste streams generated was reduced to $35,000. This cost includes the analysis of filter samples to determine the affect of fuel defects on unit 2.

CONCLUSION

The comparison of historical scaling factor data can enable the derivation of valid constant values for corrosion products and transuranic nuclides. Such comparisons can also determine the number of waste streams a plant generates. The use of the Sample Analysis Program was critical to performing this comparison at Diablo Canyon.
The waste streams which resulted from this evaluation were based upon valid statistical evidence versus process knowledge. The waste stream results were not intuitively obvious. Significant cost savings can be achieved by accurately determining the number of waste streams. Additional savings can be achieved by deriving and using site specific constant scaling factors. These savings readily pay for the resources needed to perform the evaluation.
The Sample Analysis Program is also a great aid in evaluating waste classification affects of a fuel defect or other event which could shift the radionuclide waste spectrum. The results of new samples can quickly be compared with historical data.

ABSTRACT
In the execution of disposal of low and intermediate level radioactive wastes, it is important to accurately evaluate the kind and quantity of each radionuclide in wastes. For such evaluation, correlation of non-gamma-emitting nuclides based on gamma-emitting nuclides is recommended and regarded as a practical method. This method necessitates a completion of a highly accurate and reliable non-destructive assay system of gamma-emitting nuclide for practical use. In 1992, in support of the new waste disposal program in Hungary, Paks NPP initiated a waste characterization program to determine the radiological properties of its radwastes.
A segmented gamma scanning system has been set up to measure the gamma-emitting nuclides in 200 liter low level drums following in-drum

compaction. In the framework of the program a radiochemical analysis sub-program was started to determine the long-lived non-gamma emitting radionuclides, mainly those listed in the US regulatory document (10CFR61). The radionuclides of interest have been 3H, 14C, 90Sr, 55Fe, 59Ni, 99Tc, 129I and TRUs. Sample preparation techniques and measurement methods have been selected and used. Newly developed or adopted methods have been tested on real liquid radwaste streams such as concentrates, ion-exchange resin and sludge. The measurements taken so far have revealed brand new information and data on radiological composition of waste of WWER-type reactors. In the next stage of the characterization program attempt will be made for providing correlation factors between the gamma and non-gamma emitting radionuclides in different waste streams. Short description of the methods and results on waste inventory are given highlighting the problem areas.

MONITORING PROGRAM

The goal of the monitoring program was to develop a non-destructive gamma-monitoring system that was capable of determining the inventory of gamma-emitting radionuclides in the dry active waste.

As a first step waste assay system was bought from the Canberra-Packard Company.

The description of the hardware and software of the monitor is as follows:

The software runs on an AT bus 386 computer system running under the MS-DOS operating system. The computer contains of a 2 Mb RAM memory, a 120 Mb Winchester hard disk drive, 3 serial and 1 parallel ports, VGA Color monitor, math coprocessor, and 1.44 Mb floppy disk drive.

The system utilizes a Canberra Series 35 PLUS multichannel analyzer with 4K channels of data memory.

The detector is a coaxial high purity germanium detector with a relative efficiency of 30% at 1.33 MeV, and energy resolution of 1.9 keV FWHM. The detector is mounted in a horizontal integral dipstick cryostat with a standard end cap and a 5 cm remote detector chamber. A Canberra Model 2002 preamplifier is mounted to the cryostat.

A lead collimator is used to focus the detector on defined segments of the drum. Collimator dimensions are 10 cm high by 20 cm wide by 20 cm deep. This provides an accurate 10 cm segment of the drum.

The drum assay mechanism is designed to handle containers up to 210 liter drums. These are rotated and moved vertically to accurately measure the gamma radiation emitted from the drum.

The detector collimator support frame is designed to hold the detector, shield, and collimator in the optimum orientation to measure the container being assayed. If a variety of container sizes are being measured the frame can be mounted on a trolley to optimize the detector to sample distance for each container size.

A transmission source shield and shutter is provided mounted on a pedestal and secured to the vertical drive unit to ensure correct alignment between the transmission source, drum, and the detector/collimator for accurate determination of the matrix density of the material.

The analysis software is a SPECTRAN-AT with modifications to optimize the matrix correction routines. Additional routines are provided to correct for matrix attenuation based on the transmission source intensity, and live time correction to correct for count rate losses with high activity containers.

The system is able to detect levels of 3 kBq of 60Co in a drum with a density of 0,5 g/cm3 with a drum assay time of 15 minutes. The minimum sensitivity for 137Cs 6 kBq.
The maximum positional error is less than +/- 25% for sources in different locations in the drum for containers with less than 0,3 g/cm3 density and gamma energies greater than 300 keV.
The maximum drum activity should be less than 500 MBq in the close geometry. If drums with high activities must be counted then the detector trolley should be moved away from the container to reduce sensitivity.
After assembling and testing the hardware and software, the detector was calibrated for efficiency with standard radionuclide sources by the Hungarian Bureau of Standards.
In order to evaluate various forms of miscellaneous waste packages regarding the deviation of density and activity, model waste drums were prepared and tests were performed.
Between 1989 and 1995, the radioactive wastes generated in the plant site of the Paks NPP amounts 2560 drums of 200 l compacted state having the distribution with regard to their content:

1901 drums of compacted waste material (74.2 %),
419 drums of non-compacted waste (16.4 %),
240 drums of solidified sludge (soaked up in prilled diatomaceous earth) (9.4 %).

The results of the waste assay determinations are given in Table I and II and in Fig. 1.
Table I
Table II
It seems quite clear that there are 3 dominating isotopes in the waste drums. 110mAg, 54Mn and 60Co isotopes are the most characteristic components of the waste, both for their frequency of occurrence and activity.
Fig. 1
RADIOCHEMICAL ANALYSIS PROGRAM
The objectives of the radiochemical analysis program were to develop the radioanalytical methods capable of determining the significant radionuclides (3H, 14C, 90Sr, 55Fe, 59Ni, 99Tc, 129I and TRUs) in the various waste forms destined for disposal and, provide the correlation factors between the gamma - and non-gamma-emitting radionuclides to enable to estimate the non-gamma radionuclides in wastes.
Radiochemical separation techniques developed or adapted are given below:
99Tc
Extraction chromatography is used to analyze evaporator concentrates for 99Tc. The technetium is oxidized to pertechnate using nitric acid + hydrogen peroxide and heating. This treatment also destroys most of the organic materials may be present in the concentrate. Amberlite XAD-7 resin is used to remove any organic material remaining after nitric acid and peroxide treatment. Then the pertechnate is separated from interfering elements using TEVA-Spec column. The 99Tc is measured by LSC technique.
Liquid-liquid extraction with dibenzo 18 crown 6 ether (DB18C6) in acetone-toluene mixture was also tried instead of using TEVA-Spec column. More reproducible results were obtained with DB18C6 than with TEVA-Spec. The yield in each method was tested using 99mTc tracer.
129I

The method is based on the separation of iodine from other activities by dissolution of elemental iodine into cold carbon tetrachloride. To assure chemical interchange with the iodine carrier an oxidation-reduction cycle is made. The iodide is oxidized to iodate with permanganate, reduced to iodide with bisulfite, and distilled over as free iodine in the presence of nitrite.

After washing the carbon tetrachloride with nitric acid, the iodine is reduced with bisulfite and back-extracted into water. Acidified silver nitrate solution is added to precipitate silver iodide. The chemical recovery is used as a measure of radiochemical recovery.

Two types of activity measurements were applied. Gamma counting of dried silver iodide precipitate with PGP-1500 detector and liquid scintillation counting (LSC). The AgI precipitate was dissolved by forming a chemical complex with potassium-cyanide. After one week waiting time the activity of the samples were determined by LSC.

A mass spectrometric system for measurement of 129I concentration by 129Xe ingrowth method was also developed. The system consists of a VG-5400 noble gas mass spectrometer and units for quantitative extraction of the dissolved gases from evaporator concentrate samples, purification of the extracted 129Xe after ingrowth period by means of a cryogenic cold trap filled with active charcoal. The mass spectrometer inlet system is computer controlled and capable of fully automated measurement of 129Xe samples. A 129Xe measurement takes about 30 minutes. Calibration of the measurement is done using defined aliquots of 126Xe standard. The 129Xe detection limit of the system is about 1*10-15 ccSTR. An intercalibration of the method with an LSC beta-counting was performed and within the errors of the single techniques no significant deviation was found between the two data sets.

55Fe and 63Ni

Radioactive 55Fe isotope solutions of 661 Bq and 1418 Bq 55Fe were prepared for calibration purposes. These solutions were added to the dry sample, dried with infra-red light, then the sample was powdered and homogenized. The powdered sample was placed into an aluminum sample container (diameter 10 mm, equipped with Mylar foil at the bottom) and measured with Si(Li) semiconductor X-ray spectrometer. The measuring time of the quantitative analysis was 5000 s.

Radiochemical Separation of Pu, Am and Sr Isotopes

The complete analytical procedure consists of the following steps: sample homogenization by filtration; take the residue by HCl; combine the aliquots measurement of the subsample. The further steps of the analysis:

addition of strontium carrier, and plutonium (236Pu) and americium (243Am) tracers

repeated evaporation with 65 % nitrite acid to destroy organic materials (especially complexing agents),

sample dissolution with dilute nitric acid,

separation procedure for plutonium

pre concentration of plutonium with iron hydroxide,

dissolution of the iron hydroxide precipitate with 1M nitric acid,

adjustion of the valency state of plutonium to tetravalent by consecutive reduction and partial oxidation,

chromatographic separation of plutonium on strong basic anion exchange resin from 8M nitric solution followed by the elution of interfering components and stripping of plutonium with a reducing agent (ammonium iodide in 9M hydrochloric acid solution)

evaporation and oxidization of the strip solution,
alpha source preparation by micro-precipitation technique with neodymium fluoride,
alpha spectrometry of the plutonium nuclides: 239,240Pu, 238Pu, 236Pu;
separation procedure for americium
preconcentration of americium by coprecipitation with calcium oxalate,
destruction of the oxalates with 65 % nitric acid,
chromatographic separation of americium on Tru.Spec column from 2M nitric acid solution followed by the elution of americium on Tru.Spec column from 2M nitric acid solution followed by the elution interfering components and strontium, stripping of americium with 4M HCl,
alpha source preparation by micro precipitation technique with neodyminium fluoride,
alpha source preparation by micro precipitation technique with neodymium fluoride,
alpha-spectrometry of the americium and curium isotopes: 241Am, 244Cm, 242Cm.
separation procedure for strontium
preconcentration of strontium by coprecipitation with calcium oxalate,
destruction of the oxalates with 65 % nitric acid,
chromatographic separation of strontium on Sr Spec. column (bis-tertier butyldicyclohexano-18-crown-6) from 3M nitric acid solution followed by the elution of interfering components and stripping of strontium with distilled water, precipitation of strontium oxalate,
determination of the chemical recovery by gravimetry,
checking of the purity of the sample by gamma spectrometry,
source preparation for liquid scintillation counting with Insa gel,
beta spectrometry with LSC: 90Sr, (89Sr).

Highest activity concentration and standard deviation of the radionuclides in the different waste types are given Fig. 2.

Fig. 2

CONCLUSIONS

Safety studies related to the disposal of low - and intermediate - level waste indicate that the long term risk is determined by the presence of longer-lived nuclides such as 14C, 59Ni, 63Ni, 99Tc, 129I and the transuranium elements.

As most of these nuclides are difficult to measure, the correlation between these critical nuclides and some other easily measurable key nuclides such as 60Co and 137Cs has been investigated, mainly for typical waste streams from nuclear power plants, and scaling factors have been proposed by several authors. However, the range of these factors is relatively large for some nuclides and some of therm are recognized to be plant-specific.

An automated gamma-scanning monitor has been developed to determine the inventory of gamma-emitting radionuclides in wastes. Experiences so far have indicated that the monitor can reliably determine the inventory of gamma-emitting radionuclides in the waste packages. Radiochemical methods have been developed to determine significant difficult-to-measure radionuclides.

One of the new methods developed is determination of 129I via 129Xe ingrowth by use of mass spectrometer.

In the next stage of the program the efforts will mainly be directed to the determination of the scaling factors.

REACHING OUT IN NEW WAYS: SUCCESSFUL COMMUNICATION STRATEGIES OF THE FEDERAL ADVISORY COMMITTEE ON EXTERNAL REGULATION OF DEPARTMENT OF ENERGY NUCLEAR SAFETY

Carol A. Peabody
Steven A. Frank
Advisory Committee Staff
USDOE

Glenda E. Oakley
SAIC

ABSTRACT
Secretary of Energy Hazel O'Leary appointed the Federal Advisory Committee on External Regulation of Department of Energy (DOE) Nuclear Safety (the Committee) in February 1995. The Committee's charter called for it to recommend whether and how existing and new DOE facilities should be externally regulated. The Committee's deliberations were to be conducted under the Federal Advisory Committee Act (FACA) in public through a constructive dialogue among DOE and external stakeholders. The 24 members of the Committee were drawn from a cross section of public, Federal, State, Tribal, industrial, and academic sectors, representing a diversity of expertise. The Committee's final report was submitted on January 19, 1996. The Committee's recommendations were submitted not only to the Secretary of Energy, but also to the White House Office of Management and Budget, and to the Council of Environmental Quality. The report recommended that DOE's facilities and operations be regulated by existing external entities, the specifics of which would be determined through Administration review or by Congressional legislation.
The Committee's charter and means of arriving at its recommendations presented an unprecedented and unique challenge -- the Secretary of Energy requested that the Committee provide its recommendations within only one year of its inception. The scope of the Committee's task had far-reaching impacts throughout the DOE complex. The regulatory issues involved were broad-ranging, complex, and often difficult to grasp; the affected constituency was large and varying; and the available resources were limited.
The Committee met this challenge through aggressively reaching out to the DOE community (workers, unions, contractors, managers), existing oversight organizations (OSHA, EPA, NRC, DNFSB), State and local governments, environmental advocacy groups, and local community and individual stakeholders. This paper identifies the challenges of the Committee's charter, how those challenges were met through an innovative

outreach program, and the key issues that the Committee gleaned from listening to diverse individuals from varying backgrounds, which led to its recommendations for external regulation.

WHY AN ADVISORY COMMITTEE?

Until recently, the Department of Energy (DOE) and its predecessors, the Atomic Energy Commission (AEC) and the Energy Research and Development Administration (ERDA) operated largely as self-regulatory entities in the area of safety at the Department's nuclear facilities. Currently the DOE complex is regulated under a mix of internal and external regulatory and advisory bodies that administer a maze of laws, regulations, directives, orders, and guidance. DOE's workforce suffers from intense frustration due to serious overlaps and gaps in regulatory requirements, and the failure by DOE to address hazards according to their relative risks, costs and benefits.

In response to the growing sentiment both in Congress and within the DOE and its surrounding communities that DOE "self-regulation" was inefficient and ineffective, Secretary of Energy Hazel R. O'Leary established the new Federal Advisory Committee on External Regulation of DOE Nuclear Safety (the Committee) in January 1995. The charter required the Committee to recommend whether and how existing and new DOE facilities should be externally regulated. The Committee was tasked to submit its recommendations to the Secretary of Energy, and to the White House Office of Management and Budget (OMB), and the Council on Environmental Quality (CEQ).

THE CHARTER

The charter, approved on January 25, 1995, tasked the Committee with the following:

> The Committee shall conduct an assessment of the technical, regulatory, institutional and resource issues related to the potential establishment of an external regulatory regime for nuclear safety with respect to Department of Energy facilities and operations.
>
> The assessment will include an evaluation of the historical separation between commercial and defense nuclear activities; the potential advantages and disadvantages of external safety regulation compared to the existing regulatory framework for environment, safety and health; and the concerns and criticisms that have been expressed about DOE's safety oversight by the Congress, the National Academy of Sciences, the Advisory Committee on Nuclear Facility Safety, the Defense Nuclear Facilities Safety Board, and others. Significant transition issues associated with any new regulatory regime will be identified, including a realistic appraisal of both Federal and non-Federal resource impacts.

Although the charter stated that "approximately twenty (20) Advisory Committee members shall be appointed by the Secretary of Energy for a term of two years", in March 1995 at the first meeting of the Committee, the Secretary requested a report be submitted by December 1995.

HISTORY OF SELF-REGULATION

Over the past half century, the DOE and its predecessor agencies have regulated themselves with regard to nuclear safety, as provided for under the Atomic Energy Act. The manner of oversight established in the Act reflected the agency's primary responsibilities for development and production of nuclear materials and weapons, and for many other classified national security activities appropriate in a defense environment. Production was of high priority during those times,

resulting in a legacy of safety and environmental problems at numerous DOE sites.

The nuclear mission of the Department has changed and much is now focused largely on the stewardship and dismantlement of nuclear weapons, cleanup of contaminated sites, safe decommissioning of facilities. In addition, in recent years, the DOE has become subject to an increasing number of external federal and state regulatory requirements and oversight, while at the same time internal requirements and oversight have intensified.

Activities in early 1994 demonstrated continuing national concern regarding nuclear safety at DOE facilities. In March 1994, Congress held hearings on the Federal Nuclear Facilities Licensing and Regulation Act, H.R. 3920. The Committee on Natural Resources, U. S. House of Representatives, held 2 days of hearings and heard from the NRC, the DNFSB, the EPA and other interested organizations and individuals on the need for regulating DOE nuclear facilities. At the hearings, the Department proposed that these ongoing concerns be addressed through a constructive dialogue within the DOE, other Federal agencies and external stakeholders via the formation of an independent Federal Advisory Committee.

The Secretary took action to establish an independent Committee, under the FACA, to examine whether (and how) new and existing DOE facilities and operations might be externally regulated to ensure nuclear safety. Secretary O'Leary approved the establishment of this new Federal advisory committee on July 28, 1994.

After a search and selection of a very broad and diverse group of distinguished individuals, Secretary O'Leary announced the membership of this Federal advisory committee on February 16, 1995. She named Dr. John F. Ahearne and Mr. Gerard F. Scannell as the Committee's co-chairs. Dr. Ahearne is currently a Lecturer in Public Policy at Duke University and is the Executive Director of Sigma XI Center (a Scientific Research Society). He also is past Chairman, Nuclear Regulatory Commission and the DOE Advisory Committee on Nuclear Facility Safety. Mr. Scannell is currently President of the National Safety Council. He is a former Department of Labor, Assistant Secretary for Occupational Safely and Health and former Vice President, Corporate Safety Affairs for the Johnson & Johnson Company.

The 24-member Committee represented a wide diversity of knowledge and expertise from the private sector as well as other Federal agencies. Thomas H. Isaacs, a senior career DOE official was named Executive Director of the Committee and a small senior federal staff was selected from DOE, the Environmental Protection Agency, and the Nuclear Regulatory Commission.

The Committee got to work immediately. Beginning with its first organizing meeting in Washington D.C., in March 1995, the Committee held eight public meetings in the next nine months. Organizing and planning the public meetings would have been enough of a challenge; however, since the Committee agreed to "get out of Washington" so they could hear directly from workers and the interested public, the majority of meetings were held at or near representative DOE sites.

THE CHALLENGE

The Committee's charter and the complex regulatory issues involved created unprecedented challenges for the Committee and its staff. Because of the unique make up of the Committee, there was no "text book" or

precedent to follow in planning and implementing an outreach strategy. Our challenges included the following:

COMPLEX ISSUES

The broad issue of "externally regulating DOE nuclear safety" is very complex. No group had ever evaluated the issue to the extent that the Committee was tasked. Although the charter mandated that the Committee assess the need to externally regulate "nuclear safety," the Committee found that it could not assess nuclear safety in a vacuum -- nuclear safety was inextricably tied to other safety and health issues, such as existing environmental compliance, worker safety and health, facility safety, and public health and safety. In addition, at the first Committee meeting Secretary O'Leary told the group to take a broad view of regulating DOE -- not to narrow its focus. Thus, the subjects of evaluation became more broad-ranging and even more complex. Most committees established under FACA have more narrow mandates directed at more specific problems.

BROAD CONSTITUENCY

The affected constituency was broad-ranging and all-encompassing. Given that the DOE complex involves such abroad-range of both internal and external stakeholders, the Committee was challenged with identifying and targeting a subset of representative stakeholders to participate in a constructive dialogue. This Committee did not have a "natural" constituency. Instead, the Committee staff was faced with the need to identify a sampling of all affected groups and individuals, a representative set of DOE sites and facilities, and a regional representation throughout the U.S.

SHORT TIME FRAME

The Committee's time frame for completing its charter was unusually short for an issue of this magnitude. In researching the charters and activities of other advisory committees, both within and outside of DOE, the Committee staff found that most committees had much longer time periods to conduct its work. Many committees, such as the DOE Site-Specific Advisory Boards, are under continuing charters. Secretary O'Leary tasked this Committee with only one year to present recommendations on a topic that could have significant impact to DOE workers and managers as well as facilities and operations . The recommendations, it was known from the beginning, could involve significant action by the Administration, Congress, and other state and federal agencies.

MINIMAL RESOURCES

The Committee was provided minimal resources to carry out its charter. This required creative means of leveraging existing resources within the DOE community and other agencies. The Committee's staff involved only 6 full-time professionals.

MEETING THE CHALLENGE

The Committee staff needed to be resourceful and creative to best serve the Committee. The staff worked to serve the Committee members, and this included identifying quickly what resources could best assist them.

ASSIST LEARNING CURVE

Because of the diverse make up of the Committee, many members were selected, in part, because their experience and expertise came from outside the DOE community. However, this meant a learning curve for those members. Therefore, this Committee actively sought and listened and learned from all the invited and public speakers at its meetings. In

addition, the Committee solicited papers and other information to assist in a better understanding of the complex problems related to external regulation of DOE facilities.

IDENTIFY INTERESTED PARTIES

The Committee proactively identified and obtained the participation of a broad representation of internal and external DOE stakeholders. These included:

- DOE workers and managers
- Union representatives
- DOE contractors (workers and managers)
- State and local governments
- Local businesses
- Professional organizations
- Public interest organizations
- Environmental groups

One of the major challenges for the Committee staff was to successfully identify both the internal and external stakeholders and to encourage their participation. We used a variety of approaches to inform the public and workers about the Committee's activities and solicit their input. We understood that input from a variety of viewpoints and sources would provide the Committee with useful information in the development of their findings and recommendations.

Personal Interaction by Pre-Visits with Stakeholders

The Committee staff conducted pre-meeting visits with stakeholders at or near the DOE sites the Committee planned to visit. These visits were usually held 2 to 3 weeks prior to each public Committee meeting and efforts were made to find interested persons including labor representatives and local citizens. We held meetings with federal, tribal, state, and local government representatives, as well as local and national stakeholder organizations. The staff informed every individual and group we met with of the Committee's activities and mission and encouraged them to participate in the upcoming public meeting in their area. We found many of the "usual concerned citizens" that closely follow DOE activities at nearby sites did not know of the Committee or its mission. Many also were not that interested in the topic of external regulation or did not understand that it could mean an entity completely outside DOE to oversee DOE facilities.

To remedy this lack of knowledge and to better educate parties as to the purpose of the Committee, these pre-visits served as a 'heads up" to those who might be interested in the oversight of DOE activities. Usually 2 committee staff members with one contract support person briefed DOE, contractor management, workers, and local stakeholders about the Committee's diverse membership, its origin, activities and meetings to date and how they might help the Committee in meeting its mission and providing recommendations.

Stakeholder involvement was sought at all levels. The following provide examples of the diversity of pre-visit meetings:

- Mayor of Richland, Washington
- Governor of San Ildefonso Pueblo, New Mexico
- Colorado Department of Health
- Snake River Alliance Group (Idaho)
- Chamber of Commerce in Albuquerque, N.M.
- American Nuclear Society in Richland, WA

Frankly, the staff and the Committee were pleased with the level of knowledge that many people and groups possessed. The stakeholders were, in turn, surprised we would actually travel to meet with them in their surroundings and encourage their individual participation at the upcoming Committee meeting. We also found that most parties we met with would provide information and contacts about additional interested individuals and groups. Usually we could personally meet with them while on the pre-visit, but sometimes we spoke by phone or met a day or two prior to the meeting.

In an effort to inform DOE and contract workers about Committee meetings and encourage worker participation, flyers announcing the meeting were posted and electronic mail messages were sent to employees at the respective DOE sites. Articles about the Committee and meeting notices were printed in site news bulletins.

Presentations by Stakeholders at Advisory Committee Meetings

We also involved stakeholders in developing meeting agendas based on issues specific to each site, in suggesting invited speakers to address the Committee, and participate in panel session presentations during Committee meetings. For example two opposing citizen concern groups, "Los Alamos Study Group" and "Responsible Environmental Action League" gave formal presentations at the Advisory Committee Public meeting held in Santa Fe, N.M. and participated in panel session presentations during Committee meetings.

OTHER OUTREACH MECHANISMS

Public Meetings/Stakeholder Comments: The Committee held eight meetings in nine months, all of which were open to the public. Sixty members of stakeholder organizations addressed their concerns about DOE safety. Over 350 members of the public attended the meetings. Public comment sessions were held in conjunction with all the Committee meetings. Forty seven concerned citizens shared their viewpoints and answered Committee questions.

Written Comments: For concerned citizens unable to attend the public comment sessions, different options for the Committee to receive comments and input were offered: U.S. Mail, Facsimile, and Electronic Mail.

Dissemination of Advisory Committee Information: Public information materials such as press releases, Federal Register Notices, and fact sheets were developed and distributed to keep the public informed of Committee meetings and activities. Meeting minutes, transcripts and the Committee's Status Report were also available to the public. This information was distributed upon request, at Committee meetings, and sent to DOE Reading Rooms around the country. The Committee maintained a mailing list of over 500 persons. Over 9,000 pieces of information were distributed during the Committee's tenure.

Information Center: Toll-free phone line. An information repository with a toll-free number was established to respond to information and document requests and answer Committee-related questions. Over 535 calls were received on the toll-free number.

Fact Sheet: We decided that a fact sheet was a good way of distributing important general information about the Committee. We created an "About the Committee" fact sheet which included the purpose of the Committee, described the issue of external regulation, provided information on how to both comment and obtain information, listed the membership, and indicated when and where Committee meetings would be held. The fact sheet was updated prior to each meeting, and provided a vehicle for noting both

changes in membership (due to other commitments by 2 members) and changes in meeting locations when the Committee decided it had collected enough information and needed to focus only on deciding issues and reaching conclusions.

Internet/World Wide Web: Committee information was also maintained on a World Wide Web Page on the Internet, where it could be viewed and/or downloaded.

Early in the Committee's establishment it became clear that there was tremendous interest in the Committee's work and very limited staff resources to deal with requests, so we sought new avenues for reaching out to the public. One of the areas of greatest growth is the World Wide Web. Another is the E-mail part of the Internet. We established an e-mail address specifically for the Committee and posted its address in all the press releases, Federal Register notices, and regularly updated fact sheets, along with the World Wide Web address and other methods for contacting the Committee.

We contacted the DOE-Office of Environmental Management staff and contractors responsible for the EM World Wide Web page and they agreed to create a page for the Committee work. It soon became apparent that the public was only going to use the page if it was regularly updated to provide current information. Prior to each Committee meeting we posted the agenda, press release and Federal Register notice, and after each meeting we posted the transcripts and minutes. In addition, all the subcommittee reports, internal working group reports, and staff papers have been posted. An employee at the Stanford Linear Accelerator recently e-mailed us that he though the Committee's Web page was the best in the Federal government. By the end of January we had over 28,000 accesses to the Committee's page and, after release of the Committee's final report, it was growing by over 1,000 accesses per day.

Letters to the DOE Complex Requesting Criticisms and Solutions: To make certain that all potential issues and solutions were considered, the co-chairs sent a letter to all Operations and Field Office managers, Laboratory Directors, and Program Offices. These resulted in numerous direct responses from across the complex which provided additional insights (concerns, problems, and potential solutions of day-to-day implementation of the current regulatory structure) from the DOE working management level.

Committee Members As Listeners

At Committee meetings, Committee members actively engaged in discussions with concerned citizens, workers, and management concerning safety and health issues at DOE nuclear facilities. Public comments were considered in the development of the Committee's report. There are over 400 transcript pages from public comment sessions.

The Committee listened intently to the invited speakers and the interested public. Meetings often lasted well into the night. At some meetings, the Committee stayed long after the meetings closed to discuss among themselves what they learned in the meetings.

Not only did the Committee hold meetings near the DOE sites, but also toured specific facilities at the sites in order to have a better understanding of the facilities and had some meetings at the sites to encourage worker input.

LEVERAGING EXISTING RESOURCES

To make up for the short time-frame and minimal resources, the Committee staff leveraged existing resources within and outside the DOE complex to

identify and obtain stakeholder involvement, publicize the Committee's activities, and to educate the Committee members on DOE facilities and operations. The objective was to not "reinvent the wheel" but to maximize existing resources and local knowledge. We effectively utilized DOE personnel expertise and their knowledge of the local issues at all of the sites that the Committee visited. The DOE field personnel -- from the Operations Office Managers to the Communications, Public Affairs, and Outreach offices were essential to our successful institutional program. We found the site personnel, both DOE and contractors, eager to help us arrange the pre-visits, site tours (on a very restricted time frame), and press notices. In addition, for each meeting, DOE headquarters personnel provided their distribution mechanisms so we could widely publicize our meetings both inside and outside DOE. Committee staff also attended some SSAB local meetings and SSAB members were speakers and provided other sources of information to aid the Committee members, We contracted with an existing resource, the Office of Environmental Management's Center for EM Information, to respond to inquiries and provide distribution of documents.

BENEFITS FROM STAKEHOLDER PARTICIPATION

DOE Worker Community:

The Committee heard a lot from the DOE worker community (workers, unions). What it learned was that there is a regulatory morass. The workers on the floor saw above them so many layers of management, oversight, and regulatory requirements, including different factions of DOE, that they were confused as to what requirements they had to meet and when, and who was in charge. At every site the Committee visited, the workers communicated that "things were not clear. " The Committee also heard that DOE is a dangerous place to work. They cited a lot of workplace hazards that needed to be addressed, both radioactive and nonradioactive, particularly in light of the changing mission of DOE from production to cleanup. Another concern expressed was that new workers were being brought on site who are not familiar with the very old sites and facilities and their unknown hazards. In addition, the training of subcontractors is not often the same as with the prime contractors on site.

Workers also told the Committee that, due to the manner in which DOE currently prioritizes work, some hazards were going unaddressed while less "risky" activities were being "fixed".

States:

The States were not at all unified in the need for external regulation or how it should be implemented. For example, the State of Colorado believed it could best regulate Rocky Flats. The concerned citizens near Rocky Flats also agreed with State regulation, but with the Federal government providing standards and guidance. However, other States, like the State of New Mexico, believed that DOE should take care of its own problems and that the State did not have a role to play in regulation of a Federal facility.

Public:

The public was unified in its concern for public and worker health and safety. The public generally acknowledged that DOE was more open than it had been previously but, like the workers, did not know for certain who was in charge. Local communities, including local officials, were concerned with the economic well-being of their communities in light of DOE's changing mission and the role of the community in overseeing the

safety of DOE facilities. In general, most members of the public were in favor of independent regulation outside of DOE, meaning, yes, external regulation. However, there was not a consensus among the public as to who was best suited to take on this role. The public, as did the workers, realized the need for clarity in what regulations had to be met.

DOE Managers:

The DOE managers and laboratory directors (former and current) generally agreed that the time had come for external regulation and endorsed the concept. They did not have specific recommendations, however, on who best is suited to provide the external regulation.

Committee Recommendations

All the Committee's recommendations were predicated on the core belief that a meaningful role for citizen's and workers is essential to the development of credibility and trust. The Committee noted that "Two elements are required to implement effective public participation in the regulatory process: timely and adequate information and effective means to influence the outcome." Several recommendations by the Committee were a result of the significant public participation role and the information obtained from the various stakeholders. Included in the Committee's recommendations were several directly related to State and public involvement:

States with programs authorized by EPA, OSHA, or the facility safety regulator should acquire or continue to have roles in the regulation of all respective areas of safety comparable to those they exercise in the private sector;

In principle, States should be able to enact more stringent standards as long as these do not unduly hinder a DOE mission;

Citizen's suit provisions, comparable to those in the environmental statutes, should be available for regulation of safety at DOE nuclear facilities, both with regard to enforcement against DOE and its contractors and with respect to non-discretionary statutory duties of the regulators;

The DNFSB should make its processes more open, including issuing recommendations in draft form for comment.

CONCLUSION

This was a unique challenge -- both from a public policy perspective as well as from an institutional program perspective. The was not your typical advisory committee -- in make up, dedication and cooperation and enthusiasm for the task. This was a difficult assignment for Committee members. No one had tackled a review so great for the need for external regulation. This was an unprecedented outreach effort, which was applauded by all Committee members (despite long public meeting hours) and the stakeholders we reached. This was a very rewarding effort. We met the challenge through using a proactive approach, leveraging of existing resources, and taking advantage of such new outreach tools as the World Wide Web. We've thought of writing a book on this one!

BUILDING STAKEHOLDER GROUPS
THROUGH TECHNOLOGY

P.A. Jonker
Nevada Risk Assessment/Management Program (NRAMP)*
Harry Reid Center (HRC)/University of Nevada Las Vegas (UNLV)
E. Dixon

Community Advisory Board (CAB)
Nevada Test Site

ABSTRACT
The Nevada Risk Assessment/Management Program (NRAMP) is tasked with performing an independent, integrated risk assessment of the Nevada Test Site (NTS) in close cooperation with stakeholders, who will then use the assessment to prioritize future land use options at the NTS. As part of this process, NRAMP is exploring a variety of methods for involving stakeholders and will develop the most successful methodologies into a model for other DOE sites. The Program has made technology the focus of its methods through facilities available at University of Nevada Las Vegas (UNLV) research centers. The selected technologies include a telephone survey through the Southwestern Social Science Research Center; videoconferencing in the especially equipped rooms of UNLV's TeleMedia Services; a World Wide Web HomePage via the university's Internet connection; and electronic meetings in the Decision Support Laboratory at the Harry Reid Center for Environmental Research. Successes and difficulties with these methods are being formulated into recommendations.

INTRODUCTION

In early 1994, DOE's Office of Environmental Management (EM) created a cooperative agreement that would fund innovative methods to achieve meaningful stakeholder involvement in a risk-based approach toward remediation of DOE sites across the nation. The Nevada Risk Assessment/Management Program (NRAMP) is one of five successful proposals for collecting stakeholder concerns and providing the scientific data stakeholders need to participate in an informed debate about the future. The NRAMP is housed in the Harry Reid Center for Environmental Studies (HRC) at the University of Nevada Las Vegas (UNLV) and focuses on the Nevada Test Site (NTS). Its three primary missions are to (1) work closely with stakeholders, EM, and others in developing independent risk assessments of the NTS; (2) evaluate and prioritize options for NTS restoration and future land use from a stakeholder perspective; and (3) develop a methodology for stakeholder-based risk assessments at other sites.

In Nevada, these missions are impacted by a problem more immediate than the usual human interaction difficulties: four hundred miles separate the two major population centers of Las Vegas and Reno, and even greater distances lie between the more remote regions of the state. People must come together physically before they can come to consensus on the issues. To solve the problem, team members have turned to technology.

Using UNLV facilities and research centers, the Program has focused on relatively inexpensive techniques that can be applied through cooperation with universities at nearly any site. The selected technologies include a telephone survey through the Southwestern Social Science Research Center; videoconferencing in the especially equipped rooms of UNLV's TeleMedia Services; a "HomePage" via the university's Internet connection; and electronic meetings in the Decision Support Laboratory at the Harry Reid Center for Environmental Research. In addition, the team hopes to study stakeholder reactions to electronic presentations by developing a PowerPoint "primer" that could be made available on CD-ROM.

TELEPHONE TECHNOLOGY

The NRAMP grant period (originally 18 months, now extended to 21) did not allow time for the regulation keystone process in forming a stakeholder

working group, and the team made an early decision to accept any and all participants who wished to join the Program. Traditional mailing lists and newspaper advertisements were used to announce the Program to stakeholders, but the team was well aware previous experience had shown groups recruited in these ways to be small and more representative of vested interests than the state's actual demographics.

To achieve representation without moving "keystoning," team member Dr. Dennis Soden from UNLV's Social Science Research Center used telephone technology to sample a broader base of Nevadans' attitudes toward the NTS and to collect their opinions of future land uses of the site. Working with a hired team of graduate students who had experience in telephone surveys, he oversampled the state's rural areas to ensure their representation. In all, he collected 400 opinions from the Las Vegas area, 400 from Reno/Carson City, and 400 from across rural Nevada. This is not to say that telephones reach all of Nevada's citizens. In fact, two members of the current NRAMP Working Group cannot be contacted by phone and have even been reluctant to give a specific home address. Nevertheless, the sample population reached in the telephone survey is certainly more representative of the State's general population than the working group that has been formed.

The telephone survey serves the Program as a check-and-balance on attitudes and opinions collected from the NRAMP Working Group. However, while this technology will certainly be recommended to other DOE sites where rural populations are an important factor, several caveats must be noted:

1. working groups will want to know if the survey carries more weight than their group opinions,
2. teams can expect considerable debate over the content and wording of survey items, and
3. working groups may distrust answers from the sample population and accuse callers of making leading comments - even when a "script" is used to ensure each call follows a standard format.

In general, there seems to be a reluctance to accept human comments when they are not gathered in a face-to-face situation, but given the expense of door-to-door canvassing and the notoriously low return rate for mail surveys, the telephone offers a comparatively quick and inexpensive overview of public opinion and, specifically, of rural opinion that might otherwise be overlooked. It is tempting to speculate on the kinds of survey results that may be achieved when the telephone is fully integrated with the television as has now been done in parts of Canada.

VIDEOCONFERENCING

At the start of the Program, two working groups were formed: a Northern Group in the Reno area and a Southern Group in Las Vegas. Originally, all NRAMP members attended the Southern meeting and three or four flew to Reno for the Northern meeting. However, after two months, the Northern Group remained just half the size of the Southern (i.e., 20-25 vs. approximately 10) and it became increasingly difficult to integrate Northern decisions and opinions with those in the South. In addition, the logistics and productivity loss involved in flying team members to Reno quickly became a burden. Once again, technology provided an answer. NRAMP turned to UNLV's Telemedia Services, which had recently announced its videoconferencing rooms were available to university projects. Working with Mr. Michael Stowers, Telemedia's Executive Director, the team explored its options for long distance communication. The situation

was enhanced by the close connection between University of Nevada Reno (UNR) and UNLV; electronically delivered classes are regularly scheduled between the two universities and most technical difficulties had already been solved.

Team members attended a demonstration session, learned how to use the camera controls, and chose the most effective room arrangement for the size of the NRAMP Working Group. The Southern Group immediately settled into the more appropriate of UNLV's two videoconferencing rooms and has now participated in three meetings at that location. The Northern Group has changed locations once, from the Education Building to the System Computing Services Center, and now appears comfortable in a permanent setting. Aside from minor sound difficulties, which largely involve training speakers to stand in specific locations or address their remarks to a particular microphone, the technology is now very accepted by both groups and, in fact, when the NRAMP returned to a traditional separate meeting for one month, stakeholders in the North expressed great dissatisfaction.

The facilities at the two universities allow the NRAMP to project two views to each location: a view of the room (i.e., the participants) and/or the speaker and, through a document camera, a view of presented materials such as maps, 3-dimensional objects, and overheads. In the future, the NRAMP plans to integrate presentation software such as PowerPoint or Harvard Graphics.

At this point in time, one NRAMP team member flies to Reno and presents portions of the meeting agenda from that location. Presentations are usually reinforced by sending hardcopy handouts to the North either in a pre-meeting mailing or with the attending team member. The expense of this travel, coupled with the universities' videoconferencing fees, means that the overall cost of the meetings has not been reduced (the cost of flying three or four persons to Reno is roughly equivalent to the cost of videoconferencing), but team members generally experience a considerable gain in productivity because all but one can spend the entire meeting day on task rather than travel. The most important gain, however, is in group interaction: though small, the Northern Working Group is now able to present its opinions, participate in general discussions, and be fully represented in any group issue.

Videoconferencing is highly recommended to projects with access to university facilities like those at UNLV and UNR. Cost is the major barrier to widespread use of the technology in the business community, but cooperation with universities can dramatically reduce this factor. Stakeholders adapted very rapidly to the few necessary constraints on meeting procedures, and the NRAMP team considers bringing the Northern and Southern Groups together as one of its major successes.

FUTURE TECHNOLOGIES

With the telephone survey completed and videoconferencing established as the primary meeting methodology, the NRAMP is now focusing on other technologies to enhance group communication: the World Wide Web (WWW), presentation graphics, and Group Decision Support Systems (GDSS). Team members with expertise in these areas are developing interfaces and strategies to draw more participants into the Working Group and to increase participation in general.

WWW HOMEPAGE

The World Wide Web is very close to linking even the most remote areas of the world and certainly provides an important service to states like

Nevada. As more and more stakeholders subscribe to home services (e.g., America OnLine, CompuServe, Prodigy) and access the Web, it is becoming one of the best means of distributing information needed for good community decision making. The Department of Energy has been using the technology for sometime, and in Nevada, for example, the Coordination and Information Center (CIC) operated for DOE by Bechtel gives electronic access to more than 300,000 historical documents related to nuclear weapons testing, human radiation experiment records, and many other documents concerning programs, projects, and activities.a

Universities enjoy rapid access to the Web through their dedicated lines, and projects like the NRAMP can provide physical access for online information very similar to the videoconferencing access described above. Stakeholders who cannot go online from a home computer can use university-based workstations to gather background materials and information on the issues.

At UNLV, the NRAMP has recently implemented a 12-station computer laboratory (see below) in the Harry Reid Center for Environmental Research (HRC), the home of the NRAMP, that could soon provide general stakeholder access to public DOE databases and specific access to the NRAMP HomePage being constructed by team members under the direction of Dr. Muhilan Pandian. Several kinds of information are being considered for possible entry: a photo history of land uses at the Nevada Test Site; team member photos, areas of expertise, and contact numbers; specific NRAMP documents such as the original grant, the Work Plan, and the Preliminary Risk Assessment results; presentation graphics used in the face-to-face Working Group meetings; and Geographic Information System (GIS) maps produced by the NRAMP technical team. Dr. Pandian's staff are also responsible for the development of THERdBASE, a graphical database engine for integrating and viewing risk assessment results, and the NRAMP is considering placing THERdBASE online for stakeholders.

The most important use of the NRAMP HomePage, however, could be as a collection point for comments on the difficult issues facing the Working Group. If such issues were placed on the HomePage, stakeholders could maintain a running discussion that would be available without time and space limitations for those with home access and on a regularly scheduled basis for those who wish to use the HRC laboratory. Access can, of course, be provided from DOE sites as well. The NRAMP expects many "hits" on its HomePage as additions are made to its content and stakeholders become aware of its availability.

A related idea has been explored by one of the team's technical task leaders, Dr. Dennis Weber, who suggested that all handouts and graphic materials presented in Working Group meetings be compiled into an "NRAMP Primer" for individual or class use outside of Working Group meetings. Because some of these materials have been based in electronic presentations, the team has recently begun to consider placing them on the HomePage in an interactive format. Before that occurs, however, the team would like to conduct several experiments to determine stakeholder preferences for presentations.

Several of the team's technical staff, for example, object to the flashy "fade-in, fade-out, build-from-the-right/left" capabilities of presentation applications like PowerPoint. They feel audiences are distracted from the real content of the materials. Other team members feel that audiences expect an "infotainment" format and quickly become bored with text-heavy viewgraphs. The NRAMP hopes to structure several

experiments that would provide input to these arguments and determine the best possible format for storing information on the Web in an electronic NRAMP Primer.

Once again, the idea of a HomePage is an idea that can be exported readily to other projects and DOE sites. Specific recommendations will be made about Internet technologies when the NRAMP has had sufficient time to fully implement them and to study stakeholder reactions, but there is certainly reason to believe that a HomePage is a viable choice for stakeholder groups based on its low cost and its widespread availability.

DECISION SUPPORT LABORATORY (DSL)

The Harry Reid Center's DSL was funded by a cooperative grant from the Department of Energy's Yucca Mountain Project; it is under the direction of NRAMP team member Dr. Pat Jonker, who recently implemented Ventana's GroupSystems for Windows on the laboratory's 12 computer stations. This software is a group decision support system, or GDSS, that uses a networked system of computers and a large display screen to facilitate electronic meetings. Participants use the computers for brainstorming, organizing, prioritizing, and voting on their ideas and opinions. Meetings may be held in a traditional face-to-face setting with all participants present in the electronic meeting room or in a remote access format that allows participants to sign in to the meeting from their offices at any time of the day or night.

A GDSS is ideally suited to NRAMP-type projects in which stakeholders comment on issues that will eventually be subjected to a consensus process or a vote. It overcomes many of the typical meeting problems such as lack of participation, fear of retaliation, dominance by strong personalities, and subjective minutes or records of what occurred. Because participants enter their comments anonymously from the keyboard, no one can determine who contributed a specific comment; because participants do not need to be recognized by the chair to contribute, everyone can "talk" at once; and because all input is automatically recorded, no one has an opportunity to editorialize outcomes. Votes are recorded instantaneously and the result is shown graphically on the screen.b

The DSL was used for the first time in January 1996 as a platform to collect public perceptions of risk related to DOE Risk Data Sheets (RDSs) and budget priorities from 12 participants in the RDS process.

To further enhance anonymity, all workstations in the DSL are recessed into NOVA desks that provide a large conference style table when the computers are not in use. Although only 12 stations have been installed in the lab at this time, ports are available for 12 more persons to join a face-to-face meeting with portable computers and as many as 75 persons can contribute to a remote meeting when users are not signed on concurrently. The Pentium/75 workstations are each equipped with multimedia features (i.e., CD-ROMs, sound and video boards) and, in the near future, will be connected to the Internet. They offer an ideal location for Southern group members to access the NRAMP HomePage or view DOE information from databases across the country. The NRAMP anticipates an interesting series of experiments with lab use during the remainder of the project period.

Such a laboratory and its GDSS are obviously expensive technologies that are not likely to exist at every DOE site or even at every university. But the possibilities are seductive: imagine attending a meeting while sitting in your own office where all the information you need is readily

at hand; consider signing on to read the comments generated by others at a meeting you missed and then casting your vote at 11:00pm before you go to bed; and forget the drudgery of typing up and reproducing the minutes of your meeting. While meetings as we know them will certainly not disappear in the near future, many options are appearing that will change them dramatically. The creators of Ventana's GroupSystems, for example, are already at work on a facility that will feature "floor-to-ceiling high-resolution video display walls," with each wall showing a full-size representation of meeting participants in other locations and creating the illusion that those participants are actually present.c

FUTURE PROJECTIONS

From the four major technologies discussed, the NRAMP will undoubtedly recommend the telephone survey and videoconferencing as part of a stakeholder interaction model for other sites. But with the Program at only the halfway point, time remains to experiment, not just with HomePages and group decision support systems, but a host of other possibilities. One of the great advantages of working within the university environment is the opportunity to try new applications - the most exciting of which has not yet been built or tested.

THE FERNALD CITIZENS TASK FORCE: SHIFTING THE FOCUS*

Gary Stegner
U.S. Department of Energy

John Applegate

Jack Hoopes
APR, FERMCO

Doug Sarno
Phoenix Environmental, Inc.

ABSTRACT

In August 1995, the Fernald Citizens Task Force provided the U.S. Department of Energy (DOE), the Environmental Protection Agency (EPA), the Ohio EPA (OEPA), and FERMCO with cost-effective, implementable recommendations for addressing Fernald's most pressing issues. Fernald is now proceeding with an accelerated cleanup plan to make these recommendations reality. With its initial work plan complete, the Task Force confronted a new challenge: How to shift its focus from developing recommendations designed to influence Fernald's Records of Decision to advising project managers during remedial design and remedial action. This paper reports on the experiences of the Task Force, the DOE, Fernald regulators, and FERMCO as the Task Force made this shift. In the process,

the parties encountered issues involving work plan development, membership, organization, and support resource allocation. Lessons learned as these issues were resolved are summarized. The Fernald experience supports the conclusion that "hands-on" citizen involvement in government decision-making at a major environmental remediation site can effectively transition from one area of focus to another.

INTRODUCTION

Under its original charter, the Fernald Citizens Task Force experienced unprecedented success as a U.S. Department of Energy Site-specific Advisory Board by recommending publicly accepted, cost-effective solutions to critical issues facing Fernald Environmental Management Project decision-makers. This success was the outcome of a deliberate strategy pursued by the Task Force Chair of focusing the Task Force's agenda on "big picture" issues. The Task Force incorporated its recommendations in a report delivered to the DOE in August 1995.

With its initial work plan completed, the Task Force confronted a new challenge: How should its members refocus their energies to further advance the ultimate remediation goal at Fernald?

This paper reports on interactions between the Task Force, the DOE, Fernald regulators, and FERMCO as Task Force members shifted their focus from developing recommendations designed to influence Fernald Records of Decision to a new role during remedial design and remedial action. In the process, the parties encountered and resolved work plan development, membership, organization, and support resource allocation issues. Their experiences provide insight into how "hands-on" citizen involvement in government can effectively transition from one area of focus to another.

BACKGROUND

In the 1980s, it was discovered that the Fernald facility had been contaminating local drinking water for many years. Citizen activism in reaction to disclosures of the contamination drew local and national news media attention and significant negative publicity critical of the DOE. In reaction, the DOE issued news releases and held public meetings to inform citizens of Fernald activities. Early public meetings typically provided forums for "Decide, Announce, Defend" style presentations by DOE officials, which often resulted in citizen protests and accusations. Trust between the DOE and area residents was virtually non-existent. Prompted by separate lawsuits by the state of Ohio and area citizens, the DOE began to address contamination issues that had become a matter of public concern.

In 1991, the DOE and the EPA signed an Amended Consent Agreement, establishing key milestones and strengthening the framework for federal regulatory oversight of the Fernald cleanup. As work progressed under this agreement, DOE managers began to realize that direct citizen involvement was an essential ingredient to arriving at sound decisions. In the spring of 1993, the DOE decided a citizens advisory board would be the most cost-effective means of obtaining focused stakeholder input on Fernald's most pressing issues. An independent convener was hired to identify potential Task Force members to represent the wide-ranging interests of Fernald's various stakeholder groups and to develop a draft charter for the Task Force, in conjunction with the DOE, the EPA, and the OEPA. The charter drafted by the convener, and ultimately adopted by the Task Force chair, charged the Task Force with developing recommendations on four far-reaching issues: future land use, remediation levels, waste disposition, and remediation priorities at the Fernald site.

The Task Force officially convened in August 1993. Early on, Task Force members recognized that a recommendation regarding future use of the Fernald property following remediation would give direction to its deliberations and provide a framework for other recommendations. During this time period, the Task Force also determined an independent consultant should be retained to provide the Task Force with technical and facilitation support. The Task Force chair guided the consultant in developing a work plan to promote productive use of time during the 18-month period preceding issuance of Task Force recommendations to coincide with the draft Record of Decision for Fernald's Operable Unit 5. A key to this work plan was the conscious decision of the Task Force not to review and evaluate each decision and piece of information that would be released by the DOE over that period of time, but to focus solely on developing its work plan in the time available.

VALUE ADDED THROUGH PUBLIC INVOLVEMENT

As the work progressed, the Task Force learned how site decisions were being made and how the Task Force might influence those decisions. Through direct participation at Task Force meetings, DOE and FERMCO project managers gained insight into stakeholder values and expectations. Major policy issues were discussed at length, and technical, economic, and political trade-offs were debated. These interactions ultimately yielded agreement between Task Force members and Fernald project managers on the direction the project should take. The Task Force's recommendations provided a blueprint for project managers to follow in remediating the Fernald site.

For DOE and FERMCO, the return on this investment in public involvement in the Fernald decision making process has been significant. By implementing Task Force recommendations, the project duration will be reduced from 25 years to 10 years, and United States taxpayers stand to save an estimated $2.15 billion. These savings are determined by comparing the costs in dollars and time required for off-site disposal of all Fernald contaminated materials with the balanced approach recommended by the Task Force, which calls for disposal of Fernald's most contaminated materials off site and lesser-contaminated materials on site on an accelerated schedule. Equally important is the payback in terms of increased trust and confidence among Task Force members and project personnel. By their willingness to share information and adjust positions once the perspectives of others were heard, Task Force members and project managers set the tone for future cooperation in support of the mutually beneficial goal of a remediated Fernald site.

FERNALD IN TRANSITION

During 1995, the Fernald project was in transition. The signing of the Operable Unit 5 Record of Decision by the EPA in December 1995 symbolized the conclusion of a decade-long study-and-planning phase at Fernald. The project had crossed that important threshold into the remedial design phase.

The delivery of the Task Force's recommendations in August 1995 also symbolized a turning point. With the urgency of meeting deadlines under its initial work plan removed, Task Force members could consider a future course of action. At their August 1995 meeting, a consensus emerged in support of refocusing the Task Force in a manner that would be productive and useful for project managers. Concurrently, DOE officials reiterated their perspective that the relationships between site personnel and

stakeholders established during Task Force interactions were of great value and should be sustained.

At their September 1995 meeting, Task Force members discussed, in greater depth, issues relating to their future areas of focus and methods of conducting business. These issues included work plan development, membership, organization, and support resource allocation. How these issues were approached and resolved is discussed in the following section in a "lessons learned" format.

LESSONS LEARNED

Work Plan Development

Lesson Learned:

A focused work plan enables citizen participation to have the greatest impact on project decisions.

Discussion:

An important component of the original success of the Task Force was the ability of members to stay focused on their ultimate goal and particularly to understand how each activity fit into the process of achieving that goal. This was achieved through the development of a detailed work plan which identified all activities the Task Force would undertake, the information to be evaluated and the decisions required over time. The Task Force activities were clearly linked to ongoing site activities so members could see how their input would impact the real-time decision-making and cleanup of the site. By clearly outlining the role and importance of each meeting in the decision-making process, attendance was rarely an issue.

In discussing the future of the Task Force, members expressed an aversion to becoming "just another oversight group." It was generally considered important that a new work plan should include definite end products for each area of focus. The Task Force consultant was tasked with developing such an approach.

Informal dialogue among the Task Force chair, Task Force consultant, DOE officials, and FERMCO personnel occurred frequently during work plan development. Through these discussions, current and emerging issues were identified as candidates for Task Force focus. The Task Force chair reviewed the draft work plan with the DOE Fernald Area Office director to ensure it would result in relevant recommendations for project decision-makers.

At its December 1995 meeting, the Task Force refined and adopted the work plan. The work plan focused on the following issues: the engineered on-site disposal facility, waste transportation, environmental monitoring, natural resources, waste treatment, waste disposition, recycling, accelerated schedule/priorities, complex-wide issues, radium extraction, and economic development. For each of these issues, expected actions were identified. These actions are oriented toward developing recommendations or providing comments on these important issues. On all issues, Task Force dialogue and development of recommendations or comments have been scheduled in a timely manner to coincide with upcoming project activities and schedules.

Membership

Lesson Learned:

The Task Force should periodically assess its membership to ensure balanced representation and depth of expertise.

Discussion:

Upon submission of recommendations developed under its initial work plan, submitted to the DOE in August 1995, all Task Force members had the option to resign. None chose to do so. Instead, all expressed continuing interest and commitment to involvement on the Task Force.

The Task Force discussed the issue of membership at its September 1995 meeting. During the discussion, members considered the need to ensure balanced representation and depth of expertise among its membership. A determination was made that one additional member should be recruited. The Task Force chose to appoint a search committee to recruit candidate members. More than 850 announcements and applications were mailed to area residents, with ads being placed in the three Cincinnati-area daily newspapers. Eighteen applications were received, from which four finalists were interviewed to assess level of interest, experience, and proximity to the site. The entire Task Force approved the committee's selection at its December 1995 meeting, and the new member was appointed by the DOE later that month.

The membership review and recruitment process led the Task Force to reflect on its relationships with its constituencies and reaffirmed the need for continuing broad public participation activities independent of the DOE. Both diversity and continuity were considered keys to effective membership. Members acknowledged constant monitoring of community interests and positions is important to ensure the Task Force is representative of the entire community. A consistent membership is important to maintain institutional knowledge, continued cooperation and commitment. The addition of a new member as the Task Force shifts its focus has helped broaden the perspective and experience of the Task Force. This continuity was ensured in the original ground rules for the Task Force, which includes a provision for overlapping membership terms. The member search itself also identified the level of interest in the community in serving on the Task Force and helped identify individuals who might work with the task force over time.

Organization

Lessons Learned:

Citizen groups should organize such that they can be flexible and responsive to changing needs.

Discussion:

To influence key decisions in the Fernald project's planning phase, the Task Force had adopted an aggressive schedule under its initial work plan. Extensive monthly meetings involving the entire Task Force was essential during this work because of the strategic nature of the issues being considered and the time constraints under which the Task Force was working. With the delivery of recommendations under the initial work plan complete, the Task Force acknowledged it could "shift gears" and operate with less intensity. Two changes were adopted to enable the Task Force to relax its aggressive schedule while pursuing a broad range of issues under its new work plan.

First, the membership agreed the full Task Force would meet quarterly, rather than monthly. To ensure members were informed on a timely basis, the Task Force consultant was tasked with publishing a monthly newsletter on project status and issues of concern to the Task Force.

Second, the Task Force decided to utilize a committee structure to as great an extent as necessary. This enabled Task Force members to debate and discuss a broad range of issues concurrently and promote timely

development of recommendations. It is also conducive to timeliness and responsiveness by the Task Force to emerging issues.

The next phase of Task Force activities will be focused more on reacting to site proposals and reviewing detailed design documents. A committee structure allows the Task Force to consider multiple issues concurrently and provides flexibility for scheduling meetings and addressing new issues as they emerge. In addition, the committee structure allows more direct interaction with other stakeholders interested in Fernald activities, simply because meetings will be conducted more frequently and less formally.

Technical Support

Lesson Learned:

Continuity in support resources is important to the success of the Task Force.

Discussion:

An important contributor to the Task Force's success has been full access to information relating to decision-making factors provided by the DOE and FERMCO. A side effect of this unconstrained access is the need to ensure the vast amounts of available information are synthesized into an understandable format consistent with Task Force needs. Task Force members realized this early on and requested DOE to provide for retention of an independent consultant support them. As work under the initial work plan progressed, the consultant became expert in meeting the Task Force's information needs.

The Task Force acknowledged that consistency of support would be a key element as it transitioned from one area of focus to the next. Consequently, it requested DOE to continue to provide for the services of the consultant selected to support the initial work plan. The DOE and FERMCO continue to provide access to information and work with the consultant to ensure information needs are met. FERMCO has designated an individual to provide liaison with the Task Force and the consultant. All parties recognize the importance of keeping information channels wide open.

Open, honest and trusted technical support has always been the backbone of the Task Force's success. Much of this support has rested on the work of the Task Force consultant and select FERMCO employees who have earned the trust of Task Force members over time and developed important relationships with the Task Force. The continued involvement of these individuals is key to the continuing confidence the Task Force has in the material it uses.

While the Task Force consultant works to collect, synthesize and distribute most of the information needed by the Task Force, individual members, particularly committee chairs, need to feel comfortable and confident in calling FERMCO and DOE personnel directly to ask questions, discuss issues or request information. It is through the constant give-and-take approach with the Task Force that many of the most important contributions to improving cleanup performance are made.

CLOSING

The performance of the Fernald Citizens Task Force provides compelling evidence that direct public involvement adds tremendous value to solving the difficult challenges confronting managers of environmental remediation projects. Though the main Task Force recommendations are in place, much of the critical action to implementing these decisions will be conducted during remedial design and remedial action at the site. In

its reorganization, the Task Force has positioned itself to monitor progress, identify problem areas and ensure that the spirit of its recommendations are followed. The difficulties of maintaining an effective Task Force over the long term are significant, but in our view this continuity is essential. All parties recognize the importance of building on the success and credibility of the original mission by ensuring the effective implementation of the concepts and spirit embodied by the Task Force recommendations. Focus, teamwork, knowledge and self-discipline -- all of which are important ingredients of the Fernald Citizens Task Force's success -- are all difficult to replicate. The continuation of the Task Force is the most effective approach to ensuring balanced representation of local citizenry in decisions that will impact lives and livelihoods at Fernald for many generations.

FOCUSING ON THE BIG PICTURE: CITIZEN PARTICIPATION AT ROCKY FLATS

Ken Korkia
Rocky Flats Citizens Advisory Board
9035 Wadsworth Parkway, Suite 2250
Westminster, CO 80021

ABSTRACT

The Rocky Flats Citizens Advisory Board (CAB) is part of the national network of advisory boards formed by the Department of Energy (DOE) to provide advice and recommendations on cleanup and waste management issues at weapons complex sites. Early in its operations CAB was faced with responding to specific proposals from DOE without having answered or addressed more fundamental questions or issues. Specifically, CAB was asked to comment on the design of a landfill cap to permanently dispose of waste material at the Solar Pond area at Rocky Flats. While reviewing this plan, CAB realized it first needed to address a more fundamental question, whether disposal of waste material was acceptable at Rocky Flats. Questions concerning the design of the landfill cap were irrelevant until the more fundamental question was addressed. To resolve this problem, CAB developed a workplan to address what it called the "big picture" issues. By focusing on these issues, CAB was able to develop a foundation of understanding that guided it in providing more specific recommendations on DOE proposals for the cleanup of the Rocky Flats Environmental Technology Site. A key component of CAB's work was the development of a position on waste disposal at Rocky Flats, a concept opposed by CAB. One of the earliest proposals CAB examined using its "big picture' framework was the draft Rocky Flats Conceptual Vision. This vision called for disposal of low-level and low-level mixed wastes at Rocky Flats. Having already laid a foundation of understanding on this issue, CAB was able to develop a consistent recommendation opposing the vision and offering an alternative calling for monitorable and retrievable storage of waste materials while they remained at Rocky Flats.

AN INTRODUCTION AND BRIEF DESCRIPTION OF ROCKY FLATS

The Rocky Flats Environmental Technology Site (RFETS) outside of Denver, Colorado, formerly known as the Rocky Flats Plant, began operation in the early 1950's primarily to produce the plutonium triggers for nuclear weapons. These operations continued until 1989 when Rocky Flats was

forced to shutdown due to concerns with safety at the aging facility and indirectly as a result of a raid by the Federal Bureau of Investigation and the Environmental Protection Agency over illegal environmental and waste handling practices. The 1989 shutdown was thought to be temporary, but due to changes in the world political climate, the end of the cold war, and the declining need for nuclear weapons, the mission at Rocky Flats was changed to one of cleanup in 1993.

Even with a change in mission, the legacy of its past still remains. Namely, 12.9 metric tons of weapons grade plutonium and tens of thousands of cubic meters of left-over production waste, including transuranic, low level and low level mixed forms, still reside at the site. Thousands more cubic meters of waste will be generated during the decontamination, decommissioning and environmental restoration activities slated for the future. The challenge of what to do with these wastes is of keen interest not only to the Department of Energy and the regulators, but to the local communities and citizens of the Denver metropolitan area.

HISTORY OF CITIZEN PARTICIPATION AT ROCKY FLATS

Citizen involvement with Rocky Flats began in 1969 when stories of a fire in one of the production buildings made front page headlines in the Denver papers. Rocky Flats officials claimed that there were no off-site releases from this fire, but a group of scientists at the University of Colorado in Boulder felt otherwise and conducted independent soil sampling in areas off-site from the plant. The results of this sampling confirmed that there was plutonium in the soil that exceeded background levels expected from world-wide atmospheric weapons testing fall-out. In confronting site officials with this information, the researchers demanded an explanation. The response from Rocky Flats was indeed surprising. Site officials continued to deny any contribution from the 1969 fire, but instead disclosed a previous fire in 1957 and waste handling procedures during the past two decades that were more likely the contributors of the off-site contamination.

With these surprising revelations, many community individuals near the site began to question if there were other events that Rocky Flats officials had not disclosed and also whether the site was able to operate safely in the midst of a major metropolitan area. This skepticism, combined with anti-nuclear sentiments, provided the foundation for citizen interest and involvement in Rocky Flats operations. There was, however, no real forum for an open dialogue with site representatives, as citizen participation took the form of staged protests such as rallies, a human blockade of the rail lines running into the plant, and a human encirclement of the site boundary. Political interest in the site began with the creation of a task force formed by the Colorado governor and the member of Congress from the district in which Rocky Flats resides. This task force led to the formation of the Rocky Flats Environmental Monitoring Council, which was the first true forum attended by site officials, the local governments, and interested citizens to discuss what was happening at Rocky Flats.

Formal citizen participation began in earnest in 1989 when Rocky Flats was placed on the National Priorities List of Superfund. The public participation guidelines of Superfund brought an institutionalized approach to citizen involvement and the beginning of formal meetings to seek public input into plans for dealing with the environmental contamination problems. Recognizing the value of regular stakeholder input and involvement, the Department of Energy and the site contractor

expanded the dialogue to include many other documents and programs such as strategic plans, environmental assessments, budget guidelines, and site transition plans. The volume of information generated to support site activities began to fill entire libraries and the number of public meetings associated with Rocky Flats rose substantially. A public that once complained about too little information soon began to complain about too much, with too many meetings and a lack of focus for how all the pieces of public input fit together.

THE FORMATION OF THE ROCKY FLATS CITIZENS ADVISORY BOARD

In 1992, representatives from state governments, national environmental organizations, the regulators, the Departments of Energy, Defense, and Interior, and other interested parties formed a federal advisory committee known as the Federal Facilities Environmental Restoration Dialogue Committee to address cleanup at federal sites such as Rocky Flats. One of the recommendations of this committee was to form Site Specific Advisory Boards at each of the weapons complex sites to foster stakeholder participation in the cleanup decisions.

The Rocky Flats Citizens Advisory Board (CAB) was formed in 1993 in response to this recommendation with the following mission statement: "The Rocky Flats Citizens Advisory Board, a nonpartisan, broadly representative, independent advisory board with concerns related to Rocky Flats activities, is dedicated to providing informed recommendations and advice to the agencies (Department of Energy, Colorado Department of Public Health and Environment and the Environmental Protection Agency), government entities and other interested parties on policy and technical issues and decisions related to cleanup, waste management and associated activities. The Board is dedicated to public involvement, awareness and education on Rocky Flats issues."

CAB was not formed because of a lack of citizen involvement in Rocky Flats issues. To the contrary, the period before its formation saw the rise of numerous organizations whose sole or partial mission was to address Rocky Flats, each with its own particular viewpoint. CAB from its inception was unique, however, in that for the first time, representatives from these various organizations were brought together around a common table. CAB operates by consensus, a sometimes difficult process, but one that brings often disparate views together in a common voice that is seen as a valuable tool for those who receive the advice or recommendation.

A CASE STUDY IN DECISION-MAKING: THE SOLAR PONDS AT ROCKY FLATS

One of the first major issues addressed by CAB was what to do with the solar ponds at Rocky Flats. The solar ponds were used by the site for most of its operating life to receive process waste water which was allowed to evaporate in the open air. The remaining sludge left after evaporation was periodically removed as radioactive waste. Through almost forty years of operation, the ponds leaked, contaminating the surrounding soil and groundwater. In 1994, the Department of Energy (DOE) came to CAB with a proposal to build an engineered soil cap over the ponds as the chosen method of permanently closing them.

DOE's plan was to remove the ponds' liners and surrounding soils, and then redistribute the contaminated material into the center of the solar ponds area, after which an elaborate cap would be built over the area to isolate the materials from the environment. This plan was developed with the cooperation of both the Environmental Protection Agency and the Colorado Department of Public Health and Environment. In coming to CAB

with the proposal, DOE stated that the final plan was not yet developed and would allow CAB plenty of time to review and make changes to the proposal as it saw necessary. CAB has several standing committees that work on issues in order to develop a proposed recommendation for approval by the full membership. After receiving the solar ponds proposal, CAB assigned its Environmental/Waste Management Committee the responsibility of reviewing the plan.

For several months the Environmental/Waste Management (E/WM) Committee met with DOE and the regulators in discussing the proposal. A tour was scheduled for the site, and draft copies of the plan were given to E/WM for review far in advance of the "official" public comment period. As discussions progressed, DOE fine-tuned the plan based on some of the early E/WM comments. One of the troubling aspects of the proposal was DOE's plan to include the sludge that had been removed from the ponds over the years. This material, called pondcrete, had generated controversy several years earlier because the cementation process used to stabilize the sludge had proven ineffective, as the material failed to solidify properly. Further problematic was that one of the findings of the Grand Jury investigation which followed the FBI raid in 1989 was that the site operators had failed to properly store this pondcrete material. DOE now proposed to dispose this same material as part of the solar ponds closure plan.

Fulfilling its directive, the E/WM Committee came to the full board with its proposed recommendation that CAB approve the design of the solar ponds cap with several modifications. The disposition of the pondcrete remained an issue that the Committee could not come to agreement on and asked for the board's advice. The final recommendation by the board was that DOE could build the cap, but that it would have to consider the project as an interim storage measure, and that any materials placed under the cap would need to be in a monitorable and retrievable form so that eventually they could be removed for disposal elsewhere. The full board could not come to consensus on the disposition of the pondcrete materials either. This recommendation was contrary to DOE's view that the cap would be permanent, "designed to provide a level of protection for at least a thousand years."

One of the lessons learned by CAB in its review and deliberation on the solar ponds cap was that it was being asked to make a decision on a very specific proposal without first having come to consensus on a broader issue. Namely, should any material, at any location be disposed at Rocky Flats. It became apparent to CAB that a hierarchy of more general issues and questions existed that must be answered first before other more specific proposals could be addressed. From its experience with the solar ponds, CAB resolved to develop a new approach to providing advice and recommendations to DOE and the regulators. It would develop a work plan, not driven by specific plans or proposals, but more general in nature to lay a broad foundation upon which future recommendations could be built.

LAYING THE FOUNDATION: THE DEVELOPMENT OF A CAB WORKPLAN

From its inception, the solar ponds closure plan was not the only technical proposal on which CAB was being asked to provide comment. CAB faced a fundamental question of whether it would be a reactive organization, responding only when asked, or whether it would become more proactive by compiling a list of what it termed "the big picture" issues and then developing strategies to address them. CAB chose the latter.

To begin its effort, CAB first developed a list of issues that were important to the membership. Next, these issues were combined and organized into logical program areas such as safety and health, cleanup, waste management, land use, and plutonium disposition. Members then determined which issues to address first. The results of this exercise culminated in the development of four issue areas that were assigned to the various CAB committees. These four issues were cleanup levels, waste disposal policy, plutonium disposition, and future use. The Department of Energy concurred with CAB that these issues were the most appropriate to develop, encouraging CAB to first work on the waste disposal issue. CAB also viewed the waste disposal policy as an urgent priority. This development of a waste disposal policy demonstrates how CAB identified broader issues as a prelude to developing strategies and recommendations on more specific issues and proposals.

THE CAB POSITION ON WASTE MANAGEMENT: STORAGE AND DISPOSAL AT ROCKY FLATS

The research and development of a CAB position on waste management at Rocky Flats was assigned to the CAB Site Wide Issues Committee. The committee began its work by eliciting a set of guiding principles that incorporated the group's values and beliefs associated with waste management activities. Although rather straight forward, the guiding principles are viewed by CAB as providing the foundation by which future waste management plans can be evaluated. These guiding principles are as follows:

1) Different categories of waste will remain at Rocky Flats for some period of time.
2) Waste at Rocky Flats shall be stored in the safest possible manner.
3) Waste shall be stored in such a manner that it cannot escape into the surrounding environment during the time that it remains a potential hazard.
4) Waste shall be stored in such a manner that it is fully monitorable and retrievable. In addition, there shall be institutionalized review systems in place ensuring inspection on a regular basis.
5) It is not acceptable for Rocky Flats to send waste to a facility that would not meet CAB criteria for storage at Rocky Flats.
6) Any waste storage or "disposal" facility must be selected through an objective, scientific process and include public participation.
7) The concept of "disposal" of radioactive waste is misleading due to the toxic and long lived nature of the wastes. Because wastes are out of sight, does not mean that the problem is solved.

After developing the list of guiding principles, the Site Wide Issues Committee next turned to the task of providing specific recommendations on waste management policy to the Department of Energy. These recommendations approved by CAB are:

1) Because it is unlikely that a waste "disposal" facility can be guaranteed to contain the contaminants for the life of the waste, CAB opposes the development of such a facility at Rocky Flats.
2) DOE shall develop plans for long-term storage of all wastes currently at Rocky Flats.
3) Any waste facility must be fully monitorable, with regular inspections, and the waste must be fully and easily retrievable.
4) To ensure the safest possible storage, any waste storage facility must be able to be upgraded; and if the facility cannot be upgraded the facility must be replaced.

5) No waste from other facilities shall be accepted at Rocky Flats for treatment or storage.
6) Because radioactive waste is a national issue, and because there is no guarantee that proposed "solutions" will proceed, a national dialogue must be convened that addresses the issue of waste storage and "disposal". CAB agrees to support and participate in such discussions.
7) DOE shall vigorously pursue a research program aimed at developing technologies to make radioactive waste benign (not a potential hazard).
8) The Rocky Flats Citizens Advisory Board and other external stakeholders (including regulators) shall be involved in the development and approval of all waste management plans and activities.
Through this focus on the broader, "big picture" of waste management, CAB was now in a position to evaluate specific proposals as they came forward with a common understanding of the guidelines and principles important to the members.

BUILDING ON THE FOUNDATION: THE UTILITY OF FOCUSING ON THE BIG PICTURE

After approval of its waste management recommendations, it did not take long before CAB was able to put them to use. Late in 1995, a draft Rocky Flats Conceptual Vision developed by DOE, the Colorado Department of Public Health and Environment, and the Environmental Protection Agency was released for public review and comment.
Work on the Conceptual Vision for Rocky Flats Vision began in 1995 through a cooperative effort with DOE, EPA, and the State of Colorado. These agencies had for the past several years been developing a new cleanup agreement to provide the legally enforceable framework for the cleanup of the Rocky Flats site. In the fall of 1995, the Principals from each of these agencies met in a "workout" session to come to closure on the outstanding issues between them. One of the products of their workout was the draft Conceptual Vision. This vision was based on two phases: an intermediate site condition and a final site condition. A major portion of the final site condition called for permanent disposal of numerous forms of low level wastes at Rocky Flats. In order to evaluate and comment on the vision, CAB was able to utilize its previous waste management recommendation.
A major component of the draft vision was the "long-term disposal" of wastes at Rocky Flats using landfills covered by earthen caps. Materials inside buildings, which during demolition would become low-level or low-level mixed wastes, would be added to a special cell in these landfills or would be entombed within the building foundations under a special cap.
Using its previously developed guidelines, CAB provided the following recommendation on the draft Conceptual Vision:
"Radioactive waste disposal is not acceptable at Rocky Flats. DOE should develop plans for long-term storage of waste in a manner that is fully monitored and retrievable."
CAB further added:
"Today's 'solutions' for problems at Rocky Flats should not leave problems for future generations, or preclude future generations from going beyond these 'solutions'."
At the time of this writing, final decisions had not been made on the issue of radioactive waste disposal at Rocky Flats. Preliminary discussions with DOE and the regulators indicated a willingness to examine the concept of retrievability. CAB favored this discussion and viewed it as a means to provide public health and safety benefits to the current generation, while not precluding advancements in technology that

may provide a more permanent or acceptable solution for future generations.

CONCLUSION

Effective citizen participation in cleanup decision-making at a major federal facility like Rocky Flats is very complex. In response to this complexity, the Rocky Flats Citizens Advisory Board undertook a proactive role in developing a foundation for discussing issues in a broad sense, or "big picture." Once developed this big picture would facilitate CAB's understanding of and ability to address more specific technical issues. From its experience in trying to provide a recommendation on the design of a landfill for the Solar Ponds area at Rocky Flats, CAB realized that a more fundamental issue needed to be addressed first. This issue was whether disposal of radioactive waste at Rocky Flats was acceptable, not only from a technical viewpoint, but from a social and moral perspective as well. Fully aware of the NIMBY (Not in My Backyard) criticism often leveled against citizen activists who oppose projects such as waste treatment or storage facilities, CAB developed a policy on waste disposal that opposed the concept of permanent placement of radioactive materials within a major metropolitan area, while leaving open the possibility of monitored and retrievable storage. Wastes may remain at Rocky Flats for an extended period of time, but during that time CAB anticipates technology development will continue with the hope that one day a more acceptable and lasting solution to the waste problem will be developed. CAB realized the utility of its decision to focus on the broader sense when it was asked to comment on the draft Conceptual Vision for Rocky Flats. The arguments had already been made, and the decisions and consensus views were in place. The draft Conceptual Vision called for waste disposal, an issue for which CAB had already developed a position. CAB anticipated that future versions of the Conceptual Vision would incorporate the concept of monitorable and retrievable storage rather than disposal. The reader will note that the full account of CAB's success in bringing its own "vision" for Rocky Flats to fruition is not yet complete. Final decisions on the future of Rocky Flats are not CAB's to make. It is CAB's sincere desire and hope, however, that both the Department of Energy and the regulators will realize the value of a consensus CAB recommendation and develop a final vision for Rocky Flats that meets both regulatory and community acceptance standards.

FACILITATING THE TECHNICAL:
THE ROLE OF THE TECHNICAL ADVISOR IN A COMMUNITY ADVISORY BOARD

Earle C. Dixon
Technical Advisor
NTS Community Advisory Board

ABSTRACT

A technical advisor for the Nevada Test Site (NTS) Community Advisory Board (CAB) is challenged to perform four key roles: 1) technical director, 2) administrator, 3) facilitator, and 4) spokesperson. Differences between roles performed by the technical advisor and the traditional facilitator to support an advisory board are described in this paper. Techniques used by the advisor to support the board include: summarize and simplify information; write and implement standard procedures; focus on program goals; and increase stakeholder knowledge and participation.

The primary difference between a technical advisor (TA) and a traditional facilitator is that a TA draws on scientific experience to guide them as the support base for the CAB mission and positions on issues. As an administrator, a TA utilizes scientific organizational skills and procedures to perform this role. The TA acts as a traditional facilitator during CAB monthly meetings between stakeholders and the Department of Energy. As a spokesperson for the CAB, a TA is different from a traditional facilitator because he represents a credible, technical perspective and resource on the issues and mission objectives of the board.

The technical advisor assists in the recommendation process by the simplification of information in documents and on issues that the CAB relies on to develop stakeholder input. Organizational procedures are developed and implemented by the TA to satisfy the need to have written steps guiding the way board activities are conducted. Board focus on broader though complex issues is supported by the TA emphasis on key issues requiring board review. The TA increases the technical base of stakeholder knowledge through opportunities to discuss EM programs and present board issues and mission objectives to stakeholders.

INTRODUCTION

The Community Advisory Board (CAB) for the Nevada Test Site (NTS) is a group of volunteers organized in 1994 to provide advice and recommendations to the Department of Energy (DOE) on the Environmental Restoration and Waste Management (ERWM) program. The CAB is consistent with DOE's "environmental vision," which includes the development of a strong partnership between the DOE and stakeholders. The board's establishment reflects growing opportunities for public participation in the site-specific advisory board (SSAB) process at local sites throughout the DOE complex to help deal with issues affecting local citizens.

In May of 1994 the Office of Management and Budget and the General Services Administration approved a charter that established an overall, national Environmental Management (EM) Site-Specific Advisory Board. This overall board provided authority for the creation of local site-specific boards throughout the DOE complex and it serves as the umbrella board chartered under the Federal Advisory Committee Act. Congress enacted this law in 1972 to provide standards and uniform procedures to govern the establishment, operation, administration and duration of any advisory committee.

NTS ERWM PROGRAMS

The Nevada Test Site is a unique national resource managed by the U.S. DOE Nevada Operations Office. The Site is located 65 miles northwest of Las Vegas. The 1,350 square mile facility is an area comprised of desert and mountainous terrain larger than the state of Rhode Island. The NTS was established under the Atomic Energy Commission, DOE's predecessor, and has seen more than four decades of nuclear weapons testing. In recent years the NTS has diversified into many other programs including hazardous chemical spills testing and cleanup, waste management, and development of new environmental technologies.

The Nevada Test Site Environmental Management (EM) program is part of DOE's 30-year program to address contamination from nuclear weapons programs at DOE facilities and sites. Nuclear testing and related support operations, nuclear rocket experiments, and non-nuclear experiments resulted in some contamination. Contaminants include radioactive materials, gasoline, oils, solvents, and heavy metals such as lead. EM

program objectives are to identify the nature of contamination, decide its potential risk to the public and to the environment, and to act to protect or restore the natural resources adversely affected by releases of hazardous materials.

The Waste Management (WM) program is responsible for the safe disposal of low-level radioactive and mixed waste from the NTS and other defense-related DOE and U.S. Department of Defense facilities. Waste is disposed of in shallow landfills and craters at two locations on the NTS. In addition, under an agreement with the state of Nevada, mixed transuranic waste is stored at the NTS until it can be shipped to the Waste Isolation Pilot Plant in New Mexico for disposal. Hazardous waste is accumulated at the NTS and shipped off site to an EPA-approved treatment, storage, and disposal facility.

CAB ORGANIZATION AND FOCUS

In the summer of 1993, an informal group of interested citizens, worked with DOE officials to develop a draft charter, mission statement, and bylaws. In October 1993, a public notice soliciting nominations for board membership was advertised in newspapers throughout the state. DOE forwarded the 120 applications to representatives of the state of Nevada's Environmental Protection Division (NDEP) for their review and recommendation. In February of 1994, the NDEP recommended a slate of 15 individuals to serve as initial members on the board. DOE accepted the slate of nominees and in June 1994, the Community Advisory Board for the Nevada Test Site Programs was officially approved by the Secretary of Energy.

As of December 1995, the board is comprised of 18 members representing a diversity of views. Current members include residents and workers near the NTS, environmental or public interest groups, labor and civic groups, Native American representatives, academia, and local governments. In addition to regular members, there are four non-voting ex officio members representing the DOE, the U.S. Defense Nuclear Agency, the state of Nevada, and a test site contractor organization. All board members serve a two-year term with at least one third retained for continuity and some membership terms may be staggered.

The board's charter calls for the formation of standing committees to handle specific issues and topics related to the EM program. Standing committees address areas of: budget and priorities; the NTS Environmental Impact Statement (EIS); waste transportation; future land use; issues; and administration. Standing committees are chaired by board members and open to participation from the DOE and stakeholders.

Some of the issues the CAB has reviewed include proposed plans for environmental restoration-generated waste shipments to the site, treatment plans for storage and disposal of mixed waste; funds generated from waste management; NTS EIS process; plans to manage DOE lands and facilities; equity issues relative to environmental restoration and funding; waste transportation; Draft Waste Management Programmatic EIS; and proposed Federal Facility Agreement and Consent Order outlining environmental restoration priorities for DOE sites in Nevada.

ROLE OF THE TECHNICAL ADVISOR

A technical advisor for the NTS CAB was hired through the Harry Reid Center for Environmental Studies (HRC) at the University of Nevada, Las Vegas (UNLV) under a grant provided by the DOE Nevada Operations Office in Las Vegas. The advisor's relationship with UNLV represents a credible, independent, and neutral position within the community. A university-

based advisor to support the CAB is unique among the DOE site specific advisory boards (SSAB) that are usually supported by federal contractors and a traditional facilitator. The TA is challenged to perform four key roles for the NTS CAB: 1) technical director, 2) administrator, 3) facilitator, and (4) spokesperson. In these roles the TA serves as the technical support base and primary resource for board activities, issues, and research.

Technical Director

In the role of technical director the advisor draws on scientific training to guide him as the technical support base for the CAB. A primary difference between the TA and the traditional facilitator or coordinator is the technical degree and training of the advisor. Many issues and documents of the DOE environmental management (EM) program are complex and not easily understood by board members and stakeholders. Technical persons like engineers and scientists are well suited for the study and interpretation of the complex.

A person with a degree in the technical sciences is likely to have some knowledge of or experience with federal environmental regulations and issues that would apply to cleanup activities at a DOE facility. His role is to readily develop a thorough understanding of EM activities and then consult the board in the review of issues on a regular basis. The science background helps him interpret and summarize technical issues and information into understandable and manageable pieces for the board.

Administrator

In the role of an administrator, a TA differs from the traditional facilitator because he utilizes scientific organizational skills and procedures to perform administrative duties for the board. The way a technical person executes administrative duties are likely to be based on scientific methodology for problem solving. Problem solving methods often follow a standard system of information gathering, data analysis, discussion, conclusion, and reporting. This scientific technique lends itself nicely to organizing activities and objectives on behalf of the board.

For example, board activities leading to a well organized, meeting agenda of presentation, discussion, and business are coordinated by the TA each month. He is also tasked with the execution of numerous administrative tasks like newsletters, reports to the DOE and stakeholders, management of CAB the library, attendance on behalf of the CAB at meetings and workshops, and coordination of the student intern program. Execution of administrative tasks is the most time consuming role for a technical advisor.

Facilitator

The technical advisor performs the role of the traditional facilitator during CAB monthly meetings between stakeholders and the DOE. Persons with scientific backgrounds are challenged to implement parliamentary procedures and facilitate a monthly meeting. Some technical persons may have educational training and public speaking skills through teaching science courses, however, they will typically have to learn the role of facilitator. A trained facilitator can be brought in as needed to help the TA learn and perform this role for the board.

Spokesperson

In the role of spokesperson, a TA functions as a technical consultant and clearing house of information on issues and mission objectives of the board. His full-time position requires him to be the point of contact

between members, the DOE, and the public on CAB activities. The TA is responsible for attending all meetings and workshops of interest to the CAB. He may be called upon at a meeting to present a summary of board activities related to a key issue. The TA also looks for opportunities to inform the public and other community organizations about DOE programs and board activities for stakeholder participation. Other SSAB representatives and even the media may contact the TA for information about a variety of topics on cross cutting issues and similar SSAB business.

METHODS TO FACILITATE THE TECHNICAL

Techniques used by the a TA to support the board include: summarize and simplify information; write and implement standard procedures; focus on program goals; and increase stakeholder knowledge and participation. The TA assists in the recommendation process by the simplification of information in documents and on issues that the CAB relies on to develop stakeholder input. Organizational procedures are developed and implemented by the TA to satisfy the need to have written steps guiding the way board activities are conducted. Board focus on broader though complex issues is supported by the TA emphasis on key issues requiring board review. The TA increases the technical base of stakeholder knowledge through opportunities to discuss EM programs and present board issues and mission objectives to stakeholders.

Summarize and Simplify Information

Board members frequently complain about the overwhelming reading requirements and complexity of the EM programs. Reports are often too numerous and difficult to adequately review and utilize by the average stakeholder. The science background of a TA helps him summarize technical documentation into manageable pieces more acceptable to the board. Important information is extracted and summarized in a memorandum, table, or brief report. For example, the TA summarized information from a future land use panel discussion into notebook form for each CAB member. He reviewed an EM technical strategy document and made a summary of comments in spreadsheet format for the board to use as a reference. The advisor also maintains a document library for stakeholder use.

Write and Implement Standard Procedures

An organization such as an SSAB evolves in time and becomes so active that some level of organization is required to enhance efficiency and utilize resources in a timely manner. The TA's experience of writing scientific papers, reports, and procedural manuals lends itself to the task of organizing information and describing steps in a process. He developed standard operational procedures (SOP) describing all board activities from first hand knowledge and similar information from other SSABs. The SOP describes in writing the history, mission, organization, and activities of the CAB in a single document. It also describes the duties for each part or person associated with the board to help clarify their responsibility in the overall mission objectives.

A description of board procedures helps to identify difficulties with some activities and solutions to overcome them. The SOP provides a format for the CAB and the DOE to work with on a systematic basis. The SOP helps ensure resources are allocated efficiently to plan and organize public participation opportunities in advance. Old and new board members utilize the SOP to understand CAB activities and interests. The SOP will be a resource document that continues to evolve with the CAB and is maintained by the TA with up-to-date information.

Focus on Program Goals

Board focus on broader though still complex issues is assisted by the TA who acts as a consultant to transfer information between the DOE and the CAB. The TA helps focus the activities between both parties toward common goals. With his scientific understanding of environmental processes and a increasing knowledge of site issues, a TA guides the focus of the board on issues where they will have the most impact. For example, the TA discussed with the DOE about which issues were most important for the NTS CAB focus: agreements between the state and DOE; budget; NTS EIS; and future land use. In conjunction with the board and stakeholders, an open discussion and ranking of issues for CAB focus in 1996 was conducted at a monthly meeting. From the ranking of issues for CAB focus in 1996, the monthly calendar and work plan are drafted for the board. The TA emphasizes the monthly meeting agenda to focus board review primarily on these key issues.

Increase Stakeholder Knowledge and Participation

The TA increases the technical base of stakeholder knowledge through opportunities to discuss EM programs and present board issues and mission objectives to stakeholders. The TA is an excellent position to market and speak on behalf of the board. He should be willing to speak at meetings of other community groups and other stakeholder events. Because of his technical background and affiliation with the university, the TA is able to respond readily to questions and issues under board review. For example, the TA has addressed the Nye County commissioners, a DOE declassification workshop, and a transportation workshop on behalf of the CAB. The TA also helped instruct a university class on risk assessment case study of an NTS plutonium-contaminated soil issue.

SUMMARY AND CONCLUSIONS

The TA for the NTS CAB is challenged to perform four key roles in support of the Board's mission: 1) technical director, 2) administrator, 3) facilitator, and 4) spokesperson. Differences between a TA and a traditional facilitator are based primarily on the scientific background of the advisor who uses a standardized system of problem solving to guide him in the performance of the four roles. The role of administrator demands more time from the TA than the other roles. The TA for the NTS CAB is unique among other SSABs because of his affiliation with the university which represents a credible, independent, and neutral position within the community. A technical person is also educated and experienced in the study of the complex, a skill required to comprehend and manage the large amount information pertaining to the environmental issues at a DOE facility. Four methods are used by the TA to facilitate the technical: 1) summarize and simplify information, 2) write and implement standard procedures, 3) focus on program goals, and 4) increase stakeholder knowledge and participation. These methods help manage information for the board, improve efficiency of activities, focus resources on priority issues, and enhance opportunities for stakeholder participation.

The selection of a technical person from a local university to provide major support to an SSAB is different and unique to most advisory boards. In comparison to SSAB support staff, a TA does have the advantage of being able to comprehend and organize the complex, although a disadvantage of a TA would be training him to facilitate monthly meeting discussions. All SSABs will have similar and different site issues that may or may not require the support of a TA. For the NTS CAB, the

selection of a technical advisor to support the board has helped improve the volunteer organization and focus activities toward greater stakeholder knowledge and participation in the EM advisory board process for the DOE.

ABSTRACT

The Fernald Environmental Management Project has developed a successful Low Level Waste Shipping Program in compliance with the Nevada Test Site Defense Waste Acceptance Criteria, Certification, and Transfer Requirements, NVO-325, Revision 1. This shipping program is responsible for the successful disposal of more than 4 million cubic feet of Low Level Waste over the past decade.

The success of the Fernald Low Level Waste Shipping Program is due to the generator program staff working closely with the DOE-NV Radioactive Waste Acceptance Program Team to achieve win/win situations. The teamwork is the direct result of dedicated, proactive professionals working together toward a common objective: the safe disposition of low level radioactive waste.

The growth and development of this program has many lessons learned to share with the low level waste generating community. The recognition of reciprocal interests enables consistently high annual volumes of Fernald waste disposal at the Nevada Test Site without incident. The large volumes successfully disposed serve testimony to the success of the program which is equally important to all Nevada Test Site and Fernald stakeholders.

The Fernald approach to success is currently being shared with other low-level waste generators through DOE-NV sponsored outreach programs. This paper introduces examples of Fernald Environmental Restoration Management Corporation contributions to the DOE-NV Radioactive Waste Acceptance Program outreach initiatives. These practices are applicable to other low level waste disposal programs whether federal, commercial, domestic or international.

BACKGROUND

The Nevada Test Site encompasses 1,350 square miles of land located about 65 miles northwest of Las Vegas, Nevada. Since 1951, the Nevada Test Site has been the primary location for nuclear weapons testing in the United States. Between 1951 and 1992, the Nevada Test Site was the location for 925 nuclear weapons tests. Since the late 1960s, the Nevada Test Site has been actively cleaning up the contaminated areas resulting from nuclear weapons testing and support operations. While weapons testing remains the primary mission of the Nevada Test Site, the current treaty banning testing has altered the mission to maintaining readiness to resume testing. Expanded radioactive waste disposal is one proposed alternative use of the Nevada Test Site in support of the DOE weapons complex remediation efforts.

Initial disposal of radioactive waste began in the early 1970s. Since the mid 1970s, all radioactive waste disposal at the Nevada Test Site has been restricted to one of two designated waste management areas. The Area 3 radioactive waste disposal facility utilizes subsidence craters from underground nuclear weapons tests for waste disposition. The Area 5 radioactive waste disposal facility uses shallow excavated pits and trenches for waste disposal. The volume of waste accepted and disposed in these two areas is approximately 17 million cubic feet of low level waste.

Disposal of radioactive waste from off site locations began in 1976. Waste acceptance criteria were developed to ensure waste received at the Nevada Test Site was in a form that was protective of the workers and the environment. The first waste management criteria was developed in the late 1970s titled, "Operational Radioactive Defense Waste Management Plan for the Nevada Test Site," NVO-185. Between 1978 and 1985, NVO-185 was revised four times to incorporate criteria that were evolving with radioactive waste disposal experience and regulatory changes.

In 1988, DOE Order 5820.2A was issued resulting in the development of the "Nevada Test Site Defense Waste Acceptance Criteria, Certification, and Transfer Requirements," NVO-325. This document established waste acceptance criteria which incorporated the requirements of the new order and applicable RCRA regulations. The current waste acceptance criteria, "Nevada Test Site Defense Waste Acceptance Criteria, Certification, and Transfer Requirements," NVO-325, Revision 1 was issued in June 1992 to incorporate additional regulatory changes. The existing criteria were developed to provide increased oversight of radioactive waste disposal. All generators seeking approval for radioactive waste disposal at the Nevada Test Site must comply with the requirements of NVO-325, Revision 1.

The Fernald Environmental Management Project, formerly known as the Feed Materials Production Center, is located about 20 miles northwest of Cincinnati, Ohio. Uranium metal products for the nation's defense programs were produced at the facility between 1953 and 1989. During those years the facility produced slightly enriched or depleted products for use in production reactors to make plutonium and tritium at other DOE sites. Uranium production was suspended in July 1989 to focus on environmental restoration. The Fernald workforce has been dedicated entirely to environmental restoration since 1989. Also in 1989, the site was added to the Environmental Protection Agency's National Priority List of federal facilities in need of remediation. In 1991, the DOE officially announced that production at the facility was ended and the program

management responsibility within the DOE was transferred to the Office of Environmental Restoration and Waste Management. In February 1992, an Ohio Field Office was established to oversee all aspects of a full-scale environmental restoration and waste management effort which is expected to last several years. Fernald disposed of radioactive waste in on site disposal pits until 1985, when regulations pertaining to disposal cell design forced Fernald to suspend disposal of radioactive waste in the existing cells.

THE FERNALD DISPOSAL PROGRAM

Fernald initiated radioactive waste disposal at the Nevada Test Site primarily to support ongoing production and construction waste management requirements. The volumes of Fernald waste disposed at the Nevada Test Site increased steadily from 1985 until 1990 (Fig. 1). During this time, Fernald waste volumes increased to contribute fifty percent of the total annual volumes of waste received at the Nevada Test Site. The Fernald waste volumes combined with other waste disposal volumes to increase the Nevada Test Site disposal to more than one million cubic feet of off site waste in fiscal year 1989.

Fig. 1

In 1990, a suspension of waste receipts at the Nevada Test Site resulted from a Tiger Team investigation identifying concern for verification of waste acceptance criteria compliance. This suspension caused the withdraw of all existing disposal approvals for generators shipping waste to the Nevada Test Site. Suspensions remained in effect until generators demonstrated compliance with the current waste acceptance criteria. Recognizing the importance of the Nevada Test Site disposal option to the Fernald environmental mission, the facility waste management staff immediately initiated program improvements. Fernald was the first generator to successfully complete the redesigned approval process by demonstrating compliance to the waste acceptance criteria. Fernald resumed shipments in 1990 and remained the only approved facility shipping to the Nevada Test Site through fiscal year 1991.

As a result of the 1991 DOE announcement that production activities at Fernald was officially ended, Fernald concluded that waste volumes disposed at the Nevada Test Site would have to be increased to support the new environmental restoration mission. A backlog of material originally intended for recycle in the Fernald process accumulated on site between 1985 and 1991. A substantial portion of this material would consequently be designated as waste requiring disposal. The first priority of the environmental restoration project was to address this stockpile of legacy containers. Many of these containers were stored outside and were deteriorating. Escalating costs for maintaining safe storage and repackaging legacy material for off site disposal was the primary motivation for increasing alternative disposal options. With a clearly designated environmental restoration mission, Fernald commenced the DOE-NV approval process for additional waste streams.

The DOE announcement confirming Fernald as the first DOE facility to be in full environmental remediation coincided with increased DOE-NV compliance assessment. The criteria issued in NVO-325, Revision 1, June 1992, required generators to provide more compliance documentation than previously requested. The revised waste acceptance criteria increased the level of documentation required to demonstrate compliance. The process for generators seeking Nevada Test Site disposal approval became more

rigorous. Fernald was among the first generators to obtain application approval in compliance with the revised waste acceptance criteria.

The Fernald strategy for securing approval under the revised criteria was the same approach used in 1990. Fernald focused on the largest waste streams with the least impact resulting from the revised waste acceptance criteria. The first streams submitted were the bulk contaminated trash, maintenance, and construction rubble waste streams. These waste streams are primarily characterized by process knowledge which does not require sampling and analysis. With these approvals, Fernald was able to continue remediation of large piles of scrap metal and maintain disposal outlets for waste generated by ongoing construction at the facility. The effort directed toward gaining this approval enabled Fernald to continue shipments to the Nevada Test Site which in turn enabled the facility to maintain progress on the environmental remediation mission. Having established these waste approvals, Fernald then began to seek approval of the more difficult waste streams including uranium and thorium process residues. The approval process for these waste steams required further Fernald program development because this material was amenable to sampling. This aspect required more extensive compliance documentation. Fernald demonstrated compliance by developing sampling and analysis plans and procedures, laboratory acquisition protocols, and providing analytical results for DOE-NV review and approval. This process required nearly one year to complete during which time the waste streams characterized by process knowledge continued shipments to the Nevada Test Site. Fernald and DOE-NV also developed an innovative review process which provided for conditional approval of wastes amenable to sampling. The conditional approval was pending DOE-NV review of final data packages prior to approval for shipment to the Nevada Test Site. The interim approvals allowed Fernald to ship waste for which the sampling and analysis review was completed. This development allowed Fernald to make progress toward the remediation of the facility while the full approval process continued on course.

FERNALD INITIATIVES

The process of gaining approval for individual waste streams requires at a minimum three to six months of review and response cycles for Fernald with an established program. For new generators without an established program, the approval process may be considerably longer. To accelerate radioactive waste disposal, Fernald adopted a programmatic waste stream approach to streamline the approval process. Although this approach does not match the NVO-325, Revision 1 waste acceptance criteria expectations, Fernald successfully demonstrated how the approach met the NVO-325, Revision 1 objectives. The NVO-325, Revision 1 perspective that waste streams were discrete groupings of waste containers did not match the Fernald definition of waste stream. Fernald realized that the discrete waste stream approach would require many waste stream reviews and approvals. This would unnecessarily delay the Fernald mission and or increase disposal costs. To bridge the gap in waste stream definitions, Fernald established programs that provide sufficient process controls to demonstrate compliance with NVO-325 which affords Fernald more influence over the fate of their program. The programmatic approval is based on the assumption that following routine tasks, relatively similar waste can be certified in similar processes. The fundamental requirement of the programmatic approach is to design waste streams with broad descriptions and then manage individual waste container compliance with the waste

stream approval through the characterization process. The programmatic waste stream approach reduces the time and cost required to get DOE-NV waste stream approval each time a population of waste is characterized. As Fernald worked with DOE-NV to develop this approach, the benefits became clear. Now, DOE-NV suggests to other generators to consider this approach.

To support this programmatic approval process, Fernald developed a complimentary sampling and analysis program in compliance with NVO-325, Revision 1. The NVO-325, Rev 1 requirement to review individual Sampling and Analysis Plans is minimized by a programmatic approach to waste characterization. The Fernald program provides consistency of documentation which aides the review and approval process. The consistency of characterization packages allows DOE-NV to select a representative number of sampling plans for compliance reviews. The reviews provide the level of confidence needed to overview the entire sampling and analysis program. This programmatic approach reduced the time and cost of DOE-NV compliance reviews and reduces the effort required to secure frequent individual waste stream approvals.

By reducing the approval efforts, Fernald realized that the volume of waste being approved for disposal could potentially exceed the capacity of the existing workforce and facilities. In anticipation of this impact, Fernald solicited vendor supplied waste processing services. This initiative forced Fernald and DOE-NV to think "outside of their box" and consider more than one way to manage NVO-325, Revision 1 compliance. Fernald secured DOE-NV approval for two remote vendor services contracts which enabled shipments of processed waste directly from the vendors facility to the Nevada Test Site. This was the first approval of this type ever awarded by the DOE-NV Radioactive Waste Acceptance Program team. This initiative allowed Fernald to increase waste disposal remediation by utilizing existing technology without the procurement, construction, and start-up cost of a DOE owned process. This approval required Fernald to establish a remote waste certification program at the vendors facility. Having developed this program, Fernald assumed a more independent oversight responsibility for the vendors waste management activities. This intermediate position resulted in Fernald gaining elevated awareness of their ownership in the DOE-NV Radioactive Waste Acceptance Program.

Successfully developing programmatic approvals and vendor supplied services approvals requires that the generator understands the DOE-NV program. Fernald accomplishes this familiarization by maintaining close contact with the assigned Radioactive Waste Acceptance Program representative. Fernald avoids delays and interpretation differences through open conversation. This communication minimizes the surprises and keeps all participants at the same level of understanding.

Despite the close contact and the effective program established by Fernald, some compliance discrepancies have occurred. Fernald has disposed of more than 26,600 containers requiring 3,817 shipments to the Nevada Test Site over the past decade. Non-conformances have been recorded for less than 1% of all shipments during this time. Over the past five years, Fernald has reduced the non conformance rate to than 0.5% of the shipments. This improvement is the result of maintaining a program in compliance with the DOE/NV waste acceptance criteria. This improvement is significant when you consider that the number of shipments and containers per shipment have increased during this time. Never-the-

less, despite doing the job right, non-conformances do occur. The nature of the business demands that mistakes be kept to a minimum. When non-conformances are discovered, doing the job right means accepting the responsibility of effecting corrective actions. To maintain low non-conformance rates, Fernald conducts self assessments and acts decisively when non-conforming conditions are identified. Corrective actions are completed quickly to restore compliance, improve the process, and prevent recurrence. Fernald sometimes utilizes self imposed shipment suspensions to motivate corrective action implementation. This strategy minimizes delays to the Fernald program while elevating DOE/NV confidence in the program. This dedication to program improvement is fundamental to maintaining a successful program.

INTERFACE INTANGIBLES

In addition to specific program developments, Fernald also contributes to the DOE-NV Radioactive Waste Acceptance Program development in other ways. Fernald willingly participates in information exchange meetings with other Nevada Test Site waste generators. An example is Fernald presentations of lessons learned materials at DOE-NV Waste Generator Workshops. Or when appropriate, DOE-NV refers potential generators to contact Fernald directly to evaluate this program as an example for developing their programs. Sharing information assists with developing a level of consistency across the complex which improves the generator review and approval process. This consistency reduces the time and cost of generator program development and DOE-NV approval reviews as compliance becomes more routine rather than trial and error.

Fernald further supports program consistency through generator supported audits. As a result of the limited Radioactive Waste Acceptance Program Team resources, other generators expressed concerns that Fernald was monopolizing the team time. This was perceived to be affecting other program reviews. In response, Fernald proposed and supports the DOE-NV audit team by supplementing the team with FERMCO staff. This initiative yields many dividends. One benefit is generator support makes it possible for DOE-NV to maintain the size of the audit staff while freeing permanent team personnel to address other duties. Audit team participation also enables generator personnel to visit other sites and review their programs and establish working relationships with their counterparts. Audit team participation also enables generators an opportunity to evaluate program compliance with waste acceptance criteria from the DOE-NV perspective. This interaction contributes to developing consistency of criteria compliance among the generators which reduces the time and effort required to review and approve individual programs. This program continues even after the Radioactive Waste Acceptance Program Team has been expanded because of the benefits derived from the experience.

Additional generator staff interaction is achieved through work group participation. Fernald supports generator work groups which allows generators an opportunity to provide input to Radioactive Waste Acceptance Program development. Work groups promote communication among generators and encourages an exchange of information and methodology. Fernald supports DOE-NV by participation in several work groups. The first work group supported by Fernald was tasked with RCRA characterization data package development. The work group produced a data package format guidance which has been incorporated into the Radioactive Waste Acceptance Program approval process. One recently concluded work

group activity supported by Fernald involved development of a sealed source disposal position paper. Longer term work group activities currently in progress is the NVO-325, Revision 2 rewrite and standardized waste disposal containers. Fernald continues to support work group opportunities evaluating common issues and recommending solutions to DOE-NV. When appropriate, DOE-NV supports work group deliverable and elevates proposals to higher approval authorities for concurrence. Accepted positions become available to all Nevada Test Site generators for application in their programs.

Supporting Radioactive Waste Acceptance Program and other Nevada Test Site generators is only one piece of the success formula. Keeping the stakeholders informed and addressing their concerns is equally important to the overall success of every DOE facility. Fernald has a successful community relations program with the Fernald stakeholders. The lessons learned from the Fernald facility experience demonstrates the importance of good community awareness. Fernald promotes stakeholder interaction and lends experience and support to the Nevada Test Site stakeholders programs. Fernald supports the DOE-NV stakeholder interests by attending and providing input to Las Vegas area community meetings. Fernald often sends representatives to community meetings to represent the facility and provide prompt responses to Fernald related issues. An example of the value of this service was demonstrated in 1994, when Fernald recorded the first significant shipping accident. A Fernald representative was in attendance at the Nevada Test Site Citizens Advisory Board meeting one week after the incident providing details of the accident and recovery operation. Two weeks after the event, the same representative attended a Nevada Test Site Citizens Advisory Board meeting with photographs and updated information. One month after the incident, a second individual attended a Citizens Advisory Board meeting related to transportation safety to provide first hand accounts of the accident recovery operation. Each meeting attended allowed Fernald the opportunity to personally present the Fernald side of issues and proactively address Nevada resident's concerns for LLW shipment and disposal safety. The result is an informed and accommodating attitude by Nevada Test Site stakeholders toward disposal of Fernald waste.

In addition to attending citizens meetings, Fernald supports DOE-NV studies intended to address other community concerns. Fernald voluntary provides data in support of Nevada Test Site issues such as the Environmental Impact Statement, Transportation Safety Studies, and the Performance Assessment for the disposal facilities. Fernald representatives often review Nevada Test Site documents and provide comments to assist development and implementation of new program policies.

CONCLUSION

As radioactive waste disposal costs continue to increase, maintaining efficient disposal programs becomes more important. The Fernald Environmental Management Project Mission statement... "Together DOE and FERMCO are committed to the safe, least cost, earliest, final cleanup of the Fernald Site, with in applicable DOE Orders, regulations, and commitments in a manner which addresses stakeholder concerns"

...requires that Fernald support the DOE-NV Radioactive Waste Acceptance Program if the mission goals are to be achieved. The Fernald radioactive waste disposal program consistently achieves goals established to demonstrate significant progress toward restoration of the Fernald site.

Fernald realized early in the remediation effort that success can influence future funding considerations. In recognition of this relationship, Fernald dedicates the support required to maintain an effective disposal program with the Nevada Test Site.

Fernald realizes that the Fernald mission is related to the Nevada Test Site mission and that the Nevada Test Site must remain open to off site disposal if the Fernald mission is to succeed. To achieve this objective, Fernald supports the Nevada Test Site program development and maintenance as necessary to address stakeholders concerns. Meeting local community expectations is critical to the success of both sites. Fernald accepts the obligation to do the job right and is dedicated to achieving program results that support this commitment.

Accepting a share of the responsibility for the Nevada Test Site radioactive waste disposal program success cultivates a sense of program ownership at Fernald. This ownership is the result of the recognition that the two sites destinies are closely related. Ownership motivates Fernald to maintaining a high level of performance that is in compliance with the Nevada Test Site waste acceptance criteria. Through consistent compliance with the waste acceptance criteria, a level of confidence and respect develops. The Fernald program maintains a mutually supportive relationship with DOE-NV. This relationship is difficult to establish and even more difficult to sustain. To avoid damaging this relationship, both programs must remain flexible and willing to evolve with changing conditions. Fernald dedicates considerable effort to maintain compliance with NVO-325, Revision 1 and avoid program conflicts.

Establishing effective customer relations is the primary message to be shared by promoting the Fernald program. Success is achieved through learning your customer expectations and then working to meet them. Provided your customer has an equal understanding of your expectations, developing a successful working relationship is natural. Fernald and the DOE-NV Radioactive Waste Acceptance Program Team has developed this relationship. By sharing this information, the message bridges facility and program boundaries. The key point being that by utilizing an innovative mix of dedication and interpersonal skills, Fernald and DOE-NV have implemented a mutually supportive, ergo successful, waste acceptance program in compliance with NVO-325, Revision 1 waste acceptance criteria.

43-2

RISK BASED CONCENTRATION LIMITS FOR DISPOSAL OF TRANSURANIC RADIONUCLIDES AT THE NEVADA TEST SITE

Gregory J. Shott
Reynolds Electrical and Engineering Co., Inc.

Joseph M. Ginanni
U.S. Department of Energy

ABSTRACT

The Area 5 Radioactive Waste Management Site (RWMS) is a Department of Energy (DOE) operated low-level waste disposal site on the Nevada Test Site (NTS). The DOE requires site operators to set concentration limits for disposal of low-level waste based on the results of site-specific performance assessments. Most site operators have followed a procedure similar to that used by the Nuclear Regulatory Commission (NRC) to set generic concentration limits for facilities licensed under 10 CFR 61. A typical approach consists of developing a set of scenarios and

determining the relationship between dose and waste concentration for each scenario. The concentration limits are selected as the lowest derived concentrations that meet the performance objectives. A waste classification system can be developed based on the application of different scenarios to different waste forms or disposal options.

A performance assessment that evaluates five exposure scenarios has been prepared for the Area 5 RWMS. The intruder scenarios were the limiting scenarios for most nuclides, including all the transuranics. The intruder scenarios can be used to support two classes of low-level waste. The most limiting scenario was the intruder-agriculture scenario. This scenario can be used to support a waste class allowing very near surface disposal of unstablized wastes containing transuranic radionuclides up to an activity concentration of 1 105 Bq kg-1 (3 nCi g-1). Higher concentration limits can be justified by taking credit for greater periods of radioactive decay, waste stability or facility design features. For waste disposed below the depth of common construction excavations, concentration limits can be set based on the results of a post-drilling intruder scenario. Using this scenario, concentration limits up to 3.7 105 Bq kg-1 (100 nCi g-1) can be derived for most transuranic radionuclides.

INTRODUCTION

Safe disposal of low-level radioactive waste has been assured in the U.S. by controlling the location of disposal site, the activity concentration of the waste and the waste stability. Transuranic radionuclides have always been a concern because of their long half-lives and high dose conversion factors. Prior to issuance of 10 CFR 61, disposal of transuranic-bearing waste in the near surface was commonly limited to a concentration of 3.7 104 Bq kg-1 (10 nCi g-1), based on the comparative risks of 226Ra in soil (1). With the issuance of 10 CFR 61, the NRC and Agreement States set generic limits for the concentration of transuranic radionuclides in low-level wastes that apply to all disposal sites. For transuranic radionuclides, the limits are 3.7 104 Bq kg-1 (10 nCi g-1) for Class A wastes and 3.7 105 Bq kg-1 (100 nCi g-1) for Class C waste. In contrast, the DOE has allowed disposal site operators to set concentration limits based on the results of site-specific performance assessments. Consequently, various concentration limits are in use at DOE facilities. No DOE sites accept low-level waste with transuranic concentrations exceeding 3.7 105 Bq kg-1 (100 nCi g-1).

WASTE CONCENTRATION LIMITS AND WASTE CLASSIFICATION SYSTEMS

The NRC concentration limits and waste classification system are based on the results of an analysis of the dose received by an inadvertent intruder (2). The inadvertent intruder is defined as an individual that enters the site 100 to 500 years after closure and is unaware that buried radioactive material is present. Most methods of analysis assume that the doses received by an intruder are directly proportional to waste concentration. The NRC did not consider the exposure of members of the general public through pathways such as groundwater when developing the concentration limits. This issue was left open as a site-specific analysis.

The NRC evaluated three intruder scenarios to set the concentration limits. In these scenarios, the intruder is assumed to construct a residence with a basement and reside permanently on the contaminated site. During excavation of the basement, the intruder is assumed to exhume and contact buried waste. The intruder-construction scenario is a

short-term scenario describing the exposure of an intruder during excavation of a basement and construction of a house. The intruder-discovery scenario is a shortened version of the intruder-construction scenario that assumes that the intruder identifies the hazardous nature of the waste and the exposure stops after discovery. The intruder-agriculture scenario covers the chronic exposure that occurs after construction of the house. During excavation of the basement, buried waste is mixed into the excavated soil. The waste is assumed to be indistinguishable from soil. The soil-waste mixture is used as backfill around the foundation and distributed around the residence. The intruder resides continuously on the contaminated site. The intruder is exposed by external irradiation, inhalation and ingestion of food grown in contaminated soil.

The NRC Class A concentration limit is the lowest derived concentration that yields a dose equivalent of 0.005 Sv yr-1 (500 mrem yr-1) in the intruder-construction or intruder-agriculture scenario for an intrusion event occurring at 100 years after closure (1). The intruder-agriculture scenario is limiting for most radionuclides (3). Although this waste class has no explicit depth of burial requirement, the analysis was performed with a 2 m cover (2). Class A waste carries no stabilization requirements. The 3.7 104 Bq kg-1 (10 nCi g-1) limit adopted by NRC was based on the observation that the derived limits for several important transuranic radionuclides were near this concentration and that it had been demonstrated that industry could segregate and manage waste at this concentration level (4).

Higher concentrations could be allowed if facility design could be modified to reduce the potential for intrusion, delay its occurrence or mitigate its impacts. NRC assumed that this could be accomplished by increasing cover thickness, by layering waste, by using engineered barriers or by stabilizing the waste (1). Increasing cover thickness reduces the potential for an intruder to contact waste while digging a construction excavation. Placing lower activity concentration waste on top of high activity concentration waste increases the likelihood that an intruder will recognize that waste is present and stop digging. Engineered barriers perform a similar function of warning the intruder that something unexpected is present. Engineered barriers are useful when shallow groundwater does not allow a greater depth of burial. Waste stabilization was expected to affect site performance and the consequences of inadvertent intrusion. Stabilization was assumed to be beneficial by maintaining cap integrity, thereby minimizing the potential for migration of contaminants out of the unit. Stabilization also reduces the intruder's ability to disperse exhumed waste and makes it more likely that the waste will be recognizable for a longer time.

For the transuranic radionuclides, it was realized that intruder barriers might not remain effective as long as the waste remained hazardous. The NRC noted that not all waste would contained long-lived radionuclides, and that, over time, the average concentration of waste in the disposal unit would decrease with radioactive decay. It was proposed that radioactive decay would allow disposal of individual packages exceeding the concentration limit, since the decay of short-lived waste in surrounding packages would dilute the average concentration in the disposal unit over time. The NRC eventually settled on allowing a factor of 10 higher concentration for Class C transuranic waste, based on the assumption that dilution by lower activity waste would reduce the average

concentration to acceptable levels (4). Therefore, the Class C concentration limit for transuranics was set at 3.7 105 Bq kg-1 (100 nCi g-1). All Class C waste requires a depth of burial of at least 5 m and stabilization. Both requirements are intended to reduce the potential for intrusion and its impacts.

With the issuance of DOE Order 5820.2A (5), DOE allowed site operators to set concentration limits based on the results of site-specific performance assessments. As guidance, DOE issued an example of an approach for developing site-specific waste concentration limits (3). The approach was similar to the NRC approach. A notable addition was that new scenarios were developed to account for site-specific disposal practices. These scenarios, called the drilling and post-drilling scenarios, were developed as intruder scenarios applicable to waste disposed of at depths greater than 5 m. The scenarios assume that a water well is drilled through the waste disposal unit and the drill cuttings are dispersed over the ground around the well head. The drilling scenario is a short-term scenario dealing with the exposure of the drillers. The post-drilling scenario is a chronic exposure scenario dealing with a resident that lives within the area contaminated with drill cuttings. In addition to considering intruder scenarios, a DOE site operator must also consider exposure of the general public when setting waste concentration limits. Doses from the groundwater pathway are usually the most important exposure route for the general public.

One notable difference between concentration limits derived for DOE and NRC facilities is that the limits are based on different times of compliance, dose limits and dose conversion factors. The NRC limits its intruder analyses to a period from 100 to 500 years after disposal, whereas DOE analyses typically evaluate an interval out to 10,000 years. The DOE uses the International Commission on Radiation Protection (ICRP) recommendations in Publications 26 and 30 (6,7). With adoption of the new recommendations, the DOE dose limit for the intruder was set at 0.001 Sv yr-1 (100 mrem yr-1) rather than the 0.005 Sv yr-1 (500 mrem yr-1) used by NRC. The dose conversion factors used by each Agency were developed using different methodologies and some differences exist.

DEVELOPMENT OF NTS WASTE CONCENTRATION LIMITS

The Area 5 RWMS is a shallow land burial waste disposal facility for DOE generated low-level radioactive waste. The Area 5 RWMS has disposed of NTS-generated waste since 1961 and DOE low-level waste generated nation-wide since 1978. A performance assessment has recently been prepared for the Area 5 RWMS (8). It evaluates two scenarios for exposure of the general public and three intruder scenarios. Results from these analyses can be used to develop site-specific waste concentration limits.

Site-specific issues affecting the derivation of waste concentration limits may include waste form, disposal facility design and environmental conditions. At the Area 5 RWMS, environmental conditions are probably the most important site specific issue. Waste forms received at the Area 5 RWMS are usually not stabilized. The Area 5 RWMS performance assessment takes no credit for waste stability and assumes that the waste is immediately available for transport. In addition, the facility uses no liners or engineered barriers. Waste is landfilled in shallow unlined trenches and covered with 2.4 m of native alluvium. A closure cap will be placed on top of the 2.4 m alluvium cover.

Many environmental conditions at the Area 5 RWMS are advantageous for waste disposal. Located in an area that is transitional between the

Mohave and the Great Basin Deserts, the site receives little rainfall and is subject to high evapotranspiration. Potential evapotranspiration is estimated to be 14 times greater than the annual precipitation of 12 cm (8). Under the current climatic conditions, downward flow of infiltrating water through the waste disposal cells to the aquifer is not believed to occur. In the unlikely event that recharge were to occur, the thick vadose zone (235 m) and low water contents would lead to unretarded solute travel times approaching 1 106 years (9).

The arid nature of the site also reduces the potential land uses. Permanent surface water does not occur near the site. Runoff occasionally occurs in ephemeral stream channels after intense or prolonged rainfall. The infertile soils, arid climate and extreme temperatures limit the potential agricultural uses of the site. The great depth to groundwater, 240 m, makes irrigation economically unfeasible. The difficulty of obtaining water also reduces the potential for residential or industrial development. There are no known mineral or petroleum resources near the site. Sites with similar resources in the region remain mostly undeveloped.

Scenarios for exposure of the general public were selected based on the most common land use patterns observed at similar locations in southern Nevada. Two scenarios were identified, a transient visitor scenario and an off-site ranch scenario. The transient visitor scenario assumes that the general public is exposed while visiting or occupying the site on a temporary basis. Exposure occurs through external irradiation and inhalation of suspended soil. The off-site ranch scenario assumes that a ranch has been established at the closest site with surface water. Range-fed cattle from the ranch are assumed to have access to the site. Residents at the ranch are exposed through contaminated soil transported from the site to the ranch by atmospheric dispersion and by ingestion of beef and dairy products from cattle grazing at the site. All scenarios for exposure of the general public were coupled to a release model for the intact disposal site. This model estimates the release of contamination to surface soils based on uptake by the native flora and the burrowing activities of invertebrates.

A different approach was taken for development of intruder scenarios. DOE guidance is to develop site-specific intruder scenarios (10). However, developing scenarios for low probability events, such as intrusion, based human behavior 10,000 years into the future is probably beyond what can be defended by science (11). The common land uses current observed do not include activities leading to inadvertent intrusion. Therefore, the approach used to develop scenarios for the public, selecting of the most common land uses observed, leads to the conclusion that no intruder scenarios are appropriate for analysis. Rather than attempt to develop and defend site-specific intruder scenarios, the selected scenarios were those widely used in performance assessments (1,2,3). These scenarios were assumed to be hypothetical events analyzed to set conservative waste concentration limits. The scenarios considered were the intruder-construction, intruder-discovery and intruder-agriculture scenarios used by the NRC (1,2) to develop 10 CFR 61 and the drilling and post-drilling scenarios proposed by Kennedy and Peloquin (3) for DOE facilities using deep burial. The scenarios were made site-specific by eliminating any features that were physically impossible. Physically impossible features such as aquatic food pathways or groundwater pathways were eliminated. Models describing the remaining features were parameterized with best

estimate values for a Mohave Desert site. Two scenarios, the intruder-agriculture and the post-drilling scenario were found to be limiting. The intruder-agriculture scenario was limiting for wastes disposed of in the near surface. The post-drilling scenario was limiting for waste disposed of below the depth of common construction excavations.

Waste Concentration Limits

The results from each scenario can be used to set concentration limits. The waste concentration limit is the lowest concentration at the time of disposal that causes one of the performance objectives to just be exceeded. A waste classification system can be developed from the analysis of scenarios with different waste forms or disposal methods. All transuranic radionuclide concentrations were limited by the intruder-agriculture scenario or the post-drilling scenario, depending on the depth of burial.

The analysis result required to set the concentration limit is the scenario dose conversion factor. The scenario dose conversion factor is the total effective dose equivalent at the time of intrusion divided by the activity concentration of the radionuclide at the time of intrusion. The scenario dose conversion factor includes the dose from short-lived progeny than can be assumed to be in equilibrium before the end of institutional control. The concentration limit should also include the dose from any progeny produced after disposal that can not be assumed to be in equilibrium. This requires defining a decay factor that is the maximum activity concentration of the progeny within the compliance interval resulting from a unit activity concentration of the first member of the chain. The decay factor accounts for the effects of radioactive decay and ingrowth only. After (12), the decay factor for the jth member of the chain, DFj, is given by

Eq. 1

where li is the decay constant of the ith radionuclide, t is the time and where

Eq. 2

and

Eq. 3

The time, t, is the time within the compliance interval, 100 to 10,000 years, when DFj reaches a maximum.

An expression for the concentration limit that includes the dose from all progeny that are produced after disposal can be written. The concentration limit is

Eq. 4

where CL,i is the concentration limit of nuclide i (Bq m-3), HL the dose limit (Sv yr-1), DCFj the scenario dose conversion factor for nuclide j (Sv m3 Bq -1 yr-1) and DFj the decay factor of radionuclide j (dimensionless).

The scenario dose conversion factors for transuranic radionuclides range over three orders of magnitude (Table I). Neptunium-237 had the highest factor because of its high plant-soil concentration factor and relatively high ingestion dose conversion factor. The lowest factor was predicted for 241Pu because of its limited bioavailability and relatively low internal dose conversion factor. Many of the factors are similar because of the dominance of the inhalation pathway and similar inhalation dose conversion factors. The intruder-agriculture scenario yields the highest factors, approximately two hundred times greater than the post-drilling

scenario. This is mostly attributable to the higher surface soil concentrations estimated for the intruder-agriculture scenario.

Table I

Concentration limits derived from analysis of an intruder-agriculture scenario are compared in Table II. The NRC limits were developed by analysis of an intruder-agriculture scenario at 100 years using a dose equivalent limit of 0.005 Sv yr-1 (500 mrem yr-1) and NRC dose conversion factors (1,13). The waste concentration limits of Kennedy and Farris (14) were developed as a draft DOE waste classification system. These concentration limits are based on the NRC methodology and parameters, but use a dose limit of 0.001 Sv yr-1 (100 mrem yr-1) and DOE dose conversion factors based on ICRP methodology (6,7). The Kennedy and Ferris analysis and the NTS analysis for Area 5 are similar and the concentration limits are similar for most nuclides. The Kennedy and Farris limits are derived for intrusion at 100 years and the NTS limits are derived for intrusion at the time within 200 to 10,000 years when the maximum dose will occur. The different times of compliance partially explain the large differences for the short-lived nuclides 244Cm (t = 18.1 yr) and 241Pu (t = 14.3 yr). The differences between the Area 5 RWMS and the NRC intruder-agriculture limits are largely explained by the factor of five difference in the dose limits, with the exception of 237Np.

Table II

The upper limit of transuranic waste concentrations is compared in Table III. The upper limit for NRC-licensed facilities is the Class C limit, 3.7 105 Bq kg-1 (100 nCi g-1). In Table III, the NRC limit in units of activity per unit mass have been converted to a range of values in units of Bq m-3 by assuming that waste stream densities can vary between 1.0 and 2.3 g cm-3. The NRC Class C limit was developed for an intruder-agriculture scenario and assumed intrusion into a stabilized waste form at 500 years. The concentration limits were subsequently increased by a factor of ten to obtain the final limit (4). For transuranic radonuclides, this factor of ten increase accounts for dilution with lower activity concentration waste streams. The Kennedy and Farris limits were derived by the same method used by the NRC, but again use the lower dose equivalent limit and different dose conversion factors. The NTS Area 5 RWMS limits are derived from analysis of a post-drilling scenario occurring between 200 and 10,000 years. The NRC Class C limits and Kennedy and Farris limits are very similar since the same method was used. The post-drilling scenario used at NTS supports disposal of higher activity concentrations of transuranics radionuclides. With the exception of 237Np, the post-drilling scenario supports disposal of transuranic radionuclides up to the 3.7 105 Bq kg-1 (100 nCi g-1).

WASTE FORM AND DISPOSAL CONFIGURATION

In addition to the waste concentration limit, a waste classification system should stipulate the waste form and waste disposal configuration. These should match the assumptions made in the analysis. The concentration limits derived for the Area 5 RWMS assume no special waste form. Considering factors relevant to intruder scenarios only, these waste concentration limits are potentially for unstabilized waste classes. However, waste stabilization may have benefits that are not apparent in an intruder analysis. Waste stabilization is expected to enhance performance by reducing infiltration and by reducing the potential for dispersion after intrusion. The NRC considered stabilization to be necessary because caps engineered to reduce

infiltration will become less effective if subsidence of unstabilized waste causes disruption of the cap's impermeable layers (1). However, at an arid site such as the NTS, the natural hydrologic conditions may be sufficient minimize infiltration. Evapotranspiration is so much greater than precipitation that impermeable or low permeability layers are thought to be unnecessary. Therefore, stabilization to prevent subsidence may be unnecessary if maintaining the integrity of impermeable layers in the only criterion. Large scale subsidence, however, may allow the collection of run-on and ponding of water. This may allow infiltration to significant depths even at an arid desert site. Studies are planned to evaluate this potential issue. Stabilization may still be desirable to reduce the dispersability of the waste in the near term. This is not as important for the transuranic radionuclides because the half-lives are usually longer than the life time of the waste form. Therefore, the importance of stabilization for transuranic waste streams remains uncertain until hydrologic modeling of run-on into a subsided cap is completed.

Two classes of waste are being considered for the Area 5 RWMS. Class I waste is based on the intruder-agriculture limits in Table II. The NTS Class I limits are applicable to the disposal of unstabilized waste below a depth of 2.4 m in a trench of any thickness. The Class II concentration limits are the lesser of the post-drilling limits in Table III or 3.7 105 Bq kg-1 (100 nCi g-1). The NTS Class II waste concentration limits are applicable to the disposal of wastes in a 5 m thick layer at least 4 m below the surface.

The outcome of hydrologic studies of infiltration in subsided trenches will determine if the two waste classes require stabilization. If both waste classes have the same stabilization requirements, then they could be layered in the same trench. For a typical Area 5 RWMS disposal cell, Class I waste could be disposed of at any level in the trench and Class II waste would have to be restricted to the lower 2 m of the trench.

Table III

CONCLUSION

Waste concentration limits and a waste classification system has been proposed for the Area 5 RWMS. The derived limits are based on intruder scenario analyses as widely practiced in low-level waste management. These analyses assure that transuranic waste containing up to 3.7 105 Bq kg-1 (100 nCi g-1) can be disposed of in the near surface of the Area 5 RWMS and that the performance objectives of DOE Order 5820.2A will be meet.

THE NEVADA TEST SITE (NTS) AS A WASTE DISPOSAL SITE: A HISTORICAL PERSPECTIVE

Max R. Dolenc
Leroy G. Duran
Merl K. Schwartzwalter
Bruce D. Becker

ABSTRACT

The NTS is the location of two low-level waste (LLW) disposal sites which serve both the NTS and the U.S. Department of Energy (DOE) complex. The Area 5 Radioactive Waste Management Site (RWMS) is the location of a standard shallow land disposal operation, where packaged containers of waste are stacked neatly in excavated pits and trenches. LLW, mixed waste (MW), transuranic (TRU) waste, and classified LLW are handled at Area 5. The Area 3 RWMS is the location of the atypical disposal facility, where underground nuclear test subsidence craters are used for the disposal of containerized bulk waste. These two waste sites have received over 500,000 m3 (17,000,000 ft3) of LLW since 1978, when a managed waste program was instituted.

Annual waste volumes have fluctuated throughout the 18 year history from 9,600 m3 (340,000 ft3) to 81,400 m3 (2,875,000 ft3). In FY 1995, a total of 25,063 m3 (885,000 ft3) of LLW (917 shipments) was received. This accounted for approximately 85 percent of all waste that was shipped in FY 1995 from all the DOE facilities disposing waste offsite. To accommodate future waste, an additional new cell was excavated in FY 1995. This pit measures 305 m (1,000 ft) long, 46 m (150 ft) wide, and 6.7 m (22 ft) deep, having a disposal capacity of approximately 70,800 m3 (2,500,000 ft3). The cost of excavation was approximately $445,000. This paper presents a review of the history and evolution of the NTS waste sites as major contributors for handling between 30 and 40 percent of the DOE complex LLW.

BACKGROUND AND INTRODUCTION

In 1978, DOE/Nevada Operations Office (NV) designated two areas on the NTS as RWMSs: the Area 5 RWMS and the Area 3 RWMS. The Area 5 RWMS is located on an alluvial fan within a dedicated 296 hectare (732 acre) site in the southeast section of the 3,500 km2 (1350 mi2) NTS. The disposal cells are standard, excavated, shallow-land burial pits and trenches. The Area 3 RWMS, situated approximately 24 km (15 mi) north of the Area 5 RWMS, utilizes subsidence craters which were the result of underground nuclear tests. Adjacent craters are combined by excavating out a common wall to form the cell. The structure is then completed by shaping the cell, configuring access roads into the craters, and maintaining a level stacking surface. Fill material is obtained from the area between the nested pair. Currently, seven craters over a 20 hectare (50 acre) area have been dedicated for use as disposal cells in the Area 3 RWMS.

The two NTS sites are situated in remote locations within two different closed basins, have deep groundwater tables (thick unsaturated zones), and experience an arid climate. The Area 5 RWMS is located 238 m (780 ft) above the water table; Area 3 is approximately 488 m (1600 ft) above the water table. The locations receive between four and six inches of precipitation a year. Recharge to the aquifer has been found to be virtually nonexistent (1). Waste practices have also been improved from those of earlier waste disposal sites. For example, 2.4 m (8 ft) of soil

cover is emplaced over the waste in active disposal cells to bring it to 1.2 m (4 ft) above natural grade, as compared to the typical standard 1.8 m (6 ft) cover. This additional soil cover keeps moisture from reaching the waste. Other similar management improvements have been made to ensure the maximization of safety to both the employee, as well as the general public.

Assistance is provided to Area 3 and Area 5 RWMS operations personnel by a technical support team who ensure Federal, state, and DOE regulatory requirements are met. This support includes planning, budgeting, engineering, technical support, reporting, and computer assistance. Technical support includes maintaining the Safety Analysis Report, performance assessments, Part B permitting, waste management plan, program management plans, budget documents, design reports, etc. A key support effort is provided by the DOE/Radioactive Waste Acceptance Program team who review waste certification programs of NTS generators. Waste acceptance criteria for the site are outlined in the "Nevada Test Site Defense Waste Acceptance Criteria (WAC), Certification, and Transfer Requirements," NVO-325, Rev. 1, June 1992. This document outlines the specific criteria and application process for disposal of waste at the NTS. Approval to dispose of waste at the NTS is granted only after the waste has been certified as meeting the WAC. In FY 1995, there were 14 offsite waste generators and two onsite generators disposing over 50 approved waste streams.

The operations unit is comprised of approximately 36 professional, clerical, radiological, and craft personnel. This staff is responsible for waste receipt, inspection of waste packages, reviewing shipping papers, off-loading trucks, stacking waste, recording locations using barcode readers, and covering the waste. Additional duties include preparation of radioactive waste permits, billing, and record keeping. Personnel also maintain the sites, excavate new pits and trenches, maintain equipment, support site monitoring, provide placement of concrete monuments to designate pit locations, and any other activities which ensure the smooth operation of the sites.

HISTORY

The decision to use two sites evolved from the early use of the NTS as a nuclear testing facility. As early as 1961, when radioactive waste was accumulated from testing work on the NTS, certain areas were designated as "Radioactive Waste Storage/Management Locations." Two of those areas became the present RWMSs (2).

In 1974, the NTS accepted for storage, TRU waste from Lawrence Livermore National Laboratory. In 1976, a high-specific-activity (HSA) waste shipment was received from Mound Laboratory for disposal. These events lead to the decision that DOE could use the NTS as a waste disposal location for facilities that could not dispose waste at their own sites. In 1978, detailed studies of the NTS environment and the use of this site for waste disposal became official. Fiscal support was obtained from DOE to fund a small staff and to initiate the construction of early pits and trenches. A chargeback fee was established for all waste generators.

Waste activities have increased over the years. In the 1980s, a major cleanup of the atmospheric test locations began on the NTS. Waste from tower shot locations, which included contaminated cable and equipment, soil, and other contaminated debris, was removed and disposed in the Area 3 RWMS. This task was called the Waste Consolidation Project (3). By 1988, this waste had completely filled the first nested pair of

subsidence craters in Area 3 (Disposal Unit U3ax/bl) and the unit was ready for final closure. This single disposal unit contains 219,914 m3 (7,766,197 ft3) of waste contaminated with 1211 curies of activity. However, one shipment of this waste, received in 1980, contained 1024 curies of tritium. Since 1989, all waste in the Area 3 RWMS has been placed in a second set of disposal craters, the U3ah/at unit. Although the waste consolidation project is no longer in progress, the current unit is used to dispose containerized bulk waste, typically received in transportainers. Large pieces of unpackaged waste, such as machinery, are considered for disposal there. At the end of FY 1995, over 311,500 m3 (11,000,000 ft3) of LLW had been disposed in the Area 3 RWMS. A calculation of the waste received being decayed to the year 2100 shows that only 166 curies of waste would exist in the Area 3 RWMS (this calculation omits daughter-product formation).

The Area 5 RWMS has also served the DOE complex as a waste disposal site using conventional shallow land burial practices. LLW and MW (under interim disposal authority) are disposed of at the site; TRU and MW are also stored at the site. The Area 5 RWMS has a 4.4 hectare (11 acre) portion dedicated to classified LLW and a number of Greater Confinement Disposal (GCD) boreholes. These GCD cells measure 3 to 3.7 m (10 to 12 ft) in diameter and are 36.6 m (120 ft) deep. This disposal methodology was used from 1984 to 1989 for the disposal of HSA waste. In 1989, the state of Nevada declared the GCD boreholes to be injection wells; they have not been used since. The lower 15.2 m (50 ft) of the GCD borehole contained the waste topped with a 21.3 m (70 ft) soil cover. Area 5 has the capability to dispose waste in a deeper pit, Pit 6, to a depth of 14.6 m (48 ft). This deeper cell was specifically designed to handle a thorium waste stream which requires deeper burial due to the radon flux. As the large volumes of waste being received at the NTS facilities filled the major disposal cells in use, the construction of a new LLW pit was necessary during FY 1995. The excavation of Pit 5 started on January 23, 1995, and was completed February 23, 1995, removing 166,683 m3 (218,000 loose yd3) of dirt. The bottom of the pit was plated with 2,600 m3 (3,400 yd3) of Type II soil. The floor of the pit measures 305 m (1,000 ft) long, 46 m (150 ft) wide, and 6.7 m (22 ft) deep, with all walls having a 1:1 slope, or a 45 degree angle. Included in the excavation was an access ramp built on the south end of the pit for a truck entrance into the pit. The pit has an estimated disposal capacity of approximately 70,800 m3 (2,500,000 ft3). At the current rate of waste receipt, this pit should provide disposal capacity for approximately five to six years. The cost of excavating this facility was $445,000 or $2.18 per cubic yard of soil removed from the cell. The pit was put into service on May 15, 1995.

The Area 5 RWMS receives solid waste containerized in wooden boxes, metal boxes, and 208 or 322 liter (55- or 85-gallon) steel drums. The boxes are stacked to form walls which are used to make nests for the stacking of drums. Waste is stacked in a tiered staircase configuration to within 1.2 m (4 ft) of the natural grade of the surface. A cover of soil 2.4 m (8 ft) thick is emplaced over the waste prior to developing a final closure cap.

At the end of FY 1995, over 190,000 m3 (over 6,750,000 ft3) of LLW had been disposed in the Area 5 RWMS. This volume includes waste in GCD boreholes and in the classified area. The total curie count amounts to 7,311,972 curies, which, decayed to the year 2100, amounts to

approximately 42,870 curies. Most of those curies are fission products and uranium/thorium isotopes.

There is approximately 612 m3 (21,610 ft3) of mixed TRU, received from 1974 through 1990 stored on the TRU storage pad. Since the TRU waste storage pad has not been granted interim status, the waste is being stored under a settlement agreement with the state of Nevada.

Between September 1987 and May 1990, over 5,664 m3 (200,000 ft3) of MW was disposed in Pit 3 under interim status authority. MW currently being generated on the NTS is being stored at the Area 5 RWMS on the TRU waste storage pad, also under an agreement with the state of Nevada.

STATISTICS

The comparative waste statistics presented in the following section have been taken from the latest available version (December 1995), "Integrated Data Base Report-1994: U.S. Spent Nuclear Fuel and Radioactive Waste Inventories, Projections, and Characteristics." This document is updated annually and provides the DOE complex with information, as well as information from commercial disposal sites.

At the end of 1994, a review of the NTS and DOE waste disposal records indicated that the two NTS waste facilities have received over 16 percent, by volume, of all DOE complex waste ever generated, and over 10.7 percent of all waste, considering both commercial and DOE (Fig. 1). Currently 95 percent of all curies received at the NTS have been tritium (Fig. 2). When analyzed by waste volume, however, nearly 75 percent of the waste is fission products and uranium/thorium. This is due to the large volume of NTS and Fernald waste, both of which contain fission products and uranium/thorium. At the end of 1994, over 9.8 million curies of waste had been accepted at the NTS.

Fig. 1

Fig. 2

Figure 3 is a plot of total waste volume, by year, with a curve of offsite-generated waste volume imposed upon this figure. This curve shows the major NTS cleanup activity noted earlier, which occurred through 1989 (the "All Waste" volume area less the "Offsite Waste" curve). The curve also indicates a break from trend in 1990 and 1991. This decrease in waste volume was a result of the 1990 Tiger Team assessments which impacted the NTS. Disposal capability was suspended to implement the waste acceptance criteria. The annual volume of waste disposed at the NTS, as compared to that of the entire DOE Complex shows that the NTS is currently handling about 30-40 percent of all DOE waste (Fig. 4). In 1994, the NTS accepted nearly 30 percent of all radioactive waste which was disposed from both commercial and DOE sites.

Fig. 3

Fig. 4

In FY 1995, a total of 25,063 m3 (885,000 ft3) of LLW (917 shipments) was received. This accounts for approximately 85 percent of all waste shipped offsite during the fiscal year from all DOE facilities that dispose waste offsite. Similar results were noted in FY 1993 and 1994.

CONCLUSIONS

When considering where to site a waste disposal facility or which disposal methodology to use, the primary focus should be to prevent the waste from affecting the environment and exposing the public. Both the Area 3 and Area 5 RWMSs meet that criteria. The sites are located in arid regions, with an average annual precipitation between 10 and 15 centimeters (4 and 6 in) a year. Depth to the water table is 488 m (1600

ft) and 238 m (780 ft), respectively. Studies have shown that there is virtually no recharge from the surface to the water table at the location of the RWMS's. A strict waste acceptance criteria prevents the introduction of free liquids into the waste, and requires strong waste packaging. Each one of these features alone would enhance any facilities ability to keep the hazardous material from reaching the environment, but together, as they are found at the NTS, these physical and administrative barriers provide a waste disposal condition that is quite possibly second to none anywhere in the world.

ABSTRACT

Landfill cover designs described in the Resource Conservation and Recovery Act (RCRA) technical guidance are primarily intended for humid environments. These covers are not necessarily optimal, or even appropriate, for use in arid regions such as the Nevada Test Site (NTS). The Department of Energy, Nevada Operations Office initiated the Integrated Closure Program to satisfy the need for final closure of waste disposal units at the NTS. The program will achieve the following goals:

develop and implement a cover design appropriate for use in an arid environment while meeting the intent of RCRA guidance,

permanently close existing and future waste disposal units at the NTS Area 3 and Area 5 Radioactive Waste Management Sites,

and protect public health and the environment using the best available technology.

In an Alternative Evaluation Study a cover system was developed for an inactive disposal unit named U3ax/bl. This cover system consists of two major components: a cover design consisting of a rooting and storage

layer, a geosynthetic clay liner (GCL), and a soil cement base; and a perimeter dike design consisting of soil cement (up-gradient) and rock riprap (down-gradient).

A typical RCRA cover design consists of a multi-layered system sloped at 3 to 5%. This slope is intended to promote water drainage from the cover surface. The U3ax/bl cover system differs from the typical RCRA design in several ways. An uppermost rooting and storage layer (native alluvium) provides a suitable habitat for native plants and stores moisture from infrequent precipitation events until evapotranspiration can remove it from the cover. Under the rooting and storage layer is a hard layer consisting of a GCL and soil cement intended to control water infiltration in extremely wet years as well as prevent biointrusion. The soil cement layer will also resist minor subsidence. A soil cement perimeter dike placed on the up-gradient side of the cover provides protection from run-on (flow draining onto the disposal unit). The down-gradient perimeter dike incorporates rock riprap to prevent erosion from precipitation run-off.

The U3ax/bl cover system, with a minimum design life of 500 years, will control erosion, limit infiltration, enhance evapotranspiration, function with minimum maintenance, limit upward vapor transport, discourage biointrusion, and accommodate minor subsidence. Thus, this cover system is better suited for use in an arid environment than a typical RCRA cover.

BACKGROUND INFORMATION

The Department of Energy, Nevada Operations Office (DOE/NV) has made the closure of U3ax/bl a high priority. U3ax/bl is an inactive mixed waste disposal unit located at the Area 3 Radioactive Waste Management Site (RWMS) on the Nevada Test Site (NTS). Because several closures are planned at both the Area 3 and Area 5 RWMSs, the Integrated Closure Program was initiated to develop a conceptual cover design which is transferable to similar sites saving time and money. Under the Integrated Closure Program, an Alternative Evaluation Study (AES) was conducted (July, 1994) to select a preferred cover design for U3ax/bl, to build consensus among various DOE/NV contractors, and to leave a record justifying major decisions in conceptual design. An AES is a modified form of value engineering designed to reach a technical consensus among the participants.

The goal of the Integrated Closure Program is to permanently close existing and future waste disposal units at the NTS Area 3 and Area 5 RWMSs, using the best available technology to protect public health and the environment. Because the disposal units fall under multiple regulations, an integrated approach is needed to ensure that similar wastes in similar environments receive similar closures. The closure philosophy consists of enhancing favorable natural processes, avoiding unjustifiable design inconsistencies between units, complying with applicable regulations, following standard industry practice, and applying a level of effort that is commensurate with other DOE facilities yet does not set unreasonable precedent.

WHY RCRA TECHNICAL GUIDANCE IS NOT APPROPRIATE FOR ARID ENVIRONMENTS

Conceptually, ground water is protected under Title 40 Code of Federal Regulations (CFR) Part 264 by the dual-pronged approach of prevention and correction. Under the less stringent Part 265, prevention is the primary method of protection (1). In support of these regulations, the Environmental Protection Agency (EPA) developed guidance documents that

present design parameters that comply with the requirements of 40 CFR Parts 264 and 265 (2). Covers described in the RCRA technical guidance are primarily intended for environments where precipitation exceeds evapotranspiration rates. These covers are not necessarily optimal for use in arid regions such as the NTS where evapotranspiration rates greatly exceed precipitation. The main premise in this guidance is prevention of contaminant migration through the control of run-off and placement of low permeability barriers limiting infiltration.

Recommended cover components from RCRA technical guidance include:

vegetation or surface armor on a soil layer (minimum 60 cm thick),

filter layer, drainage layer (minimum 30 cm thick), and flexible membrane liner (FML) and low permeability soil layer (minimum 60 cm thick) (2).

Optional cover components from RCRA technical guidance include:

biointrusion barrier (cobbles),

gas vent layer, and

geosynthetic filter materials (2).

RCRA requires a 30 year monitoring and maintenance period under the post-closure care and use of property section in the technical guidance (40 CFR Part 265.117). The U3ax/bl cover system has a minimum design life of 500 years which exceeds the RCRA time period. The 500 year minimum design life meets the requirements for cover longevity prescribed in DOE orders (DOE 5820.2A). Several DOE and commercial low-level waste disposal facilities in the arid western United States use a cover design life on the order of 500 years (3).

Typical conditions at disposal sites in humid regions include:

precipitation exceeds evapotranspiration (the potential for deep recharge exists),

net water movement is downward (leachate migration is toward the water table),

the water table is shallow (the distance a contaminant must travel to reach the uppermost aquifer is relatively small), and

the water table has a significant gradient that results in lateral flow (should contaminants reach the uppermost aquifer they will continue to migrate down-gradient) (4).

Conditions at the Area 3 and Area 5 RWMSs on the Nevada Test Site include:

evapotranspiration exceeds precipitation (the potential for deep recharge is small),

net water movement is upward (leachate migration is away from the water table) (4),

the water table is deep (approximately 490 m in Area 3 and 250 m in Area 5), therefore the distance a contaminant must travel through the vadose zone to reach the uppermost aquifer is large (5,6),

the upper aquifer is contained within a closed basin which does not have a gradient that results in significant lateral flow (should contaminants reach the uppermost aquifer they will continue to migrate down-gradient very slowly) (4).

Over the long-term, erosion is a bigger threat to cover integrity and performance than infiltration based on the arid environment and storm characteristics at the U3ax/bl disposal unit. U3ax/bl is located in Yucca Flat and receives an annual mean rainfall of 15.9 cm with an annual evaporation rate of 180 cm (7). This indicates that evapotranspiration is the strongest influence on the moisture distribution within the upper

alluvium. Precipitation is highly variable in Yucca Flat. Intense, isolated storms occur in the summer and long duration, low intensity storms occur in the winter (8). Between storms there are long dry periods with high evaporation rates. Relating this weather sequence to long-term closure cap performance, precipitation run-on and run-off from the high intensity storms would have the largest deleterious effects on a cover due to the erosion potential. RCRA technical guidance recommends a final cover slope of 3 to 5% to promote run-off (2). This approach, while reducing infiltration, increases the cover erosion potential thereby increasing maintenance costs unnecessarily.

THE ALTERNATIVE COVER DESIGN

In recognition that conditions vary from site to site, RCRA technical guidance and 40 CFR Part 265 allow for alternative cover designs provided long-term performance equivalent to the recommended designs is met. In meeting these performance objectives, the cover design for U3ax/bl uses an alternate approach to control erosion, limit infiltration, limit vapor transport, enhance evapotranspiration, prevent biointrusion, and accommodate minor subsidence (9). Figures 1 and 2 show the U3ax/bl cover system conceptual model.

Fig. 1

Fig. 2

The principal differences between this cover alternative and RCRA recommended designs are:

- greater thickness (1.5 m verses 60 cm) of the upper soil layer (rooting and storage layer) which provides storage capacity for water,
- no drainage layer or low permeability FML,
- low permeability layer provided by a geosynthetic clay liner (GCL) and soil cement, and
- final slope of 0.5% instead of the RCRA recommended 3 to 5%.

The key adaptation of the cover to arid areas is the uppermost 1.5 m thick rooting and storage layer consisting of native alluvium. This layer provides a suitable habitat for plants and acts as a "sponge" to store infiltrating water until the plants and evaporation can recycle the water back to the atmosphere. The relatively flat cover slope (0.5%) will reduce erosion from cover run-off. A lateral drainage layer, as seen in many RCRA cover designs, is not needed since the rooting and storage layer provides sufficient storage for all infiltrating precipitation. The lower cover layers, consisting of a GCL and a 1 m thick soil cement layer, collectively function as a low permeability barrier to downward infiltration and upward vapor transport, as well as deter biointrusion. The soil cement layer will also resist minor subsidence. The rooting and storage layer will control infiltration in most years, except in extremely wet years when the GCL and soil cement will become the primary infiltration barrier. In general, rigid layers such as soil cement may be susceptible to cracking. The GCL is included primarily to bridge over small cracks, but also as a redundant low permeability barrier. Tables I and II present a functional analysis of the cover layers and perimeter system, respectively. The use of durable, natural materials which are available on site will promote longevity, reduce maintenance, simplify construction, and lower costs.

Table I

Table II

HOW THE ALTERNATIVE COVER MEETS RCRA REQUIREMENTS

The requirements from RCRA 40 CFR Part 265.310 are:

Provide long-term minimization of migration of liquids through the closed landfill.

Function with minimum maintenance.

Promote drainage and minimize erosion or abrasion of the cover.

Accommodate settling and subsidence so that the cover's integrity is maintained.

Have a permeability less than or equal to the permeability of any bottom liner system or natural subsoils present (10).

Although the proposed cover design does not follow the specific design guidelines for a typical RCRA cover, the U3ax/bl cover design will meet the intent of RCRA 40 CFR Part 265.310. The proposed cover design meets RCRA requirements by the following:

Migration of liquids to the water table is prevented by the GCL and soil cement layers.

Maintenance is minimized by reducing the cover slope to 0.5%. This will decrease erosion of the cover caused by run-off.

The soil cement layer accommodates minor settling and subsidence.

The soil cement up-gradient perimeter dike resists run-on erosion while plants and a relatively flat cover (0.5%) resist run-off erosion.

Permeability requirements are met because the hydraulic conductivity of the GCL and the soil cement are greater, by at least several orders of magnitude, than that of the native alluvium below U3ax/bl.

ALTERNATIVE COVER DESIGN AND ENGINEERING STUDIES

A series of engineering activities have been or are currently planned to be conducted in support of the U3ax/bl conceptual cover design. These efforts will provide an engineering basis for the design of a closure cap that will meet or exceed RCRA requirements. Currently a Conceptual Design Document (CDD) is being prepared based on the preferred cover alternative from the AES. Formal value engineering studies under the direction of a certified value specialist will follow the CDD. Cost estimates will be prepared for improving functional value of the currently planned design features. Both up-front and life-cycle considerations will be addressed. Detailed cover design is the final step in the process before construction.

CONCLUSION

A RCRA alternative cover design was developed at an Alternative Evaluation Study and consists of vegetation, a rooting and storage soil layer, a GCL, a soil cement hard layer, and a soil cement (up-gradient) and rock riprap (down-gradient) perimeter dike. The cover will provide an increased level of protection against run-off erosion, run-on erosion, biointrusion, fluid migration, and minor subsidence. The cover design was developed specifically for an arid environment where evapotranspiration rates exceed that of precipitation. This design, while differing from the RCRA technical guidance, meets the requirements of 40 CFR Part 265.310 by utilizing techniques which are appropriate to arid site conditions, while enhancing long-term performance.

ABSTRACT
Six unexploded ordnance (UXO) disposal sites were remediated at the Tonopah Test Range. Each site contained various types of UXO and miscellaneous debris associated with range cleanup operations. Several

methods of waste minimization and recycling were used to assist in the clean up of the six ordnance disposal sites. Clean up operations at all six sites were performed at the same time to save time and money. Several process changes and material substitutions were made during the course of operations to minimize waste volume.

Using process knowledge, Explosive Ordnance Disposal (EOD) specialists knowledge, the RCRA scrap metal exclusion, and on-site radiological screening, items removed from the ordnance sites were segregated into recyclable, non-recyclable debris, and potentially hazardous waste piles. The above techniques greatly minimized the potential for cross contamination and mixed waste generation especially at two of the nine sites where depleted uranium was detected within some of the scrap being removed at one and soil bags of unknown origin were found at another.

All UXO were detonated to render them safe, demilitarize their appearance, and to remove inert filler so that the scrap ordnance could be recycled. Volume reduction, in the form of compacting, reduced trucking requirements substantially as well as the final disposition of the compacted material (landfill disposal vs. recycling). Based on the types of metals being recycled (i.e., aluminum, steel), transportation and disposal costs were recovered.

By the use of onsite contractors excess explosives (i.e., Composition C-4), EOD specialists were able to assist them in disposal of their explosives and cut back on the purchasing of additional explosives for demilitarization operations. Due to the various waste minimization and recycling practices, ordnance clean up and scrap removal from the six ordnance disposal sites were completed within five months. The overall project cost savings was approximately $200,000.

INTRODUCTION

The Tonopah Test Range (TTR) is a research facility with the mission to test the mechanical operation and delivery systems for nuclear ordnance and other defense-related projects. Nuclear detonations do not occur during testing because only mock nuclear ordnance is used. Sandia National Laboratories (SNL), under the authority of the U.S. Department of Energy, Albuquerque Operations Office (DOE/AL), has had historical responsibility for the operation of the facility. Through a Memorandum of Agreement with DOE/AL, primary responsibility for environmental restoration activities associated with TTR has been transferred to the DOE Nevada Operations Office (DOE/NV); however, DOE/AL maintains an oversight role of range activities (DOE/NV, 1995).

The TTR is located in Nye County, Nevada, on the northern portion of the Nellis Air Force Range. It is approximately 255 km (140 mi) northwest of Las Vegas by air (ERDA, 1975). It occupies about 1,616 square kilometers (624 square miles). The TTR is bordered on the south, east, and west by the Nellis Air Force Range and on the north by sparsely populated public land administered by the Bureau of Land Management and the U.S. Forest Service (DOE/AL, 1992). The remoteness of the TTR and its restricted airspace ensures that tests can be conducted with a high degree of safety and security (ERDA, 1975).

RECYCLING AND WASTE MINIMIZATION ALTERNATIVES ASSOCIATED WITH UNEXPLODED ORDNANCE REMEDIATION

The U.S. Department of Energy, the U.S. Air Force, and various DOE contractors have been utilizing TTR to field test conventional and special weapons, research rockets, and artillery since the late 1950's. During range clean up operations, Unexploded Ordnance (UXO) and

associated debris not retrieved as part of the test, were deposited in six locations across the range. The DOE/NV Environmental Restoration Division proposed cleaning up the six UXO disposal sites. Several methods of waste minimization and recycling were used to assist in the cleanup of the six ordnance disposal sites. Several process changes and material substitutions were made during the course of the project to minimize waste volume and type. Each disposal site was unique in the type and quantity of UXO and debris it contained. The largest site contained over 22,000 bomblets (baseball and softball sized ordnance) as well as several 500-lb and 2,000-lb bombs. Another site contained one thousand 55-gallon drums which had been used as targets, along with rocket motors and associated debris, and copious amounts of non-recyclable debris. At one site, approximately 150 rocket motors ranging in size from 5-inches in diameter and 6-feet in length to 30 to 40-inches in diameter and 12-feet in length were found.

Using process knowledge, the RCRA scrap metal exclusion, and on-site radiological screening, the Explosive Ordnance Disposal (EOD) specialists, segregated the items removed from the ordnance sites into discrete piles. The piles consisted of UXO requiring processing, recyclable scrap (aluminum and non-aluminum), non-recyclable scrap (i.e., wood, concrete), and potential hazardous waste. These techniques greatly minimized the potential for cross contamination and mixed waste generation.

All UXO were explosively detonated/processed to render them safe as recyclable scrap. To be accepted by the recycler, the scrap could not be recognizable as ordnance. In addition, it had to be less than 5-ft in length and 24 to 30-in. in diameter for the best recycling return. Due to these criteria, the majority of the scrap ordnance required further demilitarization through the additional use of explosives and/or a cutting torch. To reduce the cost of purchasing the additional explosives for demilitarization activities, an agreement was made with onsite contractors to use up their excess explosives (i.e., Composition C-4, shaped charges, detonating cord). The explosives transferred to DOE/NV had a combined Net Explosives Weight (N.E.W.) of approximately 410 lbs. This was a double cost savings for DOE since additional explosives did not have to be purchased for the project and DOE did not have to dispose of the excess explosives as hazardous waste. The use of onsite DOE subcontractors for cutting activities also reduced the overall project costs.

It was originally intended that each disposal site would have one UXO processing area associated with it. Through EOD specialists expertise and knowledge it was determined that the UXO were safe to transport. This made it possible to establish one central processing area for all six sites. Having one processing area reduced the time and money needed to mobilize and demobilize equipment and EOD personnel to each site. It also decreased the number of samples to be collected during closure activities and reduced the amount of soil potentially contaminated by UXO processing activities.

Processing techniques were refined over the duration of the project to become more efficient. This resulted in changing the type of waste generated, reducing the amount of explosives used, and increasing the number of UXO processed at each detonation. For example, the original planned method for processing bomblets included the use of PVC tubes as containers for the bomblets. This was changed to cardboard tubes prior to

the project's start since the PVC waste would not be biodegradable. During field activities it was decided to discontinue using the cardboard tubes. Experience found that filling the tubes was an unnecessary and time consuming step and that a large amount of cardboard waste was being generated. Also, without the size restriction due to the diameter of the tubes, more bomblets could be detonated during a single detonation, which in turn decreased the duration of bomblet processing.

Volume reduction was implemented at the site containing the empty target drums. Some of the drums were used for scrap containment and those left over were compacted by a drum compactor. By reusing and compacting the drums, the drums became salvageable, thus saving landfill space and reducing disposal costs. The number of truck loads required to remove the drums was decreased from ten to three which saved labor hours and transportation costs.

A total of 120 tons of steel and approximately ten tons of aluminum were shipped offsite for recycling. Transportation costs were recovered with the profits generated by recycling the scrap metal. An agreement was made between DOE/NV and one of the occupants of TTR to accept the 20 tons of non-recyclable debris removed from the six sites at their TTR landfill. This saved DOE/NV the cost of shipping the debris to either the Nevada Test Site or to an offsite landfill for disposal.

The overall project cost savings was approximately $200,000. This savings was the direct result of the waste minimization and recycling techniques discussed above, as well as the coordination of onsite contractors with project needs.

ABSTRACT

The Nevada Test Site is located 65 miles north of Las Vegas, Nevada and is the principle location where the United States Department of Energy conducted nuclear testing activities. Although all DOE facilities carried on various types of activities which created different waste management concerns, the NTS is a unique site. All the other sites in the DOE complex are dealing with waste problems which are principally the result of the poor or mismanagement of wastes generated from the production of nuclear weapons. The Nevada Test Site was, for the most part, intentionally contaminated, i.e. was identified specifically for nuclear testing. However, wastes which should and could have been managed in a fashion to minimize their environmental impacts, for the most part, were not. As a result of the activities that have been conducted, there are thousands of acres of surface and hundreds of square miles of subsurface contamination. Since these conditions have been acknowledged, both the State of Nevada and the Department of Energy, Nevada Operations Office have been attempting to correct the national perception that the Nevada Test Site, in its entirety, should be written off as a national sacrifice zone and therefore, could be the designated disposal site for all defense related waste and require only limited further evaluation.

This presentation will discuss the Department of Energy Nevada Operations Office historic and present day environmental restoration, waste management and disposal practices, how the State of Nevada's involvement has impacted both environmental restoration and waste management practices to date and concerns and issues the State feels are still inadequately addressed and remain unresolved. The management of the principal types of wastes, (solid, hazardous, mixed, low level and greater than class C) will be reviewed in relationship to State regulatory authority and how the State has or has not driven waste management practices at the Nevada Test Site. The extent to which Nuclear Regulatory Commission requirements and the Defense Nuclear Safety Board recommendations are implemented within the context of DOE's implementation of the self imposed ORDER 5820.2A "Radioactive Waste Management" will also be discussed.

HISTORY OF THE SITE AND WASTE MANAGEMENT PRACTICES

The Nevada Test Site (NTS) is a United States Department of Energy, Nevada Operations Office (DOE/NVOO), nuclear testing and research facility occupying 1350 square miles of federally owned land in southeastern Nye County, Nevada approximately 65 miles northwest of Las Vegas (1).

The NTS has been the primary continental location for the United States nuclear testing program since 1951. Programmatic functions, as defined by DOE/NVOO, include the management and disposal of wastes generated by NTS activities and by other USDOE defense-related facilities across the United States. On-going Environmental Management activities conducted at the NTS include the storage and disposal of low-level radioactive waste (LLW), storage of LLW and transuranic (TRU) mixed waste, environmental restoration efforts, and technology development projects (1). DOE/NVOO defense programs still conduct high explosive testing, subcritical nuclear tests, as well as other research and in addition, the Defense Nuclear Agency (DNA) is still conducting research at the NTS as well as other Department of Defense (DOD) entities which utilize the site for various types of testing and training exercises. All of these activities have the potential to generate wastes.

Although DOE/NVOO was not directly responsible for the activities that caused contamination that was done by all of the research labs and other tenants during testing activities, the NTS is managed by DOE/NVOO and therefore, as the landlord, they become the responsible entity. Historically, the entities associated with testing did not consider environmental or waste management issues that did not directly impact the testing mission. The disposal practices at the NTS for hazardous and radioactive material as well as solid waste had been for, the most part, unmanaged. Wastes were not adequately characterized and were inappropriately disposed (i.e. dumped onto the ground or abandoned at the point of generation, placed in subsidence craters or buried in sites that were not characterized), without concern for the contaminants fate in the environment. This practice meant documentation for a waste stream was not recorded or recorded randomly therefore, now it is very difficult to utilize process knowledge as a basis to characterize a waste stream.

As a result of the infamous Rocky Flats Raid, in 1987 DOE/HQ (Washington, D.C.) initiated what was referred to as "Tiger Team Audits", individual site audits were conducted by groups of DOE personnel from other sites. In response to the prospect of these audits, DOE/NVOO conducted their own audit and prepared an Environmental Survey Action Plan (ESAP). This document provided information on 105 sites requiring some form of action which indicated that DOE/NVOO was in noncompliance with environmental regulations and was or had potentially illegally discharged wastes. A copy of this draft Plan was made available to the Nevada Division of Environmental Protection (NDEP) for review in 1988. In addition to the ESAP, DOE/NVOO also submitted a RCRA Part B application for a Hazardous (Mixed) Waste Disposal Facility in which the Part A also identified a number of existing facilities which would be regulated under RCRA. Submittal of this information resulted in the State of Nevada formally beginning to interact with DOE/NVOO through NDEP.

After reviewing the ESAP document, NDEP began drafting a Finding of Alleged Violation (FOAV). Concurrent with the drafting of the FOAV, a Consent Order was prepared which would mandate DOE/NVOO take specific action relative to the non-compliance issues and begin to provide additional information about the NTS operations related to environmental regulations. DOE/NVOO proposed that NDEP set aside the FOAV & Consent Order and instead enter into an "Agreement in Principal" (AIP) which USDOE facilities throughout the country were negotiating with other States.

NDEP held in abeyance the issuance of the FOAV & Consent Order choosing instead to enter into the AIP that was signed by both parties on September 7, 1990. This document detailed the known environmental issues of concern and established the basis for how the two groups would interface with each other.

DOE/NVOO had always been reluctant to supply information or allow access to activities at the NTS by State personnel including NDEP employees. The stated reasons for this were the requirements which mandated secrecy and silence related to any activities associated with the development and evaluation of nuclear weapons. As a result of the AIP, access and clearance were made available to State personnel for the NTS. Beginning in January 1991, the State's presence changed from 1 or 2 days a year to 10 full time employees whose job responsibilities are totally dedicated to environmental evaluation and oversight of DOE/NVOO activities.

STATE OVERSIGHT ACTIVITIES

It became apparent that if the State was going to be effective, it would be necessary to become familiar with not only the needed environmental restoration and waste management activities but also the activities and associated management practices that created the problems. This presentation will not elaborate on the State's concerns related to program management but does acknowledge that DOE/NVOO is making significant progress in mandating that tenants address environmental and waste management issues related to proposed activities prior to them being initiated.

ENVIRONMENTAL RESTORATION

Forty plus years of nuclear testing and associated activities has left its mark on approximately 30% of the NTS. In addition to the approximately 1000 nuclear tests, there were numerous other sites, presently over 2000 identified, containing abandoned materials and wastes that needed to be characterized and corrective actions initiated. Types of contaminants at sites varied from solid and hazardous, including mixed, to low level and possibly some TRU wastes. NDEP, DOE/NVOO and DNA, the major DoD tenant, are in the process of finalizing an Federal Facility Agreement & Consent Order defining the process by which all contaminated sites will be evaluated and appropriate corrective actions implemented. These corrective actions have the potential to generate large quantities of wastes of all types.

With respect to characterization of contaminated sites, the State is particularly interested in the studies being conducted at Oak Ridge, Tennessee which question the colloidal theory of subsurface radionuclide transport. Based on a perceived migratory process which has historically indicated that most radionuclides would not travel far, contamination which resulted from the underground testing activities has been basically unmanaged. The studies suggest what was once considered to be a non-migratory radionuclide contaminant, even in groundwater could, in fact, be transient as a resultant of minute colloidal migration. This issue is of significant concern as approximately 30% of the nuclear tests, representing up to 90% of the source term, were conducted at or within the ground water table at the site. Prior to being able to manage these large contaminated areas, which potentially include hundreds of square miles, the bounds of the contaminated areas must be defined. A large portion of DOE/NVOO's efforts are presently directed toward trying to address the extent of the subsurface contamination and its potential movement.

WASTE MANAGEMENT

The State of Nevada enacted hazardous waste laws in 1981 and began to adopt the Federal RCRA regulations in 1984. NDEP has had EPA delegated authority for the federal RCRA base hazardous waste program since November 1, 1985 and was delegated federal Hazardous and Solid Waste Amendments (HSWA) authority on July 29, 1992 for mixed wastes and corrective action activities. As was noted previously, DOE/NVOO submitted a Part B Application to the state for a mixed waste disposal facility in 1988 subsequent to mixed waste being declared a regulated waste under RCRA and indicated its present facility was eligible to continue operations under interim status. DOE/NVOO later contended that the State didn't have the authority to regulate mixed wastes until it received that authority from the federal EPA. This issue has always been a point of controversy in that the USDOE, as well as other federal entities, have frequently contended that the State has no authority to act relative to a

federal facility unless so authorized by the Federal government. Presently the NDEP has both State and delegated federal jurisdiction and regulates the treatment, storage, and disposal of hazardous waste, including mixed waste, as well as air and water pollution and solid waste issues on the NTS.

HAZARDOUS (MIXED) WASTE vs LOW LEVEL WASTE ISSUES

The DOE/NVOO is currently storing, under a Consent Agreement, transuranic (TRU) mixed wastes on the NTS that are proposed to be sent to the Waste Isolation Pilot Plant (WIPP) in New Mexico. The actions and time lines to complete the characterization and have the wastes available for shipment along with the disposition of other low level mixed wastes are defined in the consent order issued in accordance with the Federal Facility Compliance Act (FFCA).

The Federal Facilities Compliance Act authorizes the States to evaluate USDOE proposed alternatives and determine how USDOE will treat and manage their mixed wastes. It is difficult to assess the treatment decisions associated with these wastes without also addressing their subsequent disposal alternatives. The State has concerns regarding USDOE's management of low level radioactive waste and to what extent it may effect acceptance of technologies for treatment of mixed wastes which result in a pure low level waste. These forms of treatment would result in the subsequent management and disposition of these wastes to be construed to no longer be under State regulatory authorities.

DOE/NVOO is performing the mixed waste disposal site evaluations utilizing the same criteria and standards that would be applicable for a Low Level Waste assessment. These evaluations need to ensure that the criteria used are also valid to assess the potential migration concerns associated with the hazardous constituents in the waste. This issue could be a significant concern for sites which could be found satisfactory only for containment of certain radioactive isotopes with short half lives. Any assessment of a site must address migration for any of the contaminants that could potentially be disposed at a site and not be limited by just those associated with radionuclides.

The U.S. EPA's proposed Hazardous Waste Identification Rule (HWIR) presents options for excluding hazardous waste from Subtitle C requirements based primarily on how the wastes are managed and on the level of hazard posed by the wastes. As proposed, once a defense low level mixed waste is excluded from the Subtitle C regulations, there will be no clear State regulatory authority to confirm that DOE/NV appropriately manages the waste. Most of USDOE's existing mixed waste could fit into this excluded category.

The management of defense related LLW is presently perceived to be under the sole control of the USDOE although Nevada's State water pollution control laws could be applied. These State authorities would be in conflict with USDOE's interpretation of the Atomic Energy Act (AEA) which allows USDOE to accumulate, store, transport and dispose of these wastes as they alone determine. Neither the EPA nor the Nuclear Regulatory Commission (NRC) has any direct authority over the waste characterized as defense low level waste. DOE/HQ continues to contend that the mixed wastes could and should be more suitably managed under the AEA, (it should be noted that the AEA contains no enforceable environmental requirements). DOE/NVOO has adopted USDOE ORDERS which are equivalent to internal policy directing themselves to perform in a certain manner, however failure to perform as directed has no negative consequences.

Allowing USDOE to remove these wastes from regulation and manage mixed waste under the AEA would basically place USDOE back into self regulation. The primary driver mandating USDOE to adequately characterize and manage their waste and to obtain funding for cleaning up environmentally contaminated sites has come from the State and federal environmental regulatory agencies who presently have this authority.

LOW LEVEL WASTE

The USDOE routinely ships Defense Low-Level Radioactive waste from its other installations around the country to the NTS to be disposed of. At the end of 1994, more than 17,158,689 cubic feet of defense low-level radioactive wastes had been disposed of on the NTS. The prospects for additional wastes to be shipped to the NTS by the USDOE from its other installations throughout the country is a certainty. To put these figures in perspective for the State, the total accumulation of radioactive waste at the US Ecology site at Beatty, Nevada, regulated under NRC agreement status until closed in 1993, totals 4,000,000 cubic feet for the 30 years in which it was in operation.

The State has had three significant concerns related to DOE/NV's accepting, for disposal, very large quantities of low level waste from off-site facilities. These issues and the current status are discussed below.

1. It is the State's position that the existing National Environmental Policy Act (NEPA) documentation under which the NTS was withdrawn, clearly did not authorize the site to function as a major disposal facility for off site wastes.

The State ultimately sued USDOE on this issue and the matter is presently within the court system. However, after the suit was filed, DOE/NVOO almost immediately initiated work on an EIS which has presently been issued in Draft for comment. To DOE/NVOO's credit, they actively sought stakeholder input into the EIS development which has resulted in a much more complete assessment of alternatives upon which acceptable decisions related to total site use, not just low level waste management, should be able to be made.

2. These wastes, classified as low level, are originating from CERCLA and/or RCRA facilities and have historically had very little characterization data to support the determination that they were not mixed wastes.

The issue revolved around the adequacy, accessibility and evaluation of waste characterization information upon which other USDOE sites made a determination that the wastes being shipped were not RCRA wastes. DOE/NVOO's Waste Acceptance Criteria, NVO-325, historically was very deficient in defining these requirements to which the State took exception. DOE/NVOO originally questioned NDEP's authority over what it asserted to be solely a LLW matter and beyond NDEP jurisdiction. NDEP indicated if necessary it would issue a Finding of Violation alleging that the wastes being disposed of were mixed wastes and there had been an inadequate determination made to demonstrate otherwise. After an initial, but brief resistance to the States position, DOE/NVOO accepted and has since welcomed NDEP's input.

Although defense LLW is not specifically regulated, all waste that is proposed for shipment to the NTS is now presumed to be mixed until adequately documented otherwise. Historically, shipments that were identified as only LLW were not required to provide as much documentation as those which were identified as mixed wastes. Information which

supported either position was maintained at the shipping site and frequently not in a readily auditable manner. Subsequent to State involvement significant improvements have occurred. The generators must now more completely characterize these wastes with clearly defined QA/QC requirements and organize their waste characterization information in a manner that is easily auditable. DOE/NV with NDEP assistance and input has defined a records management and submittal protocol for all shippers. Although NVO-325, as it exists today, is significantly improved there is still room for further improvement. One of the areas still needing development is the information supporting process knowledge determinations. There has never been a definitive requirement, until the presently proposed REVISION 2, to identify each isotope and activity level of the radionuclides in the waste, identify limits and to do so in acceptable units. Historically, the source term information that was provided with a waste shipment was a Curies per weight value for the entire waste stream which did not correlate to NRC standards of Curies per volume. This information was originally only provided for the entire shipment and not individual containers.

3. The NTS has never completed Performance Assessments for the sites where wastes were/are being disposed.

DOE/NVOO has not completed a Performance Assessment for the existing disposal sites, therefore the documentation to support that any disposal activity is environmentally sound is lacking. Although the State has significant concerns related to the ability of the facilities to provide containment, it is recognized that the actual existing waste management practices at the facilities are very acceptable. The concerns associated with the facilities ability to demonstrate adequate containment are expanded in depth in the following sections.

The NTS is different from other USDOE facilities in the fact that most of the waste it handles comes from other USDOE and DOD defense related sites. At the present time, 98.5% of the waste disposal that is managed by DOE/NVOO at the NTS is from off-site generators (2). It should also be noted that 85% of waste that has moved off-site from all other USDOE facilities around the country was shipped to the State of Nevada (2). It is the clearly stated intention of the USDOE to use the NTS for the continued disposal of large volumes of defense low-level radioactive wastes into the foreseeable future. USDOE has proposed that the NTS become the largest disposal facility in the country for low level wastes. Proposed shipments are for 1 million cubic feet per year for the next 70 plus years.

USDOE has had an internal policy, since 1988, requiring all USDOE disposal facilities to prepare a site Performance Assessment which would define the capabilities of their low level waste disposal facilities to contain the wastes which are being disposed. Standard practice for private sector facilities would have required a facility to conduct an evaluation prior to operation. To date, there has only been limited compliance with the policy directive to conduct this study on the NTS, even though it has been identified as a deficiency by the Defense Nuclear Facilities Safety Board (DNFSB), which is an oversight advisory board to the USDOE.

Part of the problem is that although DOE/NVOO has routinely requested funding to conduct site evaluation work, it has not received monies to do so because the budgets are driven by what legal requirements must be met.

Those that do not have such drivers become a low priority and therefore, routinely are below the available funding authorized.

There has been some work performed to date at two NTS locations. This site characterization work was initiated only because a portion of these areas were, or had been, utilized for hazardous waste activities and site characterization work and was required to be initiated under the regulatory requirements imposed by NDEP under its hazardous waste authorities.

DOE/NVOO is receiving and disposing of defense low level wastes at sites without a performance assessment. The State has concerns that because this assessment has not been a priority at USDOE, when the assessment is finally completed, DOE/NVOO may not be able to demonstrate the assessment is adequate due to non-existent or insufficient records for the historic waste disposed. It is also questionable if DOE/NVOO can prepare the Performance Assessment in accordance with the guidelines provided by the DNFSB.

In 1994, the DNFSB evaluated USDOE's low-level waste management program at various sites across the USDOE weapons complex. That review resulted in the DNFSB recommendation that in establishing low-level waste sites, USDOE guidance for meeting established performance assessment criteria had not been correctly applied. Reference dose criteria had not been applied to disposal facilities to determine the composite effects at contiguous burial facilities.

What this means is that on the NTS, DOE/NVOO has established low-level disposal sites in a way that significantly complicates performance assessment approaches for determining cumulative radionuclide migration to the biosphere in order to meet prescribed release standards for either USDOE or NRC disposal facilities. In the case of the two low-level waste disposal sites on the NTS, it could be argued that neither site could be adequately evaluated for meeting specific performance assessment objectives. This is not only due to limited records but also the type of historic activities conducted which encompass disposal of unique waste types like USDOE Special Case Waste (SCW) which could include NRC regulated Greater Than Class C (GTCC) waste or the equivalent and utilization of areas impacted by testing.

Because of USDOE's historic disposal practices along with a general failure to follow the agency's disposal evaluation procedures, as defined under USDOE order 5820.2A, it is argued that DOE/NVOO would be hard-pressed to meet even the minimum NRC licensing standards for commingling disposal of LLW with USDOE SCW at the NTS which could include wastes that meet the classification of GTCC.

USDOE Strategy for Management and Disposal of GTCC Low-Level Radioactive Waste and SCW

USDOE's Waste Management Programmatic Environmental Impact Statement specifically excluded the evaluation of these categories of waste. Since the NTS has disposed of this waste and is one of USDOE facilities undergoing performance evaluations for Greater Confinement Disposal of Special Case Waste, the Test Site is a plausible alternative for GTCC waste disposal. In addition, the NTS site wide EIS considers disposal of these wastes as a future possible mission of the NTS and the present version of NVO-325 makes provisions for, on a case by case basis, receipt of these wastes.

Although officially USDOE has taken very limited actions related to the GTCC-DOE\SCW, there are some ongoing activities and issues that have raised the following concerns for the State.

a. Most GTCC LLW is associated with nuclear utility waste (the largest volume being activated metals associated with spent fuel assemblies and reactor core components), and lacks concise estimates of the volume of these wastes.

b. Questions remain on whether fuel assemblies and reactor core components should be considered directly as either spent fuel or high level waste (HLW) rather than GTCC waste. Because of these uncertainties, waste treatment alternatives and storage options for reactor GTCC waste must be resolved first, before disposal.

c. Commingling of NRC regulated wastes with non NRC regulated wastes at a non NRC site raises additional regulatory issues.

d. The only public hearings held on the disposition of GTCC wastes were conducted in Washington, D.C. and Oregon. Neither of these locations have potential sites under consideration which leads the State to believe USDOE may not be interested in potentially impacted stakeholder input.

CONCLUSIONS AND THE FUTURE

This paper is being presented under the general category of success stories and one may view the contents as critical and therefore not as successes. However, the State of Nevada and DOE Nevada Operations Office relations have improved through the past years. We have worked together and realized some significant milestones such as State participation in revisions to NVO-325, participating in the off site audit process, the drafting of the Federal Facility Agreement and Consent Order for corrective actions and the FFCAct Consent Order for mixed waste management. Although we have not overcome all of the obstacles, the State is of the opinion that there has been success in obtaining recognition that there are some significant problems. Being able to provide some definition to the extent of the problems and therefore begin to address these situations must be considered as success.

We will be involved in a number of interesting interactions over the next few years: first, to expedite the process for implementing corrective actions and gaining control over the historically contaminated sites and wastes in an environmentally acceptable and cost effective manner; second, to continue the process of bringing DOE/NV activities under full and fair regulation; third, to develop the acceptable mix between State and federal authority over environmental concerns; and fourth, to accomplish the previous three in a manner that takes into consideration the broad spectrum of stakeholder concerns.

ABSTRACT

The development of the world uranium production since World War II was strongly influenced by strategic demand. While this continued within the former Soviet Union until the fall of the "Iron Curtain" uranium production within the WOCA (World Outside Centrally Planned Economics Areas) countries went through two "boom" and "bust" cycles which caused the opening and unsystematic closure of many uranium mines and mills. During the initial period of uranium production, environmental protection was of no importance and legal provisions setting the terms for proper rehabilitation, decommissioning and institutional control were missing. This situation led to uncontrolled abandonment of production sites. In the former Eastern Block countries this situation prevailed and the massive closure of uranium production capacities in recent years results in major environmental legacies due to lack of technologies and experience in environmental management, lack of financial resources and lack of a legislative and regulatory frame for decommissioning. In the Western World countries since the early seventies uranium mining is strictly regulated regarding the environmental impacts of the projects. Companies are expected to take the costs of decommissioning and restoration into account from the very beginning of the projects and to adjust them continuously during the production phase.

This paper summarizes results of an international study on decommissioning and reclamation costs of uranium production facilities commissioned by the German Federal Ministry of Economics. Within the frame of this study 14 countries with more than 100 projects were evaluated representing a cumulative uranium production of approx. three billion pounds of U3O8 and estimated rehabilitation costs of approx. 3.700 million US dollars.

Due to numerous factors which influence decommissioning costs, the variance of specific costs is quite broad ranging from a minimum of 0.12 US$/lb U3O8 to more than 40 US$/lb U3O8. The weighted average is 1.24 US$/lb U3O8. The specific unit costs per tonne of tailings range between 0.12 and 43 US$.

Factors influencing the costs can be classified as either inherent to the project and site-specific or of more general nature. One dominant inherent factor is the ore grade and ore mineralogy and the geological and hydrogeological setting of the deposit. One of the more important general factors is whether the decommissioning of the projects takes place immediately after mine closure and is financed and carried out by the mining company or is publicly funded and carried out some time after closing-down by public institutions.

During the last twenty years major technology advancements have been made in waste management from uranium mining and milling. As a result the environmental impact of production operations has been mitigated and

sustainable solutions for closing and rehabilitating these operations are available. This development has caused a shift of environmental cost (which substantially increased in absolute terms) from the decommissioning stage of a project to the planning and production stage.

INTRODUCTION AND BACKGROUND

The post World War II uranium production, including 1992, is estimated at approximately 1.8 million metric tonnes of U. WOCA countries contributed more than 1 million mt U to this total (1). Figure 1 shows the major uranium producing countries in order of their shares in the total production. Due to the fall of the 'lron Curtain', the extent, distribution and conditions under which uranium production took place in the Soviet Union and COMECON countries has been revealed in recent years. The following now independent countries were the main contributors to the Eastern Bloc total: East Germany, Czech Republic, Russia, Kazakhstan, Uzbekistan, Ukraine and Bulgaria.

Fig. 1

The development of the world uranium production since World War II (Fig. 2) was initially exclusively determined by the military demand of the superpowers. The very sharp increase until the year 1959, when total annual production went up to approx. 48,000 t U is the result of a less steep but earlier starting expansion of uranium production in the former Eastern Bloc countries due to the immediate exploitation of uranium deposits in the Soviet-occupied countries in Eastern Europe, in particular East Germany, Czechoslovakia and Bulgaria, and a dramatic increase between 1954 and 1959 by WOCA countries, mainly carried by the United States and its close allies Canada, South Africa and Australia.

Fig. 2

While uranium production in the Soviet Union and the former COMECON countries continued to be treated strictly strategically with an almost continuous increase until the middle eighties, the production development of the WOCA countries is characterized by two "boom" and "bust" cycles. After termination of highly profitable supply contracts with the US Department of Energy to cover the military demand, numerous uranium production projects particularly in the United States were given up. At that time legal provisions setting the terms for proper rehabilitation, decommissioning and institutional control were still missing. Environmental protection was not an important issue at that time. Therefore, many sites were abandoned by their owners without appropriate security and recultivation measures being taken. Some of these sites were remediated later within the frame of government financed programs. An outstanding example is the UMTRA project in the United States established under the 1978 Uranium Mill Tailings Radiation Control Act. Since 1980 twenty-four orphan mine and mill tailing sites are being remediated under this program (2). In Australia the Rum Jungle project, which ceased production in 1971, was remediated by the Federal Government during the period 1982 to 1991.

Since the early seventies, the growing environmental awareness in the mining industry of the Western industrial countries has resulted in legislation regulating the operation of new mining projects. The objective of the regulations is to ensure an adequate consideration of the overall economic and socio-economic interests in view of the impact on man and environment caused by mining. This development affects uranium production in particular because mining and processing of natural uranium entails the release of radioactive and chemotoxic substances. Their

potentially harmful effects are countered by imposing special regulations. Today, the basic legal conditions of modern uranium production in the Western World expect the producers of uranium to take the subsequent costs of decommissioning and rehabilitation into account right from the start at the feasibility stage and to adjust them continuously during the production phase.

Towards the end of the "Cold War", major uranium stocks, the decline in reactor demand, a drastic decline of uranium prices and the development of low cost and high grade deposits in Canada caused the closure of many projects in Western and Eastern countries. While in the Western industrial countries the decommissioning of these projects is ongoing and firmly regulated and mostly financed by the owner of the projects, the closure of the state-owned projects in the former COMECON countries results in extensive legacies of environmental devastation since economic and environmental aspects were of minor importance during production. Financial reserves for restoration of the mostly large production sites and plants have not been put in place. Therefore, only minor rehabilitation work is carried out at this stage. The uranium mining and milling plants of the former Soviet-German WISMUT Corporation in Thuringia and Saxony, where production ceased at the end of 1990, represent a typical example of this legacy, though unique in size (3), (4). The German Federal Government has assumed a financial obligation of 13 billion German marks (approx. 8 billion US$) for rehabilitation and decommissioning of these sites of which approx. 3.5 billion marks have been spent during the period 1990 to 1994.

STUDY ON DECOMMISSIONING COSTS

This study summarizes results of a research contract commissioned by the German Federal Ministry of Economics to Uranerzbergbau-GmbH (5). The major objectives of this research were to compile the available cost data of rehabilitation and decommissioning of uranium mining and milling sites, to analyze critical factors influencing the costs, and to draw comparisons. More than one hundred uranium projects were selected to form the basis of these investigations. They include decommissioned plants as well as projects which are still producing or which have been shut down and for which decommissioning plans, including cost estimates, have been drawn up. A separate study within the frame of the above referenced research contract included an analysis of costs of aquifer rehabilitation of in situ leaching projects in the United States.

As characteristic values for the comparison of rehabilitation costs between projects, districts and countries, specific rehabilitation costs were defined as US$ per pound U3O8 of produced or recoverable reserves and US$ per tonne of tailings. All costs were converted to US$ and adjusted to the year 1993.

RESULTS

On the basis of the time of rehabilitation in relation to production, the origin of funds and the party in charge of the rehabilitation, four types of projects can be defined (Fig. 3). The highest costs are related to the "UMTRA Title I-Type" and the "WISMUT-Type" of remediation projects. The "UMTRA Title I-Type" (Type 1) is characterized by production activities at the early stages of uranium mining when environmental impacts of the projects were neither assessed at the planning stage nor mitigated during and after production. The projects were abandoned by their former owners and a long lagtime occurred before restoration work started. The work is publicly funded and mostly carried out by public institutions which

generally have no internal in-sight knowledge of the project development and history. Therefore, a lengthy process of taking inventories, characterization of the wastes, risk assessment, planning and setting up an infrastructure, takes place before the remedial action starts. Furthermore, programmatic documents about policies and procedures have to be developed to satisfy the various stakeholders in the project to justify proposed expenditures and to meet political initiatives. The work is mostly carried out very cautiously in a step-by-step approach without an expertise based on practical experience and often in a pilot-type manner guided by R&D-work. Organizationally and operationally, the Type 1 remediation projects are more expensive than projects carried out by private mining companies. A distinct example are the very considerable differences in the costs of the US UMTRA Title I- and Title II-Programs. Fig. 3

The "WISMUT-Type" (Type 2) stands for remediation projects of former Eastern Bloc countries. Many of the above mentioned characteristics of Type 1 projects are valid. Generally the production processes have an even stronger impact on the environment and the sizes of plants are larger compared to Western standards. Furthermore, an abundance of auxiliary plants are integrated or related to the proper uranium production plant. The WISMUT case itself (6,7), due to the German reunification, takes a special position in this class. The high specific costs estimated for the WISMUT project are caused mainly by the location of the project within a densely populated area, the low ore grade, a major acid generation potential, partly employed unique exploitation methods, lacking experience and routine of regulating and permitting agencies, a dual permitting system, comparatively high personnel and particularly earth moving costs and high social costs.

The "Classical Type" (Type 3) of remediation projects is the most widely distributed one in Western countries. The mining company carries out the remediation work immediately after production ceases and the work is financed from previous earnings. The cost variation of projects within this class is largely due to project-specific factors of influence such as type of deposit, mining method and environment related factors.

Finally, the "ISL-Type" (Type 4) remediation projects represent modern projects which have gone through an extensive environmental assessment already at the planning stage. They have implemented the concept of environmental management throughout the life cycle of the project and rehabilitation is carried out in most cases progressively with the production. In situ leach uranium mines in the United States represent this type of project most distinctly.

Type 3- and particularly Type 4-projects often do not allow a clear separation between rehabilitation costs and production concurrent expenses for environmental protection.

The 14 uranium producing countries investigated in the referenced study represent a cumulative uranium production including 1993 of approx. 2 billion pounds of U_3O_8 This corresponds to approx. 63% of the cumulative world production. This production is related to 1.681 million tonnes of residues from ore processing (tailings) of which 780 million tons refer to plants producing uranium as by-product. The accumulated and estimated costs for decommissioning and rehabilitation of the investigated projects amount to 3.7 billion US$ (excluding the WISMUT project). The resulting specific rehabilitation costs are US$ 1.25 per lb U_3O_8 and US$ 2.20 per tonne of tailings. Leaving those plants out of account which

produce/produced uranium as by-product of primary production of gold and copper the specific costs per tonne of tailings goes up to approx. US$ 4.

FACTORS

The specific costs for the individual projects and countries differ widely (cf. Table I). The large variation is indicative of the dependency of the costs on numerous factors which are either project-specific, or regional or more general and location- and project-transgressing in nature.

Table I

The dominating project-specific factor influencing the specific rehabilitation costs is determined by deposit parameters such as ore grade, ore distribution, mineralogy of ore and surrounding strata and hydrogeological conditions. Production from high grade deposits like the nonconformity-type deposits in the Athabasca region of Northern Saskatchewan for example results in much less mill residues than production from comparatively low grade sandstone-type and conglomerate-type deposits. Furthermore, the nature of tailings determines the amount of work and costs for long-term stabilization. Fine grained argillaceous tailings, for instance those which resulted from the treatment of ores from the black shale deposits of the Ronneburg area in Thuringia take a high expense to dewater and stabilize while the sandy tailings of the sandstone ores of the Western United States dewater much faster and the expense for stabilization and encapsulation is substantially smaller, though long-term stabilization against erosion is a major cost factor. The rehabilitation of open pit mines is generally more expensive than of underground mines, in particular if, due to the depth of the deposit, large quantities of waste rock had to be removed and stored in dumps. Sulfitic acid generating waste rock needs particular attention in open pit reclamation and is best relocated below the groundwater level. Besides the remediation of tailings, the rehabilitation of open pit mines and related mine dumps are the most expensive restoration measures since they involve large-scale earthmoving. On the other hand, under humid climatic conditions and with acid generation in mines, mine dumps and tailings water treatment costs can become a substantial portion of the total remediation cost.

New developments in waste management, for instance the in-pit deposition of tailings that is now recognized as the best practical technology, has a cost saving effect on final restoration.

A further quite important factor influencing the costs of decommissioning is the permitting process and the permitting practice of the regulating agencies under the existing regulatory regimes.

INTERNATIONAL COMPARISON

The uranium producing countries investigated with regards to decommissioning costs and major factors of influence can be assigned to the following three groups:

1) Western industrial and other established uranium producing countries with a mining tradition, such as: Australia, Canada, USA and France, Gabon, Namibia, Niger and South Africa.

2) Former COMECON countries: Bulgaria, Czech Republic and Hungary

3) Western industrial countries with a very small production and major nuclear energy programs: Germany (West), Sweden and Spain.

For the group 1 countries, an extensive adjustment of the regulatory conditions, the prime objectives of rehabilitation and the applied restoration technologies can be stated, which in part is due to the fact

that uranium production in these countries is carried out mainly by only a few large international mining companies. The specific costs of rehabilitation in these countries lie within a relatively narrow range below or at approx. 0.7 US$/lb U3O8. The UMTRA Title I project with specific costs of 14.7 US$/lb U3O8 is to be seen as an exceptional case (cf. above).

The special conditions which apply to the former Eastern bloc countries (cf. above) are reflected in high specific rehabilitation costs of 1.5 to 3.0 US$/lb U3O8. The WISMUT project with specific costs of 13,9US$/lb U3O8 belongs into this group and is presently being analyzed in more detail.

The countries of the third group are characterized by small projects and small production. The restored sites can be considered as R&D projects. They were state-financed. The range of specific costs varies between 5.0 and 40.4 US$/lb U3O8.

CONCLUSIONS

During the last decades, uranium production was treated with secrecy in many producer countries of the world. This was mainly due to the military-strategic significance, attributed to uranium production. For the time being, a first comprehensive worldwide inventory of uranium mining projects with respect to decommissioning and rehabilitation has been established.

The decommissioning cost analysis reveals a wide variation of specific costs for rehabilitation work. It can be used for the evaluation of the cost structure of ongoing decommissioning projects, e. g. the WISMUT project in Germany. The data may be used for the estimation of future decommissioning costs of mining projects and as a baseline for the specification of financial reserves. Furthermore, the analysis gives valuable background information for optimization measures during mining in order to minimize later decommissioning costs.

Thus, the presented results of the research study can be regarded as an important contribution to the development of future uranium mines as ecologically sound and sustainable mining projects.

ABSTRACT

Since 1991, excess soil and debris generated at the Fernald Environmental Management Project (FEMP) have been managed in accordance with the principles contained in a programmatic Removal Action (RvA) Work Plan (WP). This plan provides a sitewide management concept and implementation strategy for improved storage and management of excess soil and debris over the period required to design and construct improved storage facilities. These management principles, however, are no longer consistent with the directions in approved and draft Records of Decision (RODs) and anticipated in draft RODs other decision documents. A new approach has been taken to foster improved management techniques for soil and debris that can be readily incorporated into remedial design/remedial action plans.

In accordance with proposed and selected remedies, the Removal Action Work Plan has been revised to update the soil and debris management approach to recognize recent decisions under the FEMP's Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) process. This paper describes the methods that were applied to address the issues associated with keeping the components of the new work plan field implementable and flexible; this is especially important as remedial design is either in its initial stages or has not been started and final remediation options could not be precluded. A sitewide interim policy that will allow each of the five operable units (OUs) to conduct remedial actions consistent with the respective RODs, yet achieve a consistent methodology for soil and debris management, has been developed in the Revised Work Plan. Under the revised work plan, remedial activities can proceed in advance of the remedial design under the auspices of the removal action; the removal action work plan can subsequently be integrated into the remedial design.

This paper finally identifies applications and lessons learned that evolved from the process of developing the revised removal action work plan, and provides general examples of how other facilities can benefit from this approach.

BACKGROUND

Since production operations at the Fernald site were halted in 1989, removal actions have successfully been used to address threats from the facilities, structures, and contaminants that remain. These actions have been implemented as interim measures until the final remedial actions can fully mitigate the impacts to human health and the environment associated with site contaminants. As an example, Removal Action No. 17 (RvA 17), which is programmatic in nature, was initiated to provide controlled storage of excess contaminated soils and debris generated during maintenance, construction, and removal actions at the FEMP. Specifically, it established procedures for the management and storage of soil and debris.

In establishing the procedures, thresholds were established for managing the soil in distinct piles. These initial thresholds were:

Category I Radiologically Contaminated Soils

- <100 pCi/g total uranium (U)
- <5 pCi/g total radium (Ra)
- <50 pCi/g total thorium (Th)
- No Resource Conservation and Recovery Act (RCRA) hazardous waste or polychlorinated biphenyl (PCBs) contamination

Category II Radiologically Contaminated Soils

- -> 100 pCi/g total U
- -> 5 pCi/g total Ra
- -> 50 pCi/g total Th

Category I soils could be stored in stockpiles that were covered with tarpaulins. Category II soils could be stored in stockpiles that were placed on tarpaulins and also covered with tarpaulins. Soils containing hazardous waste or PCBs were to be containerized and placed in approved storage. The area of contiguous contamination (AOC) concept that is employed under CERCLA was incorporated into the work plan such that each operable unit was to maintain its own stockpiles.

RvA 17 was to be conducted in two phases. In Phase I, the stockpiles were to be established in accordance with the above thresholds and were to remain in existence until new storage facilities could be constructed under Phase II. Once the new storage facilities were in place, the soil would be moved into them until final disposition decisions were made.

WHY CHANGE?

Since the implementation of RvA 17, several events have occurred. First, with the concurrence of the regulatory agencies, the FEMP determined that new storage facilities were not needed. The ability to dispose of some debris under the Record of Decision for Interim Remedial Action for OU3 (former production area decontamination and dismantling [D&D]) coupled with projected increases in storage capacity resulting from completion of facility D&D projects and accelerated shipments of existing and legacy wastes resulted in a reduction of scope for RvA 17 activities. Second, the RODs for each of the OUs have either been issued or are to be issued within the near term. Most notably, the ROD for OU2 (other waste units, including flyash piles, lime sludge ponds, and solid waste landfill) included the construction of an on-site disposal facility (OSDF) and associated waste acceptance criteria (WAC); it also adopted final

remediation levels (FRLs) for contaminated soil located within OU2. The OU5 (environmental media) ROD expanded the OSDF to accept additional materials, and expanded the waste acceptance criteria for the soil; additional FRLs were developed for contaminated soils within the OU5 area. The WAC were not consistent with the thresholds that existed in RvA 17. The OU5 ROD also adopted a sitewide Corrective Action Management Unit for soil remediation which includes the OSDF to replace the AOC concept that was previously utilized. Finally, the draft OU3 Remedial Investigation/Feasibility Study for final disposition of D&D debris was issued, which recommends disposal of the D&D debris in the OSDF and establishes appropriate WAC for the debris.

NEW APPROACH

As the RODs were moving towards approval, it was recognized that management of soil and debris under RvA 17 needed to be consistent with the anticipated remedial actions. Additionally, it was necessary to integrate the implementation of approved or anticipated RODs and individual remedial action plans with the management approach for soil and debris. Therefore, a team representing each of the key projects, the environmental compliance program, the environmental monitoring program, construction, and the waste management program was assembled to develop a revised removal action work plan that attained that consistency.

The key objectives established by the team included the need for the work plan to be practical (i.e., field-implementable) and the need for an easy transition for the existing soil and debris storage into the new concept. This involved integrated planning in recognition of the final disposition options for soil and debris. A flow chart was developed to aid in the development of the strategy (see Fig. 1).

Fig. 1

Information from the selected remedies or preferred alternatives for each operable unit will determine the potential to combine and reduce soil staging or storage areas. The needed information includes knowledge of:

Planned final disposition (e.g., on-property or off-site disposal);

Location and mode of transport to off-site disposal facility(ies) as applicable;

Total number of soil staging/storage areas projected during remediation;

Projection of on-site treatment requirements for on-property/off-site disposal; and

Types of staging areas required (e.g., stockpiles, container storage areas, construction of new facilities, use of existing facilities/structures).

The strategy for segregating or combining soil within an operable unit or from several operable units creates a commitment to manage each staging area according to the common planned disposition of the soil in that staging area. Generally, these criteria are based on the WAC for the designated disposal facility (see Table I); further, location criteria are based on general environmental protection requirements (e.g., floodplains/wetlands standards) and the designated FRLs for that location. Additionally, several criteria will be required for management practices for all soil stockpiles, such as run-on and run-off controls.

Table I

Table I con't.

The key criteria for debris management revolve around the final disposition and the category of debris. Several categories of debris were

identified under the RI/FS for OU3 (see Table II); these will be used by other OUs which may generate debris also. Some of these categories were administratively precluded from on-site disposal based on process knowledge of the levels of contamination; the other categories are to be designated for storage based on final disposition and characterization data. Debris to be dispositioned off-site will be containerized at the point of generation and shipped off-site as soon as practical. For debris proposed to be disposed on-property, some debris will be bulk-staged to permit the most effective handling of these media. In cases where bulk staging is desired, the debris will be managed to assure minimization of airborne emissions, and staging will occur to assure control of run-off. These debris will be staged in a manner to minimize double handling, minimize costs by optimizing container use, and minimize labor associated with maintenance. Use of bulk storage will not preclude any disposition options, including reuse/recycling. Material will be stockpiled on an existing storage pad or on the foundations of dismantled buildings.

Table II

Another important consideration in the development of the RvA 17 WP was the duration of the plan. Since the FEMP was rapidly approaching the completion of all RODs and would soon be moving fully into remedial action, there was a recognized need to limit the duration of the removal actions consistent with NCP criteria. The RvA 17 WP will remain in effect until the OSDF is in operation and the appropriate remedial action plans are implemented. It is anticipated that the remedial action plans could utilize the work plan as the basis for soil and debris management actions.

One final aspect of the RvA 17 WP was the incorporation of a sitewide non-aqueous investigative derived waste (IDW) policy. The IDW include drilling muds and cuttings from soil borings and well installation, soil, debris, and other materials from the collection of samples; residues (e.g., ash, spent carbon) from testing of treatment technologies and treatment systems; and contaminated personal protective equipment used during investigations. The IDW policy was included in this document because the material is similar to that addressed in the soil and debris management plans. Additionally, two separate policies existed for non-aqueous IDW, and this provided an opportunity to merge them and assure consistency. The established policy states that the preferred management options for non-aqueous IDW are to return the IDW to or near its source, if possible, or to manage it in accordance with the principles delineated in the soil and debris management plans.

APPLICATION/CONCLUSIONS/LESSONS LEARNED

The RvA 17 WP was conditionally approved with comment by the U.S. Environmental Protection Agency - Region 5 on first review. The Ohio Environmental Protection Agency had several comments that focused on clarification of responsibilities and integrated planning. There are several lessons learned that can be applied from the process of developing this revised removal action work plan:

Early discussions with the regulators on the approach to be used is very useful. By addressing the potentially controversial issues (primarily open bulk storage), acceptance of the concept was obtained early and led to expedited approval.

Teaming and integration is important. This work plan addressed all key issues because the important internal stakeholders participated in the development of the work plan. Additionally, a workshop approach with

participation from all affected parties within the FEMP was used to resolve all comments that were received during the initial internal review process.

Maintain flexibility. Since the site is just commencing the remedial action process, it was important to assure that remedial action options that would be defined in the remedial design/remedial action plans would not be precluded; at the same time, the approach taken in the removal action work plan had to be consistent with the direction being taken in the various RODs.

Maintain protectiveness, but use the easiest, least cost method for the short term. This was especially true in the storage of debris. Storage containers are not inexpensive, and need to be used judiciously. By demonstrating that outside bulk storage is protective, significant costs could be saved.

Use characterization methods that are field-implementable and appropriate for the waste acceptance criteria. Rely on process knowledge to the extent practicable. Where process knowledge is not sufficient, use field screening techniques; however, these field screening methodologies must be capable of measuring at the levels of the WAC and FRLs, as appropriate.

APPLICABILITY TO OTHER SITES

The CERCLA concepts that were incorporated into the RvA 17 Work Plan can be used by other sites in trying to accomplish expedited response actions using a removal action while awaiting remedial action RODs. For example, interim actions could be used to expedite remediation by excavating contaminated soil from a surface impoundment or managing it for final disposition prior to the final ROD. Additionally, the number of interim storage areas for debris and soil could be minimized and consolidated by identifying early on the final disposition options and then characterizing the material accordingly. Although this paper addresses the CERCLA arena, the same concepts are applicable to the RCRA process - interim measures (analogous to CERCLA removal actions) and corrective actions (analogous to CERCLA remedial actions).

EFFECTIVE USE OF RISK ASSESSMENTS AND THE PUBLIC COMMENT PROCESS TO ACHIEVE ACCEPTABLE REMEDIATION GOALS FOR MERCURY-CONTAMINATED SITES*

Jerome Q. Miller
Mark Barnett
Lockheed Martin Energy Systems, Inc.
Environmental Restoration Program
Oak Ridge, Tennessee

ABSTRACT

The effective use of scientific research data and the willingness to hear and involve the public in a manner that is in keeping with regulatory requirements are two important challenges affecting the cleanup of the Lower East Fork Poplar Creek floodplainsa mercury-contaminated site in Oak Ridge, Tennessee. As a result of recalculating risk levels using new information, the remediation goals and the cleanup strategy for the Lower East Fork Poplar Creek floodplains have been significantly changed. These changes reflect an important reduction in cleanup costs while ensuring protection of human health and the environment.

Use of the risk assessment process should yield an effective evaluation of information on the adverse health effects to human receptors exposed to hazardous and radioactive materials. The keys to the risk assessment's effectiveness are having an accurate understanding of the contaminant and correctly applying the remediation goal methodology. Determining effectiveness is also related future land use of the contaminated site, and future land uses will depend heavily upon the local community. Involving the public in the evaluations of the contamination and risk methodology has resulted in successfully achieving an acceptable remediation goal for all stakeholders. This project and its stakeholders have made the risk assessment process more effective by better defining the contaminant and adjusting assessment parameters in a way that affords adequate protection for human health and the environment while building stakeholder acceptance.

As a result of this synergism, the remediation goal initially set at 50 parts per million (ppm) of mercury has been changed to 400 ppm, resulting in significant reductions in both the destruction of the floodplain landscape and project costs. The volume of soils to be excavated has been decreased from 1 million cubic yards to 25 thousand cubic yards, and the cost has been reduced from approximately $1 billion to less than $20 million. The Record of Decision for Lower East Fork Poplar Creek was approved in August 1995.

BACKGROUND

The contamination of Lower East Fork Poplar Creek (LEFPC) occurred during the 1950s and 1960s when mercury was used in the manufacturing process of nuclear weapons components at the Oak Ridge Y-12 Plant in Oak Ridge, Tennessee. The mercury-contaminated waste water was initially discharged into the upper portion of East Fork Poplar Creek. Figure 1 shows historic mercury releases in the upper portion of East Fork Poplar Creek from 1955 to 1994. The contamination extends along the floodplain of this 14-mile-long creek that flows through U.S. Department of Energy (DOE), residential, and commercial property areas. The remediation of LEFPC has posed many challenges to the technical participants, regulators, and public.

Fig. 1

The LEFPC site includes two distinct but overlapping areas: LEFPC and the Sewer Line Beltway (Fig. 2). LEFPC flows 14 miles from Lake Reality at the Y-12 Plant to its confluence with Poplar Creek near the Oak Ridge K-25 Site. LEFPC flows through an area that hosts a range of human activities and land uses. The site includes creek sediment and soils, which make up the creek's 100-year floodplain. The Sewer Line Beltway consists of 10 miles of sewer lines, with one portion within the floodplain of LEFPC and two branches in the city of Oak Ridge. The Oak Ridge Sewer Line Beltway was studied because soils from the creek bank were used as excavation fill for the sewer line during the early 1980s. Because the soils around the Sewer Line Beltway present no significant risk, the beltway is not discussed further.

Fig. 2

The project began with characterization studies that charted the effects of mercury contamination on the environment. Contamination of the LEFPC floodplain can be understood by using a conceptual model for contaminant transport. The initial premise is that soil contamination in the floodplain is closely linked to hydrologic events. Contaminants from the Y-12 Plant were washed down LEFPC during high-flow conditions following

rainstorms. At least some contaminants were adsorbed onto sediment particles and were transported downstream in a suspended phase. Other contaminants were transported in a dissolved phase. During flooding, the creek overflows its banks and spreads out across its floodplain, depositing contaminated sediments on vegetation and the land. Based on this conceptual model, the remedial investigation focused on the evaluation of surface water, creek sediments, floodplain soils, and groundwater as potentially affected media. Because of the continued releases from the Y-12 Plant, the mercury in the surface water was not addressed in this remediation effort. However, the mercury contamination eventually settled into the creek sediment. During past years when the contamination originally occurred, naturally occurring events, such as flooding and erosion, created a change in the locations of the contamination. Based on the results of the investigations, the floodplain soils pose the greatest risk to human health and the environment and are the basis for the remedial action.

DEVELOPMENT OF REMEDIATION GOALS

The critical human health exposure pathway at the site was determined to be soil ingestion by children, and the initial cleanup goal was calculated at 50 ppm of mercury (soils with greater than 50 ppm mercury would be removed; soils with less than 50 ppm would remain). However, the initial risk assessment assumed all the mercury in the soils was mercuric chloride (the mercury species on which the toxicity reference dose was based), a soluble mercury compound not expected to be present in a floodplain frequently saturated with water. Previous investigations had suggested that mercury in the LEFPC floodplain was less soluble and therefore less bioavailable than mercuric chloride, possibly making the results of the risk assessment unduly conservative. Using a sequential extraction procedure for determining the species of mercury in soil, Revis et al. (6) estimated that approximately 85% of the mercury in the soils had been converted to mercuric sulfide as consequence of microbial activity in the reducing conditions of the soil. Subsequently, Revis et al. (7) also showed mercuric sulfide absorbed gastrointestinally to a lesser extent than mercuric chloride in mice feeding studies. An examination of 20 soils using optical and scanning electron microscopy also revealed a consistent elemental association between mercury and sulfur, further bolstering the idea that the mercury in the soils had been converted to mercuric sulfide. However, using a different sequential extraction procedure (5), elemental mercury was detected to a larger extent than mercuric sulfide (4). Barnett et al. (1) showed the use of the two previously used sequential extraction procedures (as well as a third) on the same set of soils produced inconsistent results, prompting questions about the utility of current sequential extraction procedures to unequivocally provide information about the mercury species in soil. For this reason, a subsequent effort was initiated to determine whether or not crystalline mercuric sulfide was present in soil. Using x-ray and electron beam methods, Barnett et al. (1) confirmed the presence of submicron crystals of mercuric sulfide in the form of metacinnabar. Because of the difficulty in extrapolating particle- and soil-specific speciation information and the lack of a reference dose for mercuric sulfide, a bioavailability study designed to measure the amount of mercury available for absorption in a child's digestive tract was conducted to provide direct (independent of speciation) information for input to the risk assessment (2). The bioavailability study used soil

leaching tests to simulate the human digestive system and determine the fraction of mercury in LEFPC soils potentially available for absorption in the human digestive tract. The study was conducted on a suite of soils from the floodplain as well as some pure mercury compounds for comparison purposes. Soil samples were collected at 2 depths from 10 sites (for a total of 20 samples) to represent a range of environmental conditions in the floodplain. Surface samples were collected within 3 inches of the surface. Deeper samples were collected in layers historically associated with the highest concentration of mercury in the floodplain. A 740-mg-portion of each air-dried soil was added to 1 liter of distilled water adjusted to pH 2.5 and allowed to leach for 4 hours, after which a filtered subsample was taken for mercury analysis. This treatment simulated the stomach. The subsample volume was replaced with distilled water, and the remaining leachate was pH adjusted to 6.5 and allowed to leach for 4 hours, after which a second subsample was filtered and collected for mercury analysis. This treatment simulated the remainder of the gastrointestinal tract.

The results of the leaching study for the 20 soil samples are shown in Table I. The total percent soluble mercury is simply the sum of the percent soluble at both pH values and represents a worst-case scenario, since some of the mercury in the soil is undoubtedly soluble at both pH values and is double counted in the simple summation. In 19 of the 20 samples, the mercury was not significantly (as a percentage) extracted at either pH. Less than 5% of the mercury was solubilized in 15 of the samples. Total soluble mercury in the 19 samples ranged from 0.3 to 14.2%, with an average of 3.2%. For one sample, however, there was a total of 45.9% soluble mercury. The high leachate concentrations for this sample are thought to reflect differences in the speciation of mercury in the sample, as this was the only sample among 20 which exhibited detectable mercury vapor in the sample headspace, which is not characteristic of mercuric sulfide (8). This sample was also the only deep, mercury-concentrated sample where total mercury and total sulfur were not well correlated. Including this sample, the average percent of mercury leached from the 20 samples was 5.3%. Attempts at more realistically simulating the human digestive system (e.g., by raising the leaching temperature to body temperature and using deoxycholic acid, a common constituent of the human digestive system) did not significantly affect the results.

Table I

Mercuric chloride and mercuric sulfide (cinnabar and metacinnabar) were also subjected to the leaching procedure. Less than 1% of the mercuric sulfide samples, both cinnabar and metacinnabar, leached in the procedure. In contrast, all of the mercuric chloride sample dissolved, producing leachate concentrations almost 1,000 times higher than the highest soil leachate. Although the procedure is a simple representation of a complex system such as the human digestive system, the solubility and hence bioavailability of mercury in LEFPC soils is obviously substantially less than pure mercuric chloride. As a result, use of a reference dose for mercuric chloride in the LEFPC risk assessment without incorporating a corresponding bioavailability factor would be unduly conservative.

The solubility information from this study was then modeled using Monte Carlo techniques, which produced a probability distribution of mercury bioavailability (3). After reviewing this information with regulators and

the general public, a bioavailability of 10% was selected. Using a bioavailability of 10%, the cleanup goal was increased from 50 ppm (based on the default value of 100%bioavailability) to 400 ppm of mercury.
The data on bioaccumulation of mercury from LEFPC mercury-contaminated soils and other soil/body burden relationships were integrated and developed into an ecological evaluation. The most sensitive group for protection is the mid-level predator. A risk management decision was made to provide the necessary level of protection, which took into account the habitat disturbance and mortality which would result from cleanup activities, balanced against the contaminant exposure risk. Mercury contamination of greater than 400 ppm provides the necessary level of protection to the environment.

IMPACTS

As the country became more environmentally conscious, federal laws were enacted to direct cleanup of contaminated sites. Priority was given to the LEFPC site because the contamination exceeded federal facility boundaries and posed a risk of uncontrolled conditions and exposure to the public. In December 1989, the Oak Ridge Reservation was placed on the U.S. Environmental Protection Agency's (EPA's) National Priorities List. This meant the cleanup of sites contaminated by DOE operations on and off the reservation would be conducted under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), which requires public participation in the cleanup process. DOE recognized the high visibility of this project and decided to involve the public early. The Record of Decision describes the selected remedy to include excavation of the contaminated media, backfilling the evacuated areas, and disposing the contaminated media in a permitted landfill at the Y-12 Plant.
Several public meetings were held to provide information to area citizens and hear their concerns about LEFPC. As the work continued, workshops were held to explain the process to the public and encourage participation by community members in selecting a preferred alternative. Also, several workshops were held with citizens who own property along the creek. The public's involvement at Superfund (CERCLA) sites typically consists of public meetings and public comment periods; however, these come late in the remedial decision process. To gain more meaningful participation early on, DOE decided to form a voluntary, informal group in May 1993 called the Citizen's Working Group (CWG). Because of its visibility and timing, the LEFPC environmental restoration project was chosen to launch a CWG as a pilot program. Volunteers for the group were solicited through advertisements and announcements to form a project-specific, broadly representative group of concerned citizens. Their task was to give DOE feedback about the proposed remedial alternatives for the creek's floodplain soils. The LEFPC CWG was not formed to be a decision-making or consensus-building group.
The CWG reviewed proposed remedial alternatives, identified concerns, and suggested new options. The group's activities were representative of the CERCLA process; therefore, they were able to maximize their ability to help DOE gain new perspectives about potential remedial alternatives under consideration. In addition, they were in a position to introduce new alternatives. Input from the group helped DOE better understand citizens' concerns related to remediation of the floodplain soils and the potential impacts to the community.
The high cost of performing environmental restoration activities resurfaced throughout the characterization and decision phase for the

LEFPC project. The public strongly emphasized the cost to remediate versus the protection of human health and the environment. Figure 3 shows a cost comparison from the feasibility study, baseline, and value engineering study. The costs reflect the estimates to perform remedial design and remedial action activities. As a result of public concern, a value engineering study was performed to give a critical examination of the preferred alternative. Each activity in the preferred alternative was examined for innovative ideas and potential performance improvements. Cost estimates were generated from a proposed list of new and modified approaches. The majority of the new approaches proved to be cost effective.

Fig. 3

CONCLUSIONS

The reason for understanding and assessing the risks for human health and environment is to derive a remediation goal. The remediation goal, 400 ppm, has been determined to be the desired in-point of concentration of mercury contaminant.. Mercury can exist in many forms, some more toxic than others. Public input, required by law, ensures that communities and people affected by past environmental practices will have a role in selecting the remedies for the problem. All stakeholders have a significant role in balancing the goal of protecting human health and the environment with remediation costs. The difficulty comes into play when a data set does not exist on the effects to the human organs and therefore must be extrapolated from animal/laboratory experimentation. At LEFPC, the effects of mercury in a soil matrix would be of greatest risk to children, based on the contaminant (mercury) and the exposure pathway (ingestion). To significantly reduce the risk of ingestion of mercury-contaminated soils, soils with greater than 400 ppm mercury will be removed and handled in an environmentally acceptable manner by excavating the contaminated soil, disposing it in a permitted landfill on the Oak Ridge Reservation, backfilling the excavated areas with clean soil, and restoring the disturbed site to its condition before remediation work.

PILOT SCALE TESTING OF SOIL WASHING ON LOW LEVEL RADIOACTIVELY CONTAMINATED SOILS

Ron Anderson
Mike Ryan
Bechtel National Inc.

Jim Hart
U. S. Department of Energy

ABSTRACT

Several sites in the Formerly Utilized Sites Remedial Action Program (FUSRAP) have shown, in laboratory studies, to be amenable to volume reduction treatment by particle size separation. This treatment using water as a carrier media is often called soil washing. The current practice, at FUSRAP sites, of excavation and hauling to a disposal facility is both expensive and produces a large volume of soil that is potentially clean but is handled with the contaminated soil. Bechtel National Inc. (BNI) has performed pilot-scale soil washing on select FUSRAP soil to demonstrate treatment/volume reduction.

The soils examined for soil washing were from the New Jersey sites, and each had undergone a laboratory characterization study that had shown that radiological contaminants were concentrated in the fine silt and clay fractions of the soil. The characterization treatment goal was 5 pCi/g for residential areas, and 15 pCi/g for industrial area. Removal of those fine fractions could produce coarse fractions of soil well below the 5/15 criteria with volume reductions of 50-80%.

To demonstrate scale-up and potential full-scale remediation, a pilot-plant study was performed using a soil washing pilot-plant originally designed by the Environmental Protection Agency (EPA) for testing on Montclair and Glenridge, New Jersey soils. This pilot plant named VORCE (Volume Reduction/Chemical Extraction) was modified to meet the specific requirements for treatment of the FUSRAP soils. After a series of tests on clean soils to develop operating parameters and system performance the machine was used to treat Maywood, New Jersey Interim Storage Site (MISS) pile soils. All tests performed to date indicate soil washing is very promising for treatment. Further tests are continuing on soils from other sites and locations.

INTRODUCTION

The Department of Energy's (DOE) Formerly Utilized Remedial Action Program (FUSRAP) consists of 46 sites in 14 states. These sites were originally used for manufacture or processing of ores and metals for support of the atomic bomb development. FUSRAP sites contain large volumes of soils (and other media) contaminated by low level radioactive contaminants particularly, thorium, radium and uranium, and in some instances metals and other hazardous contaminants.

Treatment options for these contaminated soils are limited. Options are: 1) leave in place with either institutional controls and/or engineered controls, 2) remove and dispose in an approved disposal facility or 3) treat to reduce the volume. The first option has potential for community

resistance; option two is expensive; and option three has only limited data to support its selection. From characterization studies of site soils several of the large volume sites have been identified as potential candidate sites amenable to treatment using soil washing technology.

The original concepts of soil washing have their history in the mining and metals industries. Mining processes have been used for years to concentrate metal particles for extraction as metal concentrates. Much of this equipment, i.e., trommels, screw classifiers, attrition mills, hydrocyclones, etc., originated in the mining industry.

Soil is comprised of various particle size fractions and most often the contaminates are concentrated in one size fraction. Most often this fraction is the finer silts and clays (50 mm or less). Removal of this fraction facilitates the potential for volume reduction and cheaper disposal costs. Increased surface area, cationic exchange potential, and the innate shape of these particles are important in the attraction of contaminants to the fine fraction.

Soil washing separates soils by particle sizes producing clean and contaminated fractions, using water as the fluidizing media. The clean fractions can be recombined, augmented if required and used as backfill. The contaminated fraction concentrated in a smaller volume can be shipped to an approved disposal facility for final disposition. Clean streams by FUSRAP standards are normally site dependent but 5/15 pCi/g above background is normally accepted, with 5 pCi/g for residential area soils and 15 pCi/g for industrial area soils. Results obtained from two test campaigns are discussed in this paper.

HISTORY

Two FUSRAP sites, Maywood and Wayne, located in New Jersey, have shown from characterization studies to have soil distributions with potential volume reductions of 50-80 percent. These soils follow the traditional theory of the contaminants (radionuclides) attract to the fines. Removal of this fraction, which is between 20-50 percent of the total soil, dependent upon size cut, provides a significant volume of soil that will meet clean-up criteria.

In order to verify the results of the characterization study, a pilot test was to be planned. This test would provide valuable data in determining the volume reduction and the associated cost if the soils from the Wayne and Maywood sites were treated. In order to perform this study DOE needed a pilot plant. At this time the United States Environmental Protection Agency (EPA) National Air and Radiation Engineering Laboratory (NAREL) had a machine that was available to DOE . This machine, called the Volume Reduction/Chemical Extraction (VORCE) machine, was used by NAREL for a soil washing treatment demonstration for the radium contaminated Montclair and Glenridge, New Jersey sites. The machine was transferred from EPA to DOE for use. Bechtel National, under recommendations by the United States Bureau of Mines (BOM) modified the system to meet the anticipated treatment goals. The system is a nominal 0.5 to 1 ton per hour system incorporating a series of unit operations to force separation of fine particles from the coarser oversize fractions. Significant modifications were made to feed system, attrition mills, and the fines circuit to better provide the operations required to achieve the treatment goals.

Originally, the VORCE plant was intended for mobilization to the Wayne, New Jersey site for testing and demonstration, during the fall of 1994, but community pressures precluded performing the study in New Jersey.

After evaluating several DOE locations, the Oak Ridge, K-25 site was chosen as the location for the tests. Soil was loaded and transported by intermodal container to Tennessee for the soil washing studies. Initially, equipment evaluation of the machine using clean soil was performed in the fall of 1994. Operations were suspended during winter and restarted in the spring of 1995 when equipment evaluation was continued. The original site for the machine check out was not suitable for performing radiological tests. Therefore, the system was mobilized to another area of the facility in the summer of 1995. The current location where tests on radiological soils are being conducted are constructed with a lined engineering treatment pad.

SYSTEM DESCRIPTION

The final VORCE configuration is as follows with a schematic shown in Fig. 1. The soil is fed through a 2 or 4 inch static grizzly into a feed hopper. The soil in the hopper is conveyed to the first unit process, the trommel screen, by means of a drag flite conveyor. Fine fraction soil from the trommel is collected in a sump, while the coarse fraction is discharged to a screw classifier. The screw classifier overflow is collected in the same sump as the trommel overflow. The coarse fraction from the screw classifier is discharged into an attrition mill. The attrition mill discharges into another screw classifier. Again the overflow from the second screw classifier is collected in a sump. The sump contents are fed to a hydrocyclone. The underflow from the cyclone is discharged into a hydraulic classifier. Overflow from the hydraulic classifier is discharged to a clarifier and the sludge sent to a filter press. The underflow from the hydraulic classifier is sent to a vibratory screen for dewatering. Product streams from the process are trommel oversize, secondary classifier oversize, vibratory screen oversize, and filter cake.

Fig. 1

SOIL WASHING PROCESS AND DESCRIPTION

The term soil washing is most often used to describe a series of treatment operations that either separate soils into their various particle size fractions using water (or chemicals as the carrier medium) or chemically extract the contaminant from the soil matrix. The VORCE soil washing pilot plant is strictly physical particle size separation using water as the carrier medium. The VORCE plant uses a series of unit operations to physically deagglomerate the soil and separate it into specific size fractions

A description of the process is as follows: soil is loaded onto either a 2-inch or 4-inch grizzly. The oversize material is removed by hand; the undersize passes through the grizzly into a feed hopper.

The material in the feed hopper is fed, by a drag flite conveyor, to a trommel. In the trommel deagglomeration of the soil particles occurs, and soil containing contaminants is washed from the large oversize particles. Soil particles (gravel) between 1/4-inch and 2- or 4-inches are washed clean using high pressure sprays, and report to a discharge chute as a clean fraction. The undersize material reports to a screw classifier. The screw classifier separates soil particles based on Stokes Law which states that a particle in a fluid settles at a rate that is the function of the particle's diameter. The smaller particles (with lower settling rates) overflow and are collected in an sump. A size cut of approximately 60 mesh (250 m) is performed at the screw classifier. The larger particles are removed by a screw and dewatered. The "coarse" sand is sent

to an attrition mill where the action of the mill causes interparticle abrasion to remove adhered fines from the coarse sand particles. The soil discharges from the attrition mill to another screw classifier where another 60 mesh particle size cut is made. The overflow from the second screw classifier reports to the sump, and the underflow reports to a discharge bin as a clean fraction.

The fine products from the coarse size operations collected in the sump are pumped to a hydrocyclone. The hydrocyclone is used for two purposes: 1) make a fine cut of 200 mesh (75 mm); and 2) to dewater the feed to the next unit operation. The fines overflow is collected in another sump, and the coarse underflow is fed to the hydraulic classifier. The hydraulic classifier is used for performing a fine cut between 200-325 mesh (75-45 mm). The hydrocyclone performs separations based upon centrifugal force, while the hydraulic classifier uses a combination of Stokes Law and hindered settling to make the cuts.

The fines collected from the hydraulic classifier are collected in the same sump as those from the hydrocyclone. The coarse underflow fraction is fed to a dewatering screen. The screen oversize is collected as a clean product. The fines and water from the screen are collected in the same sump as the other fines fractions. These fines are flocculated using polymer and fed to a clarifier. The flocculated fines are collected in the bottom of the clarifier and the clear water overflows into the process make-up water tank, thus providing recycling of the water.

The sludge in the bottom of the clarifier is them pumped to a holding tank prior to feeding to a filter press for final dewatering. The filter cake contains the contaminated fines, and the filtrate is recycled back to the clarifier for reuse.

SITE PREPARATION

With community pressures limiting soil washing or treatment in New Jersey, it was necessary to find a site that was acceptable for the soil washing tests. As noted earlier the K-25 in Oak Ridge was deemed best for this application. Reasons were: 1) close proximity to Bechtel, 2) could be operated under Lockheed Martin's Center for Environmental Technology as a technology demonstration program operating under their licenses or permits as required. In order to minimize uncontrolled releases of contaminated material from the soil washer an engineered and controlled site was necessary.

The radiological site was prepared near the existing K-31 building on the K-25 site. The location was a grassy area that required installation of engineering controls to minimize the potential spread of contamination. These controls consisted of a geomembrane with a double liner under the process area and a single liner under the non-process area. Gravel was placed in the area to provide drainage. Separate sumps were installed to collect rain water and spilled process water, and to keep them separate. Rain water would be sampled and segregated from process water for in-house discharge. Contaminated water was collected in a sump and recycled into the machine. Contingencies were developed so that the entire machine could be dumped and collected in a storage tank if required. Segregation of water provided valuable waste minimization.

Since the machine lacked performance testing, especially with the new modifications, it was necessary to evaluate the machine with clean soil, which could be done concurrently to the rad site preparation. The machine was set up to do clean soil performance testing in a storage area near the old powerhouse area of K-25. With no contamination potential from the

clean soil this was acceptable until contaminated soil processing. Several campaigns were performed at this location using various clean soil types to evaluate process efficiency, and to develop process parameters. Once the radiological site was completed the machine was demobilized and remobilized to the new site.

SOIL CHARACTERIZATION STUDIES

As noted above, two soils were characterized to show volume reduction by soil washing was viable. These soils were obtained from the Maywood Interim Storage Site pile and the Wayne Interim Storage Site pile. The data, shown in Fig. 2 for Maywood and Wayne show that volume reduction by particle size could produce volume reductions in the 60-80 percent range depending upon the size fraction removed.

Further studies performed by Oak Ridge National Laboratory (ORNL) also provided a soil sample from within the Oak Ridge reservation that also provided a soil with properties that would support soil washing as a volume reduction technology. This soil, deemed the CSX soil, was railroad ballast and gravel contaminated with cesium from spills near the rail yards on the Oak Ridge reservation.

Fig. 2

TREATMENT CAMPAIGNS

In order to demonstrate the effectivity of soil washing on Maywood pile soil, approximately 100 tons of soil from the pile was loaded into six intermodal containers and shipped to Tennessee for testing. No intent was made to test all 100 tons, but contingency amounts were built into the quantity ordered. The test consisted of operational settings based upon "real-time" experience, and allowing the machine to reach steady state prior to collecting samples of the feed and four output streams. Field adjustments were made as necessary to ensure proper performance. Four different series of samples were collected and analyzed for radiological content, and particle size. Isotopes of concern were Ra-226, Th-232, and U-238.

Soil was fed to the hopper using a front-end loader (ref. Fig. 1). Oversize material, greater than 6 inches, was remove by hand, as was any material collected on top of the grizzly. The feed soil sample was collected from each bucket for later compositing and mixing.

The feed rate was set at 704 lb./hr. This number appears low based on the design value of 2 tons/hour for VORCE. This lower figure was due to the mismatch in sizes of equipment, which limited the maximum quantity that can be fed to the machine without causing "sanding out" of the primary classifier. When "sanding out" occurs the separation efficiency for that particular unit process is reduced from lack of settling height.

The processed material was collected and volumes recorded, as was feed, for mass balance information. Fractions collected were as follows: 1) >1/4-inch, 2) 1/4-inch to 60 mesh, 3) 60 mesh to 200 mesh, and 4) <200 mesh.

RESULTS

Studies to date have been performed on the Maywood pile soils and the CSX soils. The studies incorporated running the machine at a steady state condition and collecting samples of the feed and all output streams; analyzing for radionuclides of concern and particle size. Data from the feed indicate a variation from the soil characterized in the previous bench scale work. Figure 3 shows the particle size distribution average for the feed soil to the plant during the Maywood study. Figure 4 shows the average rad concentration by isotope for the feed soil and the mass

reduction generated by the machine. The results of 98.6% mass recovery and 63% mass reduction track well with the theoretical results of the feed soil.

The CSX soil results are pending at this time, but preliminary data from the actual tests have shown that a 86+% mass reduction is obtainable. Much of the cesium is water soluble (concentration ranges in the water of 3300 pCi/l) necessitating water treatment prior to final disposition. Cost data was recorded but has not been reduced at this time, but it is expected to be below the costs for removal and disposal in an approved disposal facility. How much cannot be made until the data is evaluated.

CONCLUSIONS AND THE FUTURE

Initial tests indicate that soil washing is promising for certain FUSRAP sites. Sites with characteristics that show particle size separation can produce volume reduction are amenable to this treatment process. The machine is scheduled to test more soil beginning in early spring and concluding in mid-summer. A detailed report will be generated to capture the study and its results.

ABSTRACT

Soil samples from a Superfund Site contained elevated concentrations of radium-226 and thorium-230. The soil allegedly was contaminated with mill tailings from a chemical processing plant that extracted radium from carnotite ores.

Chemical extraction studies of soil samples were performed using solutions containing nitric acid, hydrochloric acid, hexametaphosphate, or combinations of hydrochloric acid and sodium chloride in single, multiple, and sequential extractions. The extractions were examined under various conditions of time, concentration, liquid-to-solid ratio, temperature, and rotational velocity. The products were analyzed for radium-226 and thorium-230. A full quadratic model of the bench-scale extraction studies for pilot-plant design considerations was examined to

determine any important interactions of temperature, concentration of extractant, and liquid-to-solid ratios.

Chemical extraction studies of soil samples demonstrated that dilute nitric acid solutions are effective in removing over 90 percent of the radium and thorium activity. Dilute hydrochloric acid solutions remove over 90 percent of the radium but less thorium. However, a sequential extraction procedure, employing hydrochloric acid followed by hexametaphosphate solutions, is equally effective in removing both radium and thorium. Hydrochloric acid could be replaced by a hydrochloric acid/sodium chloride solution, reducing the hydrochloric acid requirements for the process. A full quadratic model of the bench-scale extraction studies data revealed several important interactions between temperature, concentration of extractant, and liquid-to-solid ratios. Optimal values for these significant variables were determined using the model.

Physical separation of the whole-soil samples by particle sizing isolated a significant quantity of a soil fraction larger then 50-mesh size (0.30-mm) (+50) with radium-226 and thorium-230 concentrations less than 15 pCi/g. This fraction was extracted under optimum conditions to assess chemical treatment as a remediation technology to reduce the concentration of the contaminants to less than 5 pCi/g above background. Chemical extraction of the +50 soil fraction containing less than 15 pCi/g radium-226 and thorium-230 using the sequential extraction method described above reduces the concentrations to approximately 5 pCi/g. A combination of physical separation of whole soil followed by chemical extraction of a select particle-size fraction may offer a viable method for site remediation of radionuclide-contaminated sites by volume reduction.

INTRODUCTION

There are well over twenty sites in the United States containing soils contaminated with radium-226 and thorium-230. The Superfund site, where the soil samples used in this study were taken, was allegedly contaminated with tailings from a chemical processing plant that extracted radium from carnotite ores early in this century (1). As a result of using these tailings as landfill during construction, approximately 300,000 yd3 of soil over 95 acres were contaminated. Buildings on the site were affected to one degree or another by elevated levels of gamma radiation as well as radon-222 gas. The significant contaminants, producing the gamma radiation and radon gas, were radium-226 and thorium-230.

The contamination was the result of the presence of process tailings containing barium-radium sulfate precipitates, incompletely processed ores, and other radiominerals that are mixed with the native soils (2). The volume of contaminated soil can be reduced approximately forty percent by a process using vigorous washing and subsequent size separation with water, since the major portion of the radionuclide activity was in the smaller-sized soil particles (-50-mesh) (3). The resulting soil product has a specific activity of about 15 pCi/g radium-226. A pilot-scale operational system that incorporates the laboratory process was designed and used to test the remediation effort (4,5). Studies on uranium-mill tailings from other contaminated sites indicated that volume reduction by chemical extraction was feasible (6). A 1989 study (7) of soils contaminated with radium and thorium revealed that extraction with nitric acid removed approximately 90 percent of the

radium and thorium, producing a soil product with about 15 pCi/g radium-226 or thorium-230. Hydrochloric acid was as at least as effective as nitric acid for radium removal but not as effective for thorium. However, a sequential extraction, using hydrochloric acid followed by sodium hexametaphosphate, produced similar results as obtained with nitric acid. These results suggested a follow-up study to examine the sequential extraction protocol and to optimize the variables in the procedure.

Soil samples from the Superfund site were extracted with acid or acid/salt solutions to determine their effectiveness in removing the radium-226 and thorium-230. This paper presents the results of those extraction studies.

EXPERIMENTAL

Radiochemical Analyses

All soil samples and soil fractions were dried at 60C in preparation for analysis for radium-226 (8,9). Samples of soil and selected fractions and samples were also analyzed for thorium-230 (8-12) and, in some cases, for uranium isotopes (8-11).

Radium-226 Analysis

Dry soil samples or soil fractions were weighed in counting containers representing the appropriate standard counting geometry (10, 20, or 40 mL in a 60 mL vial; 100, 200, 300, or 400 mL in a 450 mL container). The samples were analyzed by gamma-ray spectroscopy using high purity germanium detectors. Radium-226 was identified and measured using the 186 KeV photopeak. Since only very small quantities of uranium-235 were found in the samples (less than 0.1 percent), interference by its 185 KeV photopeak was not a significant consideration.

Thorium-230 Analysis

Aliquots of soil samples and fractions were completely solubilized in hot-acid mixtures. Thorium was separated by ion-exchange chromatography and counted by alpha spectroscopy, using thorium-234 as a tracer (12) to determine the chemical yield of the procedure. The yield was determined by counting on a low-background beta counter.

Chemical Extraction -- Sample Preparation

Approximately 450-g samples of soils were analyzed for radium-226. After analysis, the samples were mixed with deionized water (5 mL/g) in a one-gallon Nalgene container fitted with a screw cap and shaken at 350 rpm on a Lab-Line Orbital Shaker at room temperature for 30 minutes. At the end of that time, they were hand screened through a 4-mesh sieve (4.75 mm) then a 16-mesh sieve (1.18 mm), using copious amounts of water to wash the soil through each sieve. As a result, three soil fractions were collected and dried at 60C: +4, -4/+16, and -16. the +4 and -4/+16 fractions were stored in bulk; the -16 fractions were divided into 40-mL portions, weighed, analyzed for radium-226 and used for extraction studies. The -50 and +50 sieve-size fractions were prepared in a similar manner, using a 50-mesh sieve (0.3 mm) only. Whole soil was dried at 60C and analyzed.

Extractions Conditions

Soil samples, prepared as described above, were extracted with acid, salt, or acid/salt solutions. Conditions were selected under the guidelines described in a previous report (7) and after interpretation of the extraction experiments described therein.

Acid Conditions

Samples were extracted with 0.5, 1.5, or 3.0 molar (M) hydrochloric or nitric acid once or twice for three hours at 30, 60, or 90C and a liquid-to-solid ratio of 2, 5 or 10 mL/g.

Salt and Salt/Acid Conditions

Samples were extracted with salt/acid solutions containing sodium chloride and hydrochloric acid. The extraction conditions were limited to 2.0 or 1.0M salt with 3.0, 2.0, 1.0M hydrochloric acid (for at total chloride concentration of 3.0M), 30, 60, or 90C, one- or two-stages, three hours at liquid-to-solid ratio of 2, 5, or 10 mL/g. Sodium hexametaphosphate was used at 0.036, 0.11, or 0.22M.

Single-Stage Extractions

A one- or two-liter spherical reaction flask was closed with a 4-neck (standard taper) cover. The cover was secured with a kettle clamp and fitted with a reflux condenser, centigrade thermometer, precision glass stirrer with Teflon paddle, and thermocouple assembly. The stirrer was rotated by a T-Line high-torque stirrer that could deliver up to 4.7 inch-pounds at 500 rpm. Stirring speed was monitored by a Cole-Palmer optical tachometer, model 8204-20. The thermocouple assembly consisted of a Glas-Col iron-constantan thermocouple, model JS 2048P, sealed in a glass tube to protect it from acid corrosion and packed with glass wool to aid the transfer of heat from the glass tubing to the metal thermocouple. Heat was provided by a mantle powered by a variable autotransformer set at 50 percent output. The temperature was monitored and controlled by a Glas-Col Digitrol, model PS 612, that was connected to the thermocouple and the variable autotransformer. Visual monitoring was available with the centigrade thermometer.

To begin an extraction experiment, an appropriate volume of extractant was added to the reaction vessel through the thermometer neck. Heating and stirring at 350 rpm were begun, and the temperature of the solution was allowed to stabilize at the selected value. The soil sample was transferred by a spatula with the aid of a small amount of water and acid solution. At the end of the extraction period, the mixture was cooled in an ice bath to room temperature. All mixtures were filtered with suction on a Whatman No. 1 filter paper using deionized water to thoroughly wash the sample on the filter paper. The filter cake (R1) was dried at 60C, weighed, and analyzed for radium-226 and thorium-230. The filtrate (F1) was subsequently filtered with suction through a 0.4 micron Nuclepore polycarbonate filter. The resulting filtrate (F2) was weighed and analyzed for radium-226 and thorium-230.

Multi-Stage Extractions

Multi-Stage extractions were performed using the method described above with the following alterations: soil samples were extracted, and the filter cake from the first filtration step of the procedure (R1) was used for the next stage of extraction. The filter cake produced by the second extraction was used for the subsequent extraction and so on until the number of extraction stages were complete.

Sequential Extractions

Sequential extractions were performed on soil samples using the multi-stage procedure described above, except that each extraction in the process was performed with a different reagent. For example, the soil sample was first extracted with hydrochloric acid, and the residue (R1) was then extracted with sodium hexametaphosphate solution.

Parametric and Optimization Studies

In order to investigate the effect of the principal parameters on radium and thorium extraction efficiency when using the most promising extraction procedures, random designs were constructed and a series of experiments following these designs was performed. The types of procedures examined were:

I) Extraction using hydrochloric acidonly radium measurements made.

II) Extraction using nitric acidradium and thorium measurements made.

III) Extraction using a mix of hydrochloric acid and sodium chlorideonly radium measurements made.

IV) Sequential extraction using hydrochloric acid followed by sodium hexametaphosphateradium and thorium measurements made.

All extraction procedures were run for three hours; and, for each procedure type, the following variables were randomized:

1) Experiment number (whether the particular experiment was performed first, second, third, etc.)

2) Liquid/solid ratio (Low = 2, Medium = 5, or High = 10 mL/g)

3) Hydrochloric or nitric acid molarity (Low = 0.5, Medium = 1.5, or High = 3.0M), where applicable

4) Extraction temperature (Low = 30, Medium = 60, or High = 90C)

5) Molarity of hydrogen ion for hydrochloric acid and sodium chloride mixes only (Procedure Type III only) (Low = 0.5, Medium = 1.5, or High = 3.0M; NaCl was included to make the chloride = 3.0M)

6) Molarity of sodium hexametaphosphate (Low = 0.036, Medium = 0.110, or High = 0.220M)for the sequential hydrochloric acid/hexametaphosphate extractions (Procedure Type IV only)

7) Extraction vessel utilized (three different vessels were available for use)

8) Detector used to count the sample (seven different GeLi detectors were available for counting)

RESULTS AND DISCUSSION

Chemical Extraction

In experiments reported earlier (7), 3M hydrochloric acid or nitric acid was found to be effective in reducing the radium-226 specific activity from about 135 pCi/g to 15 pCi/g and thorium-230 from about 127 pCi/g to 15 pCi/g; salt solutions of various types, including sodium chloride, were not effective alone. In this study the effectiveness of the hydrochloric acid mixture with sodium chloride was examined to determine if the concentration and therefore the actual quantity of hydrochloric acid used in the extraction procedure could be reduced. The data in Tables I and II indicate that 2M sodium chloride with 1M hydrochloric acid produced results similar to those obtained with 3M hydrochloric acid alone. Thus, a dilute hydrochloric acid solution, requiring only one-third the amount of acid previously used for radium-226 extraction, is a promising candidate for a chemical processing plant. Notice that the chloride ion concentration in sodium chloride/hydrochloric acid is 3M, the same concentration as in 3M hydrochloric acid. In addition, the use of the salt/acid mixtures, as the first step in a two-step process to effectively remove both radium-226 and thorium-230, is as effective as using 3M hydrochloric acid in the first step. Apparently, as long as the acid concentration is about one molar, a chloride ion concentration of approximately 3M from an alternate chloride-ion source is sufficient for effective radium-226 extraction.

Table I

Table II

The results of sequential extraction of the +50-mesh fraction and -16-mesh soil with hydrochloric acid followed by sodium hexametaphosphate are also summarized in Tables I and II. The data indicate that a sequential extraction, using either 3M hydrochloric acid or 2M sodium chloride/1M hydrochloric acid followed by 0.22M sodium hexametaphosphate, produces results with whole soil that are similar to those found in previous studies (7) of -16-mesh soil. The final specific activity of radium-226 is less than 15 pCi/g, and that of thorium-230 is less than of radium-226.

The -1/4"/+50-mesh fraction produced by the vigorous wash method developed earlier for volume reduction (7), provided surprising results with the radium-226 specific activity of about 5 pCi/g and thorium-230 specific activity slightly less.

These results offer a promising alternative for the treatment of soil and/or the potential for further reduction of the radionuclide content of the vigorously washed soil fraction to about the 5 pCi/g range by a combination of physical-size separation and chemical extraction of the +50-mesh fraction.

Overview of Parametric and Optimization Studies

Space limitations do not permit including the entire database resulting from this series of experiments here. However, Table III summarizes the best four results obtained for each procedure type. In this table and the remaining paragraphs of this section, the notation used is self explanatory except for the following point:

In conducting the sequential extraction experiment (Procedure Type IV), 3M hydrochloric acid was first used with an L/S ratio of 10 mL/g at 90C (all variables "High"); an appropriate experimental design was followed. This first extraction step was then followed by a hexametaphosphate extraction. In this case, each sample was returned to the same vessel used in the acid extraction step for hexametaphosphate processing. All other variables were randomized, and it is the levels of these latter quantities (i.e., those describing the hexametaphosphate extraction step) that are cited in Table III.

Table III

Statistical Comparisons of Radium Yields

A number of statistical comparisons were made for the percentages of reduction in sample radium content achieved using different types of procedures. These comparisons were made by matching on the relevant variables ("L/S Ratio," "Molarity of Agent," etc.) All of these considerations were conducted at the 5 percent level of significance; the results are summarized below:

Overall, nitric acid gave yields superior to those achieved with hydrochloric acid. This superiority persisted at high molarity but vanished at high L/S ratio.

Nitric acid performed better, in general, than hydrochloric acid/salt mix; this superiority persisted in extractions using high molarities but was not present at high L/S ratio.

Hydrochloric acid was superior to hydrochloric acid/salt mix in an overall sense, but this superiority vanished above 30C.

Funding limitations and the scope of work precluded investigation of a number of other comparisons that were of interest. This investigation was commissioned as a parametric study, and not, for example, as a study of the comparison of any two of these extraction procedures when they are

conducted at near optimum conditions. The reader may find the answer to other questions unanswered elsewhere (e.g., Ref. 7).

Mathematical Modeling of Radium Extraction Processes

The possibility of mathematically optimizing radium extraction procedures was a point of major interest to the Environmental Protection Agency (EPA) in this work. This investigation was undertaken generally following the methods used by Torma (13) in an earlier research endeavor, but more comprehensive computations were made possible in this work through use of the SAS (Release 5) statistical analysis system (14). In reviewing the results discussed below, it must be remembered that only 27 out of the 81 possible extraction configurations possible when varying three variables (L/S, molarity, and temperature) over three levels (Low, Medium, and High) were explored. Further, it was not possible, due to time constraints, to replicate this experiment. Thus, there is substantial opportunity for confounding of effects to appear in the statistics given below. Of course, it would have been better, in principle, to have used a replicated full factorial design for this experiment; but it was not possible to devote this level of effort to this taskthis would have required over 300 extraction experiments. In addition, since there are only 26 degrees of freedom provided by this design, one must regard with caution the results obtained when investigating models having large numbers of predictors. A summary of the modeling effort is given below. In these models the independent variables were L/S Ratio ("LS/R"), Molarity of Agent ("HCl" or "HNO3" or "H+," respectively), and Extr Temp ("TEMP"). The quadratic terms are denoted below in suggestive fashion. Examples: "LS/R_LS/R" (quadratic LS/R term); "LS/R_TEMP" (interaction between LS/R and TEMP), "TEMP_TEMP" (quadratic TEMP term), etc. The dependent variable was the Percent Radium Reduction ("Ra%_Red") achieved. The modeling investigation involved several steps for each procedure considered:

1) First, a comprehensive regression calculation was performedthat is, Ra%_R was modeled as a linear function of all subsets of the nine variables that result from linear and quadratic combinations of liquid/solid ratio, molarity, and temperature. (Note again that only three of these variables are truly independent.)
2) Secondly, the best reasonable model (if any) was identified for use in the optimization calculations: the model offering the best combination of high predictive power and low degrees of freedom (number of independent variables) was chosenthis obviously involved a subjective judgment.
3) Finally, this best model was used to predict the combination of liquid/solid ratio, molarity, and temperature that maximizes yield.

Hydrochloric Acid Model

The data recorded from the hydrochloric acid extractions proved to be exceedingly well-suited to such a quadratic modeling effort. Models with such a high degree of predictive power are very rarely observed in other than very simple physical processes. Even very simple linear models for these data are extremely statistically significant. Even more surprising, however, was the finding that only two of the independent variables, LS/R and TEMP are important in these modelsHCl (when present in the amounts considered in this experiment) is weakly related to the yield achieved.

Best Six-Term Model

Almost 90 percent of the variance of the yield is captured by a full quadratic model based on LS/R and TEMP (again, without the acid molarity variable). An interesting observation is the significant interaction

between LS/R and TEMP that occurs in this regression. Indeed, all of the terms in this model, with the exception of the constant, are significant. This model indicates that large percentage reductions in radium activity (largest t statistic magnitudes) are most strongly associated with the temperature and liquid/solid ratio variables. However, when examining these results, it is important to remember that only 27 data points were available, and, thus, there are only 21 degrees of freedom for errortherefore, the results obtained here must be viewed with caution.

Table IV

Best Seven-Term Model

The model summarized below, which accounts for almost 93% of the variance of dependent variable, is the best of the seven-term regressions. It is included here since it represents the first instance in which acid molarity was a variable in an optimum regression. (There are 20 degrees of freedom for error here.) Note that it is actually the interaction of HCl and TEMP that is significant here. As before, all variables except the constant term are significant.

Table V

Again one finds that large percentage reductions in radium are most strongly associated with the temperature and liquid/solid ratio variables.

Optimization of the Hydrochloric Acid Model

The model chosen for the optimization study was the six-term model above: Eq. 1

The usual equations for the stationary point of this surface are easily solved; the solution is LS/R = 7, TEMP = 89.6. It is important to note again, however, that a number of the variables in this model are correlated and, additionally, that there were no data points actually taken near this stationary point: thus this determination is expected to be of only nominal accuracy. It is the judgment of the authors that the appropriate conclusion from this optimization exercise is that high levels of LS/R and TEMP are optimum.

Hydrochloric Acid/Sodium Chloride Model

The remarkable success of the modeling effort for the hydrochloric acid data was repeated and even slightly exceeded by the hydrochloric acid/sodium chloride data. The results from the two modeling efforts were similar almost in every way. For example, one again finds that only LS/R and TEMP are important in models of these dataH+ was weakly related to the yield achieved. The results of two of the models considered are summarized below:

Best Six-Term Model

Almost 96 percent of the variance of the yield achieved is captured by a full quadratic model based on LS/R and TEMP (again, without the hydrogen ion molarity variable). Note that all of the terms in this modelincluding the constantare significant, and, in fact, to approximately the same degree.

Table VI

Best Seven-Term Model

The model summarized below is the best of the seven-term regressions, but it offers only trivial improvement in predictive power over the previous one. As in the case of the hydrochloric acid data, this regression is included here since it represents the first instance in which ion molarity was a variable in an optimum regression. On the other hand, one

finds that molarity is the only variable in this model that is not significant. The same cautions given above are applicable here.

Table VII

Optimization of the Hydrochloric Acid/Sodium Chloride Model

The six-term model above was optimized. Specifically, this model is:

Eq. 2

The stationary point of this surface is LS/R = 6.9, TEMP = 86.5. The similarity of these values to those obtained for the hydrochloric acid extractions is remarkable. (Of course, the same cautions discussed there apply here too.)

Nitric Acid Model

In contrast to the results above, the statistics for the nitric acid data are rather typical of regressions for physical problems: None of the models considered captures as much of the yield variance as did the previous models.

Best Six-Term Model

About 78 percent of the variance of the yield is accounted for by the variables of this model: TEMP, LS/R, HNO3, and the two interaction terms indicated. In contrast to the previous models, molarity (HNO3) is significant; the constant term is not.

Table VIII

Thorium-230 Extractions

Due to the lack of individual sample thorium-230 measurements, statistical analysis of the thorium data was not possible. However, note that when extraction methods that are effective for the removal of thorium-230 (nitric acid extraction or hydrochloric acid with or without sodium chloride followed by sodium hexametaphosphate) are used, the final thorium-230 specific activity is almost always less than that of radium-226 (7). Furthermore, the general effect of varying extraction conditions for thorium-230 yields closely parallels the patterns earlier observed for radium-226. Therefore, it is possible that thorium-230 extraction may be optimized by approximately the same extraction conditions that optimize radium- 226 extraction.

CONCLUSIONS

Chemical extraction studies of soil samples demonstrated that dilute nitric acid solutions are effective in removing over 90 percent of the radium and thorium activity. Dilute hydrochloric acid solutions removes over 90 percent of the radium but less thorium. However, a sequential extraction procedure, employing hydrochloric acid followed by hexametaphosphate solutions, is equally effective in removing both radium and thorium. Hydrochloric acid can be replaced by a hydrochloric acid/sodium chloride solution, reducing the hydrochloric acid requirements for the process.

A full quadratic model of the bench-scale extraction studies data revealed several important interactions between temperature, concentration of extractant, and liquid-to-solid ratio. For hydrochloric acid and hydrochloric acid/sodium chloride extractions, the model suggests a high degree of prediction that is based on the liquid/solid ratio and the temperature of the reaction. Within the range of concentrations selected for this study, the concentration term is much less important. In contrast, the model for nitric acid extraction includes a significant contribution by the acid concentration, in addition to the liquid/solid ratio and temperature terms.

Physical separation of the whole-soil samples by particle sizing isolated a significant quantity of a soil fraction larger then 50-mesh size (0.30-mm) (+50) with radium-226 and thorium-230 concentrations less than 15 pCi/g. This fraction was extracted under optimum conditions to assess chemical treatment as a remediation technology to reduce the concentration of the contaminants to less than 5 pCi/g above background. Chemical extraction of the +50 soil fraction containing less than 15 pCi/g radium-226 and thorium-230 using the sequential extraction method described above reduced the concentrations to approximately 5 pCi/g.

A combination of physical separation of whole soil followed by chemical extraction of a select particle-size fraction might offer a viable method for site remediation of radionuclide-contaminated sites by volume reduction. As an example, more than one-third of the soil from the Superfund Site described in this paper would be separated by simple particle-size separation, producing a fraction that would contain approximately 15 pCi/g radium-226 (3). Subsequent chemical extraction of this fraction, as described herein, would reduced the concentration to about 5 pCi/g.

Particle-size separation of soil samples from other sites yield soil fractions containing similar concentrations of radium-226 and representing from 50 to 65 percent of the total soil (5). Recovered fractions representing greater percentages of total soil material potentially make them more attractive to further contaminant reduction by chemical extraction processes. Depending on the clean-up criteria, alternate fractions with intermediate concentrations of contamination might also be candidates for extraction, if their contaminant concentration could be reduced to meet the criteria. The fraction might, therefore, be recovered and added to other fractions separated by the physical processes alone. For example, a contaminated soil might render up to 50 percent of its volume as a "clean" product by particle-size separation. A fraction with somewhat higher contaminant concentration but representing another 25 percent of the soil could be remediated by extraction producing a total volume reduction of approximately 75 percent. A physical-separation processes complemented by chemical extraction of select size fractions might result in a remediation technology that would offer, therefore, the optimum approach to volume reduction.

General Physics Corporation

Ralph Cardenuto
Raphel Corpuz
Matthew G. Wiherle
Aberdeen Proving Ground

ABSTRACT

A characterization study of radioactive contamination, hazardous waste and unexploded ordnance (UXO) at the Depleted Uranium (DU) testing area of the Transonic Range at the Aberdeen Proving Ground (APG) was conducted in the fall 1995 through the winter of 1996. DU penetrators were tested at a site located at the Transonic Range from 1973 through 1979. Although outdoor testing of DU penetrators ceased in 1979 at the 12 acre site, the need to release the site for nonradioactive use has become the goal of

the U.S. Army Research Laboratory (ARL), and the APG Health Physics Office.

APG is a Test and Evaluation Command installation within the United States Army Material Command. The mission of the installation is to develop and test military materials and to train officers and enlisted personnel in the use and maintenance of munitions. The installation was established in 1917 as two separate military reservations, APG and Edgewood Arsenal. Both were consolidated into APG in 1971. APG is located in northeast Maryland, has approximately 73,000 acres of land and water and has approximately 55 tenant organizations, many of whom are engaged in munitions development and testing.

This paper discusses development of the characterization strategy, the health and safety plan, a quality assurance project plan and the work plan. Also presented are the results of the interviews with personnel responsible for the outdoor DU testing activities, test supervisors and test technicians. Results of the surface survey for UXO and preliminary radiological data are presented.

INTRODUCTION

The purpose of the characterization was to establish the radiological status of the Depleted Uranium Study Area (DUSA) in accordance with licensee requirements and the recommendations of the Nuclear Regulatory Commission (NRC) since DU testing at DUSA ceased in 1979. The need to perform a radiological characterization is found in NRC's Branch Technical Position (BTP) "When to Remediate Inadvertent Contamination of the Terrestrial Environment." (1). According to the BTP, licensee sites which are no longer used to conduct licensed activities should be remediated to unrestricted use levels within two years of last licensed activity to preclude migration of the radioactivity. A determination was made in 1995 to cease licensed activities at DUSA.

The DUSA is located at a site within the boundaries of the Transonic Range which is in the Aberdeen Area of Aberdeen Proving Ground (APG). APG lies along the western shore of the Chesapeake Bay in Harford and Baltimore Counties, Maryland, approximately 15 miles northeast of Baltimore (Fig. 1). APG covers a total of 72,516 acres (land and water) and consists of two distinct areas: the northern portion of APG, referred to as the Aberdeen Area (AA); and the southern portion of APG, referred to as the Edgewood Area (EA) (2). The AA became a formal military post, designated as APG, in 1917. The EA (formerly Edgewood Arsenal) was appropriated by Presidential Proclamation in 1918.

Fig. 1

DUSA is located on the southern portion of the Transonic Range and was known as "Lower X-ray" operated by the U.S. Army Research Laboratory (ARL). The DUSA was used for hard-impact testing of depleted uranium (DU) penetrators. DU penetrators were gun launched against armor targets to test their effectiveness. DU is depleted of the natural percentage of U-235, and contains U-238, U-235 and U-234 all of which are radioactive. The DU penetrator testing is known to have contaminated target material and the surrounding structures and soil. Since 1979 contaminated materials and soils have been removed from the area, however a complete characterization and remediation for free release has not been performed.

METHODS

The initial step was to review the history of DUSA prior to establishing the scope of the characterization in order to determine the level of effort and resources needed to devote to the project. Subsequent to the

historical survey a work plan, health and safety plan and quality assurance project plan were developed.

Historical data was largely obtained from interviews with personnel formerly involved in testing at DUSA as little documentation about the testing program exists. Interviewees included a health physicist that was assigned to the site during the later years, two health physicists that have conducted environmental monitoring at the site, the principal test supervisor, two test foremen, and two test technicians. Data was also obtained from environmental monitoring reports.

RESULTS OF THE HISTORICAL RESEARCH

The DUSA is located on the southeast end of the Transonic Range and was used for DU testing from 1973 through 1979. Testing consisted of gun launching DU penetrators from two locations (next to Target Storage) at targets mounted adjacent to the X-ray units to the south (see Fig. 2). Stripper /deflector plates located in between the launch or shooting location were designed to strip or deflect the sabot away from the penetrator while in flight to the target. Penetrators were either completely stopped in the target or penetrated (either partially or completely) the target and impacted into a backstop located a short distance behind the targets. As a result of the testing, most of the DU melted into the target and backstops, however some DU fell onto the soils around the targets or was scattered into the surrounding area. Test technicians wore protective clothing and dosimetry while in the test area and monitored activities for radiation. Except for shot target and other designated contaminated materials, most radioactive wastes were handled through established radwaste disposal channels. Shot target and other designated materials were stored onsite in a wooded area located to the east of impact area. The shot target and other designated materials have been remediated, recycled and or disposed in an approved disposal site.

Fig. 2

After testing ceased the ARL health physicist conducted an initial site cleanup to reduce the radioactive waste inventory and to allow other non-radiological testing to be conducted at the site. This effort included removing shot target and other materials from the storage area and surveying and removing contaminated soil, sand or other materials. The health physicist estimated that approximately 12 acres should be considered suspect areas (see Fig. 3). Figure 4 shows the suspect area and the site divided into 200 by 200 foot grid.

Fig. 3

Fig. 4

ARL conducted soil sampling from 1973 to 1978, and again in 1991 as part of their environmental monitoring program. Analytical results for soil samples collected from several areas around the radioactive waste storage area and behind the backstops showed levels in excess of the release criteria for unrestricted use of 35 pCi/g (3). Most of the soil contamination was found in storage area which has been posted as a Radioactive Materials Area. Of the 165 soil samples collected from this area, 37 were greater than the 35 pCi/g limit. Concentrations ranged from background to 520 pCi/g.

The areas behind the backstops showed soil concentrations below the limit for free release with few exceptions. Soil samples collected in and around remaining site structures were below the release limit.

Further information was obtained from site visits.

Site Description

Figure 3 shows site details collected from Geographical Information System (GIS), interviews with range personnel and site visits. The 12 acre site contains the items in Table I.

Table I

Each of the structures known as X-ray 1 and 2 contain X-ray equipment mounted in U.S. Army equipment trailers. The trailers are surrounded by plate steel, ranging from two to four inches thick. The floors are gravel.

Test program material was stored in a Security Container. The original security container was moved to a location west of the Transonic Range Building (740 C) and replaced with a newer container. The replacement Security Container has been classed as an unaffected structure.

The Backstops, Stripper Plates and Target Supports are not thought to be contaminated; however, site work will involve scoping surveys to characterize them. The Catch basin for the Transonic Range will be reviewed and likely classed as an unaffected structure. Interviews with range personnel indicate that DU penetrators were not directed at this backstop.

The east side of the site was stabilized over seven years ago when a layer of landscaping plastic was laid along the east road of the site from 740 A7 to the tree line to the east, to the Bomb Safe to the north, and to the path for X-ray 1 to the west. A 4 to 8 inch layer of gravel was laid over the plastic.

Also about 7 years ago, the swampy area to the north of the firing positions was covered with 2 to 4 feet of soil to allow guns to be moved further away from the targets.

PROJECT WORK PLAN

As a result of the interviews and the site visits, the work required for the characterization was broken into six tasks. The tasks were as follows:

- Conduct surface sweeps for UXO using visual techniques and magnetometry
- Conduct radiation surveys using walkover techniques of the 12-acre site
- Conduct a geophysical survey for buried ferrous and non ferrous objects using EM 61
- Conduct radiation surveys of affected structures
- Conduct targeted soil sampling to compare with the survey results
- Develop recommendations for site cleanup if necessary

These six tasks not only formed the basis of the workplan, they were also used to scope the hazards analysis in the site health and safety plan. Individual procedures were developed for each of the tasks.

QUALITY ASSURANCE PROJECT PLAN

A quality assurance project plan (QAPP) was developed to ensure that the data from the surveys was adequate to meet the goals of the data objectives. The plan was developed according to the guidance from EPA Region III and QAMS 005 (4). Specific objectives are to be met by data collected during the characterization are summarized below:

- Determine where radiological contamination of soils and structures exists at DUSA above NRC release criteria.
- Acquire data to be used by the APG Health Physics Office to determine where remediation is required.
- Integrate data into a comprehensive GIS database which may be used to facilitate the feasibility study and license termination.
- Determine the volume of soil requiring remediation.

Determine the extent of structure contamination and, if contaminated, determine possible remediation strategies.

The plan cross referenced to the task procedures.

SITE HAZARD IDENTIFICATION AND ASSESSMENT

The Health and Safety Plan (HASP) was developed to address each type of hazard anticipated for each task of the project. Some of the hazards are seasonal related. Examples of seasonal hazards include heat stress, insect bites and stings, and animal encounters during the late spring, summer and fall and cold stress during the winter. Of particular concern was the potential for deer tick bites and possible development of Lyme disease. The other hazards include exposure to ionizing radiation, detonation of UXO, straying into an impact area during testing and tripping, cuts, and falling hazards.

The principal hazards at the DUSA site during the winter of 1996 included accidental detonation of UXO, cold stress, exposure to radioactive material, and physical hazards associated with field activities (such as tripping, falling, and cuts). The major radiation contaminants known to be on site include uranium isotopes and their progeny. The radionuclides of concern include U-234, U-235 and U-238.

Radioactive materials represent an external and an internal exposure potential while conducting site work. Inhalation, ingestion, and dermal contact hazards may exist. Due to past activities, the DUSA has the potential of having radiological contamination present. The HASP recommended general radiation surveys of the site during initial sweeps for UXO and monitoring personnel for contamination whenever personnel left the site or handled objects located within DUSA. Equipment that may have been used at other radiological sites was given a baseline frisk to compare with subsequent frisk results in order to determine whether contamination of the pieces has occurred.

A variety of ordnance types were expected in the DUSA. The DUSA was a known impact area for DU and kinetic energy penetrators as well as projectiles containing high explosives. In addition, DUSA is bounded by active ranges on three sides.

The exposure hazard associated with UXO items is related to unexpected disturbance causing leakage of contents or detonation. Hazards include possible explosion and leakage of explosive chemicals near the point of UXO discovery.

Hazards from UXO were minimized by practicing avoidance of uncleared areas until the completion of magnetometry surveys, and then conducting a magnetometry survey wherever intrusive field work was to be conducted (i.e., placing grid markers for survey reference, and soil sampling). Other UXO and hazards of straying into impact areas was minimized by establishing the site grid, clearing the site of UXO and cautioning workers to stay within the DUSA and to maintain radio contact with the U.S. Army Test Center's Range Control.

DUSA Physical Hazards

Physical hazards associated with the DUSA characterization activities included light equipment operation (e.g. generators, etc.), traversing undeveloped areas, adverse weather conditions, possible wildlife encounters and water hazards in marshes and creeks. Mitigation measures included safe field practices; safe lifting techniques; and adhering to approved plans, SOPs, and manufacturer's specifications for equipment.

RESULTS and DISCUSSION

Surface Survey for UXO and Site Preparation

The 12-acre site and adjoining ranges have been used to test projectiles containing DU, high explosives and other material therefore, the potential for UXO encounters existed. Prior to working the site, a UXO survey for surface ordnance was conducted using hand held magnetometry instruments. The U.S. Army Technical Escort detachment was contacted to render UXO items safe. Because the radiological history of the site was uncertain, a health physicist accompanied the UXO team while the UXO survey was conducted to ensure that workers did not encounter high radiation or contamination levels.

The duration required to conduct the survey for surface UXO doubled after finding numerous UXO in the first two days. The UXO survey proceeded as follows: a geophysical survey of the site was conducted to establish a 200 by 200 foot grid of the 12 acre site, once the grid was completed, one UXO expert marked lanes and directed the team that walked parallel lanes a distance equal to the swing of the magnetometer. Contacts were flagged and later investigated for ordnance.

The geophysical survey established the boundary for the surface UXO survey, radiation survey and the electromagnetic survey. A total of 24 grid points were placed at 200-foot by 200-foot intervals throughout the 12-acre site. Originally, the reference grid was to be established after the site was cleared of UXO, however because of the number of UXO discovered by the second day of site work, it was necessary to establish the grid earlier in order to conduct the surface sweep in an efficient manner. For the survey, stakes were driven at each node after the UXO contractor verified that the stake would not impact underlying UXO. Physical stake locations were needed as reference points during the radiation and electromagnetic surveys and to accurately determine the extent of remediation.

During the surface survey for UXO, the team determined if the UXO contained explosive material and whether the item was fused and armed. Scrap and nonhazardous UXO were removed to a central location for official verification by the government. Hazardous UXO were cataloged and recorded on a site map. UXO that were too hazardous to move were designated for field disposal. Those UXO requiring field disposal were surveyed for radiation as well as the general area around the item to ensure that detonation of of the UXO would not disperse DU into the surrounding area. A total of 121 UXO items were found during the surface survey. Table II has a listing of the UXO items by type. As the listing shows, approximately two thirds of the items were 105 and 155 mm projectiles and almost half of the items contained high explosives.

Table II

Table III lists the UXO items found by survey grid. A total of 33 UXO was found behind the Transonic Range Catch basin (grid ref. A2), the next highest was 13 UXO found in grid A3.

Table III

Once the survey determined that surface UXO was no longer a concern, site clearance began. Clearing consisted of moving non essential surface objects, scrap metal, materials and equipment, wood articles and debris so that the site could be effectively characterized. Surface objects pose a hindrance to the radiation survey and interfere with the EM-61 survey. This required moving fallen logs, partially buried debris and other material out of the survey area. It was also necessary to cut foliage as close as possible to the ground via brush hog in order to minimize the radiation detector soil distance.

Radiation and Electromagnetic Surveys

At the time of writing, the radiological characterization of buildings, soils and soil samples for DU contamination had not begun. Preliminary surveys of the site showed no removable contamination above background. However, contamination was found in several areas of the site including the asphalt pad leading to the radioactive materials storage area, as well as several pieces of debris discovered during site clearing. Radiation surveys showed levels between 0.15 to 0.20 Sv/h (15 to 20 mR/h) south of the backstops to 0.15 Sv/h (15 mR/h) from the backstops to the X-ray buildings and 0.05 to 0.1 Sv/h (5 to 10 mR/h) from the X-ray buildings north.

The characterization surveys of the site are to be conducted at approximate intervals of 18 inches apart with a field tested gas proportional counter. Data regarding count rate and location on site will be communicated to an on-site computer to plot count rate from the detector in the x and y direction. Once this survey is complete, biased soil sampling will be used to verify isoconcentrations from the site survey.

An electromagnetic radiation survey for submerged items and other materials that had been inadvertently left on site below the surface will be conducted after the radiation survey. The method of choice to detect submerged ferrous and non ferrous objects is EM-61. Originally the EM-61 survey was to be conducted in a manner similar to the radiation survey, that is the transmitter and receiver mounted on a cart that is pushed/pulled along survey lanes. However, there were risks identified during the surface UXO sweep from a device that transmits an electromagnetic signal in an area where proximity fused munitions may be present. The concern for proximity fused munitions is that the electromagnetic device may induce an electrical current sufficient to detonate the munition. Two proximity fused UXO were found at DUSA and for this reason the EM-61 survey will be conducted only in areas where radioactive contamination will be confirmed during radiation surveys and will be conducted using robotic tracked vehicle. The EM-61 survey will be conducted remotely at a distance of 345 meters to protect the operator from the effects of inadvertently detonating a subsurface UXO that contained a proximity fuse.

CONCLUSIONS

Although the full extent of contamination and the number of subsurface items is unknown at this time, there are several conclusions that can be made.

Based on general radiation levels, the areas designated as A2, B1, B2, C1 and C2 may require remediation. Levels varied from 0.15 to 0.20 Sv/h (15 to 20 mR/h) with peak values of 0.5 Sv/h (50 mR/h). Also based on general radiation levels the existing structures do not appear to be contaminated. The levels of DU contamination are less than those requiring personnel monitoring, but appear to be greater than the release criteria in Ref. 3 for some areas and therefore will require remediation. At this time, the most significant hazard is encountering UXO. The density may be 10 UXO per acre.

The need to perform a systematic, well-defined radiological characterization of the DUSA is found in NRC's BTP (1). According to the BTP, licensee sites which are no longer used to conduct licensed activities should be remediated to unrestricted use levels within two years of last licensed activity to preclude migration of the

radioactivity. Thus, the site should be characterized, remediated and released for unrestricted use as within the time frame negotiated with the NRC.

The guidelines in Ref. 5 should be followed. The site history proved an invaluable in particular when developing the data quality objectives and the health and safety plans. The risk from proximity fused munitions was unknown at the beginning of the project but persistence and conservative posture regarding this risk reduced the likelihood that individuals would be harmed.

Weather conditions and seasonal variations should be considered in planning for radiological characterizations of wooded/swampy areas. Timing enabled characterization during the winter months which enabled visualization of site hazards (i.e., UXO) much easier as well as site clearing. The winter characterization allowed the team to work unhindered by dear ticks, insects and snakes. It also allowed work to progress with minimal impact to the environment.

AIR CLASSIFIER TECHNOLOGY (ACT) DEMONSTRATION AT A DEPLETED URANIUM SAND BUTT

R. H. Mayer
M. E. Nelson
U. S. Naval Academy

ABSTRACT

The Department of Energy recently completed a "heavy metals in soils" treatability project which resulted in the evaluation of several different physical separation technologies. One of these was the air classification technology developed by industry and refined by the U. S. Naval Academy. The purpose of this paper is to share the results of a field demonstration using this new remediation technology for mixed waste products (i.e., soil containing both radioactive and RCRA-regulated materials) at a Department of Defense facility.

BACKGROUND

Naval Surface Warfare Center, Dahlgren Division (NSWC-DD), is located east of Dahlgren, Virginia, on the western shore of the Potomac River. Since 1918, NSWC's primary mission has been Naval ordnance testing and

development, which continues today. Currently, NSWC-DD is preparing to dispose of mixed waste products from two sites at its facility. One site is an outdoor sand butt which, as described by Halliburton (1), consists of approximately 13,000 cubic feet of sand enclosed in a large rectangular steel box with a single vertical open face (Fig. 1.) The dimensions of this enclosure are 24' x 50' x 15' (w x l x h). The back half of the enclosure is completely filled with sand which slopes forward from mid-length towards the open-face entrance. Prior to July 1991, the butt was used for both depleted uranium (DU) and conventional munitions testing. It is no longer in use because of concern over the level of contamination in the fill.

The sand butt was designed so that the fired projectiles would expend their energy in the sand. In addition to DU projectiles, the sand fill contains projectile fragments and metal dust resulting from abrasion of the projectiles on impact. The specific activity of the sand fill is 2.9 nanocuries/gram (estimated) with a radiation dose rate of (approximately) 2.5 mrem/hr measured at one foot above the sand's surface. In addition, the fill is known to contain at least eight RCRA-regulated metals including lead, mercury, and silver. The concentration of lead exceeds the "Maximum Concentration of Contaminants for Toxicity Characteristic" as per 40CFR261.24. As a result, the material in the butt is classified as a mixed waste.

Fig. 1

PROJECT SCOPE

The Department of Energy (DOE) recently completed a "heavy metals in soils" treatability project which resulted in the evaluation of several different physical separation technologies (2). One of these was the air classification technology developed by industry and refined by the U. S. Naval Academy (USNA). Subsequently, a field demonstration was arranged to assess the usefulness of this innovative technology for remediating mixed waste products (i.e., soil containing both radioactive and RCRA-regulated materials). Specifically, a limited quantity of contaminated soil from the outdoor DU sand butt at NSWC-DD was treated. EPA guidance for conducting treatability studies was followed (3).

The principle objective of this field demonstration was to evaluate the application of air classifier technology (ACT) in the recovery of the depleted uranium (DU) fragments. Also to be evaluated was the effectiveness of this technology to concurrently remove certain RCRA-regulated heavy metals; in this case, to reduce the high concentration of lead in the sand fill. As a secondary objective, an assessment of variations in certain system control parameters was undertaken to improve the overall effectiveness of the technology for future mixed-waste remediation efforts. Health, safety and industrial hygiene issues during equipment set-up, operation and disassembly were also assessed to enhance future operations.

AIR CLASSIFIER TECHNOLOGY DESCRIPTION

Air classifier technology is a physical separation technique that uses a centrifugal force effect to achieve separation of particulate matter by size and/or density. The particulate matter is fed into a separation chamber, wherein particles are imparted with a radial velocity through the action of a centrifugal fan. Ideally, the larger and/or denser particles move more rapidly to the separation chamber wall where they fall under gravity and are collected as coarse particle discharge. Smaller, lighter particles are carried upward by a circulating column of

air and collected in an outer chamber as fine particle discharge. Overall success of this demonstration was to be measured by the fraction of contaminants that could be concentrated in either of the two discharge streams.

The test equipment used in the demonstration was a Gayco-Reliance air separator system. The system includes a feed unit and the air classifier unit as shown in Fig. 2. The automatic feed unit is an Acrison model 105-DD volumetric dry materials feeder. It features a unique dissimilar-speed double concentric auger mechanism for accurate metering performance. The unit has a hopper with a capacity of 0.5 ft3 and its feed rate is variable up to 2.4 ft3/hr.

Fig. 2

The classifier unit is mounted alongside and linked to the feed unit by a feed tube. The 18"-diameter Gayco-Reliance centrifugal air classifier includes both a main fan and a centrifugal fan mounted on a common shaft (Fig. 3). The main fan develops a circulating air flow between the separation and outer chambers, while the centrifugal fan imparts radial velocity to particles of matter as they enter the separation chamber. Approval was obtained from its manufacturer, the Universal Road Machinery Company, to replace its constant speed motor (1750 RPM) with a variable speed motor which can operate at speeds as high as 2500 RPM. Motor RPM and, thus, fan speed can be controlled by adjusting a speed rheostat on the motor control box. Air circulation within the separation chamber can be controlled by adjusting the openings of the shutter assembly.

Fig. 3

FIELD PROCEDURES

The project was accomplished through the combined efforts of USNA, NSWC-DD, and Naval Facilities Command, Chesapeake Division (CHESNAVFAC) personnel. USNA personnel had the responsibility for preparing the necessary field documents, procuring field equipment and supplies, performing process operations (i.e., sieving, drying, air classifying, etc.), equipment decontamination, and final report write-up. NSWC-DD personnel performed initial site set-up activities, soil excavation and UXO monitoring, radioactivity airborne monitoring, sample measurements, final disposal of all waste generated by the process, in addition to supporting all field activities. The CHESNAVFAC personnel provided assistance in preparation of the field documents and regulatory guidance. Initially, 18 ft3 (approximately 2500 lbs) was excavated from the face of the sand fill and stored in plastic-lined containers for later processing. Three (approximate) 8-kg samples and three (approximate) 0.2-kg samples were extracted from this initial site soil for field and laboratory analysis of radioactivity and lead (Pb) concentration levels. These measurements would serve as baseline data for assessing air classifier effectiveness.

Following site preparation and equipment setup, it was necessary to remove soil particles (and portions of projectiles) greater than 2.00 mm to avoid jamming of the feeder. Initially, very large projectile fragments (i.e. several inches long) were separated from the excavated site soil by hand. Using a standard geotechnical sieve stack and shaker with a #10-size mesh screen, the initial site soil was then segregated into a coarse fraction (> 2.00 mm) and a fine fraction (2.00 mm). As before, three 8-kg samples and three 0.2-kg samples were collected from each fraction for subsequent radioactivity and lead-level analysis.

A sufficient quantity of the fine-fraction material was then processed in the air classifier system to obtain necessary coarse- and fine-discharge effluent samples. Prior demonstrations of the air classifier indicated that system performance may vary with the settings of certain system parameters -- most notably, feed rate and fan speed. Therefore, in this demonstration, feed rate and/or fan speed were varied to obtain different set points. Once again, three 8-kg samples and three 0.2-kg samples were collected from both discharge streams of each set for subsequent radioactivity and lead-level measurements.

The lab results of different fan/feed rate combinations were compared to determine their net effect on system performance and to identify control values for optimal air classifier effectiveness.

Following collection, each 8-kg sample was weighed and counted on-site for gamma activity using a sodium iodide (NaI) system to selectively measure DU gammas. These samples were then sent off-site and counted for DU gammas in a Marinelli beaker with NIST traceability. The on-site counting gave a relative measure of each sample's activity which was used to adjust parameters during testing. The off-site counting provided an absolute measurement of sample activity to compare the effectiveness of the ACT with possible regulatory standards. A mass balance was also performed on both the feed and effluent streams from the ACT. Finally, the 0.2-kg samples were used to assess lead and other heavy metal concentrations.

Following completion of air classifier operations, all equipment was decontaminated as it was disassembled. All waste products were collected in drums for subsequent disposal and the site was returned, as best possible, to pre-demonstration conditions.

Safety Precautions

Numerous safety precautions were taken including training in air classifier operations and hazardous waste handling and disposal procedures. A site-specific Standard Operating Procedure (SOP) and Site Health and Safety Plan (SHASP) were initially developed to preclude the possibility of harm to personnel involved in the field demonstration and/or in areas adjacent to the site, and to prevent any further contamination of the site and its surroundings while the demonstration was ongoing. The SHASP was forwarded for comment to the USEPA and the State of Virginia Department of Waste Management. All personnel involved in the field demonstration were required to satisfy the training requirements specified in the SHASP, including completion of an appropriate HAZWOPER safety training course and an on-site Hazard Control Briefing. In addition, all field workers underwent a uranium bioassay as well as a physical for respirator fitness.

As shown in Fig. 4, a three-zone approach was used to control migration of contamination and to minimize the potential for personnel exposure. All sieving and process operations were performed in a containment tent, the interior of which was the Exclusion Zone where the potential airborne DU hazard was greatest. The containment tent had dimensions of 142" x 98" x 96" (w x l x h). It was fabricated from PVC with the top half clear for personnel viewing of process operations. A Reduced Contamination Zone (RCZ) encompassed a protective shelter, an adjacent container/sample storage area, the equipment and personnel decontamination areas, the DU sand butt, and all immediately surrounding areas. These areas were known or anticipated to have limited DU contamination. The outermost Support Zone provided an additional buffer from the surroundings.

Fig. 4

Radiation levels within the containment tent and the adjacent areas of the RCZ were continually monitored for excessive levels of airborne radioactive material and dust. Airborne radioactive material levels were monitored by collecting particulate samples on filter paper using a Staplex high-volume air sampler located inside the tent and three HD-732 low-volume air samplers located outside the tent in the RCZ. The filters were later analyzed for radioactivity using a Tennelec alpha-beta counting system, i.e., a gas flow proportional counter. Airborne particulate monitoring was also accomplished by using a MIE model RAM-1 real-time aerosol monitor, located inside the containment tent.

RESULTS

In the field tests, the air classifier was operated at three different set points with dried soil from the fine fraction of the sieving process. These three points are denoted as follows: (1) LH - for low feed rate (15% of maximum) and high fan-motor speed (2250 RPM); (2) LM - for low feed rate and medium fan-motor speed (1750 RPM); and, (3) VLH - for very low feed rate (10% of maximum) and high fan-motor speed (2250 RPM). Several other set points were planned but not taken, because the field data indicated that these points would not improve the classifier's performance. The results obtained from these tests have been divided into the following four categories: mass and volume balance, field radiation analysis, absolute DU activity analysis, and the lead analysis.

Mass and Volume Balance

The sieving process resulted in approximately 75% (by volume) of the gun butt soil being collected as fine fraction and 25% as coarse fraction. No exact mass balance was made at this point of the study. It was later estimated that approximately 40% of the mass was collected as coarse fraction since the density of the coarse fraction was found to be greater than that of the fine fraction.

Table I shows the percent effluent collected in each of the discharge streams for each of the three set points. The mass balance is expressed as percent of the total fine fraction processed (given in parentheses) by the ACT. As can be seen, reducing the feed rate significantly increased the percentage of mass collected in the fine effluent. Also, because the coarse effluent contained more DU than the fine effluent, the LH and LM set points are considered to be impractical operational set points because of the small percentage of clean, fine effluent they produce.

Table I

Field Radiation Analysis

The average normalized radiation levels observed for the samples obtained by sieving are shown in Table II. The activity of the gun butt soil has been arbitrarily assigned a value of unity. As can be derived from this table, the coarse fraction has an average radioactivity level approximately six times that of the fine fraction.

Table II

The average normalized activity levels for samples collected from the ACT are shown in Table III for the VLH set point. For these results, the activity of the fine effluent has been arbitrarily assigned a value of unity. As shown in this table, the coarse effluent has an activity approximately 39% greater than that of the fine effluent. The fractional standard deviation presented is based on a statistical analysis of all collected samples at this set point.

Table III

Absolute DU Activity Analysis

The absolute DU activity levels of the collected samples, expressed in units of pCi/kg, are shown in Table IV. Also shown are the ratios of each sample's absolute DU activity to the gun butt soil's absolute DU activity. The results represent the average of all collected samples within a group.

Table IV

This laboratory data shows the same qualitative results as obtained by the field radiation analysis; namely, that: 1) the fine sieved fraction is lower in activity than the gun butt soil and significantly lower in activity than the sieved coarse fraction; and 2) the fine ACT effluent is lower in activity than the coarse ACT effluent. However, the activity levels of all samples were well above the 30-50 pCi/kg limit suggested by the USEPA for federal DU sites (4). Finally, it should be noted that Table IV data show the fine and coarse ACT effluents with a slightly higher activity than that of their feed (i.e., the fine sieved fraction). The authors believe that this result is due to natural variations in activity of the feed. The samples of fine sieve fraction collected for analysis differed from the material actually processed to yield the ACT effluents.

Lead Analysis

Results from the lead analysis are shown in Table V and represent the average of all samples collected within a group. The data expresses the lead concentration in units of mg/ l as well as a normalized value based on the level in the gun butt soil. As indicated, sieving the soil resulted in a significantly lower lead concentration in the fine sieved fraction compared to the site soil. Additionally, the ACT process resulted in an even further reduction in lead concentration (in the fine effluent). The fine effluent samples had a lead concentration of 1.1 mg/l or approximately 3% of that found in the collected site soil samples. The remediation improvement in the lead concentrations, as compared to the DU, is believed to be due to either of the following reasons: 1) there was a more favorable size distribution of lead and soil particles than DU and soil particles; and/or, 2) there was less chemical bonding between lead and soil particles than between DU and soil particles.

Table V

CONCLUSIONS

A number of conclusions were drawn from these tests and have been divided into the following two categories: technology evaluation and health and safety assessments.

Technology Evaluation

1) Sieving the gun butt soil prior to use of the ACT appears to produce a significant concentration of DU activity (i.e. 75% of the activity into 25% of the volume) into the coarse fraction and produces a substantially cleaner fine fraction compared to the unprocessed soil (i.e., by a factor of 3). Thus, sieving alone could potentially result in a substantial volume reduction of the soil that would need to be remediated.

2) The ACT produces a coarse fraction with greater activity than the fine fraction and thus the ACT can be used to further reduce the activity of a portion the soil. However, the ACT technology did not reduce DU activity to a level which would meet currently proposed remediation standards for federal agencies.

3) The mass split in ACT between the coarse and fine effluents is strongly affected by the soil feed rate and fan speed of the air

classifier. Slowing the feed rate and increasing the fan speed causes more soil to move into the fine effluent stream and appears to improve the separation effect of the ACT.
4) The ACT is easy to operate and maintain for reliable use in field conditions. Once the soil is dried, sieved, and loaded into a feeder, little further effort is needed to process the soil. The technology requires a level surface and a standard 110V power source.
5) The ACT appears to provide a much greater separation effect for lead than DU. Perhaps even more significant, sieving was found to reduce the lead concentration in the fine fraction by better than 6:1 compared to the unprocessed site soil.

Health and Safety Assessments

1) There was little airborne dust generated by the air classifier operation. The most dominant source of airborne dust was observed during the soil transfer operations between the containers, the sieves, the oven, and the feeder.
2) The containment tent was very effective in preventing dust from leaving the exclusion zone. No significant readings were observed in any of the three air samplers employed in the RCZ (i.e., outside the containment tent).
3) No chemical reagents were required at any time in the process and water was needed only during the decontamination and clean-up operations. No equipment or surfaces were found to be contaminated with high levels of radioactivity following the completion of the demonstration.
4) Wetting the soil prior to its excavation from the gun butt reduced the dust generated during that operation, but this necessitated drying the soil prior to sieving.

RECOMMENDATIONS

1) Since sieving alone appears to have strong potential for volume reduction, the effect of different sieve cut sizes should be investigated to determine if larger concentrations of activity and, possibly, improved volume reduction can be achieved.
2) The air classifier should be equipped with a larger fan motor in order to operate the classifier at higher fan RPMs than possible with the current USNA system. The test data indicates that higher fan RPMs may further improve the ACT's performance over what was obtained during these tests.
3) Data should be collected at lower feed rates and higher fan speed than achieved in this study. These adjustments should increase the percentage of soil in the presumably cleaner fine effluent and, thus, increase the amount of soil cleansed by this process.
4) ACT effectiveness of separating uranium from soil may be improved with triboelectrification (5). The soil would first be triboelectrified which would preferentially impart an electrical charge to the contaminate. This soil would then be fed into the ACT where separation would be enhanced under the influence of an applied electric field.

ABSTRACT
Microbes in the environments surrounding nuclear waste depositories pose several questions regarding the protection of the surrounding communities. Microbes can facilitate microbially influenced corrosion (MIC), mobilize and facilitate the transport of nuclides as well as produce gaseous emissions which can compromise containment. We have developed an analysis of the extant microbiota that is independent of quantitative recovery and subsequent growth, based on signature biomarkers analysis (SBA). Polar lipids exist in all organisms that have intact cell membranes and intact cell membranes are a requirement for life. Extraction and measurement of polar lipids indicates the biomass of

the microbes that are viable but may or may not be culturable. Phospholipid ester-linked fatty acids (PLFA) give a measure of the microbial community containing intact membranes. Phospholipids are often transformed into diglycerides by endogenous phospholipases in injured cells which retain for a time the characteristic signature profiles of the fatty acids and thus provide a measure of the viable cells with intact membranes and recently non-viable (lysed) cells. The lipid patterns of PLFA and other lipid classes also reflect exposures of the cells to nutritional imbalances, toxicity, and various stresses thereby providing phenotypic insight into the condition of the community. The lipid extraction procedure also allows recovery of the cellular DNA for probing with or without enzymatic amplification that adds extraordinary specificity for analysis for specific organisms, groups of organisms or potential enzyme activities. Specific signature lipid patterns of PLFA, steroids, respiratory quinones and lipopolysaccharide hydroxy fatty acids of the lipid A of gram negative bacteria allow detection of many groups of microbes with a quantitative definition of the community composition. Utilizing the SBA it has been possible to show that there are viable microbial communities in the host rock of potential subsurface waste deposit sites like Yucca Mountain. Research has shown that the viable biomass, community composition and nutritional status of the extant microbial community shifts with contamination, pollution, and disturbance. With SBA it has been possible to document that MIC is related in time and space to the corrosion process and to define which microbial communities are most likely to facilitate localized corrosion. Specific organism involved in uranium reduction can be identified by SBA. With the insight gained with SBA, predictions of potential effects microbial communities may have on the containment of nuclear wastes can be made.

INTRODUCTION

Microbes tend to be ignored because they are difficult to study. The classical methods of isolation and culture of microbes that are taught in most microbiology courses have been enormously successful in clinical medicine where isolation of specific pathogens establishes the diagnosis of disease and the in vitro sensitivities to antimicrobials can often predict the success of treatments. The obvious thing to do was to apply the same methods to repository system to detect the presence of microbes. Unfortunately often less than 1% of the microbes that can be detected in stained microscopic preparations can be cultured. Staining microbes in environmental samples like soils can be difficult as many are attached to soil granules and may be hidden. Agents that release attached microbes are often selective and do not release them quantitatively. The morphology of the microbes does not often reflect the function or activity so very little insight into the community structure or nutritional status is possible. Measurements of metabolic processes are complicated by the facts that most microbes in the soil are inactive, but poised for activity when nutrients appear. Adding labeled substrates to determine rates of metabolic activity induces major disturbance artifacts giving much higher rates than actually exist in the environment. This is possibly best exemplified in studies of the deep subsurface microbiota where oxygen and inorganic carbon are found in groundwater with a ground water age of greater than 1.1 x 105 years. Measurements of metabolic activity based on isotope incorporation experiments by the microbes in subsurface sediments were 103 to 106 times greater than the geochemical

evidence would predict. The metabolic activities by the subsurface microbiota indicate growth rates in centuries (27).

METHOD

A solution to the quantitative detection of microbes in the environment of nuclear storage is in signature biomarker analysis (SBA). We have concentrated on the analysis of lipids (30). Every living cell is surrounded by a lipid membrane. These lipids are quantitatively extracted from the microbiota in situ and analyzed using gas chromatography/mass spectrometry (GC/MS). Several unique classes of lipids, including steroids, diglycerides, triglycerides, respiratory quinones, -hydroxyalkanoate (PHA), phospholipid lipid fatty acids (PLFA), lipo-amino acids, plasmalogens, acyl ethers, sphingolipids, and lipopolysaccharide hydroxy fatty acids can be used as signature lipid biomarkers to characterize microorganisms or communities of microorganisms. Recently the lipid extraction has been shown to yield DNA suitable for gene probing and enzymatic amplification (12).

Phospholipids are one of the most important SBA classes, and are essential membrane components of living cells. Unlike most other biomarkers, phospholipids are typically degraded within hours following cell death. This rapid degradation of the phospholipids establishes the PLFA as ideal biomarkers for viable cells, thus, the quantification of total PLFA is an accurate measurement of living biomass (2). Because different groups of microorganisms synthesize a variety of PLFA through various biochemical pathways, the PLFA are effective taxonomic markers and can be utilized to provide insight into the community composition. PLFA analysis can provide insight into the phylogenetic relationships between organisms similar to phylogenetic analysis based on the sequence homology of 16S ribosomal RNA (8,15). Knowledge of specific lipid biosynthetic pathways can provide insight into the nutritional status of the microbial community as certain fatty acids, such as trans and cyclopropyl fatty acids, provide an indications of environmental stress. Other components indicate unbalanced growth where carbon sources and terminal electron acceptors abound but a critical nutrient prevents cell division but not growth or bioavaiable phosphate is insufficient (31). The redox level of the microbiota can be determined in situ by shifts in the composition of lipids in specific indicator microbes. The signature lipid biomarker techniques have been successfully applied to subsurface materials (33).

Fig. 1

RECOVERY OF MICROBES FROM SUBSURFACE

The detection of microbes from deep subsurface sediments that are possible repositories for nuclear materials requires convincing evidence that the samples recovered from drilling operations were not contaminated by the make-up water, drilling muds, or in handling. Signature lipid biomarker analysis has shown that the viable biomass, community composition, and nutritional/physiological status of the microbial communities recovered with strict sampling guidelines (3,26) were distinctive enough to assure that microbes in the pared cores were from the extant microbiota (17).

DETECTION OF IN SITU MICROBIAL COMMUNITY ACTIVITY

We have ample evidence that the subsurface microbial community responds rapidly to changing conditions and is thus metabolically active. Pollution readily induces shifts in the viable biomass, community composition, and nutritional status of subsurface microbial community

with an increase in viable biomass and increased proportions of PLFA characteristic of gram-negative heterotrophs (29). Increases in the type II methane-oxidizing bacteria were detected in soil columns gassed with methane and air (23). Addition of different fatty acid substrates to anaerobic sediment cores induced marked and expected changes in the bacterial community structure (25). Subsurface sediments perfused with methane, propane, air show shifts in community structure that correlate with trichloroethylene (TCE) biodegradation (4,28). Active biodegradation of petroleum hydrocarbons in subsurface sediments results in increases in viable biomass, shifts to aerobic heterotrophic bacterial PLFA, decrease in biomarkers indicative of stationary phase growth, decrease in PHA/PLFA ratio, and increases in the proportion of benzoquinone respiratory quinones indicative of aerobic electron transport activity (28). The nutritional status of microbial consortia actively degrading petroleum differs markedly from the organisms fortuitously degrading TCE in that effective TCE biodegradation is correlated with a build-up of reducing power indicated by a high PHA/PLFA ratio (23). Clearly the subsurface microbiota responds to shifts in the environment. Unpublished experiments from the Savannah River in situ TCE biodegradation demonstration showed that the changes detected in the recovered sediments were reflected in the ground water microbes collected as membrane filter retentates. The recovery of specific gene probes for methane monooxygenase and the signature PLFA of the methane-oxidizing bacteria correlated well.
Bacterial PHA and microeucaryotic triglyceride (6) are endogenous storage lipids. The relative amounts of these compounds compared to the PLFA, provides a measure of the nutritional status of specific components of the microbial community. Many bacteria form PHA under conditions of unbalanced growth such as when a carbon source and terminal electron acceptor(s) are present but cell division is limited by the lack of some essential nutrient (5,24). The determination of the ratio of PHA/PLFA has proved useful in monitoring the effectiveness of bioremediation in the subsurface--effective biodegradation of petroleum hydrocarbons correlates with a low ratio of PHA/PLFA (28) whereas the fortuitous metabolism of trichloroethylene correlates with a high ratio of PHA/PLFA (23,4).
Specific ratios of PLFA acids have been shown to correlate with physiological stress (7). Exposure to toxic environments can lead to minicell formation and a relative increase in PLFA specific to the exposures. For example, increased conversion from cis to trans PLFA occurs in Pseudomonas species with exposure to higher concentrations of phenol in the absence of bacterial growth (11). Prolonged exposure to conditions inducing stationary growth phase induce the formation of cyclopropane PLFA (7). The respiratory quinones, the detection of plasmalogen lipids and other biomarkers can be utilized to indicate the degree of microbial aerobic activity (10,31). Environments with high potential terminal electron acceptors (oxygen, nitrate) induce the formation of benzoquinones in bacteria in contrast to microbes respiring on organic substrates which form naphthoquinones. There are other lipid biomarkers such as lipid amino acids liberated after hydrolysis of the lipids can yield further insights into the conditions of the subsurface microbial microniches (31).

POTENTIAL FOR MICROBIAL INFLUENCED CORROSION

The application of SBA lipid technology to subsurface sediments recovered with the quality assurance that the communities sampled represent the extant microbiota clearly show the presence of a diverse and viable

microbiota that responds to geochemical and hydrologic gradients. The metabolic activities of bacteria found in the subsurface can produce significant risks to the containment of nuclear waste over extended periods of time. Microbes are associated with pitting corrosion (14). The ready destruction of concrete sewers by Thiobacilli (13) or buried gas transmission pipelines by acetogens (27) attest to the destructive power microbes. Microbially influenced corrosion (MIC) poses potentially serious problems in the maintenance of containment barriers (18). Microbes have been shown to particularly attack weldments (20) and are quite capable of localized MIC on "noble" substrata such as stainless steel (1). Because of these microbial potentials, it becomes necessary that a thorough understanding of the extant subsurface microbiota be known prior to the deposition of nuclear wastes.

TRANSPORT

Microbes have considerably higher hydraulic transmissivity than conservative tracers like Bromine (16). Microbes readily bind nuclides (21) and can thus transport nuclides very effectively. SBA of lipids has shown that subsurface microbial communities can respond to differences in the hydraulic conditions. The viable microbial biomass, based on total extractable PLFA, decreases with depth in sediments from the arid northwest. This viable biomass decrease with depth is slightly less pronounced in areas where there is a high recharge rate. An analysis of microbial community composition throughout the tested depth interval shows that PLFA indicative of Actinomycetes, in particular tuberculostearic acid (10me18:0), continue to represent a constant or increasing percentage of the total in the area of high recharge which was in sharp contrast to the decrease in percentage of these PLFA in the area of low recharge (33).

POTENTIAL EFFECTS

Microbial contamination and metabolic activity in the subsurface if controlled and monitored not be a major threat to the containment of buried nuclear waste. Microbes have a remarkable capacity to immobilize nuclides through the formation of insoluble compounds (19). Bacterial metabolic activities may have been responsible for the original concentration of uranium nuclides in sedimentary deposits and for their containment over the past billions of years at sites like Cigar Lake, Saskatchewan or in fission products like those at Oklo, South Africa.

ORGANISMS AT PROPOSED SITES (YUCCA)

Application of SBA lipids to potential sites has shown that microbes are present in the uncontaminated volcanic tuft of the Yucca Mountain, NV site. Concentrations recovered from the aseptic (in so far as possible) carefully prepared sites show bacteria in concentrations equivalent to 102-104/gm. Some are cuturable and show diversity and heterogeneity in their distribution (9). There are large amounts of as yet uncharacterized glycolipids and terminally branched saturated PLFA characteristic of gram-positive bacteria. No samples have been assessed after the tunnel preparation which would be expected to increase the diversity, activity and biomass of the microbes. Simply aseptically grinding the tuft in the absence of any added nutrients or water significantly stimulates microbial growth and activity (P. Amy and D. Haldeman personal communication).

ABSTRACT
Atomic Energy of Canada Limited is developing a concept for the disposal of nuclear fuel waste in an engineered vault 500 to 1000 m deep in plutonic rock of the Canadian Shield. The concept is based on a multi-barrier system. The fuel waste, isolated in corrosion-resistant containers, would be placed in disposal rooms and the containers would be surrounded by compacted buffer material (50 wt.% sodium bentonite and 50 wt.% silica sand). The rooms and connecting tunnels would be backfilled with a mixture of 75 wt.% crushed and graded host rock and 25 wt.% glacial lake clay. The final barrier would be the host plutonic rock surrounding the vault.
The backfill clay would be mined locally. The reference clay, that exhibits the appropriate sealing properties, is Lake Agassiz clay, deposited ~8,000 years ago. This clay contains 1 to 2% organic matter. The question this work addresses is "Is it possible that microbes, naturally present in the clay and groundwater and introduced during construction of a vault, could use this organic material and generate gas that could affect the integrity of the backfill barriers?". This paper describes how microbial gas production from natural organic matter present in Lake Agassiz clay is being investigated. The gases most likely produced are CH4, H2S and H2 because of the low reduction-oxidation potential expected with time in the backfill environment. A methane production rate of 48 mg CH4/kg clay.d over 193 days was observed in a Lake Agassiz clay/groundwater mixture. However, reducing conditions were achieved using an addition of thioglycolic acid, an O2-scavenger and an additional C source that may be easily-utilized by microbes. Thus, this

methane production rate may not be applicable to a nuclear vault system, and is not even appropriate as an upper bound.

INTRODUCTION

Atomic Energy of Canada Limited is developing a concept for the disposal of nuclear fuel waste in an engineered vault 500 to 1000 m deep in plutonic rock of the Canadian Shield (1). The concept is based on a multi-barrier system. The fuel waste, isolated in corrosion-resistant titanium or copper containers, would be emplaced in disposal rooms or in boreholes drilled in the floor of disposal rooms (2, 3). The containers would be surrounded by compacted buffer material (50 wt.% sodium bentonite and 50 wt.% silica sand) that would swell when saturated with groundwater (4) and ensure that transport of any contaminants was controlled by diffusion. After waste emplacement, the rooms and connecting tunnels would be backfilled with a mixture of 75 wt.% crushed and graded host rock and 25 wt.% glacial lake clay. The final barrier would be the host plutonic rock surrounding the vault (5).

The backfill clay would be mined locally, and the backfill would be prepared on site in sufficient quantities to fill the shaft and adjoining rooms. Since such an engineered facility would be large, some 9.6 million m3 of this material would be required (6). The reference backfill clay, that exhibits the appropriate sealing properties, is Lake Agassiz clay, deposited some 8,000 years ago (7). This clay contains 1 to 2% organic matter (8). It is possible that microbes, naturally present in the clay and groundwater and introduced during construction of a vault, could use this organic material and generate gas that could affect the integrity of the backfill barrier.

The objective of the work presented here is to demonstrate and test the techniques that would be used to measure microbial gas production from natural organic matter present in Lake Agassiz clay. The gases most likely produced are CH_4, H_2S and H_2 because of the low reduction-oxidation potential expected with time in the backfill environment (3). Experimental results are presented and discussed for experimental systems containing deep crystalline rock groundwater, groundwater and clay, and groundwater and backfill.

METHODS AND MATERIALS

Experimental Vessels

A 2-L fermentation vessel capable of holding a large flooded backfill clay sample (0.6 kg dry wt.), including a headspace for gas sampling, was used (Fig. 1). The vessel was fitted with probes through a septum in one of the headplate ports to continuously monitor the pH and Eh in the clay. Water samples could also be removed through this septum. Most gas samples were taken under vacuum through a Nupro valve attached to a second port. A pressure gauge was attached to measure headspace pressure. A strip-paper anaerobic indicator was positioned in the headspace of the vessel to allow a visual check for anaerobic conditions. The other ports were sealed to maintain an air-tight system.

Fig. 1

Materials

Groundwater from AECL's Underground Research Laboratory (URL) northeast of Lac du Bonnet, Manitoba, Canada, was collected from a borehole (HG4-4), intersecting a rock fracture zone identified as Fracture Zone 2 (FZ2), at a depth of 130 m (9). The properties of the Lake Agassiz clay are reported elsewhere (10, 4, 8). Radio-carbon dating, performed during this study, showed the age of the organic matter in the clay to be 23,950

270 years, containing about 5% 0.2 of modern 14C. Total organic carbon of a clay sample, analyzed using the Walkley-Black method was 7.50 mg/g or 0.75% organic carbon. The total inorganic carbon analyzed by combustion in a LECO furnace was 9.30 mg/g. The clay was air-dried, ground and sieved through a 850-m screen. A 2:1 slurry of groundwater (1230 mL) to clay (615 g) was poured into the fermentation vessel leaving a headspace of about 310 cm3. Before adding the groundwater/clay slurry, the fermentation vessel and headplate with attached probes were washed with alcohol. The slurry was left to settle, forming a layer of "surface" water on top of the clay. The fermentation vessel was wrapped with aluminum foil to prevent light infiltration and kept at room temperature (221C) for 212 d. Thioglycolic acid (C2H3O2SNa, FW 114.1, 1.125 g), added to the vessel as an O2 scavenger, forced the system to go anoxic after 32 d.

Sampling

Gas samples, withdrawn through the septum using a 10 mL Gastight syringe under vacuum through a Nupro valve were analyzed with a VGMM8-80 Mass Spectrometer for CH4, O2, CO2, SO2 and H2S. Biological Activity Reaction Tests (BARTs) for iron-related bacteria (IRB-BART), sulphate-reducing bacteria (SRB-BARTTM) and slime-forming bacteria (SLYM-BARTTM) were scored, as recommended, on the groundwater before use, and on the surface water and clay pore water at the end of selected experiments.

Microbe counts, using a modified epifluorescence microscopy counting procedure (9) were carried out in duplicate on samples of the groundwater prior to mixing with the clay. A 5-mL sample of surface water was withdrawn from the vessel during the course of the experiment for microbe counts. Final microbe counts were performed on the surface water and pore water extracted from the clay.

Total water chemistry (anion/cation by Varian SpectrAA-400, DIONEX QIC Ion Chromatograph and ICPS, ARL-3560) and total inorganic (TIC) and organic carbon (TOC) analyses (persulphate method, Astro 2001-MB) were performed on the groundwater prior to use.

Dismantling of the Vessel

At the conclusion of the experiment, the surface water from the vessel was siphoned off and the clay removed at depths of 0-4.5, 4.5-9.0 and 9.0-13.5 cm. The clay was placed into 50 mL vials and centrifuged at 1000 rpm (Relative Centrifugal Force=251 m/s2) for 20 minutes, to yield the clay pore water. The clay adhering to the headplate probes (which comprised a central plug) was scraped off and centrifuged separately. Microbe counts were done on a 10-mL sample of the surface water and on the pore waters with depth. Analyses for S (by titration of SO2 released during combustion in a LECO induction furnace), P (colorimetrically after H2SO4/HF/HNO3/HCl digestion), and N (total Kjeldahl nitrogen) (11) were performed on the clay from each of the sampled depths and adhering to the headplate probes. The remaining pore water was combined to provide sufficient volumes for BARTs, total inorganic and organic carbon, and total water chemistry analyses.

RESULTS AND DISCUSSION

Gas Analysis

The results of the gas analyses from the first experiment are shown in Table I.

Table I

Concentrations of H2 sampled from the headspace were low throughout the sampling period. Detectable amounts of CH4 were observed after only 7

days of closure of the fermentation chamber, although the oxygen levels were still high (Fig. 2) and the anaerobic strip paper indicated the system still contained O2. The system went anoxic after 32 d, when analysis showed an order of magnitude drop in the O2 concentrations (Table I, Fig. 2). The pH (~7.8) of the clay slurry remained constant throughout the sampling period. A substantial increase in the amount of CH4 produced was observed after 50 d and peak CH4 production rates of about 48 g CH4/kg clay.d were reached between 50 and 81 d, whereafter it remained constant for another 100 d (Fig. 2). This CH4 production was offset, as expected, by a drop in the O2 levels in the system (Fig. 2). A slight drop in CH4 production was observed after 119 d when a pore-water sample was removed for microbial counts which introduced air into the system (Table I). After 151 days the CH4 production dropped to 28 g/kg clay.d (Fig. 2), possibly indicating the development of less favorable conditions for methanogens. The gas composition throughout the experiment indicated that CH4 production was accompanied by CO2 production, with a small drop in N2 (Table I). Results from further experiments in which no thioglycolic acid was added, are in progress.

Fig. 2

Groundwater and Clay Analyses

The clay of this experiment contained 7.5 mg/g organic carbon (i.e.,13.3 mg/g organic matter) and 9.3 mg/g inorganic carbon. The total inorganic carbon (TIC) in the surface water of the fermentation vessel after 164 days increased from 305 mg/L to 901 mg/L (the error bars are standard deviations based on three replicate samples). The total organic carbon (TOC) increased from 0.40.02 mg/L to 45513 mg/L. The TIC increase is probably a result of the slow dissolution of the clay carbonate minerals in the groundwater. The TOC increase is partially due to the thioglycolic acid (187 mg C/L) and to the dissolution of organics from the clay. The TOC of the clay accounted for 4600 mg C. Although microbe counts increased with time (13), microbial growth did not account for the increase in TOC (13). There was no consistent variation in the pore-water microbe counts with depth in the clay sediment and significantly more microbes were associated with the pore water and clay than with the surface water.

Calculations show that microbial cells (105-107 cells/mL), assuming one cell contains between 10-13 to 10-15 g C, account for a minimum of 0.1 g C/L and a maximum of 1 mg C/L. Calculations of limiting nutrients in the system and populations of microbes that can be supported by these nutrients were carried out and are discussed elsewhere (12, 13).

Biological Activity Reaction Tests (BARTs) and Major Ion Analysis

The BART tube tests on the initial groundwater indicated a significant Fe-related bacteria (IRB) population with a very aggressive slime-forming bacteria (SLYM) population and a small sulphate-reducing bacteria (SRB) population (13). After 212 days, the SRB population increased to significant levels in the surface water while the IRB population, associated with the pore water, was highly aggressive. The initial population supported by the IRB tubes was significant despite the concentration of Fe in the initial groundwater being very low at 0.043 mg Fe/L. However, the Fe and other dissolved ion concentrations in both the pore water and surface water increased substantially during the experiment, suggesting some dissolution of the clay. After 212 days, the concentration of Fe and other dissolved ions in the surface apparently allowed the bacteria to become highly aggressive (13).

Concentrations of total S increased dramatically from 13.7 mg S/L to 897 mg S/L (surface water) and 1280 mg S/L (pore water), presumably due to dissolution of gypsum in the clay, allowing the sulphate-reducing bacteria to increase. The concentration of P in the groundwater was low enough to be considered a limiting nutrient to the microorganisms (13). However, there was probably sufficient P in the clay for microbial growth. Nitrogen concentrations also increased slightly in the pore water, however, N may still be a limiting factor for microbe growth in this experimental system.

METHANE PRODUCTION

Methane production rates of 48 g CH4/kg clay.d over 193 days of gas sampling gave a total CH4 production of 35 mg of CH4. Using the ratio of C to CH4, shows that 20 mg of C were converted to CH4. The original groundwater contained 1.0 x 105 microbes/mL. Initially there were 1.2 x 108 microbes in the system in the 1230 mL of groundwater alone. Surface and pore water after some 200 days contained 6 to 12 x 106 microbes/mL, for a total of at least 7 x 109 microbes. Assuming the population increased at least two orders of magnitude, and assuming 1013 to 1015 microbes contain 1 g C, an insignificant amount of C (1 x 10-11 g) has been converted to microbial material.

The addition of the thioglycolic acid may have provided the microbes with an additional source of C. The 1.12 g of thioglycolic acid provided 0.27 g of C, enough easily-utilized C to produce this amount of CH4. Since there was enough thioglycolic acid alone to keep this system running another two years, without having to use the perhaps more recalcitrant C of the groundwater or the clay, this system was stopped. Other experiments show methane production in groundwater without the use of thioglycolic acid.

Most likely there will be limiting nutrients (N and P) for the CH4-producing microbial population. Nitrogen has been found to be the most limiting nutrient in flooded soils (14). Oxidation of CH4 as it enters the biosphere (15) will also consume CH4 arising from depths. There are a number of additional factors that must be considered such as the effect of pressure, temperature and radiation on microbial populations within a nuclear fuel waste vault, the moisture content of the buffer material (16, 9), the concentration of salt in the groundwater, as well as the degree of fracturing in the bedrock and distance to the surface.

CONCLUSIONS

We have discussed several techniques that were used (and improved) throughout the course of a backfill gas production experiment. Methane was produced in a laboratory vessel containing Lake Agassiz clay and granitic fracture zone water. A methane production rate of 48 mg CH4/kg clay.d over 193 days of gas sampling was reached. Reducing conditions, however, were achieved using thioglycolic acid, an O2-scavenger and an additional C source that may be easily-utilized by microbes. Thus, this methane production rate may not be applicable to a nuclear vault system, and is not even appropriate as an upper bound. Calculations show N, P and perhaps even C in the groundwater/backfill may limit microbial growth in a nuclear fuel waste vault.

ACKNOWLEDGEMENTS

We thank Connie Hamon for microbe counting and BART tube analysis instruction, Grant Delaney and Merle Brown for gas analyses, Jay Hawton for groundwater collection, Dave Dixon and Dave Woodcock for providing Lake Agassiz clay and information on its source location and Lisa Lucht

for the loan of the fermentation vessel. The Canadian Nuclear Fuel Waste Management Program which has supported this work, is jointly funded by AECL and Ontario Hydro under the auspices of the CANDU Owners Group.

MICROBIOLOGICALLY INFLUENCED CORROSION OF DISPOSAL CONTAINERS FOR RADIOACTIVE WASTES

Brenda Little
Patricia Wagner
Naval Research Laboratory
Stennis Space Center, MS 39529-5004

ABSTRACT

Microbiologically influenced corrosion has been documented for all metals and alloys currently in use or proposed for packaging nuclear wastes, with the possible exception of titanium. Selection of a material that will provide a reliable physical barrier to prevent leakage of radionuclides will depend on a thorough understanding of mechanisms for microbiologically influenced corrosion, the geological/microbiological/chemical environments of storage sites and their evolution over time.

INTRODUCTION

Microbial biofilms develop on all surfaces in contact with aqueous environments. Biofilms composed of immobilized cells embedded in an organic polymer matrix are absorptive and porous, and contain solutes, heavy metals, and inorganic particles, in addition to cellular constituents (1). Biofilm/surface interfacial chemistry can be radically different from that of the bulk medium in terms of pH, dissolved oxygen, organic and inorganic species. Microbiologically influenced corrosion (MIC) is usually used to designate corrosion due to the presence and activities of microorganisms within biofilms at metal surfaces. It is important to extend the definition to include corrosive microbial metabolites that may be produced in one location and diffuse to a corrosion site. MIC is localized corrosion that results in pitting, selective leaching, crevice corrosion, under-deposit corrosion and enhanced erosion corrosion. Microorganisms can accelerate rates of partial reactions in corrosion processes and shift corrosion mechanisms. MIC of storage containers is a potential problem for safe disposal of nuclear wastes. Primary materials being considered for containment of high level nuclear waste in mined geological repositories are alloys of iron, nickel, copper and titanium. Iron and nickel are significant components of alloys being proposed for containment of low- and intermediate-level nuclear waste in either shallow land burial or deep disposal. Aluminum and stainless steel alloys are currently used in the construction of pools and racks for storage of spent nuclear fuels. Carbon steels have been used to contain nuclear wastes in marine sediments (2) and are being considered as suitable materials for the outer shell of a double shell storage container for subsurface burial. With the exception of titanium, MIC has been documented for all metals and alloys under consideration. However, because of a lack of information about subsurface/oligotrophic microbiology and the belief that g-radiation from fuel within containers would effectively sterilize storage environments, recognition of potential problems has been neglected. In

this paper mechanisms and case histories for MIC will be reviewed with particular attention to metals and alloys currently in use or proposed for nuclear waste storage.

Biofilm Formation

Presence of water, availability of nutrients/energy sources and tolerance of microorganisms to high temperature, ionizing radiation and concentrated solutes will influence development of a substantial population of microorganisms on or around nuclear waste storage containers. There is increasing evidence that microorganisms exist and flourish in unlikely environments, including radioactive and nutrient-deficient waters and deep subsurface environments. Algae, fungi, yeasts and bacteria were found in water covering the damaged reactor core at Three Mile Island (TMI) nuclear power plant (3). Bacteria survived on carbon-rich hydraulic fluid leaked from tools during defueling after exposure to g-radiation doses of 10 Gy h-1 (4). Dose rate around a nuclear waste storage container decreases with time as waste decays and decreases with increasing distance because of attenuation in buffer material.

Groundwaters in geological deposits are often saline and typically contain 101 to 105 colony-forming units ml-1 (5). Three significant biofilms containing bacteria have been identified at the Underground Research Laboratory (URL) in the Archean Lac du Bonnet Batholith in southeastern Manitoba: one at the drill hole draining through an underground structure (420 m depth), an extensive biofilm covering walls kept wet by groundwater flowing from fractures and exposed to gaseous carbon and nitrogen-containing explosives (240 m depth), and one found on the side of a large borehole (130 m depth) irrigated by water from drilling operations. The indigenous microbial population in the Canadian design disposal vault was relatively small (103 to 105 microbes cm-3) compared with surface waters (6). However, Stroes-Gascoyne (7) concluded that construction activity will introduce both microorganisms and nutrients. White et al. (8) found biochemical evidence that bacterial populations equivalent to 107 bacteria gm-1 sediment existed at a depth of 410 m in the Bacatunn clay formation near Pensacola, FL. Viable microorganisms were recovered in Nevada from ashfall tuff in a mined tunnel 350-450 m below the surface and hundreds of meters above the regional water table. Microorganisms adhere to rock surfaces and form complex, sessile biofilm populations that intervene between rock and groundwater (9). In soils and on rock surfaces, microorganisms are generally not uniformly distributed but accumulate in discrete microcolonies attached to particle surfaces to form a system composed of more or less discontinuous colonies, each in its own microhabitat (10). In natural oligotrophic environments the formation of biofilms is a survival strategy for bacterial communities. Little et al. (11) reviewed factors influencing adhesion of microorganisms to substrata. Roughness and surface chemistry of the substratum play a major role in biofilm processes during early stages of biofilm accumulation and may influence rate of cell accumulation and distribution in aquatic environments. Electrolyte concentration, pH and inorganic ions influence settlement. Hydrated oxide and hydroxide passivating films on metal surfaces provide bacteria with sites for firm attachment. Similarly, spalling or sloughing of corrosion products forces detachment of biofilms associated with corrosion products. Carbon is not always the growth limiting nutrient for microorganisms. Phosphorus and nitrogen may be limiting in some systems.

Wilkinson (12) found that, when the concentration of nitrogen in a growth medium was gradually lowered until it became limiting with C/N ratios in the range 7-10, cells growing in such a medium tended to reproduce slowly and produced copious amounts of extracellular polymer. Hydrodynamic shear stress, related to flow, influences transport, transfer and reaction rates within biofilms, as well as detachment. Temperature influences the rate of most chemical and biochemical reactions as well as transport processes within the biofilm.

In several proposed storage concepts, used nuclear fuel would be encapsulated in a metal container and buried in an underground disposal site located 500 to 1000 m subsurface. Containers would be surrounded by a compacted mixture of silica sand and sodium bentonite, known as buffer material. Safety is based on a series of barriers designed to prevent or delay toxic radionuclide species from coming into contact with man. The only absolute barrier in the system is the container. All other barriers are porous. Sodium bentonite is a cation-exchanging smectite clay mineral that swells upon contact with water. Mass transport through the buffer is expected to occur only by diffusion. Remaining void spaces will be air-filled, and entrapped oxygen will be the major source of oxidants. Depending upon specific disposal design, containers will be embedded in buffer material in either excavated rooms or boreholes filled with clay, crushed rock, and/or concrete. The next barrier in the system is 500 to 1000 m of granitic rock,clay, salt, limestone, iron ore, gypsum, bitumen, ash or soil.

Storage environments in geological repositories and their microflora will change with time. Initially, conditions will be hot and oxidizing as radioactive decay of fuel produces heat and g-radiation. Initial storage environments will be radioactive, hot, dry and nutrient deficient. Combined effects of elevated temperature, g-radiation and desiccation of the buffer material will severely limit the extent of microbial activity close to the container and might result in an abiotic zone 40 cm into the compacted buffer material (13). As fuel decays and trapped oxygen is consumed, conditions are expected to become cool and anoxic. As the container surface temperature decreases, the buffer material will become fully saturated with ground water. Length of the resaturation period could be several to several thousand years. Microbial transport and growth during resaturation will be limited because of spatial restrictions within the buffer material (mean pore size 0.1 to 0.5 m), absence of large amounts of unbound water and availability of nutrients.

MECHANISMS FOR MICROBIOLOGICALLY INFLUENCED CORROSION

Concentration Cells

The physical presence of microbial cell surfaces, in addition to their metabolic activities, modifies electrochemical processes. Adsorbed cells grow, reproduce and form colonies that are physical anomalies, resulting in local anodes and cathodes and formation of differential aeration cells. Under aerobic conditions, areas under respiring colonies become anodic and surrounding areas become cathodic. The anodic reaction will be metal dissolution and the cathodic reaction will be oxygen reduction. Mature biofilms prevent diffusion of oxygen to cathodic sites and diffusion of aggressive anions, such as chloride, to anodic sites. Outward diffusion of metabolites and corrosion products is also impeded. If areas within the biofilm become anaerobic, i.e., if the aerobic respiration rate within the biofilm is greater than the oxygen diffusion

rate, cathodic reactions can include reduction of water molecules, hydrogen ions, hydrogen sulfides or hydrated metal ions.

Reactions Within Biofilms

It is traditional to discuss microorganisms within biofilms as aerobic or anaerobic and as individual species. However, microorganisms form synergistic communities that conduct combined processes that individual species cannot. Cell death or lysis within a well-developed biofilm does not necessarily mean a cessation of influence on electrochemical processes (14). Volatile corrosive gases such as hydrogen, hydrogen sulfide, carbon dioxide or ammonia produced by microorganisms might permeate porous backfill material and contact container surfaces.

Volcanic ash, granite, clay buffers, soil and seawater contain sulfate ions and sulfate-reducing bacteria (SRB) are common in those environments. Seawater contains 1 to 10 viable SRB ml-1 irrespective of depth or sample site. Marine bottom muds contain 102 to 105 viable cells gm-1 (15). SRB were found in approximately 25% URL ground water samples (16). SRB were isolated from British bentonite, suggesting that there were strains that could survive in the clay environment (17). In anaerobic, sulfate-containing media, SRB use sulfate ions as terminal electron acceptors, producing hydrogen sulfide that reacts with metals to form sulfide corrosion products. In addition, SRB can stimulate the cathodic reaction by removal of hydrogen.

When conditions around storage containers become wet, cool, and anoxic microbial activity is possible in the immediate vicinity of storage containers. It has not been established that individual cells will be able to traverse buffer materials to reach container surfaces and form a biofilm. If the abiotic zone is repopulated, SRB are expected to dominate the microflora and SRB-influenced corrosion might be possible under the biofilm. However, the most aggressive corrosion of metals and alloys in the presence of SRB is observed when there are successive, alternating aeration-deaeration shifts. It is extremely unlikely that such shifts could occur under any disposal scenario. If repopulation of the abiotic zone cannot occur, SRB activity will be restricted to peripheral areas and impact on the container will result from diffusion of reduced sulphur species. King and Stroes-Gascoyne (18) demonstrated that inorganic sulfide will diffuse through a clay layer. It has not been demonstrated that sulfides produced by SRB will behave similarly. Most heterotrophic bacteria secrete organic acids during fermentation of organic substrates. The kinds and amounts of acids produced depend on the type of microorganisms and available substrate molecules. Organic acids may force a shift in the tendency for corrosion to occur. The impact of acidic metabolites is intensified when they are trapped at the biofilm/metal interface. Acetic acid from Clostridium aceticum and sulfuric acid produced by sulfur-oxidizing bacteria (SOB), such as Thiobacillus thioxidans, are obvious contributors to corrosion. Organic acids of the Krebs cycle can promote electrochemical oxidation of a variety of metals by removing or preventing the formation of an oxide film. Acid-producing fungal strains isolated from soil and autotrophic SOB degraded cement used as a coating material for low- and intermediate-level waste (19). Many organisms produce ammonia from the metabolism of amino acids or the reduction of nitrite or nitrate. In solution, ammonia forms NH_4^+ that can react with metal surfaces (20).

Metal-depositing organisms create environments that are conducive to corrosion. Some microorganisms catalyze the oxidation of metals, others

accumulate abiotically-oxidized metal precipitates, and still others derive energy by oxidizing metals (21). Iron-oxidizing genera that are usually cited as causing MIC are Gallionella, Sphaerotilus, Crenothrix and Leptothrix. These organisms oxidize ferrous ions to ferric ions or manganous ions to manganic ions to obtain energy. Dense deposits of cells and metal ions create differential aeration cells that effectively exclude oxygen from the area immediately under the deposit. Under-deposit corrosion initiates a series of events that are individually and collectively extremely corrosive. In an oxygenated environment, the area immediately under the deposit becomes deprived of oxygen. That area becomes a relatively small anode compared to the large surrounding oxygenated cathode. Cathodic reduction of oxygen may result in an increase in pH of the solution in the vicinity of the metal. The metal will form metal cations at anodic sites. If the metal hydroxide is the thermodynamically stable phase in solution, metal ions will be hydrolyzed by water with formation of H+ ions. If cathodic and anodic sites are separated from one another, the pH at the anode will decrease. The pH at the anode depends on specific hydrolysis reactions. The largest pH decreases are observed for alloys containing Cr+3 and Mo+3. For this reason, under-deposit attack due to metal-depositing bacteria is particularly aggressive on stainless steels. In addition, Cl- ions from the electrolyte will migrate to the anode to neutralize any buildup of charge, forming heavy metal chlorides that are extremely corrosive. Under these circumstances, pitting involves the conventional features of differential aeration, a large cathodic to anodic surface area ratio and development of acidity and metallic chlorides.

Walch and Mitchell (22) proposed the following roles for microorganisms in hydrogen embrittlement of metals: 1) production of molecular hydrogen during fermentation, which may be dissociated into atomic hydrogen and absorbed into metals, 2) production of hydrogen ions via organic or mineral acids which may be reduced to form hydrogen atoms at cathodic sites, 3) production of hydrogen sulfide which stimulates absorption of atomic hydrogen into metals by preventing its recombination into hydrogen molecules, and 4) destabilization of metal oxide films.

Microorganisms produce polymers and form gel matrices of bacterial exopolymers central to the structural integrity of microbial films. Polymeric gels can immobilize water, trap metal species/corrosion products and decrease diffusion. In general, exopolymers are acidic and contain functional groups that concentrate metal ions to form metal concentration cells. Geesey et al. (23) developed conceptual models for the acceleration of copper corrosion as a result of Cu+2 bound within exopolymers.

CASE HISTORIES

Ferrous Alloys

Eidsa and Risberg (24) and Sanders and Hamilton (25) analyzed microbial corrosion of carbon steels in North Sea oil exploration. SRB, SOB, hydrocarbon-oxidizing bacteria, iron-oxidizing bacteria, slime-forming bacteria and fungi were identified as causing corrosion. The following forms of SRB-mediated corrosion were defined: pitting caused by SRB growing in the biofilm on metal surfaces, sulfide-induced stress corrosion cracking (SCC), hydrogen-induced cracking, and blistering caused by hydrogen permeation in high dissolved sulfide conditions.

Marsh et al. (2) assessed the feasibility of disposing of heat-generating nuclear waste in deep ocean sediments in carbon steel containers that

would not be breached for 1000 years. They concluded the following: 1) the main threat to long term integrity of containers was the external environment, 2) carbon steel would not be vulnerable to localized corrosion under disposal conditions, and 3) any corrosion threat could be accommodated by making container walls sufficiently thick. The authors did not consider MIC and the specific presence of SRB in marine sediments in their predictions. Carbon steel has also been considered as a container for geological disposal (26). These authors considered three types of corrosion: corrosion by oxygen, corrosion by reduction of water, and MIC. During 1000 years service life the contribution of SRB to localized corrosion was estimated to be 1.8 mm. Overall wall thickness required to accommodate the three types of corrosion was estimated at 300 mm.

Corrosion resistance of stainless steels is due to the formation of a thin passive film. Passivity can break down under the following, usually localized, environments:

1. Dilute and concentrated HCl, HBr and HF and salts that hydrolyze these acids,
2. Oxidizing chlorides such as $FeCl_3$, $CuCl_2$ or NaOCl,
3. Seawater, except for brief exposures or when cathodically protected,
4. Some organic acids including oxalic, lactic and formic acids.

Microorganisms can produce the organic acids listed above. In addition, they can set up conditions for the formation of HCl and heavy metal chlorides. A persistent problem with the use of stainless steels is their susceptibility to crevice corrosion. Kobrin (27) identified iron- and manganese-oxidizing bacteria with localized corrosion of 304 and 304L stainless steels almost exclusively at weld seams. Pope (28) and Soracco et al. (29) described several cases of MIC in fossil fuel and nuclear power generating plants. Similarly, Puckorious (30) described the sudden failure of 304 stainless steel condenser tubes at an electric utility. There are no documented corrosion failures that can be attributed to MIC for the super stainless steels containing 6% molybdenum or more.

Sridhar and Cragnolino (31) evaluated localized corrosion of 316L stainless steel for possible storage of high-level nuclear waste materials in geological deposits without any specific reference to MIC. However, there are numerous reports of pitting and crevice corrosion due to MIC for this alloy exposed to sea, lake and service waters (11). Localized corrosion may be an important failure mechanism due to the propensity for under-deposit corrosion. Miller et al. (32) exposed 304L stainless steel samples in both vertical and horizontal planes to an inoculum of microorganisms from the TMI reaction vessel. Welded and non-welded vertical specimens showed no damage for twelve months. After twelve months, however, samples placed in a horizontal plane showed signs of corrosion at the weld.

Copper Alloys

Copper alloys are vulnerable to the following types of MIC: differential aeration cells, selective leaching, under-deposit corrosion and cathodic depolarization. Pope (28) proposed that the following microbial products accelerate localized attack: CO_2, H_2S, NH_3, organic and inorganic acids; metabolites that act as depolarizers; and sulfur compounds such as mercaptans, sulfides and disulfides. Pure copper and high-copper alloys are susceptible to SCC in ammonia-containing environments and in solutions containing nitrite or cupric acetate. Such environments might

form within biofilms. Geesey et al. (23) demonstrated that extracellular polymers produced by bacteria play a role in corrosion of copper.
The impact of sulfides on corrosion of copper alloys has received considerable attention. In soils, sulfides increased the corrosion current of brass by a factor of 40 (33). Alloy 90/10 Cu/Ni suffered accelerated corrosion attack in seawater containing 0.01 ppm sulfide after 1-day exposure (34). In the presence of waterborne sulfides, copper alloys form a porous layer of cuprous sulfide. Copper ions migrate through the layer, react with more sulfide, and produce a thick, black scale. Even if such a sulfide film were technically passivating, the film's mechanical stability is so poor that sulfide films are useless for corrosion protection. In the presence of turbulence, the loosely adherent sulfide film is removed, exposing a fresh copper surface to react with sulfide ions. For these reasons turbulence-induced corrosion and sulfide attack of copper alloys cannot easily be decoupled. In the presence of oxygen, the possible corrosion reactions in a copper sulfide system are extremely complex because of the large number of stable copper sulfides, their differing electrical conductivities, and catalytic effects. Transformations between sulfides, or conversions of sulfides to oxides, result in changes in volume that weaken the attachment scale and oxide subscale, leading to spalling (35). Bared areas repassivate, forming cuprous oxide. Neither circumstance is relevant for copper nuclear waste containers. Once anoxic conditions have been established within the disposal vault, they should remain anoxic indefinitely and there should be no mechanical disruption of intact sulfide layers should they form.
Copper canisters with 100 mm thick walls are being considered for final disposal of waste material from nuclear reactors by Swedish companies building nuclear power installations. Canisters would be placed in igneous rock 500 m below ground level. Copper plates that have been buried in three separate locations for more than 50 years as earth electrodes for lightning conductors were studied to determine the geochemical/microbiological properties of the ambient soil. Microbial activity was very low in comparison to that found in marine and brackish water sediments. Predominance of sulfides in the corrosion products did not correlate with redox potentials measured at the time of collection. Similarly, sulfide in corrosion products did not correlate with sulfate concentrations in soils. The pitting factor for two of the samples was five while the third sample was not pitted. Pitting factor is the ratio between maximum pit depth of a certain area and the mean depth of general corrosion in the same area (36).

Nickel Alloys

Commercially pure nickel and its alloys are susceptible to acid production at metal/biofilm interfaces and dealloying due to reactions with sulfide. Passivity of nickel is due to the formation of an oxide or hydrated oxide film several nanometers thick. Formation of protective films on nickel is aided by the presence of iron, aluminum and silicon. Passive films similar in structure to that observed on pure nickel are formed on Ni/Cu alloys having more than 30% nickel. Alloys containing less than this amount of nickel behave like copper. In high velocity seawater, nickel alloys are superior to predominantly copper alloys because the protective surface film remains intact under highly turbulent and erosive conditions.
Nickel alloys are susceptible to pitting and crevice corrosion attack under stagnant conditions. Monel has a marked tendency for the initiation

of pitting in chloride-containing environments where the passive film can be disturbed. Under stagnant conditions chlorides penetrate the passive film at weak points and cause pitting attack. Sulfides can cause either a modification of the oxide layer as described for copper or breakdown of the oxide film of nickel alloys. Brennenstuhl et al. (37) indicated that pitting of 3 nickel alloys containing 21-27% chromium exposed to untreated freshwater from Lake Ontario involved biofilm formation.

Aluminum and Aluminum Alloys

The corrosion resistance of aluminum and its alloys is due to an aluminum oxide passive film that is 20 to 100 thick for air-formed films. Anodizing produces thicker insulating films and better corrosion resistance. The susceptibility of aluminum and its alloys to localized corrosion makes it particularly vulnerable to MIC. After 12 months both Al 1100 (commercially pure aluminum) and Boral (a composite with a layer of boron carbide dispersed in aluminum and sandwiched between two sheets of Al 1100) showed pitting with accumulation of corrosion products in and over pits after exposure to organisms isolated from the TMI reactor vessel (32). Al 1100 also showed signs of crevice corrosion due to MIC. Kalaiyappan et al. (38) demonstrated MIC of Al 1100 and Al 6061 after a few weeks exposure to deionized water in a storage basin.

Titanium and Titanium Alloys

There are no documented case histories of MIC of titanium and its alloys. Schutz (39) reviewed titanium's resistance to MIC by discussing mechanisms for MIC and titanium's corrosion behavior. He concluded that at temperatures below 100C titanium is not vulnerable to SOB, SRB, acid-producing bacteria, differential aeration cells, chloride concentration cells or hydrogen embrittlement. Formation of occluded regions of low pH underneath a biofilm could conceivably initiate crevice corrosion in titanium alloys (18).

CONCLUSIONS

Materials being considered for containment of nuclear waste in mined geological repositories are alloys of iron, nickel, copper and titanium. With the exception of titanium, MIC has been documented for all metals and alloys under consideration. The likelihood that MIC of nuclear waste storage materials will occur is directly related to the geological/microbiological/chemical environment of the storage site and vulnerability of the container material. Combined effects of elevated temperature, radiation and desiccation of buffer materials will severely limit the extent of microbial activity close to the container and might result in an abiotic zone into the compacted buffer material. If the abiotic zone is repopulated, SRB are expected to dominate the microflora and SRB-influenced corrosion might be possible for copper and nickel alloys and carbon steels.

ABSTRACT

Low- and medium-level radioactive wastes generated at TVO I and II nuclear power units are disposed of in silo-like vaults of the VLJ Repository, constructed in the bedrock at the Olkiluoto site. With the present knowledge it cannot be excluded that after sealing of the repository, microbial degradation of the organic wastes and corrosion of the steel packages by carbon dioxide would lead to comparatively rapid gas generation and pressurizing of the silo. To acquire a realistic forecast for the post-closure scenario of the silo of low-and medium-level wastes, a pilot-scale experiment on microbial disintegration is being planned. The outlines of the pilot-scale experiment are presented here.

The experiment will take place in the Research Tunnel in the VLJ Repository. The volume-scale planned is 1:1000 (referring to a completely filled repository) requiring 16 drums filled with compacted waste. The waste to be used in the experiment will be sampled from the waste stream of the power plant. The experimental set-up will be installed in a large hole (diameter 1.5 m, depth 7.5 m) bored in the floor of the Research Tunnel. The entire experimental installation in the borehole will be placed inside a tightly sealed stainless steel tank. The environmental conditions during the experiment will be chosen to be as realistic as possible also including concrete as a supporting structure inside the tank for the 16 drums.

The rate of gas generation and the composition of the gas will be monitored. Also chemical composition of the water inside the tank as well as the disintegration products, both soluble and particulates, will be followed. The changes in the redox-conditions are particularly important after closing the pilot test tank. The experiment is designed to be run without the need of constant on site follow-up by personnel. However, manual sampling is needed for water chemistry follow-up, as well as for some additional specially prepared specimens containing waste materials which are planned to be withdrawn from the installation regularly.

INTRODUCTION

Teollisuuden Voima Oy (TVO) operates two boiling water reactor units at Olkiluoto, on the South-Western coast of Finland. The operation of TVO I and II power units produces annually approximately 100 m3 of low-level maintenance waste.

The waste consists of more or less dry materials accumulating mainly during the maintenance of the power plant. The majority of waste is packed into 200 l drums before it is disposed of into the VLJ Repository excavated in the crystalline bedrock near the TVO I/II nuclear power units. The repository has been in operation since 1992.

The VLJ Repository consists of two separate silo-like disposal vaults, one for the bituminized ion-exchange resin waste drums (capacity 17360 drums), and the other for the dry, low-active waste drums (capacity 24800 drums). The silos are situated at the depth from 60 m to 100 m in water saturated crystalline bedrock.

Before the transportation to the repository, the waste drums are loaded into concrete boxes, usually 16 drums per box, and then stacked layer by layer in the silos. An empty box weights 4000 kilograms. No backfill is placed around the drums or boxes. Figure 1 shows the silo concept.

Fig. 1

One tunnel in the VLJ Repository, the Research Tunnel, has been reserved for research purposes. One task in the Research Tunnel program has been the testing of the full face boring method. In the test three full-scale (diameter 1.5 and depth 7.5 m) deposition holes, suitable for spent fuel canisters, were bored down from the tunnel floor. One of the holes is available for studying biodegradation of the maintenance waste.

If biodegradation and corrosion proceed rapidly, the formed gases can fill an area in the crane hall, above the LLW silo. According to a simple gas dissipation calculation the gas generation rate of 6.000 m3/a (NTP) can lead to a gas volume of 500 m3 (at 6 bar) in the ceiling area of the crane hall. A corresponding volume of contaminated water would have to be displaced into the bedrock. This would be the most severe effect of the gas generation.

THE MAINTENANCE WASTE

Miscellaneous waste is generated mainly during the maintenance periods of the power plant. The wastes, consisting of cleaning towels, protecting sheets, thermal insulation material etc., are collected in transparent polyethylene bags. A sorting campaign on dry, compressible waste (1.6 tons) was performed 1995 giving distribution of waste as given in Table I. The average estimated biodegradability was 28 %. The average individual weight of a bag (after repackaging) was 8.7 kg.

Table I

In the compacting station a ram using a pressure of 12 tons compacts the waste bags into 200 l drums. Around 15 bags are pressed into one drum, which then contains 100 kg of waste on the average.

CONDITIONS AND DEGRADATION PROCESSES IN THE REPOSITORY

The void volume in the repository is planned to be filled with water. Because the seepage flow rate of the groundwater is very low, the filling is planned to be performed by using local brackish sea water or fresh surface water from a local pond. Contact with concrete will raise the pH of the water up to around 12.5. Oxygen will be consumed in aerobic microbial degradation and in corrosion of steel. The flow rate of the groundwater is very low. Resulting in an estimate it will take several thousands of years to change the whole water volume inside the silos once. Thus the groundwater flow is awaited to have only a negligible effect during the most active phase of the microbial degradation.

The buffering capacity of concrete is known to be high, the amount of free calcium hydroxide in the hydrated concrete being in the order of 100 kg/m3.

The concentrations of sulfate, chloride and magnesium are distinctly higher in sea water than in surface water or groundwater and could have some influence on the corrosion processes in the considered system.

MICROBIAL DEGRADATION

The main parameters affecting microbial activity are the availability of a carbon source and a suitable energy source. In environments like a repository, the most common electron acceptors for respiration are the sulfate ion and carbon dioxide. The former is used by sulfate reducing bacteria and the latter by methanogenic organisms. Some oxidized metals, like Fe^{3+}, Mn^{4+} and U^{6+} have also been suggested to act as electron acceptors in anaerobic conditions (1).

In the VLJ Repository, the site-specific factors affecting micro biological activity are.

1) anaerobic conditions
2) pH value around 12 in the concrete water
3) temperature around 8C
4) 6 bar pressure
5) darkness.

The microbe populations surviving in the repository environment are of two different origins (2,3):

1) autochthonous populations that exist naturally in groundwater and on rock surfaces in the deep subsurface surroundings. These microbes are able to survive in the above mentioned conditions except the high pH. However, studies on natural alkaline groundwater have shown that alkalotolerant and alkalophilic microbes were able to grow at pH values up to 11.1. On the other hand, the most alkalophilic organisms were aerobic (4).
2) allochtonous microbe populations that are introduced into the repository first during the construction of the facility and later within the waste drums and with water, as well as with other backfilling materials from the surface. These populations will partly be destroyed in the extreme conditions of the repository, but a part of them can be expected to adapt to the new environment.

The potential activities of microbes in a repository can be listed as follows (5):

1) gas generation
2) corrosion
3) redox reactions
4) formation of complexing agents
5) radionuclide migration.

The possibilities to estimate different activities are mainly based on indirect studies, e.g. on measurements of parameters connected with microbial metabolism. Estimations of microbial amounts can be done by direct calculation of cells trapped on microscope slides. This gives a rough estimate of the cell concentrations, because an independent environment is formed in each drum and the variation between drums can be considerable. ATP measurements could be one possibility to estimate the viability of the microbes.

Important parameters in assessing microbiological activity are the amount of dissolved carbon dioxide, amount of dissolved methane, pH, redox potential, conductivity and some dissolved ions, like sulfide. In the beginning of the experiment, estimation of biological oxygen consumption and determination of total bacterial counts might give valuable information of the aerobic-anaerobic transition phase.

ESTIMATE OF THE RATE OF GAS GENERATION

The potential of gas generation in the silo is based on the amount of corrodiable steel and carbon bound to biodegradable compounds. The role of the ionizing radiation in the gas generation will be negligible. The planned pilot experiment is designed to decrease uncertainties in the conservatively estimated rate of gas generation.

The estimated rate of disintegration for the safety assessment was here based on measurements from municipal dumping grounds, where a variety of different waste types is present. Anaerobic degradation takes optimally place at 35C and at pH values from 6.8 to 7.2. Deviation from the optimal conditions result in decreasing of the maximal potential gas amount and the rate of gas generation (6). The time dependency of the gas generation can be described by the maximal potential gas amount and the rate-constant of gas generation:.

Eq. 1

where

G = the amount of gas generated,

Ge = the gas generation potential per weight unit,

a = disintegration coefficient (1/a)

and

t = time (a).

In the buried layers of municipal dumping grounds a measured value for the disintegration coefficient is 0.07 /a at 10C. This rate of disintegration leads in ten years to a situation, where half of the degradable material is disintegrated. At dumping ground conditions the gas generation potential at 10C is Ge= 160 m3/ton. Half of the gas is methane, half is carbon dioxide. In the case of low-level waste disposal one waste drum has been estimated to contain 47 kg of disintegrable waste, which has a potential of generating 7.5 m3 of gas. Without any new evidence it is not justified to use much lower rates of disintegration than the above mentioned. In the estimations a value of 0.046 was used for coefficient a.

CORROSION OF THE DRUM

The stability of iron-water -system depends on the redox potential and pH conditions (7). Metallic iron is always thermodynamically unstable. The corrosion reactions producing hydrogen are

Eq. 2

in the pH range -1 - 9 and.

Eq. 3

in the pH range 9 - 13.6.

It has been estimated that microbially assisted corrosion based on carbon dioxide could take place (8, 9). In the corrosion reaction carbon dioxide is consumed at the same rate as it is produced. $FeCO_3$ is a stable end product.

Eq. 4

The above mentioned reaction is assumed to be valid, when there is ample supply of carbon dioxide. However, the possibility of the reaction to take place in the alkaline environment dominated by concrete water has not yet been evaluated.

It is assumed that the package drum will corrode according to Eq. (3). In addition, the inner surface is subjected to microbially induced corrosion; carbon dioxide generated will be bound to iron carbonate according to equation (4). The latter corrosion process is thus dependent from the microbial process through Eq. (1). The 200 l drum is made of 16

kg steel plate, thickness 1 mm and a total surface area of about 4.2 m2. The amount of steel in one drum gives 290 moles of iron yielding in corrosion 390 moles of hydrogen, which is 8.7 m3 NTP. The estimated corrosion rates are between 0.1 mm/a and 10 mm/a (10). Thus the total corrosion process would take from 100 to 10,000 years. The rate of anaerobic corrosion is assumed to be 0.1 mm per year.

Figure 2 presents the estimated gas generation as a function of time. The calculated results are presented for the amount of 16 waste drums each containing 47 kg of biodegradable material. According to this estimate

The biodegradation is complete in hundred years,

The corrosion process takes longer than biodegradation in the selected calculation example.

When a closer look is taken at the first ten years, the above conservatively estimated reaction rate leads to a gas generation rate of 15 l/day. The share of corrosion is 0.23 l/day. In this estimate it is assumed that the steel surface of the drums is attacked uniformly by corrosion. The surface is, however, protected by painting, which may give considerable protection for the drums during the initial period of the experiment.

Fig. 2

PREPLAN OF THE PILOT SCALE EXPERIMENT

The full utilization of one of the large bored holes in the Research Tunnel makes it possible to study the degradation process in the scale of one disposal unit: the concrete box, which contains 16 drums of waste. The following dimensions are derived from the initial conditions:.

The inner diameter of the protective vessel can be up to 1480 mm, four drums fit in each layer.

The height of the vessel can be 5 - 6 m (volume 9 - 10 m3) allowing four layers of drums vertically.

The experiment will consist of 16 drums, each having a volume of 200 l, weighing 16 kg (steel), and containing 100 kg of compacted waste. The drums will be perforated with small holes to allow water intrusion as well as escape of gases.

Concrete blocks are suggested for the inner structure of the vessel to support the stacked waste drums. The equilibration of concrete with water will create alkaline water chemistry. Approximately 2,000 kg of concrete structures are needed to construct the supporting system for the drums, the amount can be increased to 4,000 kg (corresponding to the whole amount of concrete in one disposal box).

Figure 3 shows the vertical cross section of the experimental set-up.

Fig. 3

It is planned that the pilot scale experiment will be started by filling the vessel with water. After that the conditions are let to develop naturally.

EXPERIMENTAL PARAMETERS TO BE MEASURED

The gaseous reaction products from the microbial degradation and corrosion are the most important parameters to be measured. This involves analyzing of dissolved gases in the water phase and released gases. If the rate of gas generation is large, the gases will be conducted out of the experimental system through a gas meter; but if only small amounts of gases are generated, they are collected, sampled and released in known quantities.

It is suggested that dissolved oxygen and hydrogen are measured directly from the water, the separating gas is sampled and its components analyzed regularly: carbon dioxide, methane, hydrogen, oxygen.

The properties of the water inside the vessel will develop in the course of time. Some parameters can be measured on-line and other parameters must be measured from water samples. It is possible to install several sampling lines to the system for sampling water inside each individual drum. It must be emphasized, that collecting and handling (analyzing) of the water samples should be performed in an atmosphere (e.g. atmospheric box) comparable to that in the studied system. The alkaline water will be very sensitive to CO2 and thus any CO2 contamination should be avoided. Follow-up of water chemistry during the experiment will give additional information about the processes involved in the control of pH and redox. Particulates and colloidal entities can be studied from obtained water samples, giving insight to radionuclide migration/retardation phenomena. Particulates can be collected on filters and the colloidal fraction can be characterized from a concentrated sample. Changes in TOC/DOC will give information on the development of organics in the water phase.

Sampling of the actual waste materials gives direct information of the degree of disintegration of the various waste components and also enables sampling of the microbes attached on the surfaces. For this purpose it is suggested that specially prepared samples representing the different waste materials and packaging materials are assembled inside the waste drums. These samples can then be withdrawn from the system at suitable intervals and studied.

Because there are no full-time workers in the Research Tunnel for taking samples, it is necessary to measure some indicative parameters on-line. It would be practical to have the sensors located in an instrument cabin nearby outside the experimental hole. Water from the experiment will be circulated constantly between the vessel and the sensors.

The prerequisite to an on-line measurement is that the sensors can operate and keep their calibration at least for the time between the sampling and inspection visits. The suggested parameters to be measured on-line are: pH, Eh and conductivity. Also dissolved gases O2 and H2 can be measured reliably by specific electrodes.

All measured signals are connected to a data acquisition system for registration and control. The measured data is saved in data files for later presentation and evaluation. The data acquisition software is capable of showing the measured data graphically on the screen in real time or to draw history graphs of quantities measured earlier. The software has a graphical user interface and it is possible to show the state of the test process continuously in a graphical process diagram. The system can be operated with a remote computer using a standard phone line.

THE PRELIMINARY TIME TABLE

After filling and closure of the experimental set-up, various environmental parameters will change simulating the closure and sealing of the real repository. After filling with water the conditions will develop from neutral to alkaline and from aerobic to anaerobic. The experiment will reach an advanced stage, when the microbial population has adapted to the conditions and the painting of the drums is not preventing the corrosion of steel. The transition phase is important as such; the growth of microbes may be so slow that it leads to an impracticable long follow-up time.

The experimental program can be divided roughly to three phases: Preparatory phase including preplanning and preliminary experiments in the laboratory, set-up phase including detailed planning and construction and research phase including start and follow-up of the experiment, Table II.

The preparatory phase will consists of background studies for the pilot plant experiment. Laboratory experiments and modeling lead to a more detailed forecast of the rate of the microbial disintegration and corrosion reactions in the repository conditions.

The set-up phase will consist of a detailed design, manufacturing and installation of the experimental equipment. The detailed characterization of waste to be brought into the experiment is included here.

The research phase will begin with filling of the system with water. The follow-up will last for several years.

Table II

ACKNOWLEDGEMENT

This work belongs to the nuclear waste research program of Teollisuuden Voima Oy and it will be a part of the European Commission Nuclear Fission Safety Program (1994 - 1998).

OVERVIEW AND DYNAMICS OF ORGANIC CARBON IN A LOW-LEVEL RADIOACTIVE WASTE DEGRADATION EXPERIMENT*

F. Caron
Environmental Research Branch
Chalk River Laboratories
Chalk River, Ontario K0J 1J0

ABSTRACT

Low-Level Radioactive Wastes (LLRW) contain substantial quantities of organic materials that will eventually decompose by microbial action after disposal, producing gases and dissolved organic compounds. An experiment was undertaken to study microbial degradation processes with LLRW, with three major purposes: i) to characterize the bulk properties of the Dissolved Organic Matter (DOM) produced by decomposition; ii) to determine its influence on the aqueous speciation of selected radionuclides, and iii) to determine the main thermodynamic parameters that can define the near-field chemical environment.

The bulk properties of the leachates and the DOM generated in the experiment were similar to those of landfill leachates. The DOM content was dominated by volatile fatty acids (VFA), likely produced by the microbial degradation of cellulose and other structural polysaccharides. The DOM has a limited complexing capacity for Cd and Co, but the elevated levels of DOM in the leachates may significantly affect Co speciation. Chromatographic separations indicated that at least 20 discrete organic compounds were present, and the total organic carbon was primarily hydrophilic (70-95%). This technique also showed that Co can form a mixture of labile and stable complexes with compounds contained in the DOM.

Calculations based on a mass balance approach suggested that microbially-mediated organic decomposition will persist for periods of decades to centuries, and this process will likely dominate the redox potential in the near-field. This, in some cases at least, simplifies the specification of near-field chemical conditions.

INTRODUCTION

Low-level radioactive wastes contain a large fraction of organic material (office wastes, paper, clothing, etc.), upon which microbial decomposition will produce a mixture of organic compounds. In addition to this, man-made complexing agents and natural organics may also contribute to radionuclide subsurface mobility (1-3).

Upon degradation, the easily available substrates (such as polysaccharides) will be utilized first, producing low molecular weight organics such as alcohols and fatty acids. Other compounds coming from the partial degradation of the source material will also be produced (e.g., gluconic acid, cellobiose, etc.). This Dissolved Organic Matter (DOM) itself is subject to further degradation to CO_2, CH_4, humification, and formation of colloidal material. The resulting DOM in the leachates will contain a mixture of various degradation compounds of different metal-binding affinities, and different degradation rates. The remaining carbon source material will eventually be more recalcitrant to decomposition, and this process can be very long (years to centuries), especially if the environment is reducing. All of these processes can affect the subsurface mobility of radionuclides by complexation and they can exert a control over the redox potential for several years, hence buffering against redox changes in the near-field of a waste disposal site.

An overview of a low-level waste degradation experiment is presented in this work. The aim is to present two major aspects that microbial degradation has on degrading wastes: (i) the production of dissolved organic compounds, which can affect speciation of nuclides and possibly their subsurface mobility; and (ii) the control that microbial degradation could have on the redox potential in the near-field, with an estimate of how long this control could last. This information is applicable to near-surface waste disposal sites, landfills, etc., and an example of application is presented for a generic near-surface repository.

EXPERIMENTAL

Description of the Experiment

Low-level wastes were compacted in bales measuring approximately 0.6 0.6 1.2 m (see (4) for a detailed description). Eight bales were placed into separate airtight carbon steel boxes, and then connected to an overflow reservoir for leachate collection in a closed-loop recirculation system (Fig. 1). The bales were monitored for gas generation for the first year after they were prepared, without addition of water ("as-received", (5)). De-ionized water was then added to each box and recirculated daily over each bale to promote degradation. Four of these bales were under "wet" mode by letting excess water seep out by gravity into the overflow container, and the other four were "flooded" by raising the outlet tube to keep the water level to about half of the height of the bale. This simulates bale decomposition under wet unsaturated conditions in a soil, and wet flooded conditions below or at the water table.

Fig. 1

Sampling and Analysis

Aqueous samples were analyzed for major cations (Na^+, Mg^{2+}, Ca^{2+}, K^+), selected metals (Fe, Zn, Mn, Cu, Al), major anions (Cl^-, SO_4^{2-}, NO_3^-, I^-), total organic carbon (TOC) and volatile fatty acid (VFA). The DOM of selected samples were also analyzed by high performance liquid chromatography (HPLC; see (6)) and for complexing capacity using an ion exchange technique (IET; see (7)). Gaseous samples were also taken to determine the major gases in the box atmosphere using gas chromatography (GC). The TOC content was analyzed using a Dohrman DC-80 Carbon analyzer, and the VFA by GC (8). The total amount of exchangeable protons was done by titration with a Tanager 8901 autotitrator.

The samples for cation and metal analysis were acidified immediately upon collection. For the anions, a 15-mL untreated leachate aliquot was passed through a bed of cation exchange resin to remove cations that could precipitate. The samples used for titrations, HPLC, IET were mixed with a cation exchange resin added in batch mode (in Na form), to remove excess metals that could precipitate. Equilibration was done for one week, after which the solution was decanted and the samples were allowed to stabilize further under room conditions in the dark without resin for 2-3 weeks (IET), 12-16 months (HPLC) and 18 months (titration).

RESULTS AND DISCUSSION

Dissolved Organic Matter Characteristics

The TOC concentrations in the bale leachates ranged from ~170 to ~7000 mg C/L (Table I). The TOC levels in the four "wet" bales (1,4-6) were generally higher than in the "flooded" bales (7-10). The amounts of TOC did not vary systematically with time for the "wet" bales, however they generally decreased for the "flooded" bales. These amounts are within the range for landfills or commercial nuclear Low-Level sites (9-11).

Table I

The VFA made up most of the TOC (Fig. 2; also see (12)). The relative VFA distribution remained nearly constant for the ~500 d period with the "wet" bales, which is evidence that the microbial degradation process controls the relative distribution of the VFA, hence likely the decomposition mechanism of the source material.

Fig. 2

Fermentation is taking place in the bale boxes, where bacteria and fungi use the cellulose matrix as a carbon source to produce alcohols, VFA and CO_2 + CH_4 gases. Both aerobic and anaerobic processes may take place simultaneously, however anaerobic processes may dominate because of oxygen depletion. Anaerobic microbial degradation may take place in several but distinct steps (13): i) fermentative bacteria living under anaerobic or facultative conditions, producing acetic acid and other VFA; ii) acetogenesis bacteria become involved in a bioenergetic symbiosis with methane-producing bacteria or other hydrogen assimilators; and iii) methanogenic bacteria predominate, producing CO_2 and CH_4 in nearly equal amounts. Rees, (1980) (11) has shown that the gas production rate was correlated with the moisture content of the wastes in landfills, and this has also been observed in this experiment. Methane and CO_2 production dominated in bales 7-10, and VFA production was dominant in the other bales, with acetic acid being the most abundant VFA species. Work on the "wet" bales (1, 4-6) is emphasized in the remainder of this work because this situation is more applicable to a near-surface waste disposal site located above the water table.

Knowing that most of the TOC is made up of VFA, the chemical composition and behavior of the balance of the TOC are unknown. Microtitration of the leachates gave curves closely related to the behavior of the VFA [unpublished], with other material of intermediate acidity in the pKa range of ~8-9 (pKa = - log Ka, where Ka is the acid dissociation constant), which is characteristic of phenolic groups. The charge density of the TOC, defined as the total amount of exchangeable protons per unit of carbon (mEq/mg C), was also typical of the values of ~15 mEq/mg C found in landfill TOC (Table II; (14)).

Table II

HPLC separation of the leachates indicated that the DOM could be separated into two general regions: hydrophobic and hydrophilic (Fig. 3a; (6, 15)). In our previous study, most of the TOC (~70-93%) was in the hydrophilic region. Several sharp peaks were found in each one of these two regions, indicative perhaps of single compounds or a small amount of compounds of similar properties. The hydrophilic peaks, eluting early (Fig. 3a), could be further separated into ~10 discrete peaks using ion pair HPLC (Fig. 3b).

Fig. 3

The three techniques and analyses used (VFA analysis, titration, HPLC) indicated that the DOM from this waste degradation experiment has properties similar to that in municipal landfill leachates. Volatile fatty acids were the most abundant class of compounds identified, making up most of the TOC in leachates in the "wet" bales. The "flooded" bales were in the methanogenesis mode, and its VFA content was smaller and distinct from the "wet" bales.

Complexation with Radionuclides

Two approaches have been used to investigate the complexation of organic material with radionuclides: the first one used the overall complexing

capacity of the leachates with the radionuclides 60Co and 109Cd, using an ion exchange technique (IET) (7). The second approach was to equilibrate the DOM with 60Co radiolabel, followed by HPLC separation coupled with a fraction collector to identify more specifically the types of compounds that are responsible for the complexation (6). The IET showed that ~4000 mg/L of TOC could affect the speciation and complex approximately 50 mg/L of Co. Complexation with Cd was much smaller, 0.54 mg/L. The HPLC technique indicated that a mixture of labile and non-labile complexes could form. The non-labile complexes were mostly associated with hydrophobic compounds, and they made up ~5% of the total radiolabel spiked in solution. Mixtures of labile and non-labile complexes of cobalt were also observed in separate experiments (1,2,17).

The impact of DOM complexation on the speciation of Cd and especially Co is somewhat uncertain. The IET is quantitative, yet non-specific, and it suggests that a substantial amount of Co could be complexed with leachate DOM. The HPLC approach is non-quantitative, but it suggests that stable complexes could be formed with hydrophobic DOM compounds.

Near-field Chemical Environment

The second aspect presented in this work is the influence and rates of organic carbon degradation on the redox potential. Carbon degradation is a dynamic system that can be related with a series of chemical redox equations. For instance, using a mass balance approach for Bale 6 between day 32 and day 391, the major changes in redox-sensitive components can be related to a series of half-cells and combined into full chemical reactions. These four reactions balance the assimilation/production of CO2, Fe(II), acetic acid (taken for VFA), N2, and CH4 in bale 6:

Eq. 1

Eq. 2

Eq. 3

Eq. 4

These reactions do not necessarily describe processes, but rather they explain the thermodynamic end result, which is path-independent. In bale box 6, a total of 0.44 mole of dissolved iron, Fe(II), was present in the leachates at day #32, compared with 2.98 moles at day #391, for a difference of 2.54 mole. This means that 0.64 reaction (1) has produced this amount of Fe(II) in this bale during this period (0.64 4 = 2.54). All four reactions above were balanced iteratively with a spreadsheet, using the initial and final amounts found in this bale. Similarly, the total contribution of reactions (2), (3) and (4) were 0.69, 3.32 and 1.68, respectively. The Gibbs free energy of each reaction (DGr) is related to the redox potential using a modified Nernst equation [18] with the measured quantities of oxidized and reduced species in the bale:

Eq. 5

The redox potential in Bale box 6 was calculated to be ~ -2.9 to -4.7 (EH ~ -0.17 to -0.28 V) at pH 5.74. It is recognized that this approach necessitates the assumption of equilibrium, which is not achieved in these boxes, as the system is dynamic, and there are undoubtedly inhomogeneities within this bale. Nevertheless, this approach provides an independent estimate of the redox potential, devoid of measurement artifacts present if an electrode is used. The mass balance approach also suggests that reactions (2), (3) and (4), involving the electron transfer from carbon atoms, account for ~94% of all electrons exchanged, whereas ~6% comes from Fe to produce Fe(II) (steel corrosion). Microbial processes, therefore, likely control the organic carbon degradation rates

and speciation, which in turn would control the redox potential inside these boxes.

Estimates of Carbon Degradation Rates

Organic carbon decomposition generally follows a first-order decay curve (19). In short-term experiments, the most easily degradable form of carbon likely controls the gas generation and the decomposition rates of the bulk of the organic carbon present. However, in long-term experiments or predictions, the model can be more complex to reflect the different types of organic carbon in soils, landfills, etc. In the case of a two-compartment model, the relationship is:

Eq. 6

The two compartments (#1 and 2) indicate organic carbon of different biodegradability. The term C0,(1) and the decay constants are usually difficult to evaluate in waste material due to the unknown composition of the contents and specific decay rates, even in these bales.

Alternatively, approximately 70% (by weight) of the wastes contains organic material (paper, plastic, textiles, etc.), and the balance is not degradable (ceramics, metals, etc.). From this 70%, approximately two thirds is moderately slowly biodegradable (MSB), and the other third is slowly biodegradable (SB) to recalcitrant material (RM). Using these approximations, and also assuming that only the fastest degrading material (i.e., MSB) is degraded over the 1-year period of the degradation experiment, equation (6) simplifies to a single decay term (the right-hand part is equal to zero). The total content of MSB carbon in bales 1, 4, 5 and 6 would be ~300 kg, of which our mass balance has indicated that a total of ~123 moles (~1.5 kg) have degraded to CO2, CH4 and DOM between day #32 and 391 for the four bales. This corresponds to a degradation half-life of 55.9 a (or k(1) = 1.24 10-2 a-1). This value is very close to the half-life of 49.5 a obtained for the "physically stabilized organic carbon" in the model of Jenkinson and Rayner (19). Under these conditions, the bale box chemical environment is likely to be dominated by the organic carbon degradation rate at least for a few decades.

Example Application to a Generic Near-Surface Repository

In this generic example (Fig. 4), a near-surface vault is located in sandy material, above the water table. The vault features a concrete roof with a service life of 500 a, designed to isolate the wastes from infiltrating water. Most of the wastes will consist of compacted bales, and our calculations assume that two thirds (65%) of the organic C in the vault is MSB, 30% is SB and 5% is RM. It is also assumed that the RM does not significantly degrade over the 10000 a period of the calculation, and the SB has a half-life of 2000 a (compared to 1980 a for recalcitrant carbon in Jenkinson and Rayner (19)).

Fig. 4

The degradation rate obtained for MSB in the bales has to be corrected for the expected dry vault environment under an intact roof. In the absence of a specific rate indicator, the gas generation rates in the "wet" bales, ranging from 0.1 to 1.3 L kg-1a-1, has been normalized to the reference gas generation rate of 0.021 L kg-1a-1, obtained previously for the dry bales (5). This is believed to represent degradation in a dry vault. This correction corresponds to a half-life of 1400 a for the MSB material, hence an initial rate constant to be used in Eq. (6). At the onset of roof failure (assumed at 500 a), water will infiltrate and accumulate in the moist bales, which is equivalent to the "wet" bales

described above, and the much faster 55.9 a half-life applies thereafter. In Fig. 4, Eq. (6) was applied in a two-step approach to describe the behavior of organic carbon before and after roof failure, using the rate constant of MSB material under dry conditions for the first 500 a, and MSB material under wet conditions after 500 a. A more simple one-step approach, neglecting the effect of roof failure, was fitted visually for comparison, and gives an overall half-life of 600 a for all the organic carbon present in the vault. This example of calculation suggests that most of the organic material will be degraded after 2000-3000 a.

In order to estimate an overall redox potential in the vault and its evolution with time, one would have to balance the reducing capacity of the material in the vault with the sources of oxidizing materials. The degradation of organic material, given above, and metal corrosion would provide the reducing capacity. Metal corrosion is likely to follow a constant rate with time, often expressed as a corrosion rate (in mm/a or equivalent) in models (20). This rate depends upon the surface available for corrosion, which is often difficult to obtain. Both these rates have to be compared to the rates of oxygen ingress in infiltrating water (after roof failure) and other mechanisms in order to estimate the overall redox potential in the vault, hence the near-field chemical environment. This type of calculation needs to be addressed separately, as, for example, low humidity in the near-field also features a high gas-filled porosity and low degradation rates, which would favor oxygen ingress; a wet environment favors higher degradation and higher oxygen consumption rates than for a dry environment, plus a smaller gas-filled porosity available for oxygen migration. In addition, after the MSB carbon is degraded, the organic carbon degradation rates would gradually decrease, potentially allowing more oxygen ingress. Hence the variations of redox potential in the near-field are expected to vary over several centuries.

CONCLUSION

A low-level waste degradation experiment was done at CRL to investigate the degradation processes. The leachate DOM was dominated by VFA and this process is likely controlled by the microbial flora present in the wastes. This resulting DOM forms labile and non-labile complexes with Co, potentially affecting its subsurface mobility. A mass balance suggested that microbial degradation is holding a reducing environment in these boxes, and this could last at least for a few decades. Some aspects of this experiment are applicable to wastes degrading within a dry vault, however, there are still uncertainties as to how long or if a reducing environment could last in the near-field.

ABSTRACT

In 1978, Congress passed the Uranium Mill Tailings Radiation Control Act (UMTRCA). The U.S. Department of Energy (DOE) is developing a program to meet the U.S. Environmental Protection Agency (EPA) ground water standards (60FR2854) at 24 uranium mill tailings sites nationwide. The inactive uranium processing site at Tuba City, Arizona, has been designated as one of the 24 sites.

As part of the U.S.-DOE's Uranium Mill Tailings Remedial Action Project (UMTRA), the DOE is currently studying alternative ground water remediation technologies to determine the most appropriate and cost effective technology. At the DOE/UMTRA Tuba City site, the University of New Mexico's (UNM) Center for Radioactive Waste Management (CeRaM) is developing an in situ bioremediation process as one possible alternative methodology. Bioremediation uses bacteria to clean the ground water of the contaminates. These contaminates include uranium, selenium, strontium, molybdenum, cadmium, nitrate, and sulfate. Through bacteria catalyzed reactions the contaminates are either converted to non toxic substances, such as nitrogen gas in the case of nitrates, or in the case of the heavy metals, they are immobilized as insoluble precipitates (ores). The paper describes the development of the in situ bioremediation process for the Tuba City site. This includes site characterization for indigenous bacteria, laboratory batch and column studies that simulate the field process, and our plans for a field observational test. The current laboratory and field site characterization tests have shown that the necessary bacteria are present and that they can catalyze the remediation reactions under field conditions.

INTRODUCTION

As part of the U.S.-DOE's Uranium Mill Tailings Remedial Action Project (UMTRA), DOE is developing a program to meet the U.S. Environmental Protection Agency (EPA) ground water standards at 24 uranium mill tailings sites nationwide. This effort is a direct result of the 1978 Uranium Mill Tailings Radiation Control Act (UMTRCA) as amended. For each UMTRA site, the DOE is currently studying alternative ground water remediation technologies to determine the most appropriate and cost effective technology (1,2). The inactive uranium processing site at Tuba City, Arizona, is one of the 24 UMTRA sites. The surface contamination was remediated in a disposal cell that was completed in 1990 and now the ground water remediation is being investigated. The University of New Mexico's (UNM) Center for Radioactive Waste Management (CeRaM) is

currently developing an innovative in situ anaerobic bioremediation process for cleaning the ground water at the UMTRA Tuba City site (3,4). Research and technology development work are conducted at the University of New Mexico in collaboration with these institutions: Montana State University, Bozeman, MT; Navajo Community College, Shiprock, NM.

REMEDIATION CONCEPT

Description of Technique

The ground water remediation technique involves in situ anaerobic biological reduction of the contaminates uranium, selenium, strontium, molybdenum, cadmium, nitrate, and sulfate. We plan to selectively grow bacteria that are currently present in very low concentration in the ground water on site. In turn these anaerobic bacteria will catalyze a series of chemical reactions transforming the water soluble contaminates into either a gas in the case of nitrates (5-9) or insoluble precipitates in the case of the heavy metals (10-19).

The in situ biological treatment should be implemented using conventional drilling and well water technology. The advantages of in situ bioremediation are that the contaminate plume is remediated and the aquifer is restored in a natural process with minimum environmental impact.

Site remediation requires that the upper most water bearing formation be restored to meet regulatory ground water requirements. This restoration process should consider cost, environmental impact and the total remediation time period. At the Tuba City, Arizona, site the plume of contaminated ground water is approximately 1500 ft down-gradient of the site and is moving on average 30 ft/year (18) towards the Moenkopi Wash. The ground water is located at a minimum depth of 60 ft below the ground surface (18) and the background ground water contains calcium, sodium carbonate and has a slightly basic pH, an oxidizing Eh and TDS 450mg/L. The plume waters contain the various chemicals (e.g., sulfates, nitrates, etc.) used in the uranium processing operations and have lower pH (6 pH 7) and lower Eh and 750LTDS7200mg/L.

Because uranium and other heavy metals appear to be retarded in their transport, as illustrated in Fig. 1, we do not believe that conventional ground water treatment methods, such as pump and treat, are likely to succeed. Also, the water table is too deep and the plume is moving too slowly to apply the permeable barrier technology. Well #906 is in the most contaminated region of the plume located at the South edge of the tailings pile, while well #908 is about 50 meters down gradient in the plume and is the second most contaminated well. Note, that well #906 has a uranium concentration 40 times the EPA MCL, while in well #908 the uranium concentration is only slightly above the EPA MCL. However, in both wells the nitrate and sulfate concentrations remain about the same, i.e., 30 and 15 times the EPA MCL standard. This decrease in uranium and molybdenum concentrations indicates strong retardation. If this initial trend persists,after more sampling wells are completed and tested, then the remediation of the heavy metals may be limited to a much smaller area, as compared to the nitrate and sulfate regions. This suggests the possible application of different in situ technologies over the various regions of the plume.

Fig. 1

Therefore, we are proposing for the Tuba City site an innovative in situ biological remediation approach. The strategy is for bacteria to chemically convert the mobile toxic species into either a gas or into

immobile precipitates. The ground water at the Tuba City, Arizona, site is contaminated with uranium, selenium, strontium, molybdenum, cadmium, nitrate and sulfate. Anaerobic bacteria from ground water samples at the UMTRA site have been shown to transform these chemical species into passive forms. Various reduction reactions are catalyzed by the bacteria as illustrated below. Sulfide is produced from sulfate reduction and then reacts to form insoluble precipitates with various heavy metals. The proposed biochemical remediation reactions are shown schematically in Fig. 2. The most contaminated region of the plume has a very low dissolved oxygen concentration of about 0.2 ppm and we anticipate, with the addition of appropriate amounts of organic nutrients, that the anaerobic bacteria will increase in number and promote the reactions illustrated in Fig. 2.

Fig. 2

As shown, these reactions convert the toxic species into materials that render the ground water harmless either through precipitation (formation of insoluble solids) or denitrification (formation of nitrogen gas). In this concept the amount of present nutrients is the limiting and controlling factor of reaction progress. As an example, only a portion of the sulfate will be reduced as needed to precipitate the heavy metals. By limiting nutrients and the amount of sulfate reduction we do not anticipate methylation. Excessive reduction of sulfate may lead to odor of the water and reactions of HS- with components of the host rocks that have not yet been evaluated. On the other hand present sulfate concentrations are too high (about 3-4 g/L) to be reduced to acceptable levels (about 250 mg/L) by bacteria without producing excess HS-. Yet this biotechnology is the least harsh methodology at hand as it enhances a natural process and accelerates the restoration of the ground water. After remediation of the ground water, bacteria are no longer needed. Solids such as UO2, CdS, etc. are stable under the given environmental conditions (Eh, pH, temperature and water composition) at a depth of >60 ft. in the sandstone formation. Though the solid compounds of the hazardous elements are not absolutely insoluble, their redissolution is limited by their extremely low solubilities, if not by slow dissolution kinetics. Solution concentrations are expected to be much lower than the regulatory limits established by 60FR2854 that parallel the drinking water standards.

The procedure is to inject organic nutrients, such as acetate, into the contaminated plume in order to support the growth of the indigenous bacteria, which in turn will perform the necessary anaerobic remediation reactions. The field implementation strategy is described in the next section. Studies to date have shown that the appropriate bacteria species are present, however, in very low concentrations because of limited organic nutrients in the water. The sandstone's permeability is high enough for in situ biotreatment, i.e., greater than 10-4 cm/sec and the dissolved oxygen concentration in the plume is low, 0.2 ppm.

Laboratory Studies

With and without the presence of sandstone core material, several batch experiments were conducted to assess the impact of the sandstone on the activity of bacteria. The number of viable bacteria in the experimental bottles was determined by standard dilution procedures with growth on Plate Count Agar. We found that the core matrix has no apparent deleterious effect on bacterial viability. Experiments will be designed to assess the interactions between sandstone surfaces and bacterial

cells.Laboratory studies using bacteria from the site have shown the ability of these bacteria to rapidly reduce nitrates. Using two isolates of bacteria, strain 906F and 906R, the rate of nitrate utilization was examined with three different carbon sources. An inorganic medium containing 200 ppm nitrate was employed with 40 mM sodium acetate, sodium lactate or sodium pyruvate added to support growth. The anaerobic cultures were examined over a period of 15 days with incubation at 16C, the ground water temperature in the plume. Nitrate concentration was determined using ion chromatography (Dionex Corporation, Sunnyvale, CA). Fig. 3 shows that nitrate reaction rates depend on the type of nutrient and that significant amounts of nitrate are reduced in a matter of days.

Fig. 3

We have performed similar experiments showing the equally rapid reduction and precipitation of uranium at temperature of 16 C using the Well #906 strain of bacteria. The transformation of the uranyl ion to uraninite (UO_2) has been documented in the literature to proceed by bacteria of special physiological types: Fe(III)-reducing, spore-forming Clostridium sp., and sulfate-reducing bacteria. Our interest in bacterial transformation of uranium has focused on the sulfate-reducing bacteria because these bacteria are widely dispersed in the ground water. Published laboratory studies indicate that high levels of U(VI) are reduced in a short time frame of several minutes to hours by enzymatic processes associated with cells of sulfate reducers. However, the potential reduction of U(VI) to U(IV) by sulfide has not been fully explored. Since hydrogen sulfide would diffuse widely in the aquifer system, it would be important to determine the effect of this reducing agent on U(VI) in the ground water. Our experiments involved the use of simulated ground water with the composition listed in Table I to match the chemical characteristics of water from well 906 at Tuba City. Various additions were made to anaerobic 150 mL bottles containing 100 mL of simulated plume water. Four different concentrations of sulfide and two concentrations of uranium were studied while incubation was conducted at two different temperatures under nitrogen atmosphere. The experiment was conducted in duplicate and values presented are averages.

Table I

The results of the study with water containing 1.2 mM uranyl acetate are presented in Figs. 4a through 4e. With no sulfide added to the anaerobic bottle, U(VI) remained in solution at 1.2 mM and no figure is shown to represent this. In the presence of 0.1 mM sodium sulfide, the concentration of U(VI) steadily declined at both temperatures; however, at 36C the transformation of U(VI) to U(IV) was more rapid than at 16C, see Fig. 4a. The results of U(VI) reaction by 0.2 mM sulfide are given in Fig. 4b, while the results with 0.5 mM, 0.7 mM and 1.0 mM sulfide are given in Fig. 4c, Fig. 4d and Fig. 4e, respectively. This experiment shows that uranium can be reduced by the production of sulfide. Hence, in our process the presence of sulfate and SRBs should lead to the precipitation of uranium dioxide.

Fig. 4

CONCLUSIONS

The plume of contaminated ground water at the Tuba City mill tailings site in Arizona contains the necessary indigenous bacteria to develop an in situ bioremediation process. Bioremediation is an attractive and potentially the preferred technique to decontaminate the ground water at Tuba City. Strong retardation, i.e., slow migration of uranium and

molybdenum was detected in the plume relative to sulfate and nitrate, indicating sorption of heavy elements on surfaces of the host rock. If desorption is slow, a pump and treat process may not be efficient, whereas in situ bioremediation takes place in the pores of the host rock (Navajo sandstone) and reaches internal surfaces. Experiments in the laboratory have shown that NO3- and U(VI) are reduced to N2 and insoluble U(IV), respectively, using indigenous bacteria from the site and organic nutrients, e.g., acetate. Sulfate reducers were also detected in the ground water and will be used to generate sulfide. Sulfide was shown to reduce UO22+ within days, supporting the respective bacteria catalyzed reaction. Other heavy metals, e.g., Cd, Mo, will be precipitated and immobilized as sulfides.

Session 46 -- STRATEGIC PATH FORWARD FOR USDOE OWNED SPENT NUCLEAR FUEL
Co-chairs: Ed J. Bentz, EJB&A;
G. Frank Cole, USDOE
46-1
OVERVIEW OF THE U.S. DOE-OWNED SPENT NUCLEAR FUEL NATIONAL PROGRAM

Frank Cole
U.S. Department of Energy
Office of Spent Fuel Management

ABSTRACT
The U.S. Department of Energy (DOE) faces a complex challenge in managing the inventory of spent nuclear fuel (SNF) generated by past production and ongoing test reactor and research reactor operations. Because ultimate disposition of DOE-owned SNF will require geologic disposal, and because DOE no longer processes SNF to recover strategic materials, SNF will need to be stored for decades. The Office of Spent Fuel Management in the DOE Office of Environmental Management (EM) is responsible for overcoming that challenge. This paper reports on SNF management program's ongoing efforts to manage the inventory of SNF. The paper discusses the recent accomplishments of the SNF management program, the program's progress on a number of outstanding issues, and plans for the near-term. Additionally, the paper serves as an introduction for the other papers in this session.
The paper shows that the SNF management program has made significant progress in a number of areas affecting the safe interim storage of DOE-owned SNF. Examples include decisions on removal of the deteriorated spent fuel from the Hanford K-Basins and the treatment and/or transfer of SNF from facilities at Savannah River and the Idaho National Engineering Laboratory. However, numerous technical, managerial, and policy issues remain as obstacles on the path forward for DOE-owned SNF. An example is

resolution of questions regarding acceptable forms and methods of storing, packaging, transporting, and disposing of the spent fuel.

THE SPENT NUCLEAR FUEL LEGACY

The U.S. Department of Energy (DOE) faces a complex challenge in managing the inventory of spent nuclear fuel (SNF) generated by past production and ongoing test reactor and research reactor operations. Because ultimate disposition of DOE-owned SNF will require geologic disposal, and because DOE no longer processes SNF to recover strategic materials, SNF will need to be stored for decades. The Office of Spent Fuel Management in the DOE Office of Environmental Management (EM) is responsible for overcoming that challenge. This paper reports on SNF management program's ongoing efforts to manage the inventory of SNF.The decision to phase out processing of DOE-owned SNF has resulted in a growing inventory. As of January 1996, DOE held 2646 metric tons of SNF in its storage facilities. The challenge of DOE SNF management is compounded by the significant differences between commercial SNF and DOE-owned SNF in terms of variety, condition, characterization, enrichment, cladding, and other characteristics. Additionally, certain vulnerabilities are associated with this SNF, including corrosion and structural degradation.

Fig. 1

DOE SNF MANAGEMENT

The general goals and practices of DOE-owned SNF management are to achieve and maintain safe storage of SNF for an interim period to ensure the protection of the environment, workers, and the public. Attaining this requires some treatment and packaging of the SNF to meet both interim storage and permanent disposal criteria.

Key SNF management guidelines are: to regionalize interim storage primarily at three sites (Hanford, Savannah River and Idaho National Engineering Laboratory [INEL]) by fuel type, and to ultimately dispose of SNF in a geologic repository.

The regionalization by fuel type approach will occur as follows:

Hanford production reactor fuel and fuel not requiring treatment will remain at Hanford; sodium-bonded Fast Flux Test Facility fuel will be shipped to INEL for treatment.

Naval fuel will be shipped to INEL for examination and interim storage.

Non-aluminum clad fuels will be consolidated at INEL, excluding Fort St. Vrain fuel, which will remain in Colorado.

Aluminum-clad fuels will be consolidated at the Savannah River Site.

More information on this approach can be found in the paper given in this session by H. Eckert.

DOE SNF MANAGEMENT AT HANFORD

Fig. 2

DOE is undertaking at Hanford a number of significant SNF management activities, and is developing or implementing certain plans for SNF management. Conditions at the K-West and K-East irradiated fuel storage basins present challenges. The K-East Basin contains irradiated N-Reactor SNF stored in open canisters, and some of the fuel has corroded. Further, the K-East Basin contains debris and approximately 50 cubic meters of sludge. Both basins have a history of leaking.

To improve near-term conditions in the K-Basins, DOE has installed seismic barriers in both basins. An Environmental Impact Statement (EIS) for the K-Basins will be completed in March 1996. Plans for Hanford SNF activities are to begin removal of the SNF and sludge from the basins in December 1998 and place it in a Staging and Storage Facility, which is to

be located in the 200 Area and completed by May 1998, at the Hanford Site by December 2000. The K-Basins path forward would complete placing the fuel and sludge in interim dry storage by the year 2006.
More information on SNF management at Hanford can be found in the papers by J. Fulton and E. Sellers.
DOE SNF MANAGEMENT AT SAVANNAH RIVER
Fig. 3
DOE is conducting numerous activities and making plans for SNF management at the Savannah River Site. An important issue at the site is the corroded reactor target slugs at the L-Reactor disassembly basin. Planned SNF activities at Savannah River include the Interim Management of Nuclear Materials (IMNM) EIS decision. An expedited EIS process for the material at greatest risk (F-Canyon Plutonium Solutions) resulted in the issuance of a Record of Decision (ROD) in February 1995. The final IMNM EIS on the remaining material was issued in October 1995. In December 1995, DOE issued an initial ROD covering the majority of the other material, which stated that the Mark 36 fuel targets are to be processed. Subsequent ROD(s) are expected to address chemical processing options from the canyon utilization study and stabilization of the Mark 16 and Mark 22 fuel targets. Additionally, DOE is developing a technical strategy to treat, package, and store the fuel in a manner suitable for placement into long-term storage or a geologic repository. In November 1995, DOE formed a Research Reactor Fuel Task Team to assist in resolving interim storage and disposal issues for the aluminum-clad highly enriched uranium (HEU) SNF at Savannah River. Last, a dry storage facility or other treatment facility is planned to open by 2003.
DOE SNF MANAGEMENT AT INEL
Fig. 4
DOE SNF management activities and plans at INEL include preparation for the dry storage facility for the Three-Mile Island core debris SNF by 1998. DOE is currently making a decision on obtaining NRC licensing of the facility. At the ICPP-666 SNF storage facility, plans are to complete reracking of the ICPP-666 basin for additional storage after the court injunction is lifted. DOE also is planning construction of a dry modular storage facility by 2003.
A related issue involves SNF at Fort St. Vrain, Colorado. DOE is negotiating with the Public Service Company of Colorado to purchase and take over the facility, which will include taking over the license of the facility. Plans are to keep the SNF at Fort St. Vrain rather than ship the fuel to INEL.
PROGRAM MANAGEMENT TOOLS
A number of documents guide SNF program management activities. The following table gives information on the documents, date of issuance, and significance to program management:
Table I
The paper by J. Baker provides information on SNF Program technology needs and capabilities, and the paper by C. Head discusses FRR SNF.
SNF PATH FORWARD
As the above indicates, DOE has projected a number of important activities for the achievement of the path forward for the ultimate disposition of DOE-owned SNF. These include:
  Develop strategy for Storage/Disposal of Al-Clad HEU at Savannah River (6/96)
  TMI Core Debris Dry Storage at INEL (9/98)

Remove SNF from Hanford K-Basins (12/99)
Dry Storage facilities at INEL (2003)
Dry Storage or treatment facilities at Savannah River Site (2003)
Continuing preparations for disposal of SNF at a geologic repository.

However, various known or unforeseen considerations may affect these plans. One obstacle is determining and agreeing on acceptable forms and methods of storing, packaging, transporting, and disposing of DOE-owned SNF. For example, the DOE Office of Civilian Radioactive Waste Management recently issued interim waste acceptance criteria that impact SNF Program chemical processing activities, among others; the final requirements are due out in March 1996. More information on this topic is to be found in the paper on preparations for geologic disposal by K. Chacey. Another obstacle involves funding uncertainties, which greatly impact SNF Program resources, activities, and schedules.

46-2
IMPLEMENTATION OF DOE-OWNED SPENT FUEL REGIONALIZATION

Howard J. Eckert

Lockheed Idaho Technology Company

ABSTRACT

In June of 1995, the Department of Energy (DOE) issued a Record of Decision (ROD) on Programmatic Spent Fuel Management for the next 40 years. The ROD authorizes the complex-wide regionalization of DOE-owned spent nuclear fuel by fuel type. This decision affects the approximately 2700 metric tons heavy metal (MTHM) of DOE-owned spent fuel currently in inventory, as well as the approximately 100 MTHM which is expected to be added to the inventory through the year 2035. Subsequent to the issuance of the ROD, a Settlement Agreement between the Department of Energy, the Department of the Navy, and the State of Idaho was reached on October 17, 1995. Requirements set forth in the Settlement Agreement will result in modifications to the ROD.

Based on the ROD, as modified by the Settlement Agreement, three DOE sites were selected for regionalized management of the Department's spent fuel inventory. Spent fuel currently in storage at the Hanford Site will remain at Hanford, except sodium-bonded fuel which will be shipped to INEL. The INEL was designated as the storage site for non-aluminum clad spent fuel, including Naval spent fuel. The Settlement Agreement restricts the amount of spent fuel to be shipped to the Idaho National Engineering Laboratory (INEL) over specified time intervals. The Savannah River Site (SRS) was designated as the storage site for aluminum-clad spent fuel. The spent fuel currently in storage at Fort St. Vrain (FSV) in Colorado will remain in dry storage there until a repository or interim storage facility outside of Idaho is developed and is accepting fuel from INEL. Once this requirement is met, FSV fuel may be transferred to INEL for treatment, then returned to Colorado for storage or transferred directly to the repository.

The Department has developed a DOE-owned Spent Nuclear Fuel Interim Storage Plan to integrate national and site-specific plans needed to safely and efficiently manage spent fuel over the next 40 years. The

scope involves the integration of planning and implementation activities associated with the spent fuel, with the facilities utilized for fuel storage, handling, characterization or conditioning, and with the transportation activities required to implement regionalization and transition of DOE-owned spent fuel into improved long-term interim storage.

This paper summarizes the activities and challenges associated with the management of spent fuel within existing facilities, the acquisition and management of new spent fuel facilities, and the transportation of spent fuel both onsite and between sites to implement regionalization by fuel type.

THE RECORD OF DECISION

During the last 40 years, the Department of Energy and its predecessor agencies have generated, transported, received, stored, and processed spent nuclear fuel at various facilities in the Department's nationwide complex. Currently, approximately 2700 metric tons heavy metal (MTHM) of DOE-owned spent nuclear fuel remain that have not been processed. Additionally, DOE-owned spent fuel containing approximately 100 MTHM is expected to be generated in the next 40 years, including possible receipt of Foreign Research Reactor spent fuel, if a decision is made to reinstitute the policy of returning such fuel to the United States.

In order to evaluate the potential impact of actions proposed to safely, efficiently, and responsibly manage existing and projected quantities of DOE-owned spent fuel through the year 2035 (pending ultimate disposition), the Department developed a Programmatic Environmental Impact Statement (PEIS). The PEIS provided four basic approaches to spent fuel management, which were then evaluated through a formal screening process and weighed against established criteria. The environmental impacts of implementing any of the alternatives were evaluated in detail and determined to be small. Two of the four candidates, the "1992/1993 Planning Basis" and "Regionalization by Fuel Type," were selected for more detailed analysis. These two candidate alternatives were then evaluated against a number of technical and nontechnical considerations, including environmental impact perception, indicated stakeholder preferences (drawn from public meetings), implementation factors, regulatory risk, spent fuel processing potential, environmental justice, and fairness. The ROD documented the bases for the Department's decision to implement the regionalization of spent fuel by fuel type (1).

This decision authorizes the regionalization and consolidation of existing and newly generated spent nuclear fuel at three major DOE sites based on the fuel type (pending future decisions on ultimate disposition). Under this decision, the fuel type distribution would be as follows:

- Hanford production reactor fuel will remain at the Hanford Site;
- Aluminum-clad fuel will be consolidated at the Savannah River Site (SRS); and
- Non-aluminum clad fuels (including Naval spent fuel) will be transferred to the Idaho National Engineering Laboratory (INEL).

For planning purposes, it is assumed that DOE-owned spent nuclear fuel that is not otherwise dispositioned will be emplaced in the first geologic repository for spent nuclear fuel and high-level radioactive waste, subject to physical and statutory limits, payment of fees, and compliance with waste acceptance requirements. (Current limitations allow for approximately 2330 MTHM of DOE-owned spent fuel, based on a

repository total of 70000 MTHM.) Except for some special-case commercial fuel, the decision does not apply to management of spent nuclear fuel from commercial nuclear power plants. The ROD does not address ultimate disposition of the Department's spent nuclear fuel.

THE SETTLEMENT AGREEMENT

Subsequent to the issuance of the Record of Decision, a Settlement Agreement between the Department of Energy, the Department of the Navy, and the State of Idaho was reached on October 17, 1995 (2). The Settlement Agreement places strict controls on shipment and storage of spent fuel at the INEL. The following is a brief summary of the requirements/restrictions imposed by the Settlement Agreement:

Allows the shipment of Naval spent fuel through the year 2035 (up to 575 total shipments with a total of 55 MTHM) required to refuel or defuel nuclear powered warships, and to examine the spent fuel created to support continued safe operation of existing warships.

Allows for essential shipments of DOE-owned spent fuel to enable the United States to recover spent fuel from reactors in foreign countries for purposes of nuclear non-proliferation, if such an acceptance policy is adopted. Allows 61 shipments of DOE-owned spent fuel prior to December 31, 2000, and 497 shipments after December 31, 2000, with maximum average annual shipment limits (includes the spent fuel at the West Valley Demonstration Project, possible additional foreign research reactor spent nuclear fuel, U.S. university research reactor spent fuel, and DOE laboratory and other spent fuel that DOE is obligated to accept for storage). Of the total 558 possible shipments, those coming from SRS would be received at INEL only as equivalent shipments of spent fuel leave INEL for storage at SRS.

Allows 244 additional spent fuel shipments from the Fort St. Vrain facility in Colorado if a repository or interim storage facility outside the State of Idaho is open and is accepting spent fuel from INEL. The fuel may then be transferred to INEL for the purpose of treatment (not storage) so that it is acceptable for the repository or interim storage facility. In the interim, this spent fuel will remain in safe NRC-licensed dry storage in Colorado.

Commits DOE to remove spent fuel from water storage pools at INEL by the year 2023, and to place the spent fuel into dry storage which is removed from the Snake River Plain aquifer to the extent technically feasible.

Prohibits any shipment of DOE-owned spent fuel to INEL after April 30, 1999, unless shipments of transuranic waste from INEL to the Waste Isolation Pilot Plant (located in New Mexico) or another facility are proceeding at a specified rate. Requires the removal of all transuranic waste from INEL by the year 2018, and the removal of all spent fuel from INEL by 2035, with enforceable requirements including payments to Idaho if spent fuel is not removed by that date.

DOE-OWNED SPENT NUCLEAR FUEL

The current inventory of DOE-owned spent nuclear fuel is composed of approximately 2700 MTHM, with an additional 100 MTHM projected to be generated over the next 40 years. Table I provides a summary of the locations and quantity (in terms of 3 metrics) of spent fuel currently existing within the DOE complex. Approximately ninety-nine percent (99%) of the existing DOE-owned spent fuel (by MTHM) is stored in facilities at four locations: the Hanford Reservation (81%); the INEL (10%); SRS (8%); and the West Valley Demonstration Project Site (1%). Naval propulsion

spent fuel comprises the majority of the projected receipts (as calculated by MTHM), with spent fuel from foreign and domestic research reactors providing another large category of spent fuel receipts. The projected increase in DOE-owned spent fuel inventories through the year 2035 represents approximately 4% by MTHM, or approximately 70% when using total mass or volume as the metric.

Table I

THE DOE-OWNED SPENT NUCLEAR FUEL INTERIM STORAGE PLAN

Planning for complex-wide management of DOE-owned spent fuel pending ultimate disposition has been impacted by both the ROD and the Settlement Agreement. DOE has developed an Interim Storage Plan to integrate national and site-specific activities proposed to consolidate, regionalize, and manage spent fuel during the interim period (3). Summaries of individual site plans are provided for the Hanford Site, the INEL, Oak Ridge National Laboratory (ORNL), and the Savannah River Site. Discussed are the national and site-specific activities needed to assure safe, interim storage within existing facilities as well as the actions underway to acquire new, primarily dry storage facilities for the longer term prior to transferring the spent fuel to the geologic repository for disposition.

A baseline Master Logic Schedule (MLS) has been developed to assist in the interim management of spent nuclear fuel and integration of complex-wide activities. This tool serves as an integral component of the program implementation strategy by establishing the logic and key milestones for the entire national program and displaying the paths that lead to permanent disposition of DOE-owned spent nuclear fuel. It is structured at several levels, with the highest levels summarizing key activities for the entire program over a 40-year period, and the lower levels providing more detail by site and facility.

Major activities proposed for the interim management of DOE-owned spent fuel are based upon managing spent fuel within existing DOE facilities, acquiring new facilities, and facilitating transportation of spent fuel between facilities. For implementation purposes, these major activities can be categorized into three general time frames or phases. Program and site priorities, budget constraints, resources availability, and scheduling/transportation requirements act to define the time frames for each phase, with some overlap expected.

Phase 1 activities are scheduled to take place approximately through the year 2000. These are the activities that are the most well-defined, and for which budget allocations or projections are already in place. These activities emphasize efforts associated with existing facilities, and in many cases represent actions that must be taken to prepare for major activities proposed in Phase 2. Budget projections and schedules reflect the priorities which have been placed upon resolution of vulnerabilities and Defense Nuclear Facilities Safety Board issues, facility upgrades, and onsite fuel consolidation. Initiation of spent fuel regionalization activities will take place on a small scale during Phase 1. Facility acquisition activities are focused on acquiring the Canister Storage Building at the Hanford Site and Three Mile Island Dry Storage facility at INEL.

Phase 2 is defined as the period beginning in the year 2001 and continuing through approximately 2006. Activities proposed in this phase are less well defined than in Phase 1, and budget projections and schedules are still under development. This phase will focus on the large

scale implementation of regionalization of spent fuel by fuel type, including transfers of fuel between the designated sites. Requested funding levels will reflect storage costs, transportation costs, and costs related to bringing on-line additional new storage facilities (e.g., the Dry Modular Storage Facility at INEL).

Phase 3 is defined as the period beginning approximately in 2007 and continuing through approximately 2035. This phase will include the completion of regionalization activities, but will focus more on the actual interim management of the spent fuel awaiting the availability of the geologic repository. During this phase there will be a measurable decrease in site budget projections, reflecting the transition to surveillance and maintenance activities.

MANAGEMENT OF SPENT FUEL WITHIN EXISTING FACILITIES

Most existing DOE storage facilities either have reached, or are approaching, the end of their original design life. Many of the facilities have vulnerabilities that may require costly upgrades or preclude reasonable life extension efforts, thereby warranting phaseout of the facility. Given sufficient funding, the prudent course of action would be to phase out these facilities at the earliest point in time. However, due to limited funding and a need to improve the near term storage conditions of much of the DOE-owned spent fuel, efforts must be undertaken to continue the use of some of these facilities. This Plan identifies those existing facilities that, while not fully compliant with today's standards, are technically adequate for continued near term use pending the acquisition of new facilities.

Hanford Site

The Hanford Site manages the largest amount of DOE-owned spent nuclear fuel with a current inventory of approximately 2133 MTHM, representing approximately 81% (by weight) of the Department's entire spent fuel inventory, the vast majority of which is production fuel.

At the Hanford Site, the most pressing issue has been the removal of N-Reactor spent production fuel from the aged K-Basins. In October 1995, all spent production fuel remaining in storage at PUREX was transferred to the K-West Basin. This fuel has been consolidated with the remaining K-Basin fuel which will be moved to a staging facility serving as the first phase of the new Canister Storage Building (CSB) scheduled to begin operation in late 1997. The completion of the removal of spent production fuel from the K-Basins is scheduled for December 1999. Once the conditioning system becomes operational at the CSB, the spent production fuel will then be cycled through a conditioning process, repackaged and moved to the main dry storage area located in the CSB, where it will remain until its scheduled transfer to the repository. The transfer of all spent production fuel to the repository is scheduled to occur between 2015 and 2035.

In addition to the spent production fuel currently in storage in the K-Basins, small amounts of non-production fuel, once used for experimental and other purposes, are also stored at other onsite facilities. Currently, this spent fuel is located in the Low-Level Burial Grounds (LLBG), T-Plant, Plutonium Finishing Plant (PFP), Fast Flux Test Facility (FFTF), and several 300-Area Buildings. In the near future, FFTF and the 300 Buildings spent non-production fuel will be temporarily moved to a 400-Area storage pad. When additional space becomes available, the spent fuel will be transferred to a 200-Area storage pad adjacent to the CSB, where all the spent non-production fuel will be consolidated with T-Plant

fuel and temporarily stored prior to being transferred to the repository site via the CSB pathway. PFP and LLBG fuels, once conditioned and repackaged at the Canister Storage Building, will await disposition via the CSB pathway at the PFP facility and 200-Area storage pad, respectively. The transfer of all spent non-production fuel, with the exception of sodium-bonded fuel from the FFTF, is scheduled to occur between 2015 and 2035. The sodium-bonded fuel is scheduled to be transferred to INEL for electrometallurgical treatment at Argonne National Laboratory-West (ANL-W), if this process is found to be feasible and practical. (This topic is addressed in Session 46 -Spent Fuel Conditioning and Processing Technologies: Needs and Capabilities," John F. Baker, William D. Clark, Jr., and James J. Laidler)

Idaho National Engineering Laboratory

The current inventory of spent fuel at INEL is 261 MTHM, representing approximately 10% (by weight) of fuel in the DOE Complex. Five major facility areas exist in and around INEL that store spent fuel: ANL-W, Idaho Chemical Processing Plant (ICPP), Power Burst Facility (PBF), Test Area North (TAN), and Test Reactor Area (TRA). Stored fuels are kept in a variety of both wet and dry configurations. The ROD identified INEL as the recipient of non-aluminum clad spent fuel, including Navy fuel, in the DOE complex (within certain limitations specified in the Settlement Agreement) for interim storage.

The INEL will consolidate spent fuel at the Idaho Chemical Processing Plant. To resolve existing vulnerabilities, fuel is being moved from an older wet storage facility (CPP-603) to a modern wet storage facility (CPP-666) or to dry storage. A new dry storage facility will be built at INEL to store damaged Three Mile Island-2 core debris . An additional dry storage facility will be built to store future receipts of Navy fuel and non-aluminum clad DOE-owned spent fuel and for further consolidation of fuel stored at various INEL facilities.

The Idaho Chemical Processing Plant historically received spent nuclear fuel from many onsite and offsite reactors for processing. However, DOE decided to phase out processing activities in 1992. The new mission of this facility area is to receive and store spent fuel. In implementing this mission, the majority of spent fuel will be consolidated in CPP-603 (Dry) from a number of onsite storage locations for temporary storage. Fuels currently stored at CPP-603 (Wet) will either be moved and placed into wet storage at CPP-666, or canned and placed in storage at CPP-603 (Dry). These activities will be completed by December 2000. As for other activities at ICPP, CPP-666 will serve as the interim storage location for Navy fuel and the near term storage location for Advanced Test Reactor (ATR) fuel. All wet storage operations within CPP-666 will cease by 2023, at which time all stored materials will have been transferred to dry storage either at the Navy's Expended Core Facility (ECF) located at INEL or at the CPP-666 location. All subsequent Navy fuel shipments which are scheduled to continue until 2035 will be received for dry storage at either the ECF or the CPP-666 directly. Furthermore, Peach Bottom fuel currently stored at INEL in CPP-603 (Dry) will be transferred to CPP-749 over a period of 12 months beginning in early 1997 where it will await transfer to the new Dry Modular Storage Facility. Beginning in 2001, receipts from ORNL will be placed in storage at CPP-749 and CPP-603 (Dry). Transfer of fuel to interim storage from CPP-603 (Dry) and CPP-749 to the new Dry Modular Storage Facility is scheduled to begin in 2003 and continue for at least a decade.

The Test Reactor Area and the Power Burst Facility, which currently store both aluminum-clad and non-aluminum clad research reactor fuel, will transfer their non-aluminum clad fuels to CPP-603 (Dry) for short-term interim storage. Aluminum-clad fuels including ATR fuel will be transferred offsite from CPP-666 to SRS, while the remaining non-aluminum clad fuel will follow the same disposition path as other CPP-603 (Dry) fuels. Fuel transfers from TRA and PBF will occur within approximately the next five years.

Test Area North stores special-case commercial fuel (including Three Mile Island core debris) and DOE experimental fuel similar to commercial nuclear fuel. A new facility, Three Mile Island (TMI) Dry Storage, is currently being planned, and will begin receiving TMI fuel currently stored in TAN (Wet) in 1998. The remaining fuels in TAN (Wet) will be transferred at the same time to the current TAN (Dry) facility for temporary storage and eventual transfer to the new Dry Modular Storage Facility. The TAN (Dry) facility will also receive fuel from West Valley for temporary storage beginning after 2000 and it will eventually be transferred to the new Dry Modular Storage Facility, along with the spent fuel currently in cask storage at TAN (Dry).

The remaining onsite fuel is stored at ANL-W, which generated spent fuel as a result of research and development activities related to advanced reactor design. Primarily, ANL-W will be designated the disposition facility/area for sodium-bonded fuel, including fuel from the Hanford Site. Following processing, fuel would no longer be classified as spent fuel and will not be managed by the spent fuel program. The high-level waste component from processing will ultimately be disposed of in the repository. If it is determined to be feasible and practical, processing of fuel at ANL-W will begin in approximately 2001 and continue for approximately eight years. An option to use a modified electrometallurgical treatment technique for the fuel at Oak Ridge's Molten Salt Reactor Experiment is being investigated and a determination as to its use will be made in the next 1-2 years.

The spent fuel currently in dry storage at Fort St. Vrain in Colorado will remain there for the near term. Receipt of Fort St. Vrain fuel will only take place if and when an interim storage facility or permanent repository is operating outside of Idaho and accepting INEL spent fuel. If these conditions are met, INEL will receive FSV fuel for the purpose of treatment only; storage or disposition of FSV fuel will occur elsewhere.

A number of different options are still being considered at INEL for long-term disposition, but the current plan is to consolidate spent fuel for interim storage at three facilities: Dry Modular Storage Facility, TMI Dry Storage, and CPP-666. Under the current plan, fuels stored in TMI Dry and CPP-666 (other than Navy fuel) would be transferred to the Dry Modular Storage Facility for conditioning/packaging before being transferred to the repository, beginning in 2015.

Oak Ridge National Laboratory

The Oak Ridge Reservation stores a relatively small amount (approximately 1 MTHM or 0.3% by weight) of DOE-owned spent fuel in comparison to the other DOE sites. Nevertheless, the large variety of types of spent fuel managed by Oak Ridge necessitates the need for an integrated disposition plan. Oak Ridge aluminum-clad spent fuel will be shipped to SRS for interim storage, and non-aluminum clad fuel will be shipped to INEL. Currently, spent fuel is stored in a variety of onsite storage areas

including retrievable dry storage units (SWSA 5N), as above ground hot cell units (Bldg. 3525 and 7920) and wet storage basins at the High Flux Isotope Reactor (HFIR) and the Bulk Shielding Reactor (BSR). Spent fuel generated at the Tower Shielding Reactor (TSR) is currently stored within the inactive reactor core. Spent fuel from the Molten Salt Reactor Experiment (MSRE) is housed in isolation within critically safe storage tanks.

Oak Ridge will ship the majority of its spent fuel located at the HFIR, BSR, and TSR facilities to the Savannah River Site beginning in 1996. Transfer of TSR and BSR spent fuel is expected to be completed by 1999. Production and transfer of HFIR fuel is scheduled to continue throughout its operating life, currently anticipated through 2015. The small amount of aluminum-clad spent fuel stored in SWSA-5N and Buildings 3525 / 7920 will be repackaged and transferred to the Savannah River Site between 1997 and 1999.

As for the non-aluminum clad fuel, Peach Bottom, Dresden and other miscellaneous fuels are stored at SWSA 5N and Building 7920. These fuels will be repackaged at Building 3525 and either returned to SWSA 5N prior to transfer to INEL, or transferred directly to INEL. Transfer of these fuels to INEL is scheduled to take place over five years, beginning in 2001, in accordance with the Settlement Agreement between DOE, the Navy, and the State of Idaho. Spent fuel from the MSRE may be processed utilizing a modified pyroprocessing technique onsite through 2005, with a determination as to using this process being made in the next 1-2 years. The high-level waste component from processing will be transferred along with other spent fuel to the repository.

Savannah River Site

The Savannah River Site manages 207 MTHM of DOE-owned spent fuel, representing approximately 8% (by weight) of spent fuel in the DOE complex. SRS currently stores the majority of the aluminum-clad spent fuel in the DOE-complex at the Receiving Basin for Offsite Fuels (RBOF), the K-,L-, and P-Reactor Disassembly Basins, and basins in the F- and H-Canyons. The F- and H-Canyons and the L- and P-Reactor basins presently manage production fuel and targets. The K-Reactor basin manages production fuel, while RBOF is currently the only facility to manage offsite and non-aluminum clad spent fuel.

SRS is finalizing a site-specific Environmental Impact Statement (EIS) evaluating options to store or process spent fuel. A combination of options including processing of deteriorated aluminum-clad fuel and dry storage of remaining spent fuel may be the preferred alternative. If the processing option is selected, deteriorated aluminum clad fuel from INEL may also be shipped to SRS for processing.

Aluminum-clad HFIR fuel from ORNL, domestic research reactors (DRRs) and other DOE facilities will be transferred to SRS for storage in RBOF or the K/L-Basins over a ten year period ending in December of 2005. During the first 24 months of these receipts, K/L-Basins will undergo upgrading to ensure the facilities continued integrity. In addition, RBOF or K/L-Basins would receive ORNL transfers of BSR and TSR fuels from late 1996 to the end of 1997, and ORNL 3525 and SWSA 5N spent fuel from 1997 through 1999. Spent fuel received at RBOF and the K/L-Basins will remain in storage until transfer to a new dry storage facility which is proposed to come on-line in about 2003. However, production fuel receipts to K/L-Basins may either be transferred to F- and H-Canyons for processing, at which time the fuel will no longer be classified as spent fuel, or the

production fuel will remain in storage at K/L-Basins until transfer to interim dry storage in 2003. Finally, those transfers from ORNL, DRRs, and other DOE facilities received after December of 2003 may go directly to a dry storage facility to await conditioning and ultimate disposition beginning in 2015.

Pending a Record of Decision on the Foreign Research Reactor (FRR) EIS, offsite receipts of FRR spent fuel to RBOF or the K/L-Basins for storage could start in late 1996. FRR spent fuel received between 1996 and 2000 may be subsequently transferred to F- and H-Canyons for processing, or remain at K/L-Basins until the transfer of all fuel from K/L-Basins to a dry storage facility in 2003. Aluminum-clad and ATR fuel receipts from INEL to RBOF or K/L-Basins will begin in the year 2001. FRR spent fuel and INEL fuel receipts to RBOF or K/L-Basins will cease in 2005; subsequent receipts might then go directly to a new dry storage facility to await conditioning and final disposition beginning in 2015.

Non-aluminum clad fuels currently stored at RBOF will be transferred to INEL. This will occur between 2001 and 2010 in accordance with the Settlement Agreement, requiring an equivalent annual number of spent fuel shipments between SRS and INEL until all aluminum-clad spent fuel presently stored at INEL has been shipped to SRS.

ACQUISITION AND MANAGEMENT OF NEW STORAGE FACILITIES

The safe, effective interim management of DOE-owned spent nuclear fuel will require the construction of several new interim storage facilities, including support facilities needed to characterize, stabilize or condition, and package the spent fuel, most probably under dry conditions. One primary driver that influences decisions as to facility need is safety, which dictates that new facilities are needed to provide improved safe management for many of the DOE-owned spent fuel types. A second driver exists in the need to prepare the spent fuel for final disposition in a geologic repository. To bring on-line these new facilities will require substantial efforts in the areas of contract management and funding, development and implementation of regulatory requirements, technology development, design selection, and National Environmental Policy Act (NEPA) analysis. When possible, new spent fuel storage and conditioning facilities are to use existing commercial technologies to minimize life cycle costs and to take advantage of commercial standards and licensing bases.

One consideration that arises during the acquisition of new facilities is the degree to which commercial industry regulatory requirements are to be adopted. The primary Federal agencies that promulgate requirements that potentially impact the management of DOE-owned spent fuel are the Nuclear Regulatory Commission (NRC) and the Environmental Protection Agency (EPA). Under the Atomic Energy Act (AEA), the NRC has regulatory authority for nuclear safety over commercial nuclear facilities as well as select DOE facilities that are identified by Congressional lawmaking. The EPA is the agency responsible for promulgating regulations implementing a number of environmental laws including, among others, the Clean Air Act, the Clean Water Act, the Resource Conservation and Recovery Act (RCRA), and the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA). Of these, the AEA and RCRA provide the majority of requirements specific to spent fuel.

In addition, a Federal Advisory Committee on External Regulation of Department of Energy Nuclear Safety has been established to provide advice, information, and recommendations on whether and how new and

existing DOE nuclear facilities and operations should be externally regulated to ensure safety. The committee's final report recommends external regulation of essentially all aspects of safety at DOE's nuclear facilities and sites. DOE spent fuel storage and treatment facilities would be directly impacted when the recommendation is implemented.

At the site level, a number of regulatory initiatives are underway in conjunction with the acquisition of new facilities. As an example, at the Hanford site the K-Basin Replacement Project has established a Regulatory Requirements Team and an Independent Review Panel to help determine the regulatory requirements needed for design and construction of the new Canister Storage Building. The Regulatory Requirements Team is comprised of DOE-Richland, Westinghouse Hanford Corporation and expert personnel, and is responsible for the identification, evaluation, and recommendation of requirements for use on the project. An Independent Review Panel consists of three nuclear industry experts who review the recommendations provided by the Regulatory Requirements Team.

The acquisition of a new Three Mile Island Dry Storage facility at the INEL also affords an opportunity for the DOE to consider new approaches towards regulatory requirements. The DOE has evaluated proposals for a company to design and construct a dry storage facility based upon proven commercial facilities that have been designed in accordance with NRC requirements. The selection of the approved vendor was completed in late 1995.

SPENT FUEL TRANSPORTATION / MULTI-PURPOSE CANISTERS

Although the main focus of the Interim Storage Plan is to document DOE plans for managing spent fuel over the next 40 years, plans must also account for eventual disposition of the spent fuel. As ultimate disposition for the majority of DOE-owned spent fuel will be in a geologic repository, the national spent fuel program is working with the Office of Civilian Radioactive Waste Management (OCRWM) to develop disposal package designs, waste acceptance requirements, and technical requirements for emplacement of DOE-owned spent fuel within a geologic repository.

One concept being pursued is the use of multi-purpose canisters (MPCs) that provide for spent nuclear fuel interim storage, transportation to the repository, and repository emplacement. The Navy is currently evaluating the use of multi-purpose canisters for interim storage and permanent disposition of naval propulsion spent fuel.

The DOE will monitor progress in this area, and effort will be made to extend MPC designs for use with DOE-owned spent fuel as necessary for preparations for disposal proceed.

COSTS

The costs for implementation of interim storage for Fiscal Years 1996 through 2001 are estimated to be on the order of $1.5 Billion, which includes both the costs for operating existing facilities as well as the cost for the acquisition of new facilities.

CHALLENGES

In order to effectively implement the complex-wide regionalization of DOE-owned spent fuel, a large number of activities must be undertaken concurrently or consecutively, with close coordination among the sites, and with consideration given to long-term interim storage and preparation of the fuel for permanent disposal in a geologic repository. There are many challenges which must be addressed, including but not limited to the following:

a) Availability and suitability of transportation casks - An adequate number of casks must be available within relatively strict time frames in order for transportation to occur as needed. The suitability of existing casks must be evaluated for the myriad of potential spent fuel types to be transported. If existing casks are found to be lacking, either modifications will be required or new casks must be designed and constructed.
b) Availability of funding - All of the proposed plans assume that the necessary funding will be provided at adequate levels and in the time frame needed in order to accomplish all the required tasks. With the current turmoil concerning government funding in general, and Department of Energy activities specifically, obtaining necessary funding will be a challenge.
c) Stakeholder acceptance - Gaining stakeholder acceptance, whether it be members of Congress, State Governors, Tribal leaders, or members of the general public, will be difficult based on the many areas of concern. These areas include economic impact, equity, risk aversion, as well as concerns that potential delays in the Geologic Repository Program may lead to de facto permanent storage in the states in which the spent fuel is being stored.
d) Technology development - Some technology development will be required in order to stabilize the condition of many of DOE's spent fuel types so that they can be safely placed into interim storage.
e) Repository Program - The current funding problems being experienced by the Department's Repository Program could impact the development work in the areas such as Multi-Purpose Canisters and the development of waste acceptance requirements for the disposal of DOE-owned spent fuel in the geologic repository. Delays in either of these two areas could require multiple handling of spent fuel in order to place the spent fuel in a form and in packages that will be compatible with the yet to be developed MPC's and meet currently unspecified waste acceptance requirements.

ABSTRACT

This paper highlights progress made during the last year toward removing the Department of Energy's (DOE) approximately 2,100 metric tons of metallic spent nuclear fuel from the two outdated K Basins at the Hanford Site and placing it in safe, economical interim dry storage. In the past year, the Spent Nuclear Fuel (SNF) Project has engaged in an evolutionary process involving the customer, regulatory bodies, and the public that has resulted in a quicker, cheaper, and safer strategy for accomplishing that goal. Development and implementation of the Integrated Process Strategy for K Basins Fuel is as much a case study of modern project and business management within the regulatory system as it is a technical achievement.

A year ago, the SNF Project developed the K Basins Path Forward that, beginning in December 1998, would move the spent nuclear fuel currently stored in the K Basins to a new Staging and Storage Facility by December 2000. The second stage of this $960 million two- stage plan would complete the project by conditioning the metallic fuel and placing it in interim dry storage by 2006. In accepting this plan, the DOE established goals that the fuel removal schedule be accelerated by a year, that fuel conditioning be closely coupled with fuel removal, and that the cost be reduced by at least $300 million.

The SNF Project conducted coordinated engineering and technology studies over a three- month period that established the technical framework needed to design and construct facilities, and implement processes compatible with these goals. The result was the Integrated Process Strategy for K Basins Fuel. This strategy accomplishes the goals set forth by the DOE by beginning fuel removal a year earlier in December 1997, completing it by December 1999, beginning conditioning within six months of starting fuel removal, and accomplishes it for $340 million less than the previous Path Forward plan.

DOE approval of the Integrated Process Strategy was received in late July 1995 and its implementation is well underway. Because this is a strategy as compared to a fully engineered solution, technical challenges must be overcome and continually adjusted while accelerated engineering, procurement, construction, and startup activities are proceeding in parallel. A comprehensive technical integration process including the requirements baseline, process flow diagrams, interface control, issues management, technical data management, and configuration control has been implemented to manage and communicate these adjustments throughout the Project. These modern business practices are central to the success of the Integrated Process Strategy for K Basins Fuel.

INTRODUCTION

At last year's WM '95 Conference, the K Basins Path Forward was described. This was a strategy for the early removal of fuel and sludge from the K Basins to quickly mitigate environmental concerns and public and worker health and safety issues. In the year since then, many changes to those plans have occurred through working with the customer, regulatory bodies and the public and incorporating changing and improved requirements. The result of this evolutionary process is the Integrated Process Strategy for K Basins Fuel. This new strategy and how it effectively meets the challenges is the subject of this paper.

Development of the Integrated Process Strategy for K Basins Fuel is as much a case study of project and business management within the

regulatory system as it is a technical achievement. The paradigms of DOE's production past are no longer operative in today's complex political, regulatory, and public involvement environment. Previously, a technical problem would be thoroughly studied and evaluated before any plans were made. A technically elegant solution would be developed without public or regulatory input. A budget and schedule would then be adopted that supported this solution, a Congressional funding appropriation obtained, and the project executed.

The SNF Project at Hanford has shown that modern business practices can be applied within the DOE system, albeit, dramatic shifts away from the old cost-plus processes are required. The business practices being applied by the SNF Project are not new or different from those used in private industry. In today's environment many factors drive the technical solution which must often be adjusted before it is fully implemented as those factors change. The SNF Project has successfully combined the practical "can do, get the job done" attitude of the past with the political, regulatory, and public realities of the present.

SPENT NUCLEAR FUEL PROJECT AND THE K BASINS PATH FORWARD

The inventory of spent nuclear fuel at the Hanford Site covers a wide variety of fuel types (production reactor to space reactor) in many facilities (reactor fuel basins to hot cells) at locations all over the Site. The 2,129 metric tons of spent nuclear fuel at Hanford accounts for over 80% of the total U.S.DOE inventory. Most (98%) of the Hanford spent nuclear fuel is 2,103 metric tons of metallic uranium production reactor fuel currently stored in the K Basins located near the Columbia River at the northern end of the Hanford Site.

These two basins each contain about 3,800 cubic meters (one million gallons) of water and were part of the K East and K West production reactor complex constructed in the 1950s. They were used to cool discharged fuel prior to chemical processing at the PUREX facility. After the K Reactors production mission ended in the 1970s, the basins were used as temporary storage capacity for N Reactor fuel while the PUREX processing facility was being refurbished and restarted. When the defense production mission ended in 1990 and PUREX operations were terminated in December 1992, part of the N Reactor fuel inventory remained in the basins with no means for near-term removal and processing. The K East Basin contains 1,146.2 metric tons of spent fuel and the K West Basin contains 956.8 metric tons of spent fuel. (This includes the 2.9 metric tons of spent fuel recently transferred from PUREX to the K West Basin.) The fuel in the K West Basin has been stored in water filled, lidded canisters containing a corrosion inhibitor and the basin environment is relatively clean and free of corrosion products. The fuel in the K East Basin, however, was stored in open canisters and some of the fuel has corroded extensively. The deteriorating fuel with no viable "path forward," and worker health and safety issues, coupled with aging facilities with seismic vulnerabilities, has been identified by several groups, including regulators, stakeholders, and the DOE, as being one of the most urgent safety and environmental concerns at the Hanford Site.

To meet these challenges, the Spent Nuclear Fuel Project was formed in February 1994. The mission accepted by the SNF Project is to "Provide safe, economic, and environmentally sound management of Hanford spent nuclear fuel in a manner which stages it to final disposition." A year ago, the SNF Project developed the K Basins Path Forward, a two-phase strategy to allow early removal of fuel and sludge from the K Basins

followed by its stabilization and interim storage. In the expedited response phase, fuel and sludge from the K East and K West Basins would be packaged in large multi-canister overpacks (MCO). The fuel would remain in the original canisters while the sludge would be placed in containers resembling the fuel canisters. The canisters would be loaded into the MCOs under water and the MCOs would remain water filled during shipping to temporary storage at a new Staging and Storage Facility. During the second phase, MCOs would be transferred from the Staging and Storage Facility to a newly constructed Fuel Stabilization Facility which would be co-located with the Staging and Storage Facility. Here the fuel and unseparated sludge would be dried and passivated in the MCO to reduce the potential hazards associated with metal fuel storage. Following this stabilization process, the MCOs would be returned to the Staging and Storage Facility for interim dry storage. This strategy would begin removal of the spent fuel and sludge from the basins in December 1998 and place it in a new Staging and Storage Facility located in the 200 Area at the Hanford Site by December 2000. The K Basins Path Forward would complete placing the fuel and sludge in interim dry storage by the year 2006 for an estimated cost of $960 million.

K BASINS PATH FORWARD APPROVAL AND REFINEMENT PROCESS

In February of 1995, the DOE formally approved the K Basins Path Forward and provided the following goals for its refinement:

Accelerate the Path Forward schedules by one year to commence fuel removal by December 1997, and to complete fuel removal in approximately two years, i.e. by December 1999.

Accelerate the schedules for fuel conditioning activities so that fuel stabilization is closely coupled with fuel removal from the K Basins.

Achieve significant cost reductions, with every attempt to complete implementation of the accelerated schedules including close coupled fuel stabilization within the fiscal year (FY) 1995 through FY 1997 budget projections.

Revise the process to avoid reopening the MCOs once fuel is loaded so that the MCOs can be welded at the K Basins.

Utilize the partially constructed Canister Storage Building (CSB) located in the 200 East Area as the Staging and Storage Facility recommended in the Path Forward strategy.

In response to the DOE's goals, the SNF Project conducted coordinated engineering and technology studies over a three-month period to establish the technical framework needed to design and construct facilities, and implement processes compatible with these goals. To achieve a timely and optimum evaluation and solution, Westinghouse Hanford Company, in conjunction with Pacific Northwest National Laboratory (PNNL), DOE staff, and several subcontractors, formed an integrated team to coordinate the studies and arrive at decisions. The overall process and timeline for developing the Integrated Process Strategy was aggressive. Beginning in April 1995, the technical options and criteria were developed, cost, schedule, and safety input provided, and the evaluations were performed. The resulting integrated process strategy was reviewed by an external advisory panel of experts between July 11-14, 1995, and their advice incorporated. The recommended strategy was finalized and provided to the DOE on July 18, 1995, for their consideration.

The decision process built upon the foundation established by the K Basins Path Forward and incorporated the schedule acceleration and

compression, and cost reduction goals. The team identified the following key technical issues which afforded flexibility for improvements:

- Selection of the process for drying and conditioning the fuel.
- Wet (flooded) versus dry shipment of fuel.
- Wet (flooded) versus dry staging of fuel.
- Canister preparation and desludging requirements.
- MCO venting and hydrogen management requirements.
- Definition of an acceptable (defensible) safety basis.

Technical and engineering trade-off studies to resolve these issues were performed and a systems engineering process then resulted in process alternatives as shown in the summary block diagram in Fig. 1. Eight integrated process options were developed from these alternatives for evaluation. These options, the evaluation results, and cost comparisons are summarized in Table I. A comparison with the initial Path Forward of the same project scope is also included. The evaluation of these alternatives included the use of systematic multi-attribute decision analysis techniques to assure a comprehensive, balanced treatment. The evaluations included assessments of technical viability, health, safety and environmental risk, and cost, schedule, and programmatic risk.

Fig. 1

Table I

Cost was a major factor in evaluating process alternatives. The guidelines provided by DOE required that about $300 million be cut from the total $960 million project cost of the Path Forward and that the near-term budget profile be met. Major cost savings are realized by accelerating fuel removal from the basins through an early significant reduction in K Basins operating costs. Options that increase the packing density of fuel and a corresponding reduction in the number of MCOs can also have a significant impact on cost. Simplified fuel conditioning processes using commercially available equipment that treats the fuel within the MCO can also reduce costs. Because cost is not the only evaluation concern, higher cost alternatives were still considered in selection of the preferred alternative.

Another major evaluation criteria focuses on achieving initiation of fuel transfer away from the Columbia River at the earliest possible date, while maintaining worker safety and minimizing life-cycle costs. Those options with high or very high schedule risk are, therefore, eliminated from further consideration. Option 6, which features shipping fuel as-is in water-filled MCOs and wet staging, has the lowest schedule risk. However, this scenario has safety concerns and high costs. Option 1 is the lowest cost, but has a number of technical and safety uncertainties. Option 7, the recommended option, has moderate schedule risk, good technical viability, and acceptable safety/risk features. Option 7 will also produce a cost savings of approximately $340 million over the original Path Forward estimate and is consistent with the DOE budget goals.

INTEGRATED PROCESS STRATEGY

Option 7 was named the Integrated Process Strategy for K Basin Fuel and recommended to the DOE as the best method of achieving the cost and schedule goals. The DOE accepted the recommendation in late July 1995 and the SNF Project began implementing the strategy. The major elements of the strategy and the schedule for their acquisition are shown in Fig. 2. Each of the individual process steps are closely interrelated. For example, the fuel retrieval operation is designed to prepare the fuel for

the drying operations that follow. The features of each process step are as follows:

Fuel Retrieval During fuel retrieval the fuel canisters will be moved to a centralized work location within pool, the fuel removed, separated from the sludge, and loaded into tier baskets. After the tier baskets are filled with fuel, five or six baskets (depending on fuel length) will be loaded into a multi-canister overpack (MCO) and the closure welded in place. The MCO will be placed in a cask, removed from the basin, and transported to the Cold Vacuum Drying Facility.

Cold Vacuum Drying At the Cold Vacuum Drying Facility, the water will be removed from the MCO before shipping it to the Canister Storage Building (CSB) by a combination of draining and cold vacuum drying. Vacuum drying will require only 24 to 48 hours to remove all of the free water. Removal of the free water greatly reduces the hydrogen generation rate and allows the MCO to be shipped to the CSB with the process valves closed, greatly enhancing safety during shipping.

Staging in the CSB Upon arrival at the CSB, the MCOs will be staged in the storage tubes until they are prepared for interim storage with the conditioning process. Venting of hydrogen generated during staging will be through a high efficiency particulate air (HEPA) filter into inerted storage tubes.

Hot Vacuum Conditioning The MCOs will be removed from staging and placed in the Hot Vacuum Conditioning Facility within the CSB where the metallic uranium fuel in the MCOs will be prepared for long-term interim dry storage in the CSB. The hot vacuum conditioning process will be designed to eliminate most of the chemisorbed water and mitigate further fuel corrosion and hydrogen generation. The MCO will be used as the process vessel and operated at approximately 300C. The process, pending validation by the testing program, will consist of heating, vacuum drying, surface oxidation, cooling, and monitoring phases. The total cycle time for hot vacuum conditioning is estimated to require approximately six to eight days. Following conditioning, the MCOs will be sealed and returned to the storage tubes where they will remain until their ultimate disposition is determined.

Fig. 2

TECHNICAL INTEGRATION

Because the Integrated Process Strategy for K Basin Fuel is a strategy as compared to a fully engineered solution, there are many technical issues to be resolved as implementation proceeds. Effective technical integration is crucial to the success of the strategy because many accelerated engineering, procurement, construction, and startup activities are proceeding in parallel. Maintaining a traceable record of how issues are resolved and how key decisions are reached is even more challenging. The SNF Project has developed a technical integration process to effectively communicate the large volume of rapidly changing technical information.

The cornerstone of this technical integration process is the Technical Baseline Description. The Technical Baseline Description is a systems engineering based body of technical information that documents the project-level functions and requirements along with enabling assumptions, issues, trade studies, external interfaces, and products. A key feature of the Technical Baseline Description is the process flow diagrams (PFD). The PFDs have been developed to provide an integrated picture of the overall Integrated Process Strategy. They document and illustrate the

material flows and interfaces among the subprojects and external interfaces. Management of the interfaces identified through the PFDs is performed by an interface control procedure. A centralized database has been developed to aid in the management of the interfaces and document agreements to maintain interface control. A technical issues management system has been implemented within the SNF Project to aid in the tracking, documentation, and timely resolution of issues. A two-tier system is used to maintain a traceable record of how issues are resolved and how key decision are made. The final element of the technical integration process is configuration management. The SNF Project has developed and implemented a configuration control procedure that keeps Project documentation, design requirements, and physical configuration of equipment and facilities consistent with each other.

SUMMARY

The SNF Project at Hanford has employed modern business practices to develop and implement a strategy, consistent with DOE budget and schedule goals, for accelerated removal of the spent nuclear fuel stored in the two K Basins. An Integrated Process Strategy for K Basins Fuel was developed through trade studies and evaluation of alternatives to select a process strategy that minimizes schedule risk and provides opportunities for cost savings. Compared to the previous Path Forward plan, the Integrated Process Strategy will accelerate the schedule for fuel removal by a year, compress the schedule for fuel conditioning and its placement in interim dry storage by more than five years and reduce the life cycle costs by more than $340 million. Implementation of this strategy is underway with engineering, procurement, construction and startup activities occurring in parallel. The evolving technical solutions supporting the strategy are continually being adjusted to accommodate changing requirements as the Integrated Process Strategy is being implemented. A comprehensive technical integration process has been established to manage changes to the technical baseline and communicate them throughout the Project.

ABSTRACT
The ultimate disposal of fuels in the DOE spent nuclear fuel inventory in a mined geologic repository may require that certain fuel types be treated prior to disposal. This could be mandated by chemical reactivity, instability of the fuel in a repository environment, or by concerns over the potential for criticality events. The Department of Energy has at hand a variety of treatment methods that could be applied to spent nuclear fuels for disposal; some of these methods represent well-established technology (the PUREX aqueous solvent exchange process, for example), some are at advanced stages of development and demonstration (e.g., the electrometallurgical treatment process and the plasma arc melting process), and other methods that have promise (such as the GMODS process, and the chloride volatility process) are at very early stages of development. Institutional issues arise when consideration is given to spent fuel processing, and these issues are clouded by misconceptions about the nature of the treatment processes proposed: in the treatment of DOE spent nuclear fuel for disposal, there is no intention, and in some cases no ability, to recover plutonium or other fissile materials, for military purposes. The fissile elements (unless the uranium is recovered for commercial use) are incorporated in the final waste forms to be disposed in a high-level waste repository. The sole purpose of the process is to place the radioactive material in a form that will be acceptable in the repository.
INTRODUCTION
The U.S. Department of Energy (DOE) presently holds title to a variety of spent nuclear fuel (SNF) types, with the total inventory amounting to approximately 2,700 metric tons (heavy metal content). This SNF is stored at a number of DOE sites around the United States, with the major components of the inventory being located at the Hanford site in the state of Washington, the Idaho National Engineering Laboratory in eastern Idaho, and the Savannah River site in South Carolina. Over 130 different fuel designs are represented in the DOE inventory; these can be grouped into 53 different categories according to common design features such as composition, cladding material and enrichment level. The fuel can be further reduced into six categories according to fuel composition: metal, oxide, graphite, cermet, hydride, and aluminum based. A large percentage of the fuel is chemically reactive and precautions must be taken during preparation of the fuel for interim storage and final disposal. A small fraction of the fuel may have Resource Conservation and Recovery Act (RCRA) features that presently would preclude them from repository disposal. A large number of the fuel types are highly enriched in either 235U or plutonium, making the final disposition of the spent fuel in a geologic repository subject to resolution of potential criticality issues. The process of qualifying such a large number of fuel types for repository disposal, which may be necessary for those fuel types differing substantially from zirconium alloy-clad low-enrichment oxide fuel (i.e., commercial light water reactor spent fuel), could be more expensive than some form of treatment.
The DOE spent fuel is presently in storage in a variety of facilities, many of which do not meet the current standards of safety and

environmental protection required of commercial spent fuel storage facilities. In some of the DOE facilities, the spent fuel has begun to degrade significantly (1) and prompt action is necessary. Current DOE planning would place the spent fuel in interim dry storage at DOE sites until such time (some 20-40 years hence) that means are available for permanent geologic disposal or a national interim storage facility is available. While this interim step would serve to prevent serious environmental consequences that could result from containment failures in existing storage facilities, it cannot be regarded as the final answer to the spent fuel disposal problem.

Disposal of DOE spent nuclear fuel in a geologic repository will be subject to the same demanding requirements on waste performance that will be imposed on commercial spent nuclear fuel as a condition for acceptance for emplacement in the repository. Even though the quantity of commercial spent fuel greatly exceeds the amount of spent fuel in the DOE inventory, the DOE spent fuel represents a set of significantly different disposal problems that may require that the fuel be processed to separate the various constituents of the spent fuel prior to disposal, or treated to place it in a form that is amenable to disposal.

INSTITUTIONAL ISSUES

The position of the U.S. Government, as held by several recent administrations and formalized by Presidential Decision Directive #13 ("PDD-13"), is that the United States will not engage in reprocessing for the purpose of separating plutonium, for military or civil uses, from spent nuclear fuel, nor will the U.S. encourage such practices by other countries (although it will be tolerated by those countries which already have such industrial capabilities or ongoing reprocessing programs). Reprocessing of spent fuel is being carried out on an industrial scale by the United Kingdom and France, and Japan is building an 800 MT/yr plant that will go into operation in the next century. The United States reprocessed irradiated fuel for several decades for the purpose of recovering defense materials, employing the PUREX process for separating plutonium in plants with capacities as high as 3,000 MTHM/yr.

European and Japanese organizations are proceeding with the reprocessing of commercial reactor spent fuels and plan to recycle recovered plutonium as mixed oxide fuel (MOX) for their commercial reactors. No such plans exist in the United States, except as an option for denaturing the stockpile of surplus fissile materials (2).

The American Nuclear Society recently convened a group of distinguished experts in the field for a review of national policy concerning plutonium recycling and future energy supplies. Among their conclusions (3) was a finding that R&D into separation and processing technologies should continue, for possible application in the future. In a somewhat related study, the National Research Council's Committee on Separations Technology and Transmutation Systems also concluded (4) that continued development of separations and transmutation technologies is desirable.

The treatment of DOE spent nuclear fuel, when it involves a separation of certain radionuclides for the purpose of facilitating their disposal, bears some relationship to the reprocessing technologies that are the subject of present controversies. However, there is a fine line between spent fuel treatment as proposed by the Department of Energy for its spent fuel and the more conventional reprocessing methods that have been used in the past for the separation of fissile materials for defense purposes. Both applications are based on fuel dissolution and separation

of fission products, but it must be emphasized that the application for disposal of spent nuclear fuel is not intended for recovery of plutonium for military use. The existing aqueous technology can be modified to limit the decontamination of plutonium, and advanced technologies that are being developed are incapable of producing separated plutonium.

PUREX PROCESSING

The capability still exists for large-scale PUREX processing in the United States, as embodied in the F- and H-Canyon facilities at the Savannah River site. The F-Canyon facility, which began operation in 1954, is a typical PUREX process facility designed primarily for low-enriched uranium metal fuel and targets. The H-Canyon facility, which also began operation in 1954, employs a modified PUREX process to support highly-enriched uranium processing, with additional facilities for production of special isotopes (e.g., 238Pu and 237Np).

In typical F-Canyon operations, aluminum-clad low-enriched or depleted uranium fuel and targets are charged to the dissolver at a rate up to 10 metric tons per day. Sodium hydroxide (NaOH) is added to the dissolver in the presence of sodium nitrate ($NaNO_3$) to dissolve the aluminum cladding. The uranium metal is then dissolved using nitric acid (HNO_3), and the resulting aqueous uranyl nitrate solution is transferred to the first solvent extraction cycle where fission products are removed and uranium is separated from plutonium. The fission product stream is diverted to the high-level waste tanks, the organic stream is recycled, and the plutonium and uranium streams proceed to the second solvent extraction cycle, which further purifies the plutonium and uranium solutions. The plutonium stream is sent to the plutonium finishing facility (F B-Line) for conversion to metal or oxide, and the uranium stream is transferred to the F A-Line facility where it is denitrated and converted to uranium oxide.

The modified PUREX process utilized in H-Canyon is specially designed to support operations with enriched uranium-aluminum alloy fuels. In the head-end portion of the facility, nitric acid catalyzed by mercuric nitrate is used to dissolve the entire uranium-aluminum fuel element. The dissolver solution is clarified and fed to the solvent extraction process. In the first solvent extraction cycle, uranium and neptunium are extracted from the fission products. The fission products and the very small quantity of plutonium from the fuel are diverted to the high-level waste tanks while the uranium and neptunium proceed to the second solvent extraction cycle. The uranyl nitrate hexahydrate solution historically was converted to uranium metal or oxide at the Oak Ridge site, and the neptunium solution is converted to oxide in the Savannah River site H B-Line. Conversion at SRS of the highly enriched UNH to oxide after blending down to low enrichments for potential commercial use is being considered.

Continuing equipment upgrades and process modifications were made over the years in both the F- and H-Canyons. In 1992, both facilities were shut down for resolution of safety concerns, conduct of operations improvements, and general maintenance. When uncertainties in the long-term mission arose, this temporary suspension of operations became an extended standby period, leaving large quantities of highly-enriched uranium and plutonium in solution awaiting conversion to stable forms. The F-Canyon and F B-Line facilities have recently restarted to support the conversion of in-process plutonium and uranium solutions to forms

suitable for long-term storage. A similar operation in H-Canyon is being planned to deal with the in-process solutions stored in that facility. There are nearly 200 metric tons (heavy metal content) of aluminum-based fuel in the DOE spent fuel inventory, including both fuels related to defense materials production and fuels from research and test reactors, both domestic and foreign. If it is determined that these fuels cannot be directly disposed in a geologic repository without prior processing, the Savannah River facilities can easily accommodate their treatment. The cost of process development is nil, and the incremental increase in high-level waste volumes would be relatively minor.

TREATMENT TECHNOLOGIES

The treatment of certain DOE spent fuel types has a sound technical basis. A number of distinct treatment technologies are available, at various stages of development. The PUREX process, has been in practice for decades and is in current use in several countries. Technologies that are still under development are designed to deal with the drawbacks usually associated with the PUREX process, such as proliferation risk, cost, and volume of wastes (both primary and secondary) produced.

Vitrification

Vitrification of DOE SNF is being developed by the Savannah River Site (SRS) to convert SNF into a borosilicate glass waste form containing fissile material. This process is a variation on the PUREX process previously described.

The technique is based upon a dissolution process without fissile material separation followed by a vitrification process. The proposed dissolution process would be similar to the existing dissolution used in the SRS processing facilities to place the SNF into a liquid state. Aluminum SNF could be dissolved in the existing canyon dissolver. Stainless steel and zirconium clad SNF would be dissolved in a electrolytic dissolver. If the existing canyon dissolvers are unavailable for processing the aluminum based fuels, the new electrolytic dissolvers could be used. The solution in the electrolytic dissolver is nitric acid saturated with boric acid. The dissolvers are operated in a batch process. The uranium concentration in the solution is maintained below 10 grams per liter for nuclear safety (criticality control). The mass ratio of cladding to uranium will vary between 3 and 60. In contrast to the historic canyon operations, the resulting solution is then transferred to a holding tank without the fissile material being chemically stripped away.

Chemical and isotopic analysis will be performed on the solution in the holding tank. The solution will be adjusted with the addition of appropriate chemicals (e.g. to a desired solids concentration). The solution is then transferred to a melter feed tank.

The feed solution, glass frit and other glass forming chemicals will be fed to a joule-heated melter. In the melter the materials will be fused together to form a borosilicate glass. The molten glass will be poured out of the melter and into stainless steel canisters. This process is similar to the process used by the Defense Waste Processing Facility (DWPF) currently completing startup at the Savannah River Site. The melter can be sized to process the feed material from at least four electrolytic dissolvers. The resulting waste form is expected to be bounded by current constraints on borosilicate glass as an approved waste form for placement in a geologic repository.

Melt-Dilution/Poison

A melt-dilution process is being developed at SRS to provide a simplified, easily demonstrated technology for the conversion of aluminum based spent nuclear fuels into a waste form suitable for emplacement in a geological repository. The product of the melt reconfiguration treatment is a compacted (volume reduced), metallic waste form that contains uranium, fission products and plutonium in an aluminum matrix, all in a "container" which has corrosion characteristics superior to those used for the LWR waste forms. This technology used a single step, melting process to reduce the volume of the spent fuel, reduce the uranium enrichment to minimize criticality risks and provide an easily characterized metallic waste form which minimizing the creation of secondary wastes. Further, if desired, by using slag-metal technology, certain radio nuclides may be selective leached so as to produce the final metallic waste form containing little volatile fission products species.

Benefits of this process include very low capital investment for the operation; a superior waste form comparable to the LWR waste forms; a flexible process which can be readily adapted to the addition of poisons; adaptable to the addition of glass frit to develop borosilicate glass waste form if necessary; and low potential for airborne contamination and radiation exposure.

The process is based on the simultaneous melting of spent fuel sections in a permanent mold that is contained in a resistance furnace. The furnace is enclosed in a chamber which is connected to an off-gas system. The spent fuel gradually fills the container in the furnace. A lid or cap would be welded to the top of the mold to provide the waste form. Depleted uranium and/or other neutron poisons, if required, could also be incorporated into the melt during melt-dilution operation. Further, glass frit can also be added during the melt-dilution process if a borosilicate glass waste form is desired for a certain variety of spent fuels.

A Laboratory scale melt facility capable of melting sections of Mark 22 aluminum clad spent nuclear fuel elements was developed at SRS. A prototype furnace was also constructed. The melt-dilution process was demonstrated with non-irradiated aluminum clad fuel tubes. Full scale demonstrations, including cap welding and both destructive and non-destructive characterization and evaluation of the simulated waste form will follow the selection of optimum container material(s). Demonstration testing using full length irradiated fuel can be subsequently initiated. Although, the melt-dilution technology is primarily applicable to the aluminum based fuels, utilization of this technology would convert this category of DOE owned, spent nuclear fuels into a repository suitable waste form with minimal impact to future disposition options should other options be required. The melt-dilution process will provide a standard waste form package that retains the uranium in form very suitable for recovery, should future generations desired to utilize the available energy. Additionally, if repository suitability is achieved simply through the introduction of nuclear poisons rather than dilution with depleted uranium, the highly enriched uranium could be recovered through a relatively simple metal smelting operation.

Electrometallurgical Treatment

A standard, cost-effective means for treating the broad variety of DOE spent fuel for ultimate disposal is needed, and the electrometallurgical treatment process being developed by DOE's Argonne National Laboratory appears to meet these requirements. By use of this process, all of the

(stainless steel or zirconium alloy clad) metal and oxide spent fuel stored at the INEL and Hanford sites can be treated by one common method, producing two common high-level waste forms. One waste form is a mineral waste that contains most of the fission products in a ceramic material produced by hot-pressing a composite of borosilicate glass and zeolite. This waste form will be of essentially invariant composition regardless of the type of spent fuel processed. The other waste form is a metal alloy, the composition of which depends largely on the structural materials present in the fuel. For stainless steel- or zirconium alloy-clad fuels, the metal waste will have an iron-zirconium alloy matrix. Minor variation of the process can be used to treat the Molten Salt Reactor Experiment (MSRE) fuel salt at Oak Ridge National Laboratory and the aluminum-based fuels at the INEL and Savannah River sites. The commonality of process equipment and waste forms offers the potential for significant cost savings in the ultimate disposition of these spent fuels.

The key element of the electrometallurgical treatment process is the electrorefining step. This process is the same as the electrorefining process used for many years in the minerals industry: an impure metal serves as the anode in the electrorefining cell, and the pure metal is deposited at the cathode by electro-transport through a suitable electrolyte. In the electrometallurgical treatment process, the electrolyte is a salt compound, lithium chloride and potassium chloride. This electrolyte was selected because the chemical properties of the actinide elements and fission product elements in the chloride system are particularly well-suited to precise control of separation parameters. Because of these properties, it is possible to deposit virtually pure uranium, free of fission products and free of contamination with transuranic elements, at a simple iron cathode suspended in the electrolyte salt. The "impurities" in the spent fuel, the active metal fission products (for example, cesium and strontium) and the transuranic elements, remain in the electrolyte salt. The noble metal fission products (including technetium) remain in the anodic dissolution baskets in the cell, together with the cladding hulls from which the fuel has been dissolved.

The cathode deposits, consisting of pure uranium, are recovered after the desired amount of material has been collected and are then sent to a cathode processor, where they are consolidated by melting; in the process, any volatile materials (such as adhering electrolyte salt) that were included in the deposit are removed by vaporization. The uranium metal ingots resulting from the cathode processing operation are packaged for interim storage until their final disposition is decided.

The combined high-level waste volume produced in electrometallurgical treatment of spent fuel is approximately 1% of the volume of high-level wastes produced in the conventional reprocessing of spent fuel, and about 20% of the volume of the spent fuel when packaged for direct disposal without treatment. The process offers the advantage that it does not produce secondary wastes, and low-level wastes are limited to the pure uranium product and to discarded process equipment components.

The electrometallurgical treatment process has been demonstrated at pilot scale with unirradiated fuels containing representative concentrations of transuranic elements and non-radioactive fission product elements. Extensive testing has been done with waste forms arising from the treatment of these unirradiated fuels. The process has been demonstrated

with unirradiated N-Reactor fuel and with simulated oxide spent fuel. Process equipment has been installed in the Fuel Conditioning Facility at Argonne National Laboratory-West at the Idaho National Engineering Laboratory, and the facility is ready for operation with spent fuels from the EBR-II reactor. Pending approval to proceed with hot operations, the equipment is being operated with depleted uranium to verify operating procedures and aid in operator training. Demonstrations with other irradiated fuel types are planned.

Glass Material Oxidation and Dissolution System (GMODS)

ORNL recently invented the GMODS for the direct conversion of SNF to borosilicate HLW glass. The process is generically applicable to many SNF types and would address the issues of multiple waste forms, SNF instability, and classified SNF configuration related to disposal. GMODS directly a) converts metals, ceramics, and amorphous solids to borosilicate glass, b) oxidizes organics with the residue converting to glass and c) converts chlorides to a clean secondary NaCl stream and glass.

GMODS is designed to produce a HLW form acceptable to the repository within the acceptance criteria as defined by the two repository mainline waste forms: light water reactor (LWR) SNF and HLW borosilicate glass. The process would produce a borosilicate HLW glass log similar in size to those from other DOE vitrification plants. No new waste form must be developed. As with other processes, it would enable the addition of depleted uranium to HEU SNF to resolve repository criticality concerns. This includes the option of processing high-enriched SNF with Hanford N and other low-enriched SNF to adequately isotopically dilute the 235U so the uranium fissile-to-fertile ratio in the glass is similar to LWR SNF and hence acceptable to the repository. The option also exists to process high-burnup SNF with low-burnup SNF to ensure that repository waste package heat load limits are not exceeded. GMODS would not separate any constituents and thus would not contribute to proliferation concerns.

The basic concept of GMODS is to directly add unprocessed SNF to a cold-wall, induction-heated glass melter with molten lead borate glass. Oxide and amorphous components of SNF directly dissolve into the glass. Metal and organic components do not dissolve in normal glasses. The lead oxide in the lead borate glass acts as a sacrificial oxide and oxidizes in situ carbon to carbon dioxide (CO_2) and metals to metal oxides. The CO_2 exits the melter as a gas. The metal oxides (uranium, cladding, etc.) dissolve into the glass. The lead reaction product of these chemical reactions (a) sinks to the bottom of the melter, (b) is removed from the melter, (c) is oxidized back to lead oxide, (d) the lead oxide is fed back to the melter, and (e) the lead oxide oxidizes more metals and organics in the melter.

After dissolution of the SNF, additional glass additives (SiO_2, etc.) are added to improve the glass quality before the HLW molten glass is poured into containers. If desired, the lead oxide can be removed from the final glass solution before solidification. This is done by adding carbon, which reduces the lead oxide to lead metal and produces gaseous CO_2. The lead metal separates from the glass and can be converted to lead oxide to process the next batch of SNF.

When chloride containing materials are fed to the melter, the non-chloride components enter the glass and the chloride reacts with the lead borate glass to produce volatile lead chloride. The lead chloride reacts with sodium hydroxide in the aqueous off-gas scrubber to yield soluble

sodium chloride salt and insoluble lead hydroxide. The lead hydroxide is recycled to the melter where it decomposes to lead oxide and steam. The sodium chloride stream is purified by ion exchange and discharged as a clean chemical waste. This potential capability allows GMODS to treat chloride containing SNF.

Laboratory demonstrations have been made of the direct conversion of stainless steel, Zircaloy-2, aluminum, uranium, cerium, and other metals to glass. Various oxides such as uranium oxide and zirconium oxide have been directly dissolved into the glass. Graphite has been oxidized. Chloride feeds have been treated with the chlorides separated to a secondary sodium chloride stream.

Plasma Arc Process

A plasma arc process for converting SNF (i.e., metal, oxide, carbide, sodium-bearing, aluminum, and zirclad) and the associated wastes (sludge, soil, metal fragments, metal containers, and concrete grits) into vitreous ceramic final waste forms is being developed at Pacific Northwest National Laboratory (PNNL). This is a direct and single-step process applicable to both containerized fuels and other types and forms of wastes. There is minimum pretreatment, sorting, and size-reduction needed for the treatment, resulting in reduced radiation exposure and treatment cost.

This process enables the addition of sludge, soil, metal containers and fragments, and concrete grits to HEU waste to satisfy the criticality concerns. The energy released in oxidizing the uranium metal fuel is used in vitrification. Minimal or no secondary wastes are generated since the particulate material removed in off-gas cleanup is recycled to the furnace for immobilization in the waste form. The fissile elements can be immobilized into a matrix that can be recovered only with difficulty or can also be immobilized into a matrix that is almost impossible for recovery, depending on the formulations of vitreous ceramics. The vitreous ceramics are durable and suitable for permanent disposal as an HLW form, or for interim storage, until a geologic repository becomes available.

Nuclear fuels in canisters or entire fuel elements are loaded directly into the furnace. A second feeder simultaneously add contaminated soils, sludges and concrete grits. The rate of the oxidation of the metal fuel charged is controlled by controlling the rate of oxygen addition, the oxygen lance standoff from the bath, and the plasma torch standoff. The waste form final compositions are controlled by the optimized combination of the nuclear fuels, sludge, soil, concretes, and minimum additives. Vitreous ceramics are formulated in such a way that they contain stable and low-solubility (in water) crystalline phases embedded in a network-former rich glass matrix. These crystals a) incorporate a large amount of metal ions, such as iron oxide, to accommodate the large iron content of the sludge; b) incorporate large contents of uranium, plutonium, and other fission products in the lattice structure; c) utilize little or no network-forming elements, such as silicon and aluminum, so these latter elements are enriched in the residue glassy matrix; and d) tightly bind to the glassy matrix so the physical integrity and mechanical strength of the waste form can be maintained.

The plasma process has been demonstrated by directly oxidizing 55-gallon drums of non-nuclear wastes into durable vitreous ceramics. The vitreous ceramics were produced on a bench scale (6 kg per hour) and pilot-scale (150 kg per hour) with metal contents of over 80 wt% and waste loading up

to 100%. The chemical durabilities of the vitreous ceramics were shown to be more durable than the most durable high-level nuclear waste glasses through extensive sets of dynamic (flow-through), static (PCT), and vapor hydration tests.

This technology, bases on established commercial equipment, was demonstrated for simulated wastes with high metal contents, and can be further developed and implemented to process actual nuclear fuels and wastes within 4 years. The development team for this technology consists of PNL (leader), Westinghouse Hanford Company, Retech, Inc. (A Lockheed Martin Subsidiary), Science Applications International Corporation, MSE, Inc., and the University of New Mexico.

Chloride Volatility Process

A chloride volatility concept is being investigated at the INEL as an advanced process for stabilizing SNF. This new technology would require 15 years to be developed as an implemented plant process. The distant schedule for repository disposal would allow the luxury of pursuing such an advanced technology that may not otherwise be considered. The concept offers the significant advantage of a single, compact process that is applicable to most fuels. It would minimize secondary wastes, segregate major nonradioactive constituents from the HLW for volume reduction, segregate fissile uranium from the HLW to resolve potential criticality concerns, and produce a common waste form glass or glass-ceramic.

The process is based on completely volatilizing the fuel element and separating the gaseous constituents. It consists of reacting the fuel with chlorine gas at high temperature (greater than 1,200oC), which causes all the fuel constituents to form volatile chlorides. The gases are then separated by molten salt scrubbing and fractional condensation. There are four major unit operations: (a) chlorination and volatilization of all the fuel components at 1,200oC, (b) removal of fission product, transuranic, and any nickel and chromium chlorides in a $ZnCl_2$ scrubber at 400oC, (c) three condensers for removing, by fractional condensation at temperatures ranging from 164oC to 2oC, $ZrCl_4$, $FeCl_3$, $AlCl_3$, UCl_6, $SnCl_4$, and I_2 vapors that pass through the scrubber, and (d) regeneration of the transferred spent molten salt by vacuum distillation to recover $ZnCl_2$ and $ZnCl_2$-soluble $ZrCl_4$ for recycle, leaving the fission product-, transuranic-, nickel-, and chromium-chlorides as residue that would be converted to oxides or fluorides for vitrification. Argon carrier gas and unreacted chlorine gas would be recycled, the Cl_2 content adjusted, and the stream split and passed through the unit operations in a continuous closed loop. Periodic shutdown of the coupled unit operations would occur for batch removal of fission product xenon and krypton gases from the carrier gas (such as by cryogenic distillation), batch transfer of the molten salt to the molten salt regenerator, and batch removal of nonradioactive constituents and uranium from the condensers.

The small quantity of fission-product/transuranic-product HLW would be converted into a waste form for repository disposal. The conversion steps to a glass or glass-ceramic form could involve fluorination and then melting with glass frit additives, or conversion to oxides by heating at 1,000oC with boric acid. Solvent extraction processes, such as transuranic extraction (TRUEX), that was developed at Argonne National Laboratory, could be applied to the fission-product and transuranic-product chlorides dissolved in 6 M HCl if their separation were desired or needed prior to immobilization.

In the chlorination step, the rate of reaction is controlled by the feed rate of Cl_2 and temperature is controlled by appropriate blending of Ar gas with Cl_2. An oxygen scavenger, such as carbon monoxide, is added as needed to prevent formation of oxychlorides when oxides are present. A CO_2 absorption bed in the off-gas system collects the carbon dioxide that is formed. Zinc chloride was selected for the scrubber medium because its low melting point and favorable vapor pressure permit its use to scrub the chlorinator off-gas at a low temperature, while being sufficiently volatile at 725oC to allow evaporative separation from the radioactive waste chlorides for subsequent recycle. For fuels with Zircaloy, some $ZrCl_4$ will dissolve in the $ZnCl_2$ until saturation is reached, after which $ZrCl_4$ will pass through. The dissolved $ZrCl_4$ can be recycled with the molten salt without further complicating the flowsheet.

Other Treatment Concepts

A number of other treatment concepts have been proposed and are being evaluated to determine their validity for further conceptual development. These include concepts of mechanical volume compaction, direct disposal in small poisoned canisters, and Can-in-canister disposal. These technologies are being explored for use with the aluminum based fuel at Savannah River, but may be applicable to fuels at other locations in the DOE Complex.

Mechanical volume compaction techniques, such as Chop and Dilute, are relatively simple methods of isotopic dilution of HEU in Al-clad fuel. The primary advantages are criticality control using either depleted uranium or poisons and the possibility of a reduced number of disposal canisters for repository disposal. Chop and Dilute involves chopping the AL-HEU SNF elements into small pieces and mixing them with similar pieces of depleted uranium aluminum alloy. To ensure against criticality in the repository, the resulting enrichment level of the mixture may have to be an equivalent low 235U enrichment. This option has the significant disadvantage that it requires a larger number of waste canisters inversely proportional to the enrichment levels allowed by the repository requirements. If the requirements for criticality control result in 1-2% 235U enrichment requirements, then the high level waste volumes will be more than produced by reprocessing (10 to 50 times) and may not produce a repository-durable waste form. Acceptability of the chop-dilute form is unlikely.

Direct disposal in small poisoned canisters is a variation on the direct disposal method proposed for commercial fuel. Because some of the DOE fuel is highly enriched, smaller canisters may be used to reduce the probability of a criticality in the repository. This methodology would reduce the 235U content in a particular area of the repository. A variation of this technique is to increase the size of the canister by including nuclear poisons with the HEU. This methodology may not be adequate in preventing a criticality in the future if it is assumed that the poisons migrate away from the HEU over time.

The Can-in-canister option, which borrows its name from the plutonium immobilization option, would involve placing already canned HEU SNF elements into DWPF canisters and then filling the canisters with HLW glass. This is may be neither a practical nor cost effective option because of the excessively large number of canisters that would be required to dispose of the SNF. Criticality control combined with the space occupied by HLW glass would significantly limit the quantity of 235U per canister. (At three elements per canister, a total of 12,000

canisters would be required). The HLW glass may be significantly cracked and would not provide a barrier against water. Qualification of this waste form for the proposed repository is problematic.

PLANS FOR THE FUTURE

There are several issues that will need to be resolved in order to solidify plans for the future, not the least of which being the issue previously discussed in the Institutional Issues section of this paper regarding "treatment/processing" for disposal versus "reprocessing" for plutonium and highly enriched uranium recovery. At the present time, as discussed previously, there are six treatment/conditioning technologies at various stages of implementation that can potentially be utilized in preparing the multitude of different (>150) DOE SNF types for disposal in the geologic repository or in a Monitored Retrievable Storage facility. The canyons at Savannah River are ready to process any of the aluminum SNF that the decision makers deem appropriate. The research and development of the Electrometallurgical Treatment technology is currently fully funded by the Office of Environmental Management and will continue to receive the necessary funding unless some unforeseen event or change occurs in the future. The funding for the other three technologies (GMODS, Plasma Arc and Chloride Volatility) is currently at a very low level, but these technologies have not been totally discounted. Changes may occur to bring these technologies to the forefront as replacements for currently funded efforts, or to provide viable alternatives so that a degree of flexibility can be retained for future decisions.

ABSTRACT

Hearings held before the House Subcommittee on Energy and Mineral Resources in March 1994, requested that officials of federal agencies and other experts explore options for providing regulatory oversight of the U.S. Department of Energy (DOE) facilities and operations. On January 25, 1995, the DOE, supported by the White House Office of Environmental Quality and the Office of Management and Budget, formally initiated an Advisory Committee on External Regulation of DOE Nuclear Safety. In concert with this initiative and public opinion, the DOE Richland Operations Office (DOE-RL) has initiated the K Basin Spent Nuclear Fuel Project - Regulatory Policy (1). The DOE has established a program to move the spent nuclear fuel presently stored in the K Basins to a new storage facility located in the 200 East Area of the Hanford Site. New facilities will be designed and constructed for safe conditioning and interim storage of the fuel. In implementing this Policy, DOE endeavors to achieve in these new facilities "nuclear safety equivalency" to comparable U.S. Nuclear Regulatory Commission (NRC)-licensed facilities. The DOE has established this Policy to take a proactive approach to better align its facilities to the requirements of the NRC, anticipating the future possibility of external regulation. The Policy, supplemented by other DOE rules and directives, form the foundation of an enhanced regulatory program that will be implemented through the DOE K Basin Spent Nuclear Fuel Project (the Project).

INTRODUCTION

The Advisory Committee on External Regulation of DOE Nuclear Safety completed its initial status report in August 1995 (2). The Committee's preliminary findings report widespread dissatisfaction within the DOE Complex with current DOE implementation of nuclear safety. The major concern was excessive redundancy of oversight functions and lack of responsibility delegated to the operating level. The findings conclude that there exists clear support in the DOE community for external regulation with a corresponding reduction in internal regulation. In its report, the Committee emphasizes that regardless as to whether the DOE moves to some form of external regulation, an effective internal system for safety management is presently needed. The preliminary report provides some indication that new DOE facilities would likely be the focus of changes in regulatory oversight, leaving existing facilities, at least temporarily, under existing regulatory arrangements.

In an effort to improve the quality of nuclear safety of new facilities and to align those new facilities with the possibility of future external oversight, the DOE and its contractor, Westinghouse Hanford Company (WHC), have established an enhanced nuclear safety program for the KBasins Spent Nuclear Fuel Project. Central to the program is DOE's Policy to achieve NRC nuclear safety equivalency in the design and construction of the Project's new facilities. This paper describes the Project's regulatory program, shares lessons learned and experiences gained in establishing the program, and provides the current status of the program's implementation. The paper's intent is to make known the existence of the Policy and related documentation developed through its implementation as information to be shared within the DOE Complex.

SPENT NUCLEAR FUEL PROJECT

The Spent Nuclear Fuel Project was established to address resolution of the safety and environmental concerns associated with the deteriorating spent nuclear fuel stored in the K Basins. In February of 1995, the DOE approved the Project's "Path Forward" recommendation for moving the spent fuel in the K Basins away from the Columbia River into the Canister Storage Building (CSB) to be constructed in the 200 East Area of the Hanford Site (3). The initial Path Forward recommendation, was refined following a detailed process alternatives evaluation in the Spent Nuclear Fuel Project Integrated Process Strategy (4). Detailed project plans developed after the Integrated Process Strategy recommendation, plan for the fuel to be removed from the K Basins, packaged in multi-canister overpacks (MCOs), drained and vacuum dried, and shipped to the CSB for interim storage. Additionally, a Conditioning Facility is planned to be constructed near the CSB to further process fuel that requires additional drying to remove chemically bound water and uranium hydride prior to interim storage in the CSB. Figure 1 illustrates the Integrated Process Strategy for the K Basins spent nuclear fuel.

Fig. 1

ENHANCED NUCLEAR SAFETY PROGRAM

Early in the formation of the Project the concept of developing an enhanced regulatory strategy by incorporating NRC nuclear safety equivalency into the design and construction of new facilities was considered. Agreement upon what constituted NRC nuclear safety equivalency was widely debated within DOE and WHC. Many different views existed with regard to organizational authorities, oversight roles, requirements, and the definition and scope of NRC equivalency. To resolve these issues, the DOE established the Policy for implementation of NRC nuclear safety equivalency. The Policy received approval by DOE Headquarters (HQ), as well as by DOE Richland (RL) and the WHC Spent Nuclear Fuel Project.

The Policy defines general terms, identifies key roles and responsibilities, and outlines the overall approach to be followed in implementing NRC nuclear safety equivalency for the Project. The Policy is limited to matters of nuclear safety; and does not apply to environmental, OSHA, chemical accident safety, and other non-nuclear safety issues, as these are covered elsewhere by DOE orders and statutory requirements.

The Policy states that the Project will achieve NRC nuclear safety equivalency by "...applying technical requirements based on those applied by the NRC to comparable licensed facilities and by adopting appropriate features of the NRC licensing process, in addition to applicable DOE orders and requirements."

The Policy was developed for the following purposes:

To achieve a set of requirements that are technically defensible and cost-effective.

To achieve in the design and construction of new Project facilities, a level of nuclear safety comparable to that of NRC licensed commercial facilities.

To enhance public understanding and confidence in the safety of the new facilities by following an enhanced regulatory strategy.

The Policy defines nuclear safety equivalency for the Project as:

Applying technical requirements which meet the nuclear safety objectives of the NRC regulations for fuel conditioning and storage

facilities. These include requirements regarding radiation exposure limits, safety analysis, design, and construction.

Applying administrative requirements which meet the objectives of the major elements of the NRC licensing process. These include formally documented design and safety analyses, independent technical review, and opportunity for public involvement.

Technical requirements, in the context of the Policy, are considered to be the design and construction measures (as opposed to pre-operational or operational measures) that are mandated by the NRC regulations. The DOE orders and directives form the basis of all aspects of the Project. The DOE design and construction requirements are supplemented by the additional NRC requirements of Title 10, Code of Federal Regulations (CFR), Parts 0-199, in order to establish NRC nuclear safety equivalency. NRC guidance and precedents, illustrative of implementation of the regulations, were considered optional rather than mandatory. However, such guidance was reviewed and incorporated, where applicable, during the Project's implementation of the Policy.

The Policy establishes nuclear safety oversight for the Project and defines organizational roles and responsibilities. The relationships between Project oversight organizations is illustrated in Fig. 2. Nuclear safety oversight from DOE-HQ is provided by the offices of Environmental Management (EM) and Environmental, Safety, and Health (EH). To facilitate accelerated safety authorization schedules, the Policy established a Regulatory Requirements Team (RRT), comprised of DOE-HQ, DOE-RL, and WHC to review and approve selected regulatory requirements and to facilitate the safety review and authorization process for the Project's facilities. The RRT is chartered to assist the contractor with the task of evaluating NRC regulations and guidance to determine the supplemental requirements that would apply to the Project. Other specific responsibilities of the RRT include; review and approval of requirements, review of new facility safety analysis reports, and input to the preparation of DOE safety evaluation reports.

The Policy also established an independent review process to ensure that the requirements selected as the basis for Project's activities provide an acceptable level of worker safety, public health and safety, and protection of the environment. The process utilizes reviews by both DOE-EH staff and an Independent Review Panel (IRP). The IRP is comprised of nationally recognized technical experts, not associated with the Project, that provide high-level external oversight of the requirements selection process. Specific responsibilities of the IRP include: overview of the requirements selection process, review of safety analysis documentation, and verification that Project facilities meet DOE's Policy for nuclear safety equivalency.

Fig. 2

PROGRAM INFRASTRUCTURE

Figure 3 illustrates the Project's regulatory document hierarchy that forms the key elements that guide implementation of the Project's enhanced nuclear safety program. DOE rules and directives form the foundation of requirements for the Project. These requirements are supplemented by DOE's Policy for NRC nuclear safety equivalency. From this point, the Project has developed documentation along two paths. One path establishes the management infrastructure of the program (organization charters, program baselines, schedules, etc.). The other

path provides technical direction for further definition and implementation of program requirements.

Fig. 3

The Project Management Plan establishes the management basis for the Project (5). The plan defines the Project boundaries and identifies the plans, organizations, and management systems that are to be utilized on the Project. The plan specifies the development of project and sub-project management plans, like the Project's Regulatory Program Plan and Public Involvement Plan, and cross-project topical plans and reports that focus on technical plans and activities, like the Regulatory Strategy and Safety Management Plan.

The Regulatory Program Plan is the management plan for the Project's nuclear safety program (6). This plan establishes and describes plans for implementing and complying with nuclear safety regulatory requirements applicable to the Project's facilities and activities, including the key objectives and requirements identified in the Policy for NRC nuclear safety equivalency. The document discusses Project requirements for planning, budgeting, and scheduling specific tasks such as preparation, review and approval of Safety Analysis Reports (SARs); establishing a regulatory requirements database and commitment tracking system; and managing regulatory compliance.

In parallel with the establishment of the Policy, the Regulatory Strategy (7) was developed to obtain agreement with DOE on an approach for identifying nuclear safety requirements, performing appropriate safety analyses, preparing safety documentation, and obtaining the necessary approvals and authorizations for each of the Project's major facilities. For the Project's new facilities, DOE Order 5480.23, Nuclear Safety Analysis Reports, and its implementing standard, DOE-STD-3009-94, Preparation Guide for U.S. Department of Energy Nonreactor Nuclear Facility Safety Analysis Reports, will be used to prepare safety analysis documentation. The DOE order and standard will be supplemented by the format and contents guidance of Title 10, CFR, Part 72, Licensing Requirements for the Independent Storage of Spent Nuclear Fuel and High-level Radioactive Waste and NRC Regulatory Guide 3.48, Standard Format and Content for Safety Analysis Reports for an Independent Spent Fuel Storage Installation (Dry Storage), in order to help demonstrate the NRC nuclear safety equivalency objective. Parallel to the development of the Regulatory Strategy was the creation of official charters for the RRT and IRP to focus their efforts and define their responsibilities and membership.

The Safety Management Plan (8) further defines the requirements identification process and establishes the plan to achieve compliance with requirements through development of appropriate safety analyses and design documentation. The document details plans and schedules for preparation, review, and approval of the safety analysis documentation. The plan also establishes the approach for integrating the safety analysis, safety documentation, and independent safety reviews with the Project's design, construction, and startup activities. The plan clearly defines organizational responsibilities within the Project for safety documentation and independent review requirements.

NRC EQUIVALENCY PROCESS

Consistent with the DOE's Policy, a comprehensive evaluation of Title 10, CFR, Parts 0-199, and potentially relevant NRC guidance, including NRC Regulatory Guides, NRC NUREG and SECY documents, Standard Review Plans,

Inspection and Enforcement Notices and Bulletins, was performed against applicable DOE requirements. An evaluation of Title 10, CFR, Part 72, less subparts A,C,J, and K, against applicable DOE requirements performed by Scientech, Inc., under contract to DOE-HQ, was also included in the evaluation. A review was also performed of a current license renewal application under Title 10, CFR, Part 70, Seimans Power Corporation, Application for Renewal of Special Material License No. SNM-1227 (NRC Docket No. 70-1257), at the direction of the IRP to identify any "revealed regulations" (i.e., NRC requirements imposed during the licensing process that are not called out in the regulations). The results of this review are provided in the Spent Nuclear Fuel Project Path Forward - Nuclear Safety Equivalency to Comparable NRC-Licensed Facilities report (9).

Equivalency was established for the most part by the DOE regulations and orders. In some instances WHC procedures and instructions were used to establish equivalency for the Project. A listing of additional NRC requirements that were deemed applicable to the Project were documented in the following reports Spent Nuclear Fuel Project Path Forward - Additional NRC Requirements (10) and Multi-Canister Overpack - Additional NRC Requirements (11). Completion of this process was a significant step toward achieving NRC equivalency in the design and construction of the Project's Path Forward facilities.

ACCOMPLISHMENTS

The Project has nearly completed development of the documents described above that support implementation of its regulatory program. The NRC nuclear safety equivalency policy was approved by DOE in August 1995. The RRT was established in April 1995. The RRT tentatively meets on a weekly basis via video conference. Video conferencing provides an economical means of expediting, facilitating, and coordinating the safety documentation within several organizations which may be separated by several thousand miles. The IRP's membership was defined in June 1995, and the team has held three meetings, in June, September, and December of 1995. A comparison of NRC to DOE requirements has been completed and is in the final stages of review and approval. The requirements assembled from this process are being incorporated into the project design basis through the development of Functions and Requirements documents and performance specifications for the Project's facilities. The Project's Regulatory Strategy and Program Plan have been established and approved. The Safety Management Plan is currently being drafted, and preparation of new facility safety analyses are underway.

CONCLUSION

The DOE is implementing an enhanced regulatory program for Hanford's KBasins Spent Nuclear Fuel Project to provide an increased level of nuclear safety in the design and construction of planned new facilities. The basis for the approach to provide an enhanced regulatory program is DOE's Policy for achieving nuclear safety equivalency to comparable NRC-licensed commercial facilities. By establishing the Project's nuclear safety program and completing a review of regulations to establish NRC nuclear safety equivalency, DOE has taken the first steps toward achieving greater nuclear safety in the design and construction of the Project's new facilities. Implementation of the Policy for NRC nuclear safety equivalency will better align these facilities for the possibility of future external regulation by the NRC. Documents described in this

paper are available for use by the DOE Complex in the development of similar enhanced regulatory programs related to nuclear safety.

PREPARING DOE SPENT NUCLEAR FUEL FOR ULTIMATE DISPOSITION: MEETING REQUIREMENTS AND MANAGING TECHNICAL RISK

K. Chacey
J. Carlson
S. Gomberg
J. Thompson
U.S. Department of Energy

ABSTRACT

The Department of Energy (DOE) Office of Spent Fuel Management, within the Office of Environmental Management, has undertaken a program to ensure safe existing storage, provide for interim storage, and to prepare for ultimate disposition of DOE spent nuclear fuel (SNF). In the past, most DOE SNF was chemically processed in order to recover plutonium or uranium for the nuclear weapons program. However, with the phaseout of chemical processing throughout the DOE complex, most of the remaining SNF must now be managed until its ultimate disposition, rather than for the few years of storage originally envisioned.

This paper focuses on the challenges and issues surrounding the development of disposal requirements for DOE SNF. A critical element of successfully preparing DOE SNF for ultimate disposition is understanding the requirements that must be met for such disposition. Geologic disposal is the primary option under consideration for the ultimate disposition of most DOE SNF. The Office of Civilian Radioactive Waste Management (RW) is pursuing the development of a geologic repository for the disposal of SNF and high-level waste (HLW). The Office of Environmental Management (EM) has had intensive interactions with RW which will help ensure preparation of DOE SNF for geologic disposal consistent with RW program constraints and requirements. Interactions between EM and RW will also help balance the risk, effort and costs imposed on each program.

INTRODUCTION

Developing requirements for the geologic disposal of DOE SNF is a relatively new initiative. Prior to 1992, DOE had generally planned to manage its SNF by reprocessing it and vitrifying the resulting HLW for disposal in a geologic repository. In 1992, DOE decided to phase-out reprocessing of its spent fuel and began to consider other options, including the possibility of direct disposal in a geologic repository. Interactions between EM and RW resulted in the identification of a planning base for the geologic disposal of DOE SNF. Under this planning base DOE would dispose of all of its spent fuel, not otherwise dispositioned, in the first repository, subject to a number of constraints such as meeting licensing and disposal fee requirements. Recent interactions between EM and RW have now also established the need for disposal requirements specifically for DOE SNF.

Formal interactions between EM and RW began in August 1994 with the first meeting of the DOE SNF Steering Group. In July 1994, the Director of RW had recommended formation of an EM/RW steering group, and identified a number of key issues a steering group should focus on, including repository schedule impacts, criticality control, canisterization, potential regulatory issues regarding the Resource Conservation and Recovery Act, Safeguards and Accounting issues, and establishment of appropriate Interagency Agreements/Disposal Fees. EM concurred on the need for this Steering Group and further recommended that resolution of these issues be used to help establish disposal requirements for DOE SNF. Later in 1994, RW began to examine existing acceptance requirements in order to determine their applicability to DOE SNF and develop disposal requirements specifically for DOE SNF. A document, "Preliminary Requirements for the Disposition of DOE SNF in a Deep Geologic Repository," hereafter referred to as the Preliminary Requirements, was issued in December 1995. This document, developed under a quality assurance program, would be used by EM to plan quality affecting activities for the preparation of DOE SNF for geologic disposal.

DISCUSSION

RW began developing disposal requirements for DOE SNF by examining existing waste acceptance requirements for commercial SNF and HLW. In many cases these existing waste acceptance requirements were taken directly from the Code of Federal Regulations (CFR), especially 10 CFR 60, "Disposal of High-Level Radioactive Wastes in Geologic Repositories," and 10 CFR 961, "Standard Contract for Disposal of Spent Nuclear Fuel and/or High-Level Radioactive Waste." These requirements were, therefore, also directly applicable to DOE SNF and provided the essential components of the disposal requirements for DOE SNF. Other requirements for HLW and

commercial SNF were derived from information gathered by the RW program to date (e.g., site characterization activities, licensing strategies, interpretation of regulations, production specifications for HLW). However, these requirements often need to be verified because they represent the best knowledge to date and could change. In most cases these requirements were potentially flexible and some latitude may be acceptable as long as regulatory compliance is maintained.

Establishing disposal requirements for DOE SNF based on precedents set by commercial SNF and HLW was sometimes difficult. DOE SNF often does not have the same characteristics as commercial SNF. Different sizes, configurations, enrichments, fuel matrices, fuel claddings, burn-ups, etc., all represented potential complications in the establishment of requirements. These characteristics also represent potential complications in preparing DOE SNF to comply with the requirements. In some cases, standardization requirements developed in order to minimize facility' costs, are difficult to apply to DOE SNF with dissimilar sizes and configurations.

DOE SNF also has characteristics different from those of vitrified HLW. The production specifications for vitrified high-level waste are the most developed technical specifications for any material to be disposed of in a repository. Thus these specifications were initially viewed as potentially useful when developing disposal requirements for DOE SNF. However, it was recognized early in the process that production specifications for a manufactured waste form were not always appropriate for DOE SNF because it is constrained by its existing configuration and characteristics (although treatment technologies for some types of DOE SNF may produce a manufactured waste form). Some tests or verifications performed for vitrified HLW may not be necessary or appropriate for DOE SNF. Thus, the HLW production specifications were only of limited value for development of disposal requirements for DOE SNF.

Development of disposal requirements also is difficult because the bases for some existing waste acceptance requirements are still to be verified. This is due in part to the fact that RW is still receiving, and will continue to receive for a number of years, information from site characterization activities at the candidate repository site. In addition, the RW disposal facility has not yet been designed, built, or licensed. Design changes necessitated by future developments or interactions with regulators cannot be accurately predicted at this point. For example, the thermal design bases for the repository have not been finalized and may result in significant changes to the thermal limits placed on waste packages at the repository. Also, RW's implementation of the Multi-Purpose Canister (MPC) concept is being reconsidered and may cause changes to configuration requirements for the repository. The characteristics of DOE SNF, once repository designers are fully cognizant of them, may also cause modifications in the design of the repository which may require changes to the disposal requirements.

Development of other requirements for DOE SNF was problematic in that it was unclear how to apply systems level requirements to individual DOE SNF forms and/or packages. For example, 10 CFR 60.131(b)(7), found in the section of 10 CFR 60 that outlines design criteria for the geologic repository operations area, reads: "All systems for . . . isolation of radioactive waste shall be designed to ensure that a nuclear criticality accident is not possible unless two unlikely and concurrent or sequential changes have occurred in the conditions essential to nuclear criticality

safety." Although this requirement applies to systems for the isolation of radioactive waste and is not applied directly to the DOE SNF forms or packages themselves, the design and performance of DOE SNF forms and/or packages are critical components of the system being evaluated for compliance with this requirement. It appears appropriate, therefore, to place some form of the requirement on the DOE SNF form and/or package, even though the requirement is mandated at the systems level.

Similarly, the requirements of 10 CFR 60.135, "Criteria for the waste package and its components," are addressed primarily in the context of not compromising "the function of the waste packages or the performance of the underground facility or the geologic setting." The application of these requirements is more complex as they are often applied to the waste package itself, which is in close proximity to the DOE SNF. The requirements of 10 CFR 60.135 also in some cases refer directly to the contents of the waste package and thus have a direct impact on DOE SNF. Still, the impact of the performance of DOE SNF forms and/or packages on the performance of the system must also be evaluated, which makes for a potentially complicated allocation of performance requirements. Future interactions between EM and RW must address the appropriate performance allocation required for DOE SNF.

The draft Preliminary Requirements were completed and issued for review in June 1995. Representatives from the Office of Naval Reactors, the Idaho National Engineering Laboratory, the Savannah River Site, and the Hanford site participated in the review for EM. RW also had a number of participants in the review. Final comments on the document were submitted in July 1995. Comment review and resolution were completed in November 1995 and the document was issued in December 1995.

As part of the comment resolution, EM and RW reached agreement on the purpose and use of the Preliminary Requirements. There were concerns that, although this document was prepared under Quality Assurance procedures, the Preliminary Requirements were not yet incorporated into the official RW technical baseline. Part of the EM and RW agreement established that disposal requirements for DOE SNF will be incorporated into the RW technical baseline in early spring of 1996. Following issuance of the disposal requirements, draft documents demonstrating DOE SNF program compliance will likely be issued within a year, although the exact details of these documents are yet to be determined.

RESULTS

Development of Preliminary Requirements for the geologic disposal of DOE SNF, and the related interactions between EM and RW, resulted in a number of lessons and insights regarding the application of, and compliance with, disposal requirements for DOE SNF.

The RW program baseline has been established based on the characteristics of commercial SNF and, to a lesser degree, vitrified HLW. This program baseline optimizes repository design and other system features around SNF that is low-enriched, in oxide form, having a relatively small number of fuel types, and a relatively large amount of data with a Quality Assurance pedigree. Given the very different SNF types represented in the DOE inventory, a whole new suite of issues has emerged. There are new issues regarding compliance with disposal requirements, interpretation of disposal requirements, and other new unforeseen issues based on RW's experience with commercial SNF.

Probably the chief challenge regarding the evaluation of DOE SNF for geologic disposal is the large number and variety of DOE SNF types. Using

some simplifications, DOE SNF may be considered to fall into one of approximately a dozen fuel types. However, if these simplifications are removed and subcategories of fuels are included, the number of DOE SNF types may exceed 150. In addition, if the primary characteristics of SNF are considered, including enrichment, fuel matrix, fuel cladding, burn-up, size and configuration, DOE SNF spans the complete spectrum. Enrichments vary from virtually depleted uranium to enrichments in the high ninety percentiles. Fuel matrices include a number of oxide forms, uranium-Aluminum alloys, carbides, uranium metal, and many others. Fuel claddings include commercial Zircaloys, stainless steels, and aluminum alloys. Burn-up of DOE SNF ranges from almost fresh fuel to deeply burned fuel. There are also a very large number of sizes and configurations of DOE SNF.

Beyond the challenges posed by the number and variety of DOE SNF types, there is the challenge of gathering reliable data, with the appropriate pedigree, for all the DOE SNF types in order to assess compliance with disposal requirements. Data are needed to accurately assess not only the existing physical characteristics of the DOE SNF, but also to assess the long-term performance of DOE SNF in the repository environment.

A large amount of data exists for DOE SNF. However, unlike commercial SNF, most of which was produced and utilized under Nuclear Regulatory Commission (NRC) approved quality assurance programs, most DOE SNF was not maintained under such programs. Some DOE SNF types, such as the ATR and the TRIGA, have a strong pedigree with adequate records traceability. Furthermore, some DOE SNF has safeguards and accountability data which may provide an extensive record of its characteristics. However, for some DOE SNF, only limited storage records exist, making it difficult to assay its physical characteristics. In some cases these existing records may be inadequate to support the data needs of RW. In other cases, the traceability of the data may call into question its adequacy.

The costs for using even existing data to support disposal of DOE SNF could be quite large. One cost estimate based on data needed to support the License Application Annotated Outline is a minimum of five million dollars for DOE SNF types with good records. The costs of developing information for disposal of some types of DOE SNF, which do not have an adequate data base, could exceed ten million dollars.

The high enrichment of DOE SNF also poses challenges for the EM and RW programs. Maintenance of criticality control for highly enriched SNF is more complicated than criticality control for commercial SNF, which is almost exclusively low enriched. When considered over the long time periods being used to predict repository performance, this demonstration of criticality control becomes even more challenging. The high-enrichment of some DOE SNF may also make it more attractive for diversion and thus may require the introduction of more stringent safeguards and accounting requirements. Furthermore, much of the highly-enriched DOE SNF has relatively low radiological and thermal output which may mean that it will not have some of the self-protecting characteristics of commercial SNF, which has relatively high radiological and thermal output.

Degradation of some portions of the DOE SNF inventory poses a significant technical challenge. For up to 5-10 percent of the DOE SNF inventory, degradation, and/or other undesirable characteristics, introduce substantial uncertainty in preparation for geologic disposal. This has raised the possibility that some DOE SNF may have to be treated prior to disposal. In fact, recent decisions by the Department regarding the DOE

SNF inventory at the Savannah River Site have resulted in a plan to process those DOE SNF types that threaten the environment, safety and health of workers and the public.

Thermal limits anticipated for the repository also pose a challenge to a portion of the DOE SNF inventory. Currently, RW anticipates pursuing a repository design with a thermal limit that may be as high as 400 C for a certain period. Temperatures this high would likely have a negative effect on aluminum-clad SNF, a common fuel type in the DOE SNF inventory. Aluminum cladding is normally subject to deformation at temperatures above 180 degrees C. EM and RW have begun to assess potential solutions to this challenge.

CONCLUSION

The development of disposal requirements for DOE SNF has been an extensive and difficult effort. The existing RW disposal requirements were not designed with DOE SNF in mind, but were created for a repository containing HLW and commercial SNF. In addition, regulatory requirements for HLW and commercial SNF may create compliance difficulties for some types of DOE SNF.

As this program progresses, EM and RW face challenges. Some of these challenges naturally draw the two programs to work together. However, for other challenges there are conflicting objectives which drive each program. It will take leadership and enlightened cooperation on the part of both programs to advance the best solutions for the Department.

Management of programmatic uncertainty and risk are an important part of the cooperative efforts of EM and RW. RW's licensing activities are currently focused on the licensing of commercial SNF for disposal in a geologic repository. Some DOE SNF types pose new issues for the licensing of a repository. Resolution of these issues in a very conservative manner could impose very large costs on the DOE SNF management program, especially when certain packaging and conditioning alternatives are considered. However, less conservative approaches could potentially jeopardize the success licensing.

In summary, EM and RW must work carefully together to develop a program to prepare DOE SNF for disposal and to develop a repository program which will minimize costs to the Department and the American taxpayer. Although EM and RW have made progress in this area with the establishment of a formal interface between the two programs and the establishment of Preliminary Requirements for the disposal of DOE SNF, much more remains to be accomplished.

DEVELOPMENT OF A STANDARDIZED DISPOSAL CONTAINER FOR THE DEPARTMENT OF ENERGY'S LOW LEVEL WASTE

Stephen Warren
U. S. Department of Energy
HQ

Sonny Goldston
Westinghouse Savannah River Site

Julie D'Ambrosia

EnviroTech Associates, Inc.

ABSTRACT

The Department of Energy (DOE) is the largest generator of low level radioactive waste (LLW) in the United States (generating nearly 70% of the total national volume). In 1993, DOE disposed of more than 50,000 cubic meters of LLW.

This waste is packaged in a variety of containers and disposed of via shallow land burial at the Hanford Reservation in Washington state, the Idaho National Engineering Laboratory in Idaho, the Los Alamos National Laboratory in New Mexico, the Nevada Test Site in Nevada, the Oak Ridge Reservation in Tennessee, and the Savannah River Site in South Carolina.

In 1995, the Department initiated an effort to develop a standard container for disposal of DOE's LLW. The objective was to enable DOE to order larger numbers of containers at one time, thereby reducing purchasing costs. Further, DOE anticipated that a standardized container had the potential to reduce costs in two additional ways: 1) by enabling new disposal container fabricators to enter the market, competition would be enhanced and prices reduced; and 2) by enabling the generating and disposal sites to concentrate on a single container, future storage, loading and disposal operations would be simplified, different types of equipment required for these operations would be minimized, and operating costs would be reduced.

To ensure a new container would be used by the different DOE sites, a development team was established. This team included representatives from the major generating and disposal sites. Representatives of the Transportation Management program were also included, since another objective was that the container be a DOT-certified 7A Type A transportation package. A key factor in site acceptance and use of this container was the process of achieving consensus among generators and disposal operations personnel at DOE sites.

This paper describes the process followed by the Department's recycle policy development team, including the container development team, to identify key factors important to ensuring equity in recycling and to ensure that recycling could be pursued in a cost-effective manner. Information is also presented on the objectives and process of development of the standardized container, as well as the specific parameters (fabrication metal, size, handling requirements etc.) of the container.

BACKGROUND

Millions of tons of potentially recoverable materials have accumulated over the years at U.S. Department of Energy (DOE) sites and facilities now undergoing environmental restoration. These materials include thousands of tons of scrap metals that can be recycled into new products, to conserve natural resources and avoid costly disposal. While some recoverable materials can be free-released and possess a significant market value, other materials are contaminated either on the surface or in mass, which limits their reuse or recycle in the open market.

The DOE environmental restoration program is considering a national policy for recycling radioactively contaminated scrap metals (RSM) within the DOE complex. The existing inventory of metals in scrap piles has been variously estimated to include from 150,000 to 400,000 tons of RSM. A large percentage of this is radioactively contaminated carbon steel (RCCS), the focus of the policy analysis. The "Recycle 2000" policy under consideration is investigating the fabrication of RCCS into ingots or

waste containers to provide for better management of DOE wastes. Risks and costs of transportation would be associated with shipping the RCCS from the DOE metal-generating sites to the processing (including fabrication) or disposal sites and shipping the products (i.e., ingots or waste containers) from the processing site(s) to disposal or use sites. The DOE environmental restoration program has initiated an assessment of the risks and costs associated with transporting RCCS and its potential products throughout the DOE complex.

THE RECYCLE 2000 POLICY PROPOSAL

To provide for responsible management of RCCS, the Department proposed the following policy: By the year 2000, 50% of low-level waste disposal containers will be fabricated from DOE-generated RCCS. These disposal containers, to be used one time only, will be used exclusively for disposal of low-level waste (LLW) generated by the Environmental Management (EM) program. If insufficient newly generated RCCS is available to meet the 50% goal, the proposed policy would be to refrain from burying potentially recyclable RCCS (i.e., that material already stored in scrap piles at various sites) and to use all available containers made from RCCS.

AN INNOVATIVE POLICY DEVELOPMENT APPROACH

Historically, DOE developed policies, then talked to stakeholders to explore how to implement the already-selected policy. As DOE's culture has changed, stakeholder involvement in decision making has increased dramatically. For the Recycle 2000 Policy concept, DOE invited stakeholders to identify their concerns prior to DOE's decision to pursue developing this policy. If the Recycle 2000 concept is pursued, it will be the first DOE policy decision incorporating stakeholder values and input prior to establishing the policy.

THE PROCESS

DOE identified a broad range of stakeholders to be involved in evaluating the proposed policy. These included DOE sites, regulators, industry, Public Interest Groups, local and State government (elected officials and business development representatives), and labor representatives.

A small group of these stakeholders reviewed the Recycle 2000 concept in July 1994. They were generally supportive of concept but wanted broader review. In response to this input, DOE invited a larger group of stakeholders to a December 1994 workshop to discuss the proposed policy. The workshop consisted of 42 participants from 26 organizations.

The result of this workshop was that stakeholders were supportive of the recycling concept subject to certain conditions, which included:

- protective of public and worker health and safety;
- developed through an open, credible process;
- economic compared to other viable waste disposal options;
- equitable (takes into account equity among sites and States);
- environmentally responsible, neither compromising cleanup nor adding to existing problems; and
- designed not to preclude further recycle initiatives.

Based on the above workshop conclusions, and a request from workshop participants for more and better information upon which to base policy development, DOE committed to conducting analyses of potential health and safety impacts associated with recycling radioactively contaminated scrap metal, the transportation of this material for purposes of recycling, and the cost of recycling. In addition, in response to a workshop recommendation, DOE also committed to developing a standardized low-level

waste disposal container suitable of being fabricated out of radioactively contaminated scrap metal.

The Recycle 2000 policy options considered in the various analyses mentioned above are as follows:

Option 1: Continuing RCCS disposal operations as currently practiced;

Option 2: Processing RCCS into ingots (volume reduced form) for disposal; and

Option 3: Processing RCCS into disposal containers for one-time use within the EM program.

Although initial discussions did not focus on a particular type of RSM, DOE narrowed the scope to focus exclusively on RCCS because it is abundant across the complex, its low market value limits incentive for decontamination and release, and it is suitable for waste management containers in demand with the EM program.

STANDARD CONTAINER DEVELOPMENT

As stated above, DOE had committed to developing a standardized low-level waste container suitable of being fabricated out of RCCS. Yet DOE had additional incentives for developing a standard container. DOE is the largest generator of low-level radioactive waste (LLW) in the United States (generating nearly 70% of the total national volume). In 1993, DOE disposed of more than 50,000 cubic meters of LLW via shallow land burial at the Hanford Reservation in Washington State, the Idaho National Engineering Laboratory in Idaho, the Los Alamos National Laboratory in New Mexico, the Nevada Test Site in Nevada, the Oak Ridge Reservation in Tennessee, and the Savannah River Site in South Carolina. The DOE LLW generating sites package this waste using various sizes of containers. This results in transportation-related inefficiencies, the need for differing disposal site equipment, and potential for disposal site void space. Even the DOE "B-25-type" container is not standard, as it is modified at most sites in both external dimensions and engineered capacity.

In 1995, the Department initiated the effort to develop a standard container for disposal of DOE's LLW. The objectives for the initiative were:

Design a family of standardized low level waste disposal boxes (M-100 series)

Enhance economies of scale through larger DOE orders of uniformly designed containers

Improve transportation efficiencies by minimizing variety of disposal containers used by DOE waste generators

Minimize void space at disposal sites through use of standard size containers

Reduce uncertainty for vendors of what is a "B-25-type" container

Among the various M-100 container requirements are the following:

The M -100 series containers must be easily fabricated, using standard tooling and nonproprietary parts;

The M -100 series container design must accommodate both RCCS and commercial fabrication paths;

Each M-100 design must use a single gauge or metal thickness for all components (i.e., all 8-gauge or all 12-gauge components); and

The M -100 series containers must meet Waste Acceptance Criteria for all DOE low-level waste disposal sites.

The M-100 series of containers are designed so a fully loaded container can be lifted by forklift or overhead hoist and the container is suitable as a six, 55-gallon drum overpack.

To ensure that a new container would be used by the different DOE sites, a consensus approach to container development was used. A container development task force was established that included representatives from the major generating sites and disposal site operators. This included representatives from Oak Ridge, Savannah River, Idaho, Hanford, and Nevada. Representatives of DOE's Transportation Management Program were also included, since another objective was that the container be a DOT-certified 7A Type A transportation package.

The prototype 12-gauge, 7A-type (M-103/7A/12/90) container has been fabricated, and testing was completed in September 1995. M-100 information is being shared with commercial low-level waste generators and disposal site operators. Follow-on activities include:

Integrating M-100 containers into DOE procurement

Establishing DOE-wide commitment to use M-100 container designs for low level waste disposal

Value-analyzing M-100 designs to minimize cost of manufacture (while retaining performance requirements)

If "Recycle 2000" concept pursued, promote manufacture of M-100 containers from RCCS.

Due to the preliminary success of the standard container initiative, DOE expects to implement the fabrication and use of the standard container regardless of the outcome of the recycle policy decision.

TRANSPORTATION RISK ANALYSIS

A transportation risk analysis was conducted to provide an assessment of potential human health risks and developed unit risks and costs for transporting RCCS scrap between DOE sites. A summary of the report of the risk analysis (1) was presented at the September 1995 Recycle workshop. The report notes that the RCCS may be generated from DOE activities (current or future) or from decommissioning of DOE facilities. The transportation system risk estimates reflect preliminary information regarding the quantities of RCCS at some sites and the spectrum of radioactive contamination in RCCS at various types of DOE facilities. Transportation risks for the three options (shown above) were analyzed. For Options 2 and 3, conceptual system configuration alternatives for processing RCCS at two regional sites or one national site are also evaluated. Risks and costs of transportation would be associated with shipping the RCCS, its products (i.e., ingots or waste containers), and secondary wastes. Specifically, this assessment considers truck or rail transportation of 1) purchased containers to DOE RCCS-generating sites, 2) RCCS in boxes to disposal sites, 3) RCCS for processing into ingots or fabrication into containers, 4) ingots to disposal sites, 5) containers fabricated from RCCS to user sites, and 6) secondary waste to disposal sites. All transportation is assumed to occur by truck and rail services that are available commercially.

Given the current stage of DOE decommissioning operations, the information currently available did not permit a full-scale analysis of transportation risks. Complete RCCS inventory (physical quantity and activity) information for each major DOE site is not available; data on scrap inventories have only been compiled for a limited number of sites and there are no estimates for future scrap generation. Without extensive inventory estimates, it is not possible to determine the number of

shipments required and the associated risk totals for DOE's alternatives. Therefore, the analysis was limited to providing unit risk and cost data elements.

The risk assessment methodology used was consistent with the DOE Environmental Management Programmatic Environmental Impact Statement (EM PEIS). The endpoints analyzed were:

Cancer incidents and fatalities due to external radiological exposure from routine operations;

Cancer incidents and fatalities due to external radiological exposure from accidental release;

Cancer incidents and fatalities due to exposure to vehicle exhaust emissions from routine operations; and

Injuries and fatalities from vehicle accident trauma.

The analysis indicated that total risk is dominated by traffic accident risks. Specifically, radiological transportation risks are a small part (10% or less) of total risk for transportation of RCCS and RCCS-fabricated boxes. Additionally, due to more people being in close proximity to roads than rails, truck transportation resulted in a higher external dose than rail transportation of RCCS and RCCS-fabricated boxes. Risks from shipping the empty fabricated containers are generally lower than for unprocessed RCCS because of the potential removal or immobilization of radioactivity by the metal melting process. Risk factors that include injuries are about a factor of 10 higher than those for fatalities alone. Risk factors including total cancer incidence are about 50% higher than those for latent fatalities. Because trucks travel in close proximity to exposed populations, truck transportation results in slightly higher risks than rail transport.

Unit transportation risk factors for all options (estimated health effects/shipment mile) are on the order of 10-7 - 10-8. These include fatalities, fatal and non fatal cancers, injuries, and severe genetic effects. For both truck and rail transportation, risks varied between the three options by less than a factor of 2, indicating that all three options were roughly equal in terms of risk.

TRANSPORTATION COSTS

The assessment provides fixed and variable unit costs (dollar/shipment-mile). Fixed and variable costs vary by transport mode (truck or rail), by distance traveled, and by the form of RCCS (scrap, ingots, fabricated containers, or secondary wastes). In practice, the costs may be affected by the number of shipments and the time period covered by the contract. Either truck or rail may have lower variable costs, depending on the dimensions and weight of the material being hauled and the shipping distance. Higher costs are assumed for secondary waste transportation because of greater handling and certification costs for this material. In general, variable costs decline as shipping distance increases, and variable costs are higher per ton for fabricated containers (empty) than for scrap haulage.

Transportation costs associated with implementing any of the three options ended up contributing between 2 and 12% of the total option cost. A centralized processing site yielded the highest transportation costs, contributing 10-12% of the total option cost, while a regionalized processing site yielded transportation cost contributions of 7-9%. Continuing present operations yielded the least transportation cost contribution of 2%. Transportation costs associated with processing to ingots for volume reduction ($1.72/ft3 for regionalized processing and

$2.65/ft3 for centralized processing) were slightly less than transportation costs associated with fabricating disposal containers from RCCS ($2.12/ft3 for regionalized processing and $3.26/ft3 for centralized processing).

(For the centralized processing scenario, all RCCS origin sites shipping to a single processing site. A U.S. geographic centroid represents the fictitious centralized destination site. For the regionalized processing site, waste generating sites ship to either of two regional processing centers. The analysis showed that total risk is proportional to mileage, and Option 1 has the lowest estimated risk due to this option resulting in the lowest mileage. The analysis also showed that lower risk results from two regional processing facilities rather than a single, centralized processing facility, due to the RCCS and RCCS-fabricated boxes being transported over fewer miles. Additional processing sites did not provide substantial reductions as compared to two sites.)

CONCLUSION

Based on the transportation risks and costs, as well as other data presented at the workshop, participants encouraged DOE to establish a recycling policy with a 2-3 year demonstration, then reevaluate the success and cost of the policy. The participants felt that a decision based on the limited cost data available so far would result in the selection of either Option 2 or Option 1, and workshop participants clearly believe the "right thing for the environment" is to make disposal containers from RCCS. Participants also encouraged DOE to clearly state in the policy that a box made from RCCS is not waste, but is a product. This distinction will enable any site to use a box made from RCCS from either its own site or any other site without causing disposal site concerns. Participants also encouraged DOE to explore conducting a demonstration of RCCS recycling if it appeared too difficult to establish an EM-wide policy.

Based on the strong support for recycling indicated by workshop participants, DOE staff has developed a draft policy package to be submitted for management approval. This package recommends that the Office of Environmental Management establish a policy that recycling of contaminated metals should be pursued.

Based on the consensus of the container development team, DOE staff is also developing a draft policy package for issuance by HQ management. This package will inform field management of the standardized container and will encourage its use. This package will also enable aggregate purchasing of standardized containers, and may ease the practical aspects of making standardized containers out of volumetrically contaminated carbon steel.

One of the demonstration activities being conducted in advance of formal approval of the recycling policy is the Savannah River Site's contract with Scientific Ecology Group (SEG) in Oak Ridge to accept contaminated lead for decontamination and reuse. By the end of 1995, the SRS had shipped 20 tons of contaminated lead to SEG to begin the demonstration of an effective decontamination technology. It is expected that the lead will be recycled for reuse and a per unit volume cost will be established, which will support future decontamination and recycle activities. Additionally, 20 tons of contaminated HEPA filter frames have been shipped to SEG for treatment through melting and recycle/reuse. The radioactively-contaminated lead items were shipped to SEG as scrap metal for recycling, not as waste. The distinction is important so that the

scrap metal can be recycled and not, instead, disposed of as DOE-generated waste.

DOE will be identifying and implementing additional innovative approaches to ensure recycling is pursued to the maximum extent possible across the complex.

Susan Jablonski
Texas LLRW Disposal Authority

ABSTRACT

In response to questions from members of the public regarding the Texas Low-Level Radioactive Waste Disposal Authority's application for license to develop and operate a LLW disposal facility, the effects of a highly improbable transportation accident were analyzed. This paper summarizes the results major activities in the analysis, considers the probabilities of such an accident, and identifies sources of conservatism in the analysis.

INTRODUCTION

Members of the public have commented that the application for a license to develop and operate a low-level radioactive waste (LLW) disposal facility that was submitted by the Texas Low-Level Radioactive Waste Disposal Authority (the Authority) did not adequately address transportation risks. One comment requested that the Authority evaluate the effects of a worst case transportation accident occurring in an urban area.

The Authority is not obligated under applicable Texas laws or regulations to justify that the potential impacts of transportation accidents are within acceptable limits. Nevertheless, the Authority performed and reported the results and conclusions of the requested analyses. The conclusion is that members of the general public would not suffer unacceptable risks if the postulated worst case transportation accident were to occur in a densely populated urban area.

An extreme accident involving the burning of the worst waste streams for external gamma radiation and inhalation exposures was postulated to occur at two separate urban locations. The accident was assumed to involve the collision between a truck transporting LLW and a tanker truck filled with

gasoline or similar fuel. The waste containers were assumed to rupture and their contents to be consumed by the fire over a three hour time. The accident was characterized by a series of extreme assumptions that ensured the projected radiological impacts would not be underestimated. The approach to estimate the radiological impacts of the hypothesized accident involved six major steps:

1) Identify and characterize all waste streams that will be disposed at the Texas LLW disposal facility.
2) Screen waste streams from the respective generators for their potential to produce external gamma radiation and inhalation exposures.
3) Identify likely waste transportation routes from the respective waste generators.
4) Define the worst-case transportation accident scenario.
5) Perform calculations to estimate radiation exposures to the public as a result of the worst-case transportation accident using the RADTRAN4 computer code.
6) Summarize and interpret results of calculations.

This paper focuses on the methodologies used to identify the limiting waste streams to be considered in the analyses. It also addresses the probability of the accident analyzed actually occurring and identifies sources of conservatism in the analyses.

IDENTIFYING THE CRITICAL WASTE STREAMS

As noted above, the first step in the process was to identify all sources of LLW. The Authority had projected waste volumes and characteristics expected for disposal at the proposed disposal facility in earlier publications (1,2). Waste stream characteristics were based on the results presented in those documents. Because the objective of these evaluations was to estimate the effects if the accident were to occur, no information about shipment rates were necessary to conduct the requested analyses.

The premise of screening all waste streams is that the critical waste stream(s), those likely to produce the worst radiation exposures, depend only upon their radionuclide concentrations. That is, the details of the RADTRAN4 calculation are immaterial to determining the potential for producing radiation exposures. This screening approach, described below, implicitly assumes that the entire radioactive inventory of a waste container is available to produce exposures. This assumption is clearly a substantial conservatism that is further discussed below.

The concentration of each radionuclide in each waste stream was multiplied by two dose conversion factors -- one for external gamma exposures and the other for inhalation exposures. The product was further multiplied by factors to render the result in common units. The product is a "figure of merit" that differs from the actual hazard only by some multiplicative factor that accounts for processes and phenomena that do not depend upon waste stream characteristics. Thus, waste streams with larger figures of merit present greater risks of radiation exposure.

Each waste stream from each generator was evaluated for its potential to produce external gamma and inhalation radiation exposures. This process is illustrated in Table I for LLW waste steams generated at the Comanche Peak nuclear power plant. The process was applied identically for waste streams from all other generators, although non-utility wastes were treated as a composite from all non-utility waste generators. Table I demonstrates that, for Comanche Peak waste streams, cobalt-60 is the primary source of potential radiation exposure (considering both external

gamma and inhalation radiation exposures) with plutonium-241 as the secondary source.

Table I

The sum of the products described above is a figure of merit that represents the total potential for radiation exposure for the waste stream. These total across all radionuclides are shown at the bottom of Table I.

As noted above, each waste stream from each generator was screened as depicted in Table I and described in the preceding paragraphs. The screening of waste streams generated at the Comanche Peak nuclear power plant is summarized in Table II as a further illustration of the screening process. In the table, the figures of merit (the sum of all radionuclide products within waste stream) are tabulated for both external gamma and inhalation exposures for each waste stream. Radionuclide characteristics of Class C resins and filters, denoted with bold text in Table II, have the greatest potential of producing radiation exposures.

Table II

As a final illustration of the waste stream screening process, Table III summarizes the results for all generators expected to deliver waste to the proposed Texas LLW disposal facility. The waste stream with the greatest potential to produce radiation exposure is presented for each generator. As shown in the table, Class C resins and filters from the Comanche Peak nuclear power plant have the greatest potential for producing both external gamma and inhalation exposures. The characteristics of this waste stream were used in RADTRAN4 calculations of the impacts of the worst-case transportation accident.

Table III

PROBABILITY OF WORST-CASE TRANSPORTATION ACCIDENT OCCURRING

The very act of selecting such a severe accident ensures that the probability of the accident occurring will be low. Everyday experience tells us that extreme accidents occur rarely. Accident statistics confirm this casual observation. For example, among non-collision accidents, only 2.8 percent also involved fires in 1990. Whereas 35,885 accidents occurred in 1990 involving motor carriers in interstate transport, only about 5 percent of these also involved hazardous materials. Of all hazardous materials shipped, only an extremely small fraction is LLW (5). In 1985, about 250 billion ton-miles of freight were hauled by vehicles regulated by the Interstate Commerce Commission. In that same year, about 3,700 accidents involving trucks occurred that resulted in fatalities. This yields an annual fatal accident rate for trucks of about 1.5 X 10-8 fatalities per ton-mile. If the assumption is made that the accident considered in these analyses results in the death of at least one individual, this accident rate can be used to infer the expected number of accidents involving LLW (6). The amount of waste expected for disposal at the Texas LLW disposal facility over its lifetime is about 170,000 tons (1,2). The typical shipping distance (from Houston to El Paso) is about 750 mile. Given the accident rate stated above, about 2 accidents involving LLW shipments would be expected over the facility's operating life.

By contrast, in 1985, 3,825 motor vehicle accidents occurred in Texas that resulted fatalities (6). Thus, over the minimum 20-year operating life of the Texas LLW disposal facility, about 76,000 traffic accidents severe enough to produce fatalities might be expected. The potential of a

few accidents involving shipments of LLW to the Texas LLW disposal facility cannot add measurably to this potential transportation impact. In the analyses of transportation risks performed in response to public questions regarding the Texas LLW disposal facility license application, the accident was assumed to occur in an urban area. The probability of this occurring is small because of the relative number of miles near urban areas and in rural areas. Over the 750-mile trip to the disposal facility from Houston, less than about 50 miles could be in urban areas typical of that assumed in these analyses (namely near Houston and San Antonio). On the basis of miles alone, the probability that the postulated accident would occur in a rural area where radiological impacts would be much smaller is over 90 percent. Only a 7-percent probability exists that the accident would occur in the postulated urban area.

CONSERVATISMS INHERENT IN PROJECTED RADIATION EXPOSURES

Numerous conservative assumptions were made in estimating impacts of LLW transportation to the Texas LLW disposal facility. Among these include:

Accident occurs in an urban area.

Accident involves a truck transporting gasoline or similar fuel which results in a 3-hour fire.

Contents of all waste containers in the shipment are released and available to be consumed by the fire.

The fire consumes all waste in the shipment, releasing the entire radioactive inventory of the shipment into the atmosphere.

Were the effects of these conservatisms to be quantified, they would amount to several orders of magnitude. It is highly unlikely that the projected impacts of the worst-case LLW transportation accident would be as large as reported by the Authority.

ABSTRACT

The Transportation Technology Department of Sandia National Laboratories develops analytical and computational tools for the U.S. Department of Energy to assess the radiological consequences and risks from the transportation of radioactive materials by all modes. When large quantities of materials are to be transported, movements may occur over an extended period of time in what is collectively referred as a "shipping campaign." Since the routes over which the shipments occur often remain the same, cumulative exposure to individuals inhabiting the population zones adjacent to the transport links must be estimated. However, individuals do not remain in the same residences throughout their lifetimes and, in fact, move quite often. To appropriately allocate exposures among populations over extended periods of time, perhaps years, a model has been developed that accounts for three population categories; the original populations residing in areas adjacent to the transport links, and both the individuals moving into and out of any designated areas. The model described herein accounts for these populations and will ultimately be incorporated as a user option in the RADTRAN computer code, used for estimating the consequences and risks associated with the transport of radioactive materials.

The simplified methodology is an extension of previous work that uses available census data to determine the total exposed population strictly as a function of the original population, and is therefore applicable to a wide range of problems. It is important to note the mathematical constructions are predicated upon census data in terms of "households," and as such may not be applicable to individuals. The households are contextually integrated into populations, inclusive of several regional, property-utilization, and density subgroups. The result is an expression specifying the total population (in terms of "households") residing in an area over time t years. Significantly, only the original population and the average time of residence need be known. With respect to the transportation of radioactive materials, the relationship provides an estimate of the total exposed population over an entire shipping campaign while only knowing the initial population density. The method has several strengths including simplicity, dependence on few critical parameters, and a firm foundation in empirical data. The inherent advantages from application of this methodology are twofold: 1) the calculated average dose to members of the public residing near transportation routes will decrease as not all persons remain near a link for the full period of the shipping campaign, and 2) the statistical data are amenable to uncertainty analyses, which in turn yields improved dose-consequence estimates for the population group.

INTRODUCTION

The Transportation Technology Department of Sandia National Laboratories develops analytical and computational tools for the U.S. Department of Energy to assess the radiological consequences and risks from the transportation of radioactive materials by all modes. When large quantities of materials are to be transported, movements may occur over an extended period of time in what is collectively referred as a

"shipping campaign." Since the routes over which the shipments occur often remain the same, cumulative exposure to individuals inhabiting the population zones adjacent to the transport links must be estimated. However, individuals do not remain in the same residences throughout their lifetimes and, in fact move quite often. To appropriately allocate exposures among populations over extended periods of time, perhaps years, requires a model that accounts for three population categories: 1) the original populations residing in the areas adjacent to the transport links, 2) individuals moving out and 3) individuals moving into residences in the designated areas. The model described here accounts for these conditions and will be incorporated as a user option in the RADTRAN computer code for transportation consequence and risk analysis (1). RADTRAN is a computer code for estimating the consequences and risks associated with the transport of radioactive materials.

METHODOLOGY

The most mathematically elegant model would be predicated on an analytical "double exponential," composed of terms describing positive exponential biological ingrowth and negative exponential decay, with the latter made up of terms describing both individuals moving away and mortality. However, the associated coefficients describing these sub-populations must be empirically derived and can restrictively lead to instances in which the model does not apply to specific populations. Therefore, we selected the simpler methodology developed here, which is an extension of previous work (2) that uses available census data and is applicable to a wide range of problems.

As a prerequisite in presentation of the methodology, it is necessary to define the major variables:

P0 = Initial population in designated area
Pin = Population moved into designated area
Pout = Population moved out of designated area
Premaining = Population remaining in designated area
Ptotal = Total exposed population in designated area

The key to solution is application of two initial conditions: 1) over the time periods of interest, population distributions within the relatively small areas being analyzed are modeled as remaining constant, and 2) all established residences are modeled as being occupied. The latter condition means that although individual households may leave an area, other households move in to occupy the vacated residences (100% occupancy). Thus, although individuals in the population Pin are distinct from the individuals of Pout, the population groups are approximately numerically equivalent in magnitude (PinPout).

This simplified procedure allows determination of the total exposed population (Ptotal) strictly as a function of P0. Further, the 100% occupancy condition slightly overestimates the actual population. As some households may move to another residence within the area and since housing-unit occupancy may not be 100%, the calculated total population size will also be an overestimate (unless localized rapid population growth has occurred). The methodology proceeds from determination of the original population P0, through summation of all individual link/bandwidth populations comprising the complete route. Over the time interval of interest (the period of the shipping campaign) household populations Pout and Pin will move out of and into the sample space, respectively. The quantity of interest, the total exposed population Ptotal, consists of the original population P0 plus Pin, comprising the

population of individuals who moved into the sample space during the campaign (Fig. 1, Eq. 1). At the end of the shipping campaign, P0 consists of the populations of households which remained (Premaining) plus those which moved out of the sample space (Pout) (1)(Eq. 2).

It is important to note that the procedure considers populations and that the mathematical constructions are predicated upon census data expressed in terms of "households," and as such may not be applied to individuals. The households are contextually integrated into populations, inclusive of several regional, property-utilization, and density subgroups. Although some of the data subsets are available (Table I) and may be incorporated into the model, only the aggregate of all households is considered here.

Fig. 1

The result is an expression specifying the total populations (in terms of "households") residing in an area over time t years (Fig. 1, Eq. 3). Significantly, only the original population and the average time of residence need to be known. With respect to the transportation of radioactive materials, the relationship allows an estimate of the total population exposed over the entire interval of a shipping campaign to be developed, strictly as a function of the initial population density and duration of the shipping campaign. The derivation of the remaining variable Rt is adapted from published census data analyses (2).

Curve-fit coefficients, shown in Table I, were applied to empirically determine the fraction of households moving into an areas St, and the fraction remaining in their current residences Rt.

St = Fraction of households which moved into current residence t years before survey

Eq. 4

Eq. 5

Eq. 6

Table I

The following example illustrates derivation of an equation to calculate the total exposed population of "all houses" for a multi-year shipping campaign. Values listed within Table I are first used to develop an expression for Rt.

Fig. 2

Substituting the relation for Rt of Eq. 7 into Eq. 3 yields

Eq. 7 into Eq. 3

Eq. 8

In a recent environmental assessment of the impacts of transporting foreign research reactor spent nuclear fuels (3), a total population of approximately 139,403 persons was estimated to be exposed during highway transport along the route from Charleston, SC to the Savannah River Plant near Barnwell, SC. For a shipping campaign lasting 10.0 years, substitution of time t = 10 years and initial population of P0= 139,403 persons into Eq. 8 yields a total potentially exposed population Ptotal = 261,747 persons. Significantly, the total potentially exposed population (Ptotal) is nearly twice the initial population (P0), formerly the only value used in dose-consequences analyses of shipping campaigns.

CONCLUSION

A method has been developed for estimating the total potentially exposed population of persons residing near transportation links, during time intervals required to complete a shipping campaign based upon U.S. Bureau of Census data and analyses (2).

This method has several strengths including simplicity, dependence on few critical parameters, and a firm foundation in empirical data. Conversely, two weaknesses of the method are: 1) one cannot readily account for rapid changes in overall population density (examples being explosive population growth or decline resulting from abrupt socioeconomic changes brought about by extensive construction projects or military facility closures), and 2) it is not possible to account for less than 100% occupancy factors. However, in all cases but those associated with rapid growth, the method yields estimates that are slightly conservative (i.e., overestimates the total exposed population). Should a route segment experiencing rapid and significant growth be identified in a specific application, then additional calculations may be required to improve the population estimate for that link.

The ultimate consequences of application for this methodology are twofold. First, the calculated average dose to members of the public residing near transportation routes will decrease, as not all persons remain near a link for the full time period of the shipping campaign. Secondly, the statistical data presented in Table I are amenable to uncertainty analyses, which in turn yields improved dose-consequence estimates for the population group.

ABSTRACT

The Department of Energy (DOE) and other Federal agencies continue to spend millions of dollars on National Environmental Policy Act (NEPA) and other analysis of transporting radioactive materials. This is a particular problem associated with high-level and transuranic waste and spent nuclear fuel. This paper will show the folly of continuing this expensive and time consuming analysis.

A very high degree of safety has been achieved, both domestically and worldwide, through rigorous implementation of the comprehensive Department of Transportation (DOT) and Nuclear Regulatory Commission (NRC) transportation and packaging regulations. There are no reported deaths or serious injuries due to the radioactive nature of the cargo.

There are few, if any, such large scale industrial activities around the globe with this enviable safety record. DOE, NRC, and other federal agencies have exhaustively analyzed and demonstrated the intrinsic safety of transporting radioactive materials. Further NEPA analysis, is clearly not warranted.

This paper will examine the evidence supporting its title thesis. Specifically, it will document the compelling support represented by:

- Recent (and comprehensive) DOE NEPA analysis
- Environmental impact analysis done by the Nuclear Regulatory Commission (NRC)
- NRC's NEPA Rule contained in 10 CFR 51
- Office of Technology Assessment review of the safety of hazardous materials transport

The sum of this analysis will demonstrate the efficacy of the regulatory framework for transporting radioactive materials, thus eliminating the need for further NEPA analysis.

REGULATORY FRAMEWORK

Recommendations for radiation protection standards come from the International Commission on Radiation Protection (ICRP) and the U.S. National Council on Radiation Protection and Measurements (NCRPM). These organizations are composed of physicians, radiologists, and scientists specialists specializing in the biological effects of radiation. Independent reviews are provided by the U.S. National Academy of Sciences and the United Nations Scientific Committee on the Effects of Atomic Radiation. The International Atomic Energy (IAEA), an agency of the United Nations, issues and updates Basic Standards for Radiation Protection (Safety Series No. 9), which reflects the recommendations made by the ICRP, following review by IAEA member state-designated experts. In turn, IAEA also issues and updates the Regulations for the Safe Transport of Radioactive Material (Safety Series No. 6), which considers the requirements of Safety Series No. 9. Although written in regulatory language, IAEA's Safety Series No. 6 may only legally serve as recommendations. However, the U.S. Department of Transportation and the U.S. Nuclear Regulatory Commission have structured their regulations covering U.S. shipments on requirements of IAEA Safety Series Nos. 6 and 9. These standards are based on more than 50 years of research and experience with radioactive materials and their safe transport. No other standards have been so extensively reviewed and agreed upon by international experts, organizations, and nations.

SUPPORTING ANALYSIS

Recent DOE experience in preparing major EISs continues to involve significant analysis of transporting radioactive materials--particularly spent nuclear fuel (SNF) and radioactive waste. Since the inception of NEPA, such analysis has never shown transportation of radioactive materials significantly impacting people or the environment. This analysis is in itself very costly and increases cost by stretching schedules. The following are examples of analysis which provides compelling support for a categorical exclusion.

DOE NEPA ANALYSIS

1. Department of Energy Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Final Environmental Impact Statement (EIS) (April 1995) - Volume I of this EIS evaluates the impacts of managing DOE-owned spent nuclear fuel SNF. It includes the most exhaustive analysis of

transportation risks for SNF by sea, rail, and highway done anywhere. All of the alternatives, including those that could involve up to 9,200 shipments, would have very small environmental consequences. The results are conclusive--this is a very low risk activity. Similarly, the risks and consequences for the Volume 2 transportation activities are very low. The Agency preferred alternative here includes enhancing ongoing spent fuel management, environmental restoration, and waste management activities to meet current and expanded waste management needs. Significant shipments of spent nuclear fuel, transuranic, mixed low-level, and low level wastes were considered in the analysis. The Record of Decision was issued on May 30, 1995.

2. Draft Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel - This Draft EIS was issued in April 1995 and public comments are being received. The most significant component of analysis is on transportation risks and impacts for SNF. Activities covered include sea transport, handling in ports, overland transport by highway and rail, and receipt at DOE sites. Up to 22,700 SNF elements (721 cask loads) could be accepted at one or more of 5 different sites. This is a thorough analysis of a massive domestic and international SNF shipping campaign. Again, the risks and environmental impacts are found to be insignificant.

3. Environmental Assessment (EA) of Urgent - Relief Acceptance of Foreign Research Reactor Spent Nuclear Fuel (April 1994) - This EA considered acceptance of up to 409 SNF elements from Europe. This document contains an extensive transportation analysis projecting no significant impacts. A Finding of No Significant Impact (FONSI) was issued and the spent fuel was received in September 1994.

4. Draft Waste Management Programmatic Environmental Impact Statement for Managing Treatment, Storage, and Disposal of Radioactive and Hazardous Waste (PEIS--Predecisional Draft May 12, 1995) - This Draft PEIS is now in internal concurrence with anticipated issue in July. It examines the risks and impacts of alternative future configurations for selected waste management facilities. All waste types are considered including high-level, transuranic, low-level, low-level mixed, and hazardous. Alternative configurations are decentralized, regionalized, and centralized. Each has a transportation component with the centralized alternative which would involve massive shipments of all waste types. The preliminary conclusion is there is insignificant risk due to the radioactive nature of the cargo in transit. As with any commodity in normal transportation commerce, the predominant risk (while still low) is with potential non-radiological highway and rail accidents.

5. Final Environmental Impact Statement--Waste Isolation Pilot Plant (WIPP) (October 1980) - The original EIS in its "Authorized Alternative" examined the impacts of shipping transuranic waste to WIPP. It included both contact and remote handled shipments at a 500 per year level. The analysis was done for both highway and rail shipments with very low impacts calculated. This EIS was supplemented in January 1990 to evaluate the environmental impacts associated with new information and changes in the proposed action. In the supplement, the analysis of transportation activities was greatly expanded including maximizing rail (vs highway) shipments, and an all-highway scenario (20,903 shipments). Impacts from the radiological nature of the shipments are low.

6. Environmental Assessment--Return of Isotope Capsules to the Waste Encapsulation and Storage Facility, Hanford Site, Richland, Washington

(May 1994) - This EA examined the environmental impacts of transporting cesium-137 capsules to Richland from Colorado (309) and Virginia (25). On-site transfer of 33 capsules from Pacific Northwest Laboratory was also included. The cesium inventory analyzed ranged from about 675 to 725 kilocuries per shipment. A FONSI was issued on May 11, 1994 and the Colorado shipments are now complete.

NRC NEPA ANALYSIS

1. Nuclear Regulatory Commission, NUREG-0170, Final Environmental Statement on the Transportation of Radioactive Materials by Air and Other Modes (1977) - This was the definitive NEPA study supporting nationwide movement of radioactive materials for over a decade. It provided a generic method to characterize the potential severity of transportation accidents. The risks and consequences were analyzed and found very low. However, this document has not been updated and both major and minor shipping activities began to be independently evaluated (WIPP for example in 1980). The analysis, however, remains undisputed by more recent NEPA documents -- risks are indeed low.

2. Nuclear Regulatory Commission, NUREG/CR-4829, shipping Container Response to Severe Highway and Railway Accident Conditions (1987) - This is commonly referred to as the "Modal Study". The Modal Study was the result of an initiative taken by the NRC to refine more precisely the analysis presented in NUREG-0170 for spent nuclear fuel shipping casks. Whereas the NUREG-0170 analysis was primarily performed using best engineering judgments and presumptions concerning cask response, the modal study relies on sophisticated structural and thermal engineering analysis and a probabilistic assessment of the conditions that could be experienced in severe transportation accidents. Design parameters of the representative casks were chosen to meet the minimum test criteria specified in 10 CFR 71. The study is believed to provide realistic, yet conservative, results for radiological releases under transport accident conditions. It's accident severity scheme is the basis for consequence analysis in DOE Spent Nuclear Fuel EIS work today.

3. Shipment of Core Rubble from Three Mile Island (TMI) in Pennsylvania to Idaho - A very significant DOE precedent was set on these shipments. DOE determined that the TMI shipments fall within a categorical exclusion. In reaching its conclusion DOE relied on:

NUREG-0170, Final Environmental Statement on the Transportation of Radioactive Materials by Air and Other Modes (1977).

NUREG-0683, Final Programmatic Environmental Impact Statement Related to Decontamination and Decommissioning of Radioactive Waste Resulting from March 28, 1979 Accident: Three Mile Island Nuclear Station, Unit 2 (March 1981).

The Department stood firm on the issue of environmental analysis requirements and completed the highly controversial TMI-2 shipping campaign between July 1986 and April 1990. The all-rail campaign included 49 cask load of damaged nuclear fuel and core rubble in 22 shipments.

NRC NEPA RULE

The NRC's NEPA rule is contained in 10 CFR 51, Environmental Protection Regulations for Domestic Licensing and Related Regulatory Functions. These regulations cover their basic licensing activities including the ability to possess and transport radioactive materials. The presumption in 10 CFR 51 is that the licensing of an activity (not the activities conduct or implementation) is the action triggering a potential to impact the environment.

A wide variety of transportation (distribution) and use of radioactive materials are listed as CX in 10 CFR 51.22(14). Included are radiopharmaceutical, generators, sealed sources, gauging devices, instruments, waste, uranium munitions, and other source and by product material. It is estimated there may be as many as 2 million of such shipments yearly. In addition to supporting our transportation proposal, this suggests EH-s B2.6 change is totally unnecessary. A DOE CX for packaging, transporting, and storage of sources (which happens infrequently) is a minor operational activity not worthy of a specific CX. Proposed change B1.29 covering "occasional" transportation appears gratuitous and short sighted in light of NRC's position. Conceivable DOE could avoid its own restrictive NEPA rule by having a licensee make DOE shipments.

One final comment on transportation -- NRC also addresses the "controversy" issue. In section 51.22(b), exceptions to CX eligibility include "special circumstances" which appears to address the "controversy" question in CEQ 1508.27(b)(4). For NRC, these special circumstances center around unresolved conflicts concerning alternatives uses of available resources. There is no indication "controversy" is simply organized activists complaining about environmentally benign activities.

NRC's rule on SNF storage is even more supportive of Jill Lytle's proposal on SNF/HLW storage. NRC provides a CX for SNF storage for 30 years beyond the life of a reactor (10 CFR 51.23). This includes storage in reactor basins and both onsite and offsite independent spent fuel storage installations. This CX strongly suggests DOE should go even farther and make HLW/SNF storage a CX. You may want to take the lead and set up a meeting with EH on the subject.

Section 10 CFR 51.22(c)(11)(ii) allows a CX for activities where "there is no significant increase in individual or cumulative occupational radiation exposure". As an excluded class of action, this would have an immense effect on streamlining NEPA in the Department. It seems inconsistent DOE is moving from self-regulation to considering NRC regulation and not adopt the more aggressive (and fully justified) NEPA rule of an independent regulator. In fact the entire 51.22(c)(11) CX provision is ripe with significant opportunities for DOE to base its own NEPA streamlining on NRC precedent. It is also an excellent opportunity for EH to far exceed its monetary savings goal for streamlining. And -- it takes the "high road" of following the NRC lead.

CONGRESSIONAL REVIEW

1. Office of Technology Assessment (OTA)--Transportation of Hazardous Materials (July 1986) - This document was prepared at the request of Congress as a comprehensive assessment of the regulations, information systems, container safety, and training for emergency response, and enforcement as it deliberated reauthorization of the Hazardous Materials Reauthorization Act. A select and prestigious advisory panel led this definitive review of the "system" responsible for safe transport of over 1 billion tons of hazardous materials per year. For radioactive materials, this report cited areas for improvement and some arguable criticisms. However, concerning certified shipping containers, OTA stated:

"The NRC cask certification process is, of necessity, painstaking and time-consuming. The proven safety record of NRC-certified casks, however, provides a degree of public confidence in casks. OTA finds that technical

evidence and cask performance in service indicate that NRC performance standards yield spent fuel shipping cask design specifications that provide for a very high level of public protection--much greater than that afforded in any other current hazardous materials shipping activity."

AN EXAMPLE OF NEPA EXCESS

The Office of Nuclear Energy is preparing an Environmental Impact Statement for the Medical Isotopes Production Project: Molybdenum-99 and Related Isotopes. A Predecisional draft was issued in September, 1995. The objective of this project is to develop a backup capacity for 10-30% of the U.S. demand over the next 5-10 years. The U.S. currently imports all these isotopes from Canada. The project would also include the capability to supply 100% of U.S. demand if the Canadian reactor is shut down. Molybdenum-99 decays into technetium-99 and is the most widely used medical isotope in the U.S. There are about 36,000 procedures each day using technetium-99.

This project on close examination is a very modest undertaking involving modified use of an existing DOE reactor. Reactors at Los Alamos, Oak Ridge, Sandia, or Idaho could be used. Also included in the project is the capability to fabricate targets, process irradiated targets, and package and ship recovered isotopes. A priori, from decades of past experience, the project would clearly have minimal environmental impacts. It would contribute virtually nothing to cumulative impacts at DOE sites with massive (by comparison) nuclear activities.

The Department could have easily supported a categorical exclusion (CX) for this project based on NRC regulations. The NRC's NEPA rule is contained in its Environmental Protection Regulations for Domestic Licensing and Related Regulatory Functions (10 CFR 51). If this project were being done by a NRC licensee, it would have been a modification to a license and thereby a CX. This prior NEPA analysis and conclusion by an independent regulatory authority should have been considered in deciding to do an EIS. In today's environment, a CX might be extreme. However, the NRC experience alone could have been sufficient justification for selecting an Environmental Assessment (EA) as the proper NEPA document for DOE.

The draft EIS contains extensive analysis of transporting radioactive materials. The EIS level of analysis is conspicuously extreme. It is a CX under 10 CFR 51 which should have been invoked. The EIS baseline for analysis is 3,225 shipments per year. By comparison (for this NRC categorically excluded activity), there are an estimated 2,000,000 shipments yearly in the U.S.

In the past, an important precedent was set for invoking a NRC CX. The Department conducted the entire Three Mile Island core rubble shipping campaign (Pennsylvania to Idaho) based on a CX. The DOE relied on prior NRC NEPA analysis in taking the position. This position was never challenged in court since the legal precedent was clear. DOE steadfastly defended this position in spite of congressional objection.

Finally, much is said about "controversy" as a justification for EIS levels of analysis. Its hard to imagine a more controversial shipping campaign than TMI core rubble. Its also hard to imagine something as beneficial as isotopes production being challenged for less than an EIS level of NEPA review.

CONCLUSION

A very high degree of safety has been achieved, both domestically and worldwide, through the rigorous implementation of comprehensive transportation and packaging regulations. There are no reported deaths or serious injuries due to the radioactive nature of the cargo. There are few, if any, such large scale industrial activities around the globe with this enviable safety record. Both DOE and NRC have exhaustively analyzed and demonstrated the intrinsic safety of transporting radioactive materials. This analysis coupled with its underlying (extremely) conservative assumptions, show a categorical exclusion is clearly warranted and will result in significant savings.

ABSTRACT
The remedial strategy for addressing contaminated environmental media was recently finalized for the U.S. Department of Energy's (DOE) Fernald Environmental Management Project (FEMP) following almost 10 years of detailed technical analysis. The FEMP represents one of the first major nuclear facilities to successfully complete the Remedial Investigation/Feasibility Study (RI/FS) phase of the environmental restoration process. A critical element of this success was the establishment of sensible cleanup levels for contaminated soil and groundwater both on and off the FEMP property. These cleanup levels were derived based upon a strict application of Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) regulations and guidance, coupled with positive input from the regulatory agencies and the local community regarding projected future land uses for the site. The approach for establishing the cleanup levels was based upon a Feasibility Study (FS) strategy that examined a bounding range of viable future land uses for the site. Within each land use, the cost and technical implications of a range of health-protective cleanup levels for the environmental media were analyzed. Technical considerations in deriving these cleanup levels included: direct exposure routes to viable human receptors; cross-media impacts to air, surface water, and groundwater; technical practicality of attaining the levels; volume of affected media; impact to sensitive environmental receptors or ecosystems; and cost. This paper will discuss the technical approach used to support the finalization of the cleanup levels for the site. The final

cleanup levels provide the last remaining significant piece to the puzzle of establishing a final site-wide remedial strategy for the FEMP, and positions the facility for the expedient completion of site-wide remedial activities.

INTRODUCTION

The Fernald Environmental Management Project (FEMP) is nearing the conclusion of the Remedial Investigation/Feasibility Study (RI/FS) process, with Records of Decision (RODs) for all five operable units at the facility due to be completed by July 1996. With the conclusion of the RI/FS process, the attention of the facility is now being directed to the safe and efficient implementation of remedial actions.

Operable Unit 5 at the FEMP represents all of the environmental media (soil, sediment and groundwater) that have been impacted by past uranium production operations and waste disposal practices at the site. A ROD was recently issued for Operable Unit 5, completing over 10 years of intensive environmental investigations into the conditions at the site. The ROD established final cleanup levels for all of the environmental media and defined a strategy for the permanent disposal of contaminated soil and sediment in an on-property engineered facility. This paper is focused on the approach applied to finalize cleanup levels for soil; however, the methods were similar for the other environmental media. These cleanup levels and the associated waste management approach provide the last component to a comprehensive site-wide remedial strategy for the FEMP.

The strategy for finalizing these cleanup levels involved a process of consensus building with local residents, the Ohio Environmental Protection Agency (OEPA), the U.S. States Environmental Protection Agency (EPA) and DOE, and in marrying the CERCLA decision process with the deliberations of a citizens task force formed to make recommendations on cleanup levels and final land use.

A key objective of the RI/FS decision-making process was to arrive at final cleanup levels that were protective to existing and future human and ecological receptors as well as cost effective and implementable. Characterization data collected during the RI phase of the study revealed that small changes (i.e., reductions) in cleanup levels for the principal contaminants of concern would yield large increases in projected soil excavation volumes. With these large increases in the volume of contaminated media requiring excavation, equally dramatic shifts in remedial costs were predicted. Thus, the stakes were high at the FEMP to arrive at cleanup levels for soil that satisfied stakeholder concerns regarding long-term protectiveness and were economically sensible.

BACKGROUND

The FEMP, formerly known as the Feed Materials Production Center, is a 1050-acre DOE facility located approximately 18 miles northwest of Cincinnati. The FEMP is situated in a rural setting near the village of Fernald, Ohio. The FEMP operated from 1952 until 1989 as a large-scale production facility extracting uranium from ores and ore concentrates to yield high-purity metal products in support of U.S. defense programs. During the 38-year production history of the facility over 500 million pounds of uranium metal products were shipped from the FEMP to other DOE sites across the country. In 1989, with a decline in product demand and increasing environmental concerns, production operations were permanently shut down. In August 1991 the site was officially declared closed and the facility renamed to reflect its new mission.

The topography of the area includes gently rolling uplands with steep hillsides along major streams, such as the Great Miami River. Surface drainage on the FEMP is from east to west and south into Paddys Run, with the exception of the northeast corner which drains east toward the Great Miami River. Groundwater beneath the FEMP is found in two principal geologic units: the glacial overburden (ranging in thickness between zero and 50 feet) and the sand and gravel of the Great Miami Aquifer. Groundwater occurring in the glacial overburden is considered "perched," in that it is contained within silty sand lenses residing within a low-permeability, clay-rich soil. The underlying Great Miami Aquifer is the principal drinking water supply for the region and is regulated as a sole-source aquifer under the Safe Drinking Water Act.

In December 1984 the release of approximately 200 pounds of uranium from a plant dust collector was reported to the National Response Center. This release notification focused nationwide attention on the environmental issues at the facility and produced increased oversight by the DOE, EPA and OEPA. Local residents at the site formed a watchdog group entitled the Fernald Residents for Environment, Safety and Health. The high public and political profile surrounding activities at the FEMP has remained relatively unchanged since this initial release in 1984.

The RI/FS process was initiated at the FEMP under a Federal Facility Compliance Agreement between EPA and the DOE. The work plan for the study, prepared by DOE in 1988, identified 39 site areas for investigation. To enhance implementation of the RI/FS, the 39 areas were grouped into five "operable units" by combining similar waste areas or related environmental concerns. The operable unit concept was incorporated into the April 1990 Consent Agreement between EPA and the DOE. The RI/FS and any required cleanup of specific operable units at the FEMP are guided by the Consent Agreement as amended in September 1991, and associated work plans. These documents provide procedures and schedules to ensure investigations are conducted in compliance with federal and state environmental laws. Due to confirmed contaminant releases to the environment identified during the initial stages of the RI, the FEMP was placed on the National Priorities List in November 1989. Operable Units 1-4 are termed "source" operable units and include the former production area and associated waste management areas that were the initial points of contaminant release to the environment. Operable Unit 5 addresses all environmental media on and off the FEMP property impacted by contaminants released from the facility. Each operable unit is being managed in accordance with the schedules set in the Amended Consent Agreement, with RODs for all operable units due to be completed by July 1996.

To foster community input into the decision process, the DOE chartered the Fernald Citizens Task Force. The Task Force, which is comprised of local government officials and residents, labor leaders, FEMP employees and community leaders, focused on making recommendations to decision makers on preferred cleanup levels, waste disposition strategies and future land uses for the FEMP property. Throughout the development of the Operable Unit 5 FS and the ROD, DOE has attempted to consider the evolving deliberations of the Task Force.

The RI identified widespread contamination of surface soil, sediment and groundwater both on and adjacent to the facility as a legacy of the 38-year production mission. The RI identified over 90 contaminants of concern in the various environmental media and uranium as the predominant

contaminant. The following is a brief discussion of the findings of the RI as it pertains to soil at the site. Additional information on soil contamination and the findings for other media are available within the Remedial Investigation Report for Operable Unit 5.

Contamination of surface and subsurface soils occurs within and beyond the FEMP property boundaries. The highest concentrations of uranium in surface soil were found in the former production area at the location of the scrap metal pile (greater than 8000 parts per million [ppm]). Contamination in subsurface soil appears limited to the FEMP property with levels of uranium, up to a hundred times background levels, found in soil at depths as great as 20 feet. Some of the highest subsurface contaminant levels (greater than 400 ppm of total uranium) were found near the former processing facilities where acidic uranium solutions were handled in large quantities.

Concentrations of approximately 20 ppm of uranium (about five times background) were identified in surface soil samples collected off property immediately adjacent to the eastern and northeastern boundary of the FEMP. Uranium was detected at above-background concentrations (generally less than two times background) in a widespread area off the FEMP property; up to 11 square miles of surface soil are projected to have been impacted at these low concentrations. The source of these low concentrations is emissions of dust particles to the atmosphere from plant stacks over the FEMP's 38-year production history.

Radium, thorium, fission and uranium activation products, and inorganic and organic contaminants were also observed in surface and subsurface soils on the FEMP property. The areas affected by these contaminants are localized, with the highest concentrations typically found in association with areas exhibiting the highest uranium concentrations.

TECHNICAL APPROACH TO ESTABLISHING CLEANUP LEVELS

As is the case at many Superfund sites, remediation at the FEMP requires the removal, treatment, and disposal of hazardous source-area materials and the cleanup of environmental media (soil and groundwater) contaminated by the migration of materials from the source areas. There is little dispute over the need to remove, treat, and/or dispose of the source materials themselves; likewise, there is little dispute over the need to restore the Great Miami Aquifer (a protected sole-source aquifer) to full beneficial use, including use as a drinking water supply. Rather, as noted by the Fernald Citizens Task Force in their deliberations, it is the cleanup of the contaminated soil that poses a difficult management problem because: 1) there are large volumes of contaminated material with associated high costs of cleanup; 2) the risk presented by contaminated soil is real but the harm is seldom imminent; 3) the technology for treating contaminated soil is often imperfect; and 4) the materials that are removed during cleanup must be disposed of somewhere and no place is eager to host them.

At the FEMP, the environmental cleanup question can be summarized as: how much contaminated soil must be removed from the site to make it acceptably safe for persons on or near it? The answer to this question is, in turn, driven by two considerations: protection of the groundwater aquifer under the site, and evaluation of risks to persons in contact with the surface soil.

In this section, the major steps in establishing safe, land-use specific, cost-effective cleanup levels for soil are described. From these levels, estimates of the volumes and areal extent of affected soil are derived

for a range of potential risk levels under consideration. The volumes and areas of affected soil serve as the foundation for the development and evaluation of remedial alternatives. They are used throughout the process to judge the viability of remedial technologies and process options, as well as to size and estimate the cost for specific remedial alternatives. To develop cleanup levels that ultimately would achieve regulatory agency concurrence, DOE employed a multistep process (summarized in Fig. 1) that began with the identification of a range of viable potential future land uses for the site, referred to in the FEMP's FS process as land use objectives. For each respective land use objective, the process began with the development of risk- and receptor-based preliminary remediation goals (PRGs) and ended with the identification of preliminary remediation levels (PRLs). PRLs differ from PRGs in their derivation in that PRLs consider the site-specific, naturally occurring background concentrations of the constituents. PRLs also consider analytical limits that affect the ability to detect the constituent in environmental media, and soil-based applicable or relevant and appropriate requirements (ARARs) and to be considered (TBC) criteria that establish maximum regulation-based concentration levels for the constituents in the environment. These PRLs are then used as the contaminant-specific remediation goals to develop and evaluate remedial alternatives for soil. The PRLs are adopted as legally binding final remediation levels for the selected remedy following public concurrence with the Proposed Plan and the issuance of a signed ROD by EPA and DOE. Each of the specific steps comprising this process is described in the subsections that follow.

Fig. 1

Definition of Land Use Objectives and Associated Receptor Scenarios

A range of potential future land uses was used as the foundation for the identification, initial screening, and detailed evaluation of viable remedial action alternatives. The same potential future uses also provided the framework for identifying risk-based exposure scenarios and the hypothetical reasonable maximally exposed (RME) individuals for which land use-specific remediation levels were established.

The land use objectives were developed to take into consideration the progressive deliberations of the Fernald Citizens Task Force. The prevailing land use of the region, residential farming, was used as the point of departure for establishing the following land use objectives:

Land Use Objective 1 examined the viability of returning the entire on-property area to full unrestricted use following cleanup, including the potential for establishing a hypothetical family farm on any portion of the property. For this and all of the other land use objectives, affected off-property areas were examined only in context of the existing land use in the region, residential farming. A hypothetical resident farmer was, therefore; used as the target receptor for both the on- and off-property affected areas. For this receptor, the exposure pathways considered in the setting of soil cleanup levels included: incidental ingestion; dermal contact; direct radiation; fruit and vegetable products; meat and milk products; inhalation of suspended solids; and leaching to groundwater.

Land Use Objective 2 provided for the establishment of an on-property, consolidated management area for contaminated soil, with unrestricted use of all remaining areas of the property. This land use objective considered the potential for establishing a hypothetical family farm, following cleanup, on any portion of the FEMP property outside the area where the contaminated materials are consolidated. A hypothetical

resident farmer was used as the target receptor for the on- and off-property areas outside the consolidation area. For the consolidation area, a hypothetical trespasser is used as the target receptor. For the trespasser receptor, the exposure pathways considered in the setting of soil cleanup levels include: incidental ingestion; dermal contact; direct radiation; and inhalation of suspended solids.

Land Use Objective 3 also provided for the consolidation of contaminated soil in a central area, but restricted potential uses of the remaining areas of the property through the application of institutional controls. This objective considered the potential for establishing recreational, commercial/industrial, or undeveloped open space on any portion of the FEMP property outside the area where the contaminated materials are consolidated. For the hypothetical receptors that represent these land uses, the exposure pathways considered in the setting of soil cleanup levels included: incidental ingestion; dermal contact; direct radiation; and inhalation of suspended solids. For the area of consolidation, a hypothetical trespasser receptor was used in a manner similar to Land Use Objective 2.

Land Use Objective 4 provided for minimum consolidation of contaminated soil with access and future use of the Fernald property restricted. This land use objective contemplated maintaining the entire 1050-acre property under restricted access for waste management purposes. For this land use, a hypothetical trespasser was used to guide the development of cleanup levels, similar to the use of this target receptor for the consolidation area designated in Land Use Objectives 2 and 3.

By using the land use objectives approach to formulate remedial action alternatives, decision-makers are provided with a comprehensive but manageable array of alternatives. From this array, decision-makers are provided with the required information from which to evaluate technical site constraints, required administrative controls, and the overall cost implications of moving from totally restricted to progressively less restricted land use possibilities.

Identification of Constituents of Concern

The Operable Unit 5 baseline risk assessment evaluated constituents of potential concern (CPCs) and exposure pathways to ascertain their present and potential future impacts on human health. Not all CPCs identified in the baseline risk assessment pose significant health risks, and many need not be considered in future remedial activities. Contaminants of concern (COCs) are those constituents that remain a concern following evaluation in the baseline risk assessment process. Only those contaminants identified as posing a concern at the site need to be considered in the development and evaluation of remedial alternatives. The purpose of restricting the number of COCs is to focus on the contaminants that require implementation of remedial actions to ensure the protection of human health and the environment.

The National Contingency Plan establishes a point of departure for acceptable risk as one in a million (10-6) for carcinogenic compounds, including radionuclides. The acceptable limit for noncarcinogenic effects is a hazard index (HI) of 1.0. A HI of greater than 1.0 is considered indicative of a potential toxic effect. However, because multiple contaminants are considered, the screening point for selection of COCs for the FEMP was set at an incremental lifetime cancer risk (ILCR) of 10-7 and an individual HI of 0.1 to the hypothetical on-property farmer to ensure no significant COCs were ignored. Any contaminant with a risk

level or HI less than this screening point is not considered further. For soil contaminants, this screening point considered both direct exposure to contaminated soil as well as the potential impact to groundwater through cross-media pathways.

Using this screening process, 89 soil-based COCs were identified at the FEMP site. Based on the site's uranium-processing history, uranium was found to be the primary COC with the remaining soil COCs generally falling within the concentration-based contamination envelope represented by uranium.

Risk-Based Preliminary Remediation Goals (PRGs)

For each of the COCs discussed in the previous subsection, land-use-scenario-specific PRGs were calculated for each target receptor, using a target HI of 0.2 for noncarcinogenic effects and/or the selected target risk for carcinogenic effects (ILCRs of 10-6, 10-5, and 10-4). The risk-based PRGs were calculated using the equations and parameters for all exposure pathways as detailed in the site's EPA-approved Risk Assessment Work Plan Addendum. The PRGs that are calculated through the process yield health-based contaminant concentration levels for surface contact-related exposure pathways that are protective at each of the target risk levels considered.

Screening of PRGs to Ensure Protection of Groundwater

For purposes of reducing the number of target risk levels and associated risk-based PRGs requiring consideration in the development of remedial alternatives, a screening process was adopted for affected soil. The premise behind this screening process was to determine the maximum uranium concentration that could reside within the soil and still ensure the continued protection of the Great Miami Aquifer (i.e., for a performance period of up to 1000 years into the future, as required by the federal Uranium Mill Tailings Radiation Control Act). For this screening process a cross-media protectiveness goal was adopted to ensure that groundwater concentrations of uranium resulting from the leaching of soil constituents to groundwater do not exceed drinking water quality requirements following completion of remedial actions.

Using a one-dimensional groundwater solute transport model (ECTran) and average hydrogeologic conditions at the site, a maximum soil total uranium concentration of 154 ppm was calculated as the upper-bound value above which undesirable groundwater impacts would be anticipated. This screening-level cross-media-based PRG (i.e., "CPRG") thus represents the upper limit from which to assess the protectiveness of the risk-based PRGs calculated in the previous step. All PRGs with a higher value than the screening-level CPRG would be dropped from further consideration.

To illustrate the results of risk-based PRG development and CPRG screening, the following Table I summarizes the risk-based soil PRGs for uranium for each of the receptor scenarios under consideration. The land-use specific, risk-based PRGs that fall in the shaded area of the table exceed the screening-level CPRG of 154 ppm, and thus would not be expected to be protective of groundwater at the FEMP site (and are therefore eliminated from further consideration).

Table I

Development of Cross-Media PRGs

Following the initial screening process, a more detailed, location-specific analysis was conducted to further evaluate the potential for cross-media impacts, including impacts to media other than groundwater. Cross-media impacts occur when contaminants from waste or an

environmental medium, such as soil, are transported into another medium and result in the potential for secondary exposure to a receptor. When this occurs, receptors can be exposed to these contaminants by an exposure pathway indirectly related to the contaminant source.

The PRGs that passed the groundwater CPRG screening in the previous step were evaluated further using location-specific modeling that considered actual (rather than average) hydrogeologic conditions present within 125- by 125- foot grids across the 1050-acre FEMP property. The detailed evaluation also considered the location-specific potential for contaminants to enter the air and surface water resources as well as groundwater. Reverse-modeling fate and transport simulations were used to ascertain the concentration in the source medium necessary to yield the critical concentration in the receptor medium over a 1000-year performance period.

The results of the simulations were used to further screen the risk-based PRGs to those that are fully protective through both direct contact and indirect (i.e., cross-media) exposure routes. To facilitate the development and presentation of PRGs for soil which could be implemented in the field as part of a remedial action, the mapping of the common physical attributes of the FEMP property discussed above were simplified into three zones, established on the basis of similarities in the hydrogeologic and geochemical characteristics of the soil. The most restrictive physical and geochemical conditions and the controlling transport pathway within each of the individual zones were applied to the entire zone for each individual COC. The derived CPRGs for each of these zones were then arrayed and the most restrictive value identified for each COC was considered. Finally, for uranium, the simulations also considered the varying leaching potentials of the several geochemical forms of uranium that exist in the FEMP environment. The limiting values derived from the evaluations were then used in the development of modified PRGs that fully consider cross-media impacts to groundwater, surface water, and air.

For uranium, the principal COC at the site, the results of the detailed CPRG evaluations indicated the need to further adjust downward the risk-based PRGs developed in the previous step. The simulations indicated that in those areas where more-leachable uranium species are present (primarily in the 135-acre former processing area at the site), a maximum allowable soil concentration of 20 ppm total uranium is necessary to fully protect the Great Miami Aquifer over the full duration of the 1000-year simulation period. In the remaining areas of the site where less-leachable uranium species are present, a maximum allowable soil concentration of 100 ppm total uranium is necessary to fully protect surface water resources in the site area, and ultimately to protect the aquifer from surface water infiltration. Therefore, the 20 ppm and 100 ppm CPRG values provide thresholds that the risk-based PRGs cannot exceed and remain protective of the aquifer.

Identification of Chemical-Specific ARARS and TBCs

CERCLA does not provide for one set of cleanup criteria for universal application to waste sites, but requires that sites attain, or seek a waiver of, federal and state environmental laws and regulations (i.e., ARAR), and meet the intentions of other pertinent considerations (TBCs). Therefore, in addition to meeting the risk-based remediation levels established for each land use objective, all the viable alternatives must satisfy ARARs specified in federal and state environmental laws and

regulations. Over 100 individual ARARs and TBCs were identified that affect the design and implementation of the cleanup at the FEMP. However, the primary ARARs for soil are:

State of Ohio siting criteria for solid waste disposal facilities

Resource Conservation and Recovery Act requirements for treatment of contaminated media and the design of engineered containment facilities

State of Ohio rules for control of particulate emissions and dust

Uranium Mill Tailings Radiation Control Act regulations regarding the management of materials at inactive uranium processing facilities.

Most of the identified requirements address the design and execution of the remedial alternatives, rather than specifying specific concentration-based cleanup levels for soil. The ARARs also govern the handling of residual materials that may be generated during treatment processes.

Establishment of Modified PRGs

Modified PRGs represent an intermediate product in the derivation of PRLs. They are established for each COC by comparing, for the land use scenario and risk level of interest, the risk-based PRGs with available ARARS/TBCs and the appropriate CPRGs, and then selecting the lowest of the values. At this juncture, the lowest value is termed a modified PRG and is carried forward to the next step.

Establishment of COC Background Levels

For each of the naturally occurring and anthropogenic COCs that are present at the FEMP, the 95th percentile of the background distribution of the COC in environmental media was determined through a statistical analysis of contaminant concentration data gathered as part of the Operable Unit 5 RI. These background concentrations were used in the development of PRLs primarily when the modified PRGs fell below the background concentrations.For uranium, the FEMP's key COC, a 95th percentile background concentration in soil of 3.7 ppm was established.

Analytical Detection Limit Considerations

The final element in the development of PRLs was the establishment of the lowest reasonable and achievable analytical detection limits for the 89 soil COCs. These detection limits were used in the PRL development process for those COCs with modified PRGs that fell below analytical detection limits. The detection thresholds were based on experience at the FEMP regarding actual instrument detection limits reported by subcontract laboratories for requested analyses at analytical support levels C and D. For soil, a 25 percent moisture content was assumed in the detection level development; for sediment, a 60 percent moisture content was assumed.

Development of PRLs

PRLs differ from modified PRGs in that PRLs consider the practicality of obtaining and verifying the attainment of a remediation goal. This differentiation is important to allow the development of cost-effective alternative remedial actions.

PRLs for nonradiological COCs were developed in a two-step process. First, all modified PRGs were reviewed against the routinely achievable analytical detection limits. For PRGs below this limit, the analytical detection limit was substituted as the PRL. Next, the modified PRGs were compared to background concentrations in the local environment. In the event the modified PRG was less than the 95th percentile of the background distribution for that constituent, the PRL was considered indistinguishable from background concentrations and the target PRL was set at the 95th percentile background value.

Based on EPA Region 5 policy, a slightly altered approach to developing PRLs for radiological constituents was adopted. First, the 95th percentile background concentration was added to the modified PRG. This value was then compared to the analytical detection limit and the higher of the two values was adopted as the PRL. In two instances background was not added to the modified PRGs for radiological COCs to derive PRLs: if the modified PRG was based directly on an ARAR/TBC or if the modified PRG was based upon a CPRG derived on the basis of attaining an ARAR/TBC in the aquifer.

Estimation of Excavation Area Footprints and Volumes of Contaminated Soil

In order to estimate the volume of contaminated soil at the FEMP site requiring excavation, a solid block model of the top 30 feet of soil was developed. The model consisted of a three-dimensional representation of the FEMP extending to a depth of 30.5 feet. The total model volume was divided into discrete volumes, or solid blocks. Subsurface blocks represented a volume of soil 125 feet by 125 feet by 1 foot deep. Surface soil blocks were 6-inches deep to support a more refined estimate of contaminated soil at shallower depths where contamination is more prevalent.

The solid block model was based upon the results of soil samples collected from various locations and depths across the FEMP site. These sampling results provided uranium concentrations only at the point from which the samples were collected. A geostatistical analysis technique known as kriging was used to establish contaminant concentrations between sampling locations at the center of each model block.

The kriging program employed an ellipsoidal search, using a distance of 16 feet in the vertical direction and 275 feet in the horizontal direction. In other words, when estimating the concentration of uranium within a block, the model searched 16 feet in the vertical direction and 275 feet in the horizontal direction for sampling points with which to establish a spatial relationship for calculation of the contaminant concentration within a block. If no sampling points were found within the search ellipsoid, no estimate of concentration was made for that block.

The resulting uranium concentrations from kriging the solid block model were used to estimate the soil volumes above the maximum contaminant level that require excavation. Furthermore, since the average concentration in each block was known, the excavated soil could be classified as to its ultimate disposition.

Proposed remediation areas (referred to as footprints) and volumes of affected media were estimated for those actions required to achieve each of the four land use objectives over a range of potentially viable PRLs. The PRLs considered under each of the land use objectives were developed to bound the range of potential cleanup levels deemed practical for the site. Volume estimates were performed for a total of nine cases.

A summary of the relationship between uranium soil concentration and affected soil volume is presented in Fig. 2.

Fig. 2

FORMATION AND EVALUATION OF REMEDIAL ALTERNATIVES

There were many remedial technologies and process options initially considered for the cleanup of each of the affected media at the FEMP site. Arraying these process options together produced in excess of 2000 remedial alternatives that could be applied at the site. Using the four land use objectives as a guide, 10 viable remedial alternatives were identified from the long list for further consideration in the initial

screening step of the FS. The alternatives were first compared with one another to identify meaningful differences and then evaluated with respect to implementability, effectiveness, and cost. Only the alternatives judged as most promising on the basis of these evaluation factors were retained for further consideration and analysis. The screening process resulted in the selection of seven remedial alternatives that were sufficiently distinct, yet potentially implementable and effective. Each of the seven alternatives, along with the no-action alternative, is listed below (the number accompanying the alternative corresponds to its land use objective):

No-Action Alternative This alternative was retained to provide a baseline for comparison in accordance with regulatory requirements.

Alternative 1 Excavation and Off-Site Shipment - Under this alternative, soil with contamination exceeding final remediation levels would be excavated and shipped to an off-site licensed disposal facility. Excavated areas would be regraded to reach a predetermined final surface grade that would allow for use of the property as a family farm. Two differing remediation levels were considered; the first case had as an objective the protection of future receptors (in this case a hypothetical on- and off-property farmer) at an ILCR of 10-6 and a HI of less than 1.0. The second case was designed to provide protection to these same receptors at a 10-5 level and a HI of less than 1.0. This alternative would result in the excavation and off-site disposal of 9.6 million cubic yards of soil (10-6 risk level) at a present worth cost of $4.2 billion, and 2.7 million cubic yards (10-5 risk level) at a present worth cost of $1.1 billion. At the 10-6 risk level, approximately 11 square miles of off-property farmland would be disturbed for remedial purposes, and approximately 1 square mile at the 10-5 risk level.

Alternative 2A Engineered Disposal Facility - Under this alternative, a consolidated waste management area would be established and the remaining areas of the property would be made available for unrestricted use. Contaminated soil exceeding final remediation levels would be excavated and placed in an engineered above-grade disposal facility. The facility would be situated in an on-property area displaying the best available geologic conditions. Contaminated soil not meeting waste acceptance criteria for the facility would be shipped to an off-site licensed disposal facility, unless a more economical technology emerged that was deemed more prudent to apply to this soil to attain the acceptance criteria. As in Alternative 1, two different remediation levels were considered for the area outside the disposal facility and for the off-property area: ILCR levels of 10-6 and 10-5 for a hypothetical on- or off-property farmer, and HI values less than 1.0. For all COCs, the waste acceptance criteria for the disposal facility were set at values that would protect neighboring populations and the drinking water quality of the Great Miami Aquifer for a performance period of up to 1000 years. This alternative would result in the excavation and disposal of 9.6 million cubic yards of soil (10-6 risk level) at a present worth cost of $2.1 billion, and 2.7 million cubic yards (10-5 risk level) at a present worth cost of $560 million. At the 10-6 risk level, approximately 11 square miles of off-property farmland would be disturbed for remedial purposes, and approximately 1 square mile at the 10-5 risk level.

Alternative 2C Consolidation with Off-Site Shipment - Under this alternative, contaminated soil exceeding remediation levels would be excavated and, depending on contaminant concentration levels,

dispositioned either in an on-property earthen-covered, revegetated consolidation area or at an off-site licensed disposal facility. Two risk and cleanup levels, consistent with the receptor scenarios of Alternative 2A, were evaluated for this alternative. The waste acceptance criteria for the consolidation area would be established to ensure protection of neighboring populations and the underlying Great Miami Aquifer, and the consolidation area would be managed as an off-limits area to the public. This alternative allows a direct comparison of the cost of off-site shipment to the cost of on-site disposal in an engineered disposal facility (Alternative 2A). This alternative would result in the excavation and disposal of 9.6 million cubic yards of soil (10-6 risk level) at a present worth cost of $4.2 billion, and 2.7 million cubic yards (10-5 risk level) at a present worth cost of $750 million. At the 10-6 risk level, approximately 11 square miles of off-property farmland would be disturbed for remedial purposes, and approximately 1 square mile at the 10-5 risk level.

Alternative 3A Engineered Disposal Facility - This alternative is identical in concept to Alternative 2A, except the area outside the disposal area footprint is made available for restricted (nonresidential and nonfarming) land use. The alternative considers use of the on-property area for commercial/industrial, developed park, and undeveloped park land uses, and a 10-6 risk level for these on-property, nonfarming land uses was used to guide the analysis of this alternative. For the off-property area, two risk levels were considered: an ILCR of 10-5 for the residential farmer (consistent with Alternatives 1, 2A, and 2C above) and an ILCR of 3.5 x 10-5 for the residential farmer, which corresponds to a HI set at its maximum permissible value of 1.0. This alternative would result in the excavation and disposal of soil ranging from 2.4 million cubic yards (industrial land use paired with a 10-5 ILCR for the off-property residential farmer) at a present worth cost of $530 million, to 1.8 million cubic yards (undeveloped park land use paired with a HI of 1.0 for the off-property residential farmer) at a present worth cost of $420 million. At the 10-5 risk level for the off-property area, approximately 1 square mile of farmland would be disturbed for remedial purposes, and approximately 1 acre or less would be disturbed at the HI=1.0 risk level.

Alternative 3C Consolidation with Off-Site Shipment - This alternative is identical in concept to Alternative 2C, except for the changes in land use and the receptor scenarios described for Alternative 3A. The same quantities of soil would require excavation as in Alternative 3A; however, the costs resulting from the need for off-site disposal in this alternative would range from $720 million (industrial land use example) to $610 million (undeveloped park land use example).

Alternative 4A Engineered Disposal Facility - This alternative is identical in concept to Alternative 2A, except the area outside the disposal area footprint is not made available for productive use following remediation; i.e., the entire 1050-acre site is rendered off-limits to the general public. For this alternative, a trespasser receptor scenario (at an ILCR of 10-6) is used to guide the development of cleanup levels. For the off-property area, the same risk levels for residential farming as described under Alternatives 3A and 3C were used. This alternative would result in the excavation and disposal of soil ranging from 2.2 million cubic yards (trespasser scenario paired with a 10-5 ILCR for the off-property residential farmer) at a present worth cost of $450

million, to 1.8 million cubic yards (trespasser scenario paired with a HI of 1.0 for the off-property residential farmer) at a present worth cost of $420 million.

Alternative 4C Consolidation with Off-Site Shipment - This alternative is identical in concept to Alternative 2C, except for the changes described above for Alternative 4A. The same quantities of soil would require excavation as in Alternative 4A; however, the costs resulting from the need for off-site disposal would range from $640 million (using a 10-5 ILCR for the off-property area) to $620 million (using a HI of 1.0 [3.5 x 10-5 ILCR] for the off-property area).

IDENTIFICATION OF LEADING ALTERNATIVE AND SITE-WIDE RISK ANALYSIS

Of the five operable units at the FEMP, Operable Unit 5 is chronologically the fourth to identify and issue a preferred remedy for the site. Each of the operable units is expected to provide a progressive evaluation of the projected site-wide remedy, using the best available information at the time, to predict the acceptability of post-remediation conditions. This projected site-wide remedy incorporates the selected (identified in a ROD), preferred (identified in a Proposed Plan), or leading remedial alternative for each operable unit, as appropriate. The intent of the analysis is to progressively monitor the interfaces among the operable units to ensure that the final site-wide remedy is well thought out, cost effective, and ensures the long-term protection of human health and the environment. The site-wide risk analysis that accompanies the evaluation, termed a Comprehensive Response Action Risk Evaluation (CRARE), also provides for a comprehensive assessment of the impact of multiple carcinogenic and noncarcinogenic compounds, multiple exposure pathways, and the incremental risks due to background levels of contaminants on human health. To conduct the risk analysis of the adopted site-wide remedy, a hypothetical undeveloped park user was the target on-property receptor.

The results of the risk analysis indicate that the adopted site-wide remedy would result in a 90.7 percent reduction in carcinogenic risk to an undeveloped park user of the Fernald property following remediation. Of the carcinogenic risk projected to remain following remedy implementation, 80 percent is due to the presence of naturally occurring background constituents. The estimated residual carcinogenic risk from all constituents and pathways, inclusive of natural background risk, is estimated to be 2.1 x 10-5 following remediation. Similarly, the risk analysis projects a 96.5 percent reduction in noncarcinogenic health effects (i.e., HI) for the undeveloped park user following implementation of the site-wide remedy. Naturally occurring background constituents will account for approximately 69 percent of this residual noncarcinogenic risk. The residual HI from all constituents and pathways, inclusive of natural background contributions, is estimated to be 0.059.

OVERVIEW OF THE SELECTED REMEDY AND CORRESPONDING CLEANUP LEVELS

In conjunction with the Fernald Citizens Task Force recommendations, DOE, EPA, and OEPA selected Alternative 3A, excavation of contaminated soil and placement in an engineered on-property engineered disposal facility, as the preferred remedy for contaminated soil at the FEMP site. This alternative was selected because it provides a remedy that is reliable over the long term, yields the lowest overall short- term risks, is less costly when compared to the other alternatives, and employs proven technologies which are implementable.

During the solicitation of community and stakeholder input for the remedy decision, it became clear that virtually no stakeholders or members of the public were interested in seeing the on-property area of the FEMP site returned to residential farming following remediation. From this basis, and on the recommendations of the Fernald Citizens Task Force, DOE, EPA, and OEPA collectively agreed to adopt Land Use Objective 3 (i.e., the restricted, nonfarming land use objective) for the setting of on-property cleanup levels. Individual constituent PRG values for the undeveloped park receptor were then set at an ILCR of 10-6 and a HI of 0.2, recognizing that at these target values other nonforming land uses (commercial, industrial, developed park, etc.,) would be possible for the site while meeting the corresponding land use-specific risk range targets (1 x 10-4 to 1x 10-6 ILCR and HI=1) considered acceptable by EPA in the National Contingency Plan. PRLs were therefore developed for the selected remedy from this PRG target risk level, using the sequence of steps outlined in this paper. As indicated by the CRARE evaluation, the individual constituent PRLs are fully health protective when considered collectively from a multiple constituent/multiple exposure pathway perspective. These PRLs also protect the Great Miami Aquifer from cross-media transport pathways.

For the affected off-property area, all parties agreed that a residential farming land use scenario should guide the selection of cleanup levels, as this is the predominant land use in the area. It was agreed that the cleanup levels should not exceed a 10-4 ILCR level or a HI of 1 for any site contaminant present outside the FEMP property boundary. Because uranium is considered to be the only site-related constituent in soil that resides outside the property boundary, the cleanup level was set at 50 ppm (inclusive of background), which corresponds to a HI of 1.0 and an ILCR of 3.5 x 10-5. The most striking consideration in selecting this level was the volume of soil that would require excavation beyond the FEMP property boundary if a 1x 10-6 residential scenario were chosen: a total of 5,200,000 cubic yards of soil would be removed and up to 11 square miles of farmland would be disturbed, with considerable loss of vital topsoil. The tradeoffs to achieve a 10-6 risk level were found by all parties to be disproportionate to the benefits achieved. A key ingredient to the stakeholders' understanding of the tradeoffs and benefits of the various cleanup levels under consideration was the highly successful public-forum deliberations and presentations conducted by the Fernald Citizens Task Force.

Summary of Key Accomplishments

The strategy for establishing health-protective soil cleanup levels, as outlined in this paper, has led to a cost-effective, environmentally sound approach to site remediation at the FEMP. Most notably, through the cross-media impact considerations adopted in this strategy, the site's top environmental priority -- the long-term protection of the Great Miami Aquifer -- will be realized, resulting in the unrestricted availability of groundwater from the aquifer for the foreseeable future following the cessation of remedial operations. Recognition and ultimate achievement of this priority remains absolutely critical to maintaining the outstanding public stakeholder support for the remedy that is currently enjoyed by the FEMP.

By shipping the most contaminated soil off site, and keeping the lightly-contaminated materials on site in an engineered disposal facility, the remedy represents a balanced, fair approach to site remediation. It is

estimated that this element of the remedy, in conjunction with the realistic cleanup levels that were selected, results in a cost savings of over $3.6 billion when compared to the cost impacts of adopting the most stringent cleanup levels (i.e., those corresponding to a 10-6 incremental lifetime cancer risk) and adopting a full offsite shipment and disposal alternative. The selected cleanup levels also eliminate the need for significant physical disturbance to off-property wetlands, habitats, cultural resources, natural vegetative communities and cultivated croplands. Over 11 square miles of off-property disturbance to such resources would be required to achieve a 10-6 incremental lifetime cancer risk, which in the view of the Fernald decision team represents only a marginal improvement in an already acceptable set of off-property risks that exist under current conditions. Removal of soil to the 10-6 level would remove tremendous quantities of topsoil from currently productive agricultural lands.

The soil cleanup levels that were established through the process are each individually health-protective, satisfy ARARs, consider the incremental health risks attributable to naturally occurring background concentration levels, and, when considered collectively through all exposure pathways, fall within the acceptable risk range required for CERCLA sites by EPA's National Contingency Plan regulations. By arriving at the selection of these levels in an open public forum, in concert with the deliberations of the Fernald Citizen's Task Force, citizen trust and understanding of DOE's top cleanup objectives and priorities was gained. DOE cannot be successful at Fernald or anywhere else for that matter without the continuing dialogue and understanding that was displayed among the various stakeholder groups during the Operable Unit 5 remedy selection process.

As the final chapter in the effort, the PRLs that were developed through the Operable Unit 5 FS became legally binding final remediation levels in January, 1996, when the ROD for Operable Unit 5 was signed. This ROD brought to completion the 10-year RI/FS process for addressing environmental impacts at the FEMP site, and set in motion a comprehensive remedial design and construction program to aggressively implement the successful remedy decisions reached collectively and cooperatively by the decision team.

STREAMLINED SITE CHARACTERIZATION APPROACH IN SUPPORT OF REMEDIATION OF U. S. NUCLEAR REGULATORY COMMISSION LICENSED FACILITIES

M. (Sam) Nalluswami
U.S. Nuclear Regulatory Commission
Low-Level Waste and Decommissioning Projects Branch
Division of Waste Management
Office of Nuclear Material Safety and Safeguards
Washington, DC 20555

ABSTRACT

Under the U.S. Nuclear Regulatory Commission's (NRC's) requirements for decommissioning, radiological and environmental characteristics provide the basis for preparation of an appropriate decommissioning (remediation) plan for decontamination and decommissioning (D&D). Because of reduced Federal resources, a proposed streamlined approach to review site characterization information has been adopted. NRC's 1992 "Action Plan,"

D&D process, and the streamlined site characterization approach are discussed and summarized.

INTRODUCTION AND PURPOSE

NRC's mission is to ensure adequate protection of the public health and safety, the common defense and security, and the environment in the civilian use of nuclear materials in the United States. The main purpose of site characterization and remediation is to achieve part of the objectives of NRC's mission (i.e., protection of the public health and safety and of the environment).

One way to achieve this purpose is to clean up and remediate (to meet the regulatory standards) the sites with radiological contamination before termination of license. Limited Federal resources are an important driving force in NRC's pursuing a streamlined approach for site characterization. The NRC staff presented this approach to the Commission, on May 19, 1995, and to NRC's Advisory Committee on Nuclear Waste (ACNW), on July 27, 1995. On September 28, 1995, the ACNW wrote to NRC's Chairman, identifying "...the initial definition of the scope and magnitude of the contamination problem..." as one of the two signal milestones in the decommissioning of a site (1). The NRC staff agrees that characterizing a contaminated site is one of the two critical milestones in the decommissioning process (2). Recently, NRC Chairman Dr. Shirley Ann Jackson stressed that, as we move into the 21st century, it is imperative that NRC perform decommissioning reviews (which include site characterization) with a cost-efficient and streamlined approach (3).

SITE CHARACTERIZATION IN NRC'S ACTION PLAN

On April 2, 1992, NRC published the "Action Plan" (4) to ensure timely remediation of sites listed in the Site Decommissioning Management Plan (SDMP). The main purpose of the "Action Plan" was to initiate actions to accelerate the cleanup of SDMP sites, with the overall objective of ensuring timely and effective cleanup.

The key elements of the "Action Plan" are:

1) Cleanup Criteria
2) Finality (NRC's decision to terminate a license will relieve the licensee from any further obligation, to NRC, to conduct additional cleanup, as long as the licensee decommissions the site in full accordance with an approved decommissioning plan.)
3) Timing
4) Site Characterization
5) Procedures to Compel Timely Cleanup

As indicated, Site Characterization is one of the key elements of the "Action Plan" pertaining to the SDMP program. NRC issued in July 1992, and then again in November 1994, the draft Branch Technical Position (BTP) on "Site Characterization for Decommissioning" (5). This BTP provides a detailed explanation of various issues connected with the characterization of a contaminated site. According to NRC's "Action Plan," some decommissioning actions have been delayed because of inadequate site characterization information.

DECONTAMINATION AND DECOMMISSIONING PROCESS

Site characterization, which leads to decontamination and decommissioning (D&D), is an important element of the D&D process. To protect the public health, safety, and the environment, D&D needs to be performed at sites with radiological contamination. NRC defines "decommission" in 10 CFR Parts 30, 40, and 70 as "...to remove (a facility) safely from service

and reduce residual radioactivity to a level that permits release of the property for unrestricted use and termination of license" (see 10 CFR 30.4, 40.4, and 70.4).

The D&D planning process starts as a preplanned activity at the cessation of the operation of a facility or at the moment of discovery of a contaminated site. Typically, the following steps or a combination, including site characterization, may be involved in the general D&D process:

Cessation of operation or discovery of contamination (usually by the licensee or by NRC inspectors)

Assessment of radiological status of the site (by the licensee)

Performance of scoping survey (by the licensee)

Determination of necessity for decommissioning (by comparing scoping survey results with guideline values) (by the licensee)

Preparation of site characterization plan (usually including sampling and analysis plan, radiological control plan, health and safety plan, and quality assurance and quality control program) (by the licensee)

Performance of site characterization (including sampling and analysis) (by the licensee)

Preparation of site characterization report (with emphasis on radiological and environmental characteristics, and including sample results) (by the licensee)

Preparation of the decommissioning plan and, sometimes, an environmental report (by the licensee)

Performance of D&D (remediation) (by the licensee)

Performance of the final termination survey and preparation of a final survey report (by the licensee)

Performance of the confirmatory survey and preparation of a confirmatory survey report (by NRC)

Termination of the license and release of the site (by NRC)

In understanding the appropriateness of site characterization in the D&D process, it is important to look into the background information leading to characterization. Contamination might occur inadvertently, accidentally, or because of normal operating processes. Based on the definition and criteria for decommissioning, the licensee or site owner prepares an assessment of the radiological status of the site either at the cessation of operations or at the time of discovery of contamination. The next step is the performance of a scoping survey to provide the basis for initial estimates of the level of effort required for planning the characterization survey and for decommissioning. This typically consists of limited direct measurements (6) (exposure rates and surface activity levels) and samples (smears, soil, water, and material with induced activity) obtained from site locations. The scoping survey provides a preliminary assessment of site conditions or preliminary characterization, relative to guideline values.

Figure 1 shows the general decommissioning process (7).If remediation is required -- based on the scoping survey results and preliminary characterization -- then comprehensive site characterization information is essential for preparing a decommissioning plan. As an example, for "Source Material" licenses, the following rule applies in preparing a decommissioning plan that includes site characterization data:

Section 40.42 (f)(4)(i) - "A description of the conditions of the site or separate building or outdoor area sufficient to evaluate the acceptability of the (decommissioning) plan."

Similar rules are applicable for "byproduct material," under 10 CFR 30.36; for "production and utilization facilities," under 10 CFR 50.82; for "special nuclear material," under 10 CFR 70.38; and for "spent fuel and high level wastes," under 10 CFR 72.54.

SITE CHARACTERIZATION

Under the NRC's requirements for decommissioning, radiological and environmental characteristics of a site provide the background information and basis for the preparation of an appropriate decommissioning plan. The questions to be asked, based on the site characterization information, are: 1) What is the effect of leaving the contamination as it is on the site (no action)? 2) What remediation alternatives for unrestricted use or restricted use levels are acceptable?

To perform efficient and economical D&D, it is important to evaluate the radiological and environmental characteristics of a site. Further steps in the D&D process depend on the reliability and accuracy of the site characterization data. Characterization is the measurement or sampling and analysis required to gather needed information, usually about the type and quantity of contaminants present in or on a material (8). The purpose of site characterization is to determine, on a site-wide basis, the extent, amount, type, and nature of radiological contamination of: 1) surface and subsurface soils (geologic); 2) surface and ground waters (hydrologic); and 3) buildings and equipment. In addition, if decommissioning includes stabilization onsite of residual radioactivity, another key objective of site characterization is to establish the environmental characteristics of the site sufficiently to assess the long-term fate of the residual radioactivity.

Some licensees and site owners, under the SDMP program, made limited or no progress on site characterization (7). Under previous procedures and policies, NRC staff typically had reviewed site characterization plans and site characterization reports to ensure that licensees had established the extent and type of radiological contamination before developing decommissioning plans (7). In November 1992 and November 1994, NRC conducted public workshops, on the SDMP program, that emphasized the importance of site characterization in successful decommissioning. The final rule on "Timeliness in Decommissioning of Materials Facilities" (59 FR 36026) added a requirement to submit characterization data with the decommissioning plan. This approach implements the "Timeliness Rule," thereby increasing reviewer and licensee efficiency. NRC has clearly established and communicated its expectations, both to the licensees and to other responsible parties, regarding site characterization in support of decommissioning.

Previously, various steps were performed sequentially or in series as shown in Fig. 1. This was to ensure that licensees had established the extent and type(s) of radiological contamination before initiating decommissioning (remediation). In typical cases, NRC staff invested approximately one-half to a full person-month of effort (spread out over several months) in reviewing each site characterization plan and report (8). Figure 2 shows the iterative process used in the conceptual flow diagram of the SDMP site characterization (5). Figure 3 shows a general site characterization procedure.

Based on experience to date in reviewing site characterization plans and reports, and in response to reduced Federal resources, the NRC staff developed a streamlined approach for reviewing site characterization

plans and reports (7). The previous approaches had been costly and had resulted in delaying decommissioning. The NRC staff has changed the procedures by not reviewing site characterization information until reviewing the decommissioning plan. The decommissioning plan is required by the rules promulgated in the Code of Federal Regulations, Title 10. It is sufficient to submit the characterization data along with the decommissioning plan, instead of separately submitting the characterization plan and report before submitting the decommissioning plan. This streamlined approach promotes a more coordinated and focused review of site characterization information, because the reviewers will be compelled to emphasize issues that affect the selection and implementation of a decommissioning approach. This alternative is consistent with NRC regulations, which require characterization data to be submitted with the decommissioning plan (7).

Fig. 1

Fig. 2

Fig. 3

The revised approach should promote parallel resolution of characterization and decommissioning issues that, in many cases, are interdependent. However, delaying the review of characterization data may result in later identification of significant information gaps. NRC will partially compensate for this risk by increasing routine contact with licensees through site visits and meetings, and by paying heightened attention to licensees and responsible parties that have lower levels of performance or complex site characterization issues. Resources thus conserved will then be focused on those sites needing increased staff attention, or on other NRC priorities.

NRC staff discussed these changes with such representatives of industry as the Nuclear Energy Institute (NEI) and the Fuel Cycle Facilities Forum (FCFF) (9). NRC staff agreed with NEI and FCFF that there should be early communication of site characterization plans and issues, to minimize the potential for significant data gaps later in the D&D process.

Implementation of this streamlined approach will reduce the expenditure of NRC resources. In some cases, this approach may delay decommissioning, and increase resource expenditure by the licensee or responsible party. For example, if significant data gaps in the characterization data are identified during the review of the decommissioning plan, additional characterization may take more time and resources, because of remobilization of personnel and equipment, to conduct the investigation. Although, in many cases, NRC is no longer going to review site characterization plans, licensees will still benefit from developing such plans for their own uses. A site characterization plan needs to address the nature and locations of: 1) previous operations involving use of radioactive materials; 2) effluent release points; and 3) buildings and equipment used in the operations. In addition, a site characterization plan should focus on the subsurface environment, with emphasis on groundwater impacts, in those situations where loose radioactive materials may be buried or released into the subsurface.

It is the responsibility of the licensee or responsible party to ensure that adequate expertise and resources are devoted to characterization planning and performance. The NRC staff will work closely with the licensees or responsible parties to ensure that they are aware of existing guidance, and to provide timely informal comments to identify significant data gaps (7).

The ultimate purpose and use of the site characterization information is to develop an appropriate decommissioning plan for the site. According to the "Wall Street Journal" dated April 4, 1995 (10), and the weekly report, "Inside E.P.A." (11), just cleaning up the nation's contaminated former nuclear-weapons facilities will cost $230 billion and will take 75 years. In addition, there are non-nuclear-weapon-related sites with radiological contamination. The draft BTP (5) emphasizes the importance of obtaining accurate and relevant characterization data for a site, to save time and money.

Key elements to be considered in a comprehensive site characterization program are (8):

1) Review historical information.
2) Define characterization objectives.
3) Prepare a sampling and analysis plan to meet objectives
4) Conduct sampling and measurement.
5) Review, analyze, and verify data.

The above elements need not be all-inclusive and serve as general guidelines. Site-specific modifications may be required.

NRC, U.S. Environmental Protection Agency, U.S. Department of Energy, and U.S. Department of Defence are developing a "Multi-Agency Radiation Survey and Site Investigation Manual," (MARSSIM) (12), which contains a section on characterization surveys.

Reducing the effort, time, and resources needed to acquire characterization information, while still ensuring adequacy, is the principle behind NRC's proposed streamlined approach. NRC staff will provide sufficient regulatory guidance for the licensees to understand the requirements of the criteria and rules.

CONCLUSIONS

Under NRC's requirements for decommissioning, radiological and environmental characteristics provide the basis for preparation of an appropriate remediation plan.

Based on experience to date in reviewing site characterization plans and reports, and in response to reduced Federal resources, the NRC staff has developed a streamlined approach for reviewing site characterization plans and reports. The streamlined approach to site characterization identifies all contaminated areas and safety hazards, provides information needed to evaluate the most cost-effective remediation options, reduces the risk of having to re-remediate contaminated areas, and minimizes the overall remediation cost. The purpose of the streamlined approach to site characterization is to determine, on a site-wide basis, the extent and type of radiological or chemical contamination. The ultimate purpose and use of the site characterization information are to prepare an appropriate environmental remediation plan for the site, so as to reduce residual radioactivity to a level that allows release of the property for unrestricted or restricted use. Previous approaches have been costly and have resulted in delaying decommissioning. The staff plans to review site characterization information in conjunction with the decommissioning plan. This approach should promote parallel resolution of characterization and decommissioning issues that, in many cases, are interdependent. NRC hopes that this change in approach will highlight issues that affect the selection and implementation of a decommissioning process. However, this approach may result in later identification of significant data gaps. There should be early and constant communication with licensees about

site characterization plans and issues, to minimize the potential for significant data gaps later in the decommissioning process.

SUCCESSFUL COMPLETION OF A RCRA CLOSURE FOR THE FERNALD ENVIRONMENTAL MANAGEMENT PROJECT

John M. Lippitt
Ken Kolthoff
Fernald Environmental Management Project
P.O. Box 538704
Cincinnati, OH 45253-8704

ABSTRACT

This paper discusses the successful completion of a RCRA (Resource Conservation and Recovery Act) closure of a hydrofluoric acid (HF) Tank Car at the Fernald Environmental Management Project (FEMP). The FEMP is a facility owned by the Department of Energy (DOE) that is on the National

Priorities List of hazardous waste sites and is undergoing CERCLA (Comprehensive Response, Liability Act) remediation. The FEMP is also subject to closure under RCRA and Ohio Hazardous Waste rules. The HF Tank Car Closure was conducted by the Fernald Environmental Management Corporation (FERMCO), the contractor responsible for FEMP facility clean up and closure. Through a combination of sound planning and team work, the HF Tank Car was closed safely and ahead of schedule. During over 22,000 hours of field work required for construction modifications and neutralization of some 9,600 gallons of HF and decontamination rinseates, there were no OSHA recordable incidents. The system design avoided additional costs for constructing a new system and subsequent dismantling for disposal or reuse at another facility by maximizing the use of existing equipment and facilities. The successful closure of the HF Tank Car demonstrated the FEMP's commitment to reducing risks and cleaning up the facility in a manner consistent with objectives of RCRA regulations and the Ohio Environmental Protection Agency (EPA) Hazardous Waste Rules. This in turn, facilitated ongoing negotiations with the Ohio EPA to integrate RCRA closure and the ongoing CERCLA remediation activities. This paper addresses why the unit was clean closed under an approved RCRA Closure Plan. The integration of the EPA regulations for RCRA and CERCLA programs and the DOE-Orders impacting design, construction and operation of an acid neutralization system is also reviewed. The paper concludes with a discussion of lessons learned in the process of preparing the closure plan and through final project close out.

INTRODUCTION

FEMP facility clean up and closure actions must be responsive to existing enforcement actions by both the USEPA and Ohio EPA. In July of 1986, the DOE entered into a Federal Facility Compliance Agreement and initiated a preliminary Remedial Investigation and Feasibility Study. In March of 1986, the Ohio EPA filed a complaint against the DOE which ultimately lead to in a Consent Decree signed in December 1988 by DOE and the Ohio EPA. Because there are no tri-party agreements between USEPA, Ohio EPA and DOE, enforcement actions and responses have been separate and independent and the FEMP has conducted dual compliance programs. The challenge facing the DOE and FERMCO (contracted by DOE in 1993 to oversee site remediation) is to establish an approach to site remediation that integrates RCRA facility closure requirements and the CERCLA requirements for remediation of all contamination.

The success of the HF Tank Car Closure project illustrates how a project team can coordinate and integrate multiple support organizations and regulatory requirements to ensure safe, effective and timely remediation. To achieve successful completion of the project, the project team coordinated engineering, construction and operation activities with support services from multiple organizations (e.g., radiation control, safety and health, quality assurance, and etc.). The closure actions were planned and implemented in a manner that integrated the multiple requirements of DOE Orders and USEPA, OSHA, and Ohio EPA rules and regulations.

OVERVIEW OF THE HF TANK CAR CLOSURE PROJECT

The subject of this paper is the completion of RCRA clean closure of the HF Tank Car. The HF Tank Car was a circa 1940 rubber-lined steel rail car containing an estimated 5,000 gallons of 30 percent hydrofluoric acid (HF). Preliminary evaluation of the HF Tank Car determined that the age of the tank car and the highly corrosive nature of HF posed a significant

threat for release. Although the car was apparently in good condition, the age of the car was a cause for concern. Had the rubber liner failed the HF would have readily corroded through the steel tank car and been released to the environment.

HF is highly corrosive to steel and human tissue and is most corrosive at approximately 35 percent concentration. HF is also toxic, even at relatively low concentrations due to the affinity of free fluoride ions to calcium. Upon exposure to HF, workers experience extreme burning sensation in the eyes and respiratory system. However, the full effect on exposure to the skin, particularly at lower concentrations is often not felt for several hours because it is readily absorbed and migrates toward the calcium rich bones in the body. In the process, significant subcutaneous tissue damage can occur, causing gangrene in severe cases. When HF enters the body it also causes an electrolyte imbalance by removing calcium from the blood which can lead to cardiovascular difficulties.

The FEMP elected to remediate and clean close the HF Tank Car under a RCRA Closure Plan because extensive media contamination was not considered likely. The Ohio EPA had also identified the HF Tank Car as a high priority due to concerns for possible release. By completing clean closure under an approved closure plan, the FEMP increased their credibility with the Ohio EPA concerning RCRA closures which should facilitate ongoing negotiations for RCRA\CERCLA integration.

The original closure plan for the HF Tank Car was submitted in May of 1992. Implementation of closure actions were delayed by repeated cycles of Ohio EPA reviews and submittal of revised closure plans addressing Ohio EPA comments. Historically the FEMP had been reluctant to initiate closure actions prior to Ohio EPA approval. In addition, progress was hindered because the groups responsible for writing plans were not responsible for implementing actions. This created confusion and poor coordination of activities.

In February 1994, FERMCO established an integrated project team with a designated project manager and key contacts from various support organizations and DOE site representatives. The function of the project team was to coordinate, plan and schedule the field work for construction (prior to formal approval of the closure plan), and integrate the various regulatory requirements and FERMCO policies and procedures. The resolution of the final Ohio EPA comments required completion of the bench-scale testing and development of the conceptual design (see discussions below). As a result, the final approval of the Closure Plan was not received until July 1994. The proactive approach of the project team made it possible to complete the HF Tank Car closure within the required 180 days after approval.

Key to Success: Involve and integrate support and performing organizations, including DOE, into a project team focused on how to get work done.

The project team identified and worked through the following seven major project phases.

Phase 1 - Bench-Scale Testing

The first stage was to characterize the acid in the HF Tank Car and evaluate treatment options. Samples of the HF were collected and assayed to confirm the basic chemical properties and characteristics of the solution. Four treatment options were identified and evaluated based on health, safety, technical, and feasibility considerations. Lime slurry

neutralization was selected for further testing and evaluation. A Bench-Scale Test Plan was developed to evaluate and confirm the feasibility of lime slurry neutralization, identify process limits, characterize treated waste streams, and provide data to support the design of a full-scale treatment system. The results confirmed that the best results were obtained by adding HF at a controlled rate to a prepared, agitated neutralization slurry consisting of 10 weight% solid using a mixture of 30% calcium carbonate and 70% lime. In addition, analysis of the resulting neutralized solids and liquid wastes indicated they would no longer be RCRA hazardous. Table I lists the physical and chemical properties of the reagents and neutralization products determined by the bench-scale tests.

Key to Success: Stopped making assumptions and collected hard data to characterize waste for treatability and provide data for system design.

Phase 2 - Conceptual System Design

After confirming that lime slurry neutralization was feasible, three alternatives for neutralization and filtration were identified and evaluated for implementability, time required to implement, regulatory and site limitations, and qualitative cost impacts. Each criteria was assigned a relative ranking between a low of 1 and high of 3 and a cumulative score was calculated. The evaluation and selection of alternatives were reviewed and discussed by the project team. This process allowed early identification of interface and coordination issues (e.g., quality assurance issues and interface requirements between the project and FEMP site facilities). In addition, a preliminary hazard analysis was conducted and recommended safety controls were identified for inclusion into the detailed design.

The alternative selected required new pumps, piping and controls to allow use of an existing 1,400 gallon existing tank equipped with solids feeder unit. The existing tank, located within the same general area as the HF Tank Car, had been installed for HF neutralization but had never been used. The neutralized slurry was to be transferred using portable tanks to an existing on-site operation (referenced as Plant 8) for filtration across a rotating vacuum filter drum. The filtered solids would be collected, drummed and sampled at Plant 8, to determine\confirm disposal requirements, and the filtrate would be collected, tested and discharged to the FEMP wastewater treatment system. The conceptual system design avoided additional costs for constructing a new system and subsequent dismantling for disposal or reuse at another facility by maximizing the use of existing equipment and facilities. Figure 1 is the conceptual process flow schematic.

After the conceptual design and functional design requirements were identified, a Conceptual System Implementation Plan (CSIP) for HF Tank Car Closure was prepared and submitted to DOE. The purpose of the document was to provide an integrated discussion of planning, testing and design activities to support the closure of the HF Tank Car. The CSIP was also used to evaluate and document compliance with Ohio EPA regulations, DOE Orders and FEMP policies and procedures.

Key to Success: Integrate preliminary hazard assessment and safety concerns into conceptual design and functional design requirements.

Table I

Phase 3 - Detailed System Design

The detailed system design defined requirements and specifications necessary for construction and use of the HF neutralization system.

Detailed design included specifications and drawings for the modifications necessary to provide a metering pump, water supply piping and batch controller, piping and valves to transfer HF from the tank car to the neutralization tank, piping and valves to transfer neutralized slurry to portable tanks for transport to the Plant 8 for filtration, and minor modification to the portable tanks to provide agitation and hose connections for neutralized slurry loading and unloading. The final design provided additional process control instruments, with interlocks to the HF transfer pump power, to stop HF addition if the temperature, pH, level, or pressure exceeded process design limitations.
Fig. 1
Design reviews were performed by the project team for the initial and final design packages. An independent review was performed on the final design package. After resolving all comments, a final Certified-for-Construction (CFC) Design package was issued. After CFC, all drawings and specifications were controlled and could only be changed through a formal design change procedure.
After CFC and before major construction activities began, a secondary design review was conducted and a revised CFC package was issued. This design review was conducted to ensure consistency with recent changes to the FERMCO engineering procedures and to ensure that design problems that had been recently encountered on another similar FEMP project were not repeated.
Phase 4 - Construction and System Testing
Construction activities were conducted in accordance with the CFC drawings. Configuration Management was maintained to document construction and confirm design requirements were not compromised. Based on the Safety Assessment, a high level of documentation and quality assurance was required. Test plans for construction acceptance testing and system operability testing were prepared and implemented to confirm that the system was constructed and operated in accordance with the design. Although more problems than expected were encountered in servicing existing equipment and instrumentation, construction and testing was completed without incident.
Key to Success: Proper configuration control precludes making field changes inconsistent with the design and operating requirements.
Phase 5 - Operating Procedures and Operator Training
In order to complete the HF Tank Car closure within the required 180 day regulatory limit, it was not possible to wait until the system construction was completed before preparing the operating procedures and initiating operator training. To compensate, the procedures were initially developed based on the engineering specifications and drawings. A selected working group of project team members conducted a series of joint table top reviews. The operator training was set up in modules designed to maximize the ability to defer training on system components until the construction was completed and a field walk through could be conducted. As part of their training, the operators were tasked to walk through and verify the procedures in the field. They were encouraged to provide comment for improvement of the procedures. When construction was completed, the final procedures were completed and incorporated many of the operators comments. The final procedures were reviewed with the operators and a final field walk through was conducted. The operations manager then qualified each operator by oral exam and field simulation. In addition, the operators were involved in the conduct of the final

system operability testing to increase their understanding of how the system functioned. Because of their involvement in the development of procedures and testing of the system, operator acceptance of the procedures and performance during operations were noticeably above average.

Key to Success: Enhancement of operator acceptance and performance through their involvement in developing procedures and testing and evaluating system operations.

Phase 6 - Operation and Processing

The neutralization of acid and decontamination rinseate was initiated on June 12, 1995 and completed on July 21, 1995. Within days of the system start up, operations personnel identified opportunities for improvement which decreased the time required for slurry preparation. The 9,600 gallons of acid and rinseate neutralized included 1,082 gallons more HF and 2,712 more rinseate than originally estimated. Despite the increased volumes, expedited processing was achieved and neutralization was completed 3 weeks ahead of schedule.

On at least 3 occasions, potential problems were identified and averted by Operations personnel based on system walk downs and inspections prior to initiating HF transfer (as required by the Operation's Standing Orders prepared to comply with DOE Conduct of Operations).

Phase 7 - Project Close Out

There were two main elements for project close out. First, completion of all field work including the utility isolation and shut down of the HF neutralization system, dismantling and staging the decontaminated rail cars, release of the portable tank for other uses in support of site remediation, and staging drummed filter solids for shipment to the DOE Nevada Test Site (NTS) disposal facility. Second, documentation of work completion including certification by an independent, qualified, registered engineer to complete RCRA closure requirements; compilation of final costs, including, final accruals for all labor, subcontractors and materials charges, identify those documents (e.g., standing orders for operation, operating procedures, health and safety plans, and etc.) that are inactive and not applicable to ongoing work, and closure of associated charge numbers.

All processing of HF and decontamination rinse waters were completed by the end of August. The activities for facility isolation and shut down, dismantling of the rail cars, staging of the dismantled rail cars components for a future project to complete recycling or disposal, characterization and staging of drummed filter solids pending shipment to NTS, and release of the decontaminated portable tank for on-site use were completed before the end of September (i.e., within the 1995 Fiscal Year). The RCRA certification report was submitted October 3, 1995. The Ohio EPA issued approval of the closure certification report on November 27, 1996 and closure of applicable charge numbers and site documents have been completed.

SUMMARY AND CONCLUSIONS

The highlighted keys to the HF Tank Car Project success are applicable to most any project and illustrate ways to improve project performance. In summary:

A team approach improves the ability to identify, schedule and address tasks and issues before they become obstacles and cause delays. Keep a focus on the work to be done.

Don't make assumptions, characterize waste for treatability not just for hazardous waste determinations.

Define and verify process chemistry and operational requirements to be addressed in design of treatment system.

Integrate safety requirements into system design, as early as possible.

Once the design has been certified-for-construction, configuration management is essential. Without a detailed understanding of how the design components interact, minor changes can have major impacts.

Involvement of operating personnel in the process of developing procedures and systems testing enhances operator acceptance and performance.

The establishment of a project team focused on how to get the work done represented a fundamental change in approach. Focusing on planning and design based on technical requirements to implement the work is critical. It is all too easy to fall into the trap of trying to design work to fit EPA regulations or DOE Orders. Regulations and orders define what you need to do, not how. Limited progress was made on HF Tank Car project between May 1992 and February 1994. However, once the project team focused on determining the technical requirements the project began to move forward. The most direct indicators of the effectiveness of the project team were the safety record and expedited processing of HF. Without compromising safety, the neutralization of HF and decontamination rinseates was completed 3 weeks ahead of schedule and included processing 1,082 gallons more HF and 2,712 gallons more rinseate than scheduled. There were no OSHA reportable incidents during the 22,000 hours of field work required for construction modifications and neutralization of the 9,600 gallons of HF and decontamination rinseates.

LACK OF CONSISTENCY IN STATE RCRA PROGRAMS: A THREAT TO REGULATORY REFORM AFFECTING DOE

Judith Weintraub
Lisa Matis
Brown & Root Environmental

ABSTRACT

The Resource Conservation and Recovery Act (RCRA) regulatory reform process is threatened by the failure of the Environmental Protection Agency (EPA), States, and the regulated community to address the contradiction between:

the requirement that RCRA regulations in authorized State programs be consistent with the Federal program and other authorized State programs, and

the prerogative of States to promulgate RCRA regulations that are more stringent and broader in scope than the Federal RCRA regulations. Assigning primacy to stringency, which has been EPA's practice in recent RCRA rules containing regulatory reform elements, appears to ignore the legislative history of RCRA, EPA's own regulations, and relevant court decisions. Failure to address this problem jeopardizes the possibility that certain forms of the Department of Energy's mixed waste may qualify for disposal at radioactive waste disposal facilities.

As a first step, this paper recommends that the contradiction between consistency and stringency be addressed in regulatory preambles and other appropriate forums. If the contradiction is not addressed, RCRA's

ultimate goal, protection of human health and the environment, may be compromised.

LEGISLATIVE BACKGROUND

The Resource Conservation and Recovery Act (RCRA), like other environmental laws, authorizes States to administer their own programs under the statute. Under section 3006(b) of Subtitle C of RCRA (42 U.S.C. 6926), Authorized State Hazardous Waste Programs, State hazardous waste programs must be:

equivalent to the Federal program,

consistent with the Federal program and with State programs applicable in other States, and

amenable to adequate enforcement of compliance.

State programs that fail to exhibit these attributes cannot be authorized. Once authorized, a State program can be withdrawn if it is not administered and enforced in accordance with RCRA Section 3006 requirements.

These provisions of section 3006 date from the original RCRA legislation, Public Law 94-580, passed in the House and Senate in September of 1976. The legislative history of the Act shows that the purposes of the Federal/State partnership were to:

provide uniformity among the States as to how hazardous wastes are regulated,

prevent some States from becoming the dumping ground for hazardous wastes, and

utilize State enforcement personnel to implement the provisions of the Act. (1)

Section 3009 of Subtitle C of RCRA (42 U.S.C. 6929), Retention of State Authority, originally provided that after the Federal RCRA program becomes effective, no State may administer a program less stringent than the Federal program. Neither the statutory language nor the legislative history addressed the question of whether more stringent State requirements were preempted by Section 3006.

Section 3009 was amended in 1980 by Public Law 96-482, which added the following sentence.

> Nothing in this title shall be construed to prohibit any State or political subdivision thereof from imposing any requirements, including those for site selection, which are more stringent than those imposed by such regulations. (1)

The amendment was introduced by Senator Bumpers of Arkansas, whose speech supporting the amendment on the Senate floor referred to:

the incident at Love Canal,

Government Accounting Office (GAO) findings that the hazardous waste regulatory program could not adequately safeguard public health and the environment,

Environmental Protection Agency (EPA) estimates of a 4 to 6 percent annual increase in the amount of hazardous waste being generated,

EPA projections of the siting of increased numbers of commercial hazardous waste treatment and disposal facilities, and

the possible location of a hazardous waste disposal site near a small community in his home state (1).

At the time, there was no discussion or recognition of the possible contradiction between requiring State programs to be consistent with the Federal program and allowing them to be more stringent. Consequently, the Act did not confer primacy on either consistency or stringency.

In the House debate preceding the passage of the Hazardous and Solid Waste Amendments (HSWA) of 1984, the meaning of equivalence was discussed. Congressman Florio of New Jersey explained that equivalence did not mean point-by-point equivalence.

State requirements should be equivalent in overall effect to the Federal program, without the necessity of showing point-by-point equivalence. (1)

In addition, he stressed the importance of bringing State hazardous waste experience to bear in the RCRA Subtitle C program, instead of removing this experience from consideration, and noted that several of the most important RCRA amendments being considered by Congress originated in State programs (i.e., the land disposal restrictions and the regulation of small quantity generators). (1)

Congress believed that it was important for the changes contained in HSWA to take effect as soon as possible. Consequently, section 3006(g) was added to the law to provide that EPA regulations promulgated pursuant to these amendments take effect in authorized State programs on the same date that such requirements take effect in other States. (1)

REGULATORY BACKGROUND

Since 1981, EPA regulations implementing sections 3006 and 3009 of RCRA have addressed the potential contradiction between stringency and consistency by clearly assigning primacy to consistency. To obtain approval, a State program must be consistent with the Federal program and with State programs applicable in other States (40 CFR 271.4). In particular, the following aspects of State programs are deemed to be inconsistent:

  any aspect of the State program which unreasonably restricts, impedes, or operates as a ban on the free movement across the State border of hazardous wastes from or to other States for treatment, storage, or disposal at facilities authorized to operate under the Federal or an approved State program (40 CFR 271.4(a));

  any aspect of the State law or the State program which has no basis in human health or environmental protection and which acts as a prohibition on the treatment, storage, or disposal of hazardous waste in the State (40 CFR 271.4(b)); and

  a manifest system that is inconsistent with the manifest system in the generator standards in 40 CFR 262 (40 CFR 271.4(c)).

Under 40 CFR 271.1(i), States may:

  adopt or enforce requirements that are more stringent or extensive than the Federal requirements, or

  operate a program with a greater scope of coverage than the Federal requirements.

However, 40 CFR 271.1(i) has always required that more stringent, more extensive, and broader requirements be consistent with the Federal program and other authorized State programs. After the passage of HSWA, EPA added paragraph (j) to 40 CFR 271.1. Paragraph (j) lists the HSWA requirements that take effect in authorized State programs on the same date that such requirements take effect in other States.

The implementation of HSWA and other amendments to RCRA in the mid-1980s to early 1990s generally caused RCRA regulations to become more stringent and broader. Most of the deregulatory or less stringent changes of those years, such as the satellite accumulation provisions of 40 CFR 262.34 and the corrective action management unit/temporary unit (CAMU/TU) rule, failed to raise significant consistency issues. During this period, the authorization of State programs was generally focused on whether the

programs were equivalent to, and at least as stringent as, the Federal program.

JUDICIAL BACKGROUND

In June 1987, North Carolina enacted a law that prohibited commercial hazardous waste treatment facilities from discharging waste water into surface water upstream from a public drinking water supply intake unless a dilution factor of at least 1000 at the point of discharge existed. Upon initial review of the law, EPA determined that the law was inconsistent with RCRA and began proceedings to withdraw North Carolina's authorization. After the administrative law judge (ALJ) hearing the case decided that the law was not inconsistent with RCRA, EPA accepted the recommendation of the ALJ and did not withdraw the program.

Laidlaw Environmental Services, Inc. and the Hazardous Waste Treatment Council petitioned the courts for a review of EPA's decision. In 1991, the United States Court of Appeals for the District of Columbia upheld EPA's decision and denied the petition for review. (2)

Among other things, the Court held that

Because the EPA is charged with the administration of RCRA, we defer to its interpretation whenever the statute is silent or ambiguous with respect to a specific issue. So long as the agency's interpretation is reasonable and consistent with the statutory purpose, we must uphold it.... While it is true that RCRA requires 'consistency' between state and federal programs, it does not mandate uniformity; in fact, the statute expressly reserves to States the authority to impose site-selection standards that are 'more stringent' than those imposed by federal authority. Consequently, the Regional Administrator's ruling that the North Carolina statute could be found 'consistent' with federal law...was not in conflict with the federal statutory scheme. (2)

In other cases, however, the provisions of more stringent State laws and regulations that have the potential to threaten the consistency of the national hazardous waste program have been struck down by the courts. Such provisions have involved the imposition of higher waste management fees on wastes generated out of state, or of more stringent permit conditions on facilities that accept waste originating out of state. These challenges have generally been won on the basis that the provisions violate the Commerce Clause of the U.S. Constitution, which denies States the power to regulate interstate commerce.

In one of the most important cases of this kind, the Hazardous Waste Treatment Council took action against the State of South Carolina and the South Carolina Department of Health and Environmental Control for promulgating of regulations that would:

- restrict the transfer of hazardous wastes to South Carolina facilities from States which have not reciprocated by providing treatment and disposal capacity for hazardous wastes within their borders,
- impose quotas on the quantities of such wastes otherwise permitted, and
- create a mandatory preference for wastes generated in South Carolina. (3)

The plaintiffs contended that these laws conflicted with and were preempted by the Federal hazardous waste management regulatory program, thus violating the Supremacy Clause of the U.S. Constitution and federal regulations prohibiting such laws (40 CFR 271.4). (The Supremacy Clause of the Constitution establishes that the laws of the United States take precedence over State laws.) The plaintiffs also raised concerns

regarding the constitutionality of the requirements under the Commerce Clause of the Constitution. (3)

The defendants countered that the laws, Executive Orders, and regulations in question did not conflict with the U.S. Constitution's Commerce Clause because:

South Carolina's hazardous waste management program had received EPA approval, and

Congress' intent was for each State to be permitted to implement its own hazardous waste program. (3)

The defendants cited Section 3009 of RCRA as indicating that States cannot be prohibited from imposing requirements more stringent than the Federal standards. (3)

The U.S. District Court granted injunctive relief based on the challenges raised under the Commerce Clause, and it offered the opinion that the plaintiff could also prevail in possible future actions under the Supremacy Clause of the U.S. Constitution. (3)

RCRA REGULATORY REFORM

In recent years, RCRA implementation efforts have focused on reform and rationalization. The success of these efforts may further advance environmental protection by making specific and general improvements to the RCRA regulatory structure. Specific improvements include changes to remove the impediments to beneficial recycling of industrial hazardous wastes and to improve the voluntary collection of hazardous wastes generated by households. General improvements include changes to improve the allocation of limited social resources, focusing these resources on wastes posing the greatest risks to human health and the environment. Table I lists recent proposed and final RCRA rules that contain regulatory reform elements.

Table I

EPA's recent analyses of the applicability of these regulations in authorized States can be reduced to a formula, presented in Table II.

Table II

According to the formula, authorized States are never required to adopt less stringent rules. More stringent rules must always be adopted by authorized States; they become effective immediately if they are HSWA rules, or when the State amends its RCRA program to incorporate them if they are non-HSWA rules.

The unquestioning application of this formula fails to raise important issues associated with consistency and the potential conflict between consistency and stringency. In all of the regulations listed on Table I with the exception of the proposed munitions rule, no analysis is performed to determine if a State's failure to adopt a Federal RCRA regulation change that is less stringent renders the State program inconsistent with the Federal program and with other authorized State programs.

Other important stringency/consistency issues raised by the proposed and final rules on Table I are listed below.

If a less stringent RCRA rule improves overall environmental protection, should it be considered less stringent?

Should program improvements relating to the elimination of outdated, confusing, and unnecessary language be evaluated in terms of stringency?

Is allowing waste to be treated using an additional treatment method less stringent if the method provides at least equivalent protection of

human health and the environment as the methods currently authorized? What if a new treatment method provides superior protection?

Is it more important to evaluate stringency or consistency when changing a definition, such as the definition of on-site, if the change affects large numbers of RCRA facilities?

If authorized States do not amend their rules to include equivalent and consistent provisions, does the Hazardous Waste Identification Rule address the petition for rulemaking submitted by the Chemical Manufacturers Association, the recommendations made by the Dialogue Committee on Hazardous Waste Identification, and the court decision in Shell Oil v. EPA?

In the munitions rule, EPA recognizes that the failure of authorized States to adopt the rule as proposed would prevent the rule from achieving its intended goal.

Today's proposal raises an issue regarding State authority because Congress clearly expected EPA to develop national standards for waste munitions through the RCRA rulemaking process. Although today's rule would lay out such national standards, States under the standard RCRA approach could enforce their own more stringent standards under their own State programs. This situation, at least in theory, could lead to just the sort of piecemeal approach that the FFCA was intended to avoid (60 FR 56488; November 8, 1995).

The munitions rule also recognizes the Department of Defense's (DOD's) need for national consistency in managing waste munitions, given DOD's national defense mission, nationwide presence, and logistical and operational needs.

Unfortunately, however, the preamble to the proposed munitions rule fails to address the contradiction between consistency and stringency in sections 3006 and 3009 of RCRA, and instead suggests an alternative approach to achieving consistency. (This approach relies on an argument that the scope of the waiver of sovereign immunity in section 6001 of RCRA does not permit a State to impose more stringent requirements than those contained in the Federal regulation if the requirements would result in unfair discrimination against Federal agencies. Because military munitions are unique to the military, EPA argues that more stringent regulations would thus be discriminatory. This paper will not comment on the merits of this alternative approach except to note that if it were adopted, it would reach far beyond military munitions and affect hazardous waste items that are unique to the Department of Energy (DOE) and to other Federal agencies.)

Continued failure to address contradictions between stringency and consistency when new regulations are proposed and promulgated ignores:

the legislative history of RCRA, which shows that Congress intended the law to provide for uniform regulation of hazardous waste, but allowed States to promulgate more stringent requirements because the Federal program was weak and the amount of hazardous waste being generated annually was increasing;

EPA's own regulations, which assign primacy to consistency; and

Court decisions, which encourage EPA to interpret ambiguous aspects of the RCRA statute and find that lack of consistency sometimes violates the Commerce Clause of the U.S. Constitution and may violate the Supremacy Clause as well.

It also threatens the RCRA reform effort because:

States have a powerful disincentive to adopt RCRA reform measures if a consequence of adopting these measures is that the State could become the preferred location for the treatment and/or disposal of some classes of wastes (the "NIMBY" syndrome).

Some reform efforts, such as efforts aimed at streamlining regulation of universal wastes, require national coordination to truly succeed. It is doubtful that States can achieve national coordination on their own. The history of efforts to site commercial low-level radioactive waste disposal facilities absent enforced consistency and national coordination leaves little room for optimism. Under the Low Level Radioactive Waste Policy Act of 1980, each State is responsible for providing disposal capacity, either by itself or in cooperation with other States (compacts), for all of the low-level waste (LLW) generated within its borders.

Limited progress was made until Congress enacted the Low Level Radioactive Waste Policy Amendments Act of 1985 (LLRWPAA), Pub. L. 99-240, 42 U.S.C. 2021, which established a series of milestones, penalties, and incentives to ensure that the regional compacts and States made adequate progress toward being able to manage their LLW. In particular, the "take title" provision of the Act would have required a State or compact that could not provide disposal capacity for its LLW after January 1, 1996, to take possession of waste from generators notifying that the waste was available for shipment. In 1992, the Supreme Court struck down the constitutionality of this provision of the LLRWPAA, removing the primary incentive for States and compacts to progress with developing new LLW disposal capacity. (4)

No new LLW disposal facilities have opened since 1980, and existing disposal sites have either closed or imposed restrictions on their receipt of LLW. As a result, many LLW generators are faced with making arrangements for expanded on-site storage of their LLW until additional disposal capacity is available. This situation appears to pose a greater threat to human health and the environment than the disposal of LLW in new facilities licensed under Nuclear Regulatory Commission regulations in 10 CFR 61 or equivalent State (i.e., Agreement State) regulations.

RCRA REGULATORY REFORM AND DOE

DOE has submitted two major regulatory reform proposals to the EPA Hazardous Waste Identification Rule docket. These proposals involve:

an exemption from Subtitle C of RCRA for immobilized mixed waste debris disposed of in low-level waste disposal facilities, and

an exemption from Subtitle C of RCRA for vitrified waste forms.

DOE analyses to support these proposals conclude that they are at least as protective of human health and the environment as current RCRA rules and that they could achieve this level of protection at a much lower cost.

From a radiological perspective, however, granting the DOE-proposed exemptions would appear to be more protective of human health and the environment overall than requiring the continued management of the subject waste forms under RCRA. Given that there are no currently operating DOE disposal facilities for mixed waste residuals, granting the exemptions would permit earlier disposal of these wastes. Disposal is more protective of human health and the environment than above-ground storage because it further isolates the radionuclides in these waste forms from human and environmental receptors.

If the contradiction between consistency and stringency is not addressed, EPA's concurrence with DOE's proposals may be irrelevant. Unless the States hosting major DOE LLW disposal facilities (Washington, Nevada, Idaho, New Mexico, Tennessee, and South Carolina) incorporate these changes in their authorized State programs, DOE will not be able to dispose of immobilized mixed waste debris or some vitrified waste forms in radioactive waste disposal facilities.

The preamble to the proposed HWIR rule suggests that State adoption of HWIR reform proposals affecting mixed waste will be a problem and explains that EPA intends to publish a supplemental proposal on mixed waste exit criteria (see 60 FR 66400; December 21, 1995). Hopefully, the proposal will confront the contradiction between consistency and stringency and recognize that the same arguments that support the need for a consistent munitions rule (i.e., DOD's national defense mission, nationwide presence, and logistical and operational needs) apply at least equally to DOE's mixed waste.

CONCLUSIONS/SOLUTIONS

There is often a contradiction between requiring RCRA-authorized State programs to be consistent with the Federal program and allowing them to be more stringent than the Federal program. The contradiction is most evident when determining what should be considered a hazardous waste, and appropriate waste treatment and disposal requirements. Regulatory reform that affects waste identification, treatment, and disposal intensifies this contradiction.

This paper does not present innovative solutions to this problem or advocate that EPA begin withdrawing authorized State programs for reasons of inconsistency. Instead, it makes the modest suggestion that the problem be recognized and discussed in regulatory preambles and other appropriate forums.

In particular, equivalency and consistency should be addressed even when EPA promulgates a less stringent rule. Authorized State programs that fail to adopt equivalent, less stringent regulations should be examined for consistency with the Federal program. Otherwise, States have a strong disincentive to adopt many less stringent changes.

Also, the meaning of "less stringent" and "more stringent" should be evaluated in the context of RCRA reform. Does it mean more rigorous protection of human health and the environment under RCRA alone, or under all environmental laws and programs? If it means more rigorous protection under all environmental laws and programs, some RCRA reform initiatives that are currently considered less stringent would become more stringent.

Failure to address the contradiction between stringency and consistency imperils regulatory reform efforts. In the case of DOE's mixed waste, failure to address the contradiction may result in lesser human health and environmental protection if radioactive wastes that could be safely disposed of now remain in long-term storage until new mixed waste disposal facilities are built and permitted.

ZERO ACCIDENTS IN THE REMEDIATION BUSINESS

B.R. Thomas
OHM Remediation Services Corp.
Post Office Box 551
Findlay, Ohio 45839-0551

ABSTRACT
While many industrial hygiene concerns are encountered at a hazardous wastes site during characterization and remediation activities, experience indicates that these problems can be controlled adequately. Personal exposure to airborne chemicals are effectively controlled primarily because a plan is prepared to review the chemical hazards that are likely to be encountered. Unfortunately, the hazards that are likely to represent a concern are safety issues including slips, trips, and falls.
Consequently, it is injuries to employees that are the principal concern. This presentation describes the elements of a "Zero Accident" program and the improved statistics resulting from its implementation.
At the beginning of 1994, the Midwest Region of OHM Remediation Services Corp. (OHM) implemented a program to supplement the existing industrial hygiene program to reduce accidents at work sites. The management of the Midwest Region made a commitment to promote and support the philosophy of zero accidents and established that goal as part of the Region's business plan. The Regional Safety Management Review Committee was established and identified the key elements that were necessary to accomplish the goal of zero accidents. These were management commitment, training for employees, job safety analysis, accident investigation, and employee recognition program. While each of these elements existed before January 1994, the "Zero Accident Program" emphasized the importance of and the relationship between these elements in eliminating injuries at a job site. The "Zero Accident Program" provided a baseline for supporting the interaction of these elements. The program also provided a vehicle to communicate the ground rules for effective and safe job performance. The program was communicated throughout the Region in a variety of ways including training classes for site supervisors and foremen to review their roles in achieving zero accidents.
The emphasis on zero accidents has paid off already. The current OHM OSHA recordable injuries rate is down by 52% from 1994 and 63% over the last 3 years. This has produced an estimated cost savings of $213,000 for 1994 and $1,274,000 for the last 3 years. The Experience Modification Rate has dropped by 45% from 1994 and is down 72% over the last 3 years. The number of job sites that achieved zero injuries in 1994 was up by 54% from 1993. With the continued implementation of the "Zero Accident Program," this effort will continue to improve each year and clearly demonstrates that a goal of zero accidents for all remediation job sites is realistic and achievable.

INTRODUCTION

Work at a hazardous waste site poses a variety of risks and hazards to the workers assigned to the remediation tasks. There is a potential to be exposed to airborne hazardous chemicals such as volatile organics that may be flammable or poisonous when inhaled. Chemicals at the job sites may be corrosive or absorbed if they come in contact with the skin. Heavy metals or semivolatile chemicals may be encountered in hazardous concentrations. Employees may be required to work in environments where extreme temperatures are encountered and therefore, may experience heat or cold stress. There are several types of controls to limit personal exposures, particularly engineering controls or administrative procedures. Engineering controls may include remotely operated tools or the use of local exhaust mechanical ventilation. Administrative procedures may limit the duration of the work or specify the time of day that work is performed. If the controls are not adequate, the members of the work crew may be required to wear personal protective equipment to limit exposures via the inhalation pathway or limit skin contact. Personal protective equipment is also effective to protect employees during a spill or unexpected release. The use of personal protective equipment also helps to limit the spread of contamination and serves to increase the effectiveness of the decontamination process.

Chemical hazards have been controlled effectively in the past on OHM job sites. Controls to limit exposures are planned in advance and are accompanied by monitoring with direct reading instruments or sampling for the presence of hazardous chemicals. A health and safety plan is prepared in advance to document the controls to be implemented and the conditions requiring additional controls which may arise. Alarms or action levels are established for the sampling systems to warn the workers that conditions are changing and that precautions are necessary. The plan documents the consequences of overexposure and the actions required to limit the symptoms. The plan also prescribes the methods of decontamination that are required and the steps to be followed to limit the spread of contamination. A review of the employee exposure results at most of the OHM job sites and the results of the medical surveillance for OHM employees indicates that the controls are effective. Personal exposures are found to be significantly below the permissible exposure limits established by the Occupational Safety and Health Administration (OSHA). Current technologies to perform monitoring and analysis at the same time are sufficient to provide instant warnings regarding the presence of hazardous chemicals. Chemical hazards are adequately controlled.

Other hazards are encountered at hazardous waste sites which are severe and can result in injuries to the workers performing the tasks. Working around construction equipment or on elevated surfaces presents potential hazards that offer few warning signs and represents a serious risk of injury. Even simple hazards, such as construction debris or lifting bulky loads, often result in injuries to waste site workers. The hazards are exaggerated by the use of personal protective equipment where the field of vision for the employee is reduced or the protective clothing may snag or be trapped. This hazard may result in a worker tripping and falling to the ground. The hazardous waste site is a dangerous place to work if controls are not implemented to limit the construction hazards.

The OHM Midwest Region implemented a program to manage the construction hazards typically found at job sites that result in accidents and injuries. Regional management personnel pledged a commitment to minimize

accidents at job sites and provide the resources necessary to reduce the hazards. The Regional management personnel agreed that all accidents are preventable and as a result a "Zero Accident Program" was designed and implemented. The program was designed to reduce injuries to employees and ultimately reduce the cost of workmen's compensation and the corresponding medical costs. The "Zero Accident Program" also served to promote the idea of performing each task and the entire project without defects. To the extent that the members of the work crew perform without mistakes the project is completed in a quality manner and more closely to the original schedule that was established.

ELEMENTS OF A "ZERO ACCIDENT PROGRAM"

The elements of the "Zero Accident Program" that were adopted by the Midwest Region of OHM are described below. Many of the steps and applications were first described by the Construction Industry Institute (1) (CII) in a study completed in 1993. The study examined many companies who had implemented a formal safety program in their construction projects and were successful in managing the hazards likely to be encountered. The CII published a list of the elements of safety programs that had been found to be effective. OHM reviewed the list of programs and found many similarities to programs already in place. Each of the companies interviewed explained the connection between unsafe practices, accidents, and injuries to employees. It was explained that the rate of injuries to employees could not be reduced until the number of unsafe practices was reduced. As depicted in Fig. 1, it was estimated that there are more than 300 unsafe work practices and non-injury accidents for each major personal injury (2). The poor work practices that contribute to the major injury are the same as those contributing to the non-injury accidents. The severity of the injury depends on chance. Not all accidents result in a personal injury, but the number of accidents needs to be reduced in order to decrease the number of injuries and minimize the chance that a serious injury may occur.

Fig. 1

Management Commitment

Regional management personnel were first required to confirm their commitment to operate in this manner. While the concept seemed to be an easy decision in theory, the resources needed to implement the program are not without certain conflicts. The Region formed a Safety Management Review Committee chaired by the Regional Vice President to evaluate the effectiveness of the program being implemented in the Region. The Committee is also attended by the Health and Safety Director and representatives from Technical Services, Human Resources, and Operations. The Committee reviews the injuries that occurred during the previous month and discusses the root cause of each incident as identified during the accident investigation. The Committee may elect to invite the project manager and/or the site supervisor to discuss the incident and the corrective actions. The Committee is responsible for establishing changes in procedures and work practices in order to avoid the reoccurrence of the incident at a job site anywhere within the Region. Minutes of the meeting are published and distributed for review by the project managers and operations managers. The Committee is a key element in promoting the prevention of accidents at the job sites.

Many job sites form a similar safety committee hosted by the site supervisor or project manager. These project safety committees serve to resolve concerns identified by the employees assigned to a particular

task on that job site. The committees are chaired by the site supervisors and attended by selected project team members, including laborers. The project safety committees perform site safety inspections and serve as the investigation team in the event of an accident. Minutes of each meeting are issued and distributed to the Regional Committee. Issues that are common to other job sites are discussed at each job site and common solutions are implemented.

Training for Employees

All OHM employees are experienced and participate in a variety of training programs. All personnel that work at job sites as well as many others attend the training classes required by OSHA regarding work at a hazardous waste site. Specific training is provided regarding the chemical hazards that can be expected at job sites. Training is also provided to review the correct operation of equipment, including pumps, chainsaws, high pressure water cleaner, or other small tools that may be used at a typical job site. Training is provided for equipment operators to review the correct use of selected heavy equipment, including excavators, loaders, and cranes. Training is provided in the form of classroom sessions accompanied by practical exercises where the employees can practice the criteria that were described in the classroom sessions. Training is also provided at each job site. At the beginning of each shift, the employees review the safety features of a particular piece of equipment or the results of a recent incident or personal injury. These "tailgate safety meetings" are a good forum for employees to express concerns or ask questions regarding the events of the previous days and confirm that work is proceeding as expected. Regardless of the type of training, the information provided to each employee is critical in avoiding an accident or personal injury.

Job Safety Analysis

Training is required for employees before the project begins, but it is important to focus on likely hazards before a specific task begins. It is appropriate to analyze a task to identify the hazards likely to be encountered and the appropriate controls. The job safety analysis (JSA) is performed by the safety professional and the supervisor or foreman to describe the tasks and the equipment to be used. The analysis can be simple or elaborate according to the complexity of the task. Each member of the work crew reviews the JSA before the task begins so that the hazards are clear and the corrective actions are understood. The process of the JSA also serves as a mechanism to plan the task and verify that the correct tools and personnel are ready for use. This approach helps each team member to understand how the task should be performed and helps provides him or her the information needed to identify a change or problem that was not expected. By addressing the problem as it is identified, the supervisor and the work team minimizes the likelihood that an accident may occur and reduces the potential for a personal injury.

Accident Investigation

Despite all of the analysis and training, conditions exist at the job site which may not be recognized and may result in an accident or personal injury. It is appropriate to investigate the root cause of the incident and identify the corrective actions that would reduce the likelihood of the incident being repeated. The purpose of the investigation is to identify how the incident could have been prevented and recommend the corrective action. The investigation should be

conducted as soon after the incident as possible so that all of the witnesses are available to provide information about the conditions that led up to the incident. Where available, the project safety committee serves as the investigation team and prepares a report for review by the Regional Safety Management Review Committee. A team of project personnel are well suited to identify the root cause and the suggested corrective actions. The members of this team are the most familiar with the operation and the equipment being used and they are the same people who must implement the corrective actions.

The Regional Safety Management Review Committee is responsible for reviewing the corrective actions at the job site. The Regional Committee is responsible for reviewing similar circumstances at other job sites and determine if changes in procedures are required. Members of the Regional Committee convey the results of the investigation team to all other job sites. They challenge the members of other teams to eliminate the root causes of the incident and reduce the hazard that could result in a personal injury. The members of the other project teams are encouraged to identify all potential hazards, not just the one condition that previously occurred. The investigation of an injury is one of the few positive things that stems from a personal injury. Any information which helps to eliminate the personal injury in the future is of value.

Employee Recognition Program

An effective program results in a project team who achieves its goal and can complete a project in an efficient, safe manner. It is appropriate to recognize the achievements made by the members of the project team and reward their hard work. A recognition program must emphasize performance of each individual and also encourage the team members to work in a synergistic manner. A team that works together to reduce job site hazards is more effective than employees who are focused only on their specific assignments.

OHM has implemented a program to recognize outstanding safety performance of the project team as well as individuals. The awards vary from monogrammed baseball caps or jackets to dinner out for the crew members. The important feature is that the work crew selects the award that is a priority for its members and establishes a milestone by which the award may be accomplished which may be related to the progress of the project. For example, the project team members may choose to receive a monogrammed jacket after completing the project (2 months in duration) without any injuries recorded on the OSHA 200 log. The project safety committee petitions the Regional Committee to approve the award and track the performance of the project team. The work crew reports problems to the project management personnel and makes sure that they are resolved as soon as practical. If the milestone is accomplished, each member of the crew is given an award as originally described. Project teams have selected a wide variety of awards from clothing, equipment, travel vouchers, or bonus checks.

Awards are also granted for individuals within the Region that complete a year without an OSHA recordable injury. The awards are selected by the Regional Safety Management Review Committee and distributed to eligible individuals. Clothing and equipment are commonly awarded with more expensive awards assigned to individuals who have completed multiple years without a recordable injury. There are many methods to reinforce the success of safe work practices and each method serves to emphasize the importance of the "Zero Accident Program."

RESULTS

The "Zero Accident Program" is showing dividends for the corporation. The rate of OSHA recordable injuries has dropped by more than 63% over the last 3 years (see Fig. 2). Two of the OHM profit centers, Midwest Region and Southeast Region, recorded their last lost work time injury in 1994 and have accumulated over 2.6 million labor hours without a lost time injury. The number of job sites that were able to achieve zero injuries is increased over the last 2 years by 54%.

OHM's Experience Modification Rate, published by the insurance companies to reflect the cost of injuries compared to other companies in the same industry, continues to decline. It is currently 87% below the expected average and it has dropped by 50% each year for the last 2 years. As importantly, many of our clients are recognizing this effort by offering monetary incentives to complete the project without any incidents.

Fig. 2

CONCLUSIONS

1. The chemical hazards encountered at a hazardous waste site can be managed so that exposures to employees are acceptable. The hazards stemming from construction activities represent the major source of personal injury and must be controlled.
2. There is a connection between accidents and personal injuries. In order to reduce personal injuries, a company must reduce accidents at the workplace. It is practical to expect that injuries can be reduced to zero by minimizing accidents and the conditions that contribute to accidents.
3. A "Zero Accident Program" requires the commitment of management to promote the elements and provide adequate resources to correct the discrepancies.
4. The "Zero Accident Program" has been successful for OHM since the spring of 1994. The rate of OSHA recordable injuries has dropped by 63%. The Midwest Region has accumulated over 1 million hours without a lost time injury since the program started.

ISV TECHNOLOGY TRANSFER FROM BATTELLE/PNNL TO GEOSAFE CORPORATION TO ISV JAPAN

James E. Hansen
Jack L. McElroy
Geosafe Corporation

ABSTRACT

The In Situ Vitrification (ISV) technology was invented by Battelle Pacific Northwest National Laboratory (PNNL) for the U.S. Department of Energy (DOE) in 1980. The technology involves the electric melting of contaminated soil and debris, in situ, for purposes of destroying organic contaminants and permanently immobilizing hazardous and radioactive heavy metals. The ISV technology has been developed and demonstrated on a broad range of contaminants, soil types, and waste materials and debris. Geosafe Corporation (Geosafe) offers ISV remediation and waste treatment services on a large-scale commercial basis, and has recently completed its third major site remediation project.

The ISV technology was transferred from Battelle/PNNL to Geosafe starting in 1988. Subsequently, Geosafe has transferred the technology to a new company, ISV Japan, Limited (ISVJ) starting in 1995. This paper reviews the technology development and commercialization chronologies for the ISV technology, and then discusses the technology transfer processes that were performed during that time. Eight (8) basic elements of the technology transfer process are presented, including: 1) license rights, 2) technical information, 3) laboratory test/demonstration know-how, 4) commercial production technology know-how, 5) provision of experienced staff members, 6) continuing technical assistance, 7) financial/investment support, and 8) shareholder positioning. The two technology transfer events (Battelle/PNNL to Geosafe, and Geosafe to ISVJ) are contrasted relative to these eight elements.

The authors believe that the technology transfer model represented by the 8-elements listed above, is very effective. It is noted that one weakness of the process lies in the area of estimating the time and costs associated with translating a laboratory demonstrated technology into a commercial production technology. It is recognized that technical operating know-how is critical to the success of effective technology transfer; and provisions must be made to ensure that knowledgeable staff are made available to the recipient of a technology transfer, until such time that they possess the needed know-how themselves. In the Battelle/PNNL to Geosafe technology transfer, this need was met by Battelle's provision of full-time experienced technical and business development staff to Geosafe. In the Geosafe to ISVJ technology transfer, this need is being satisfied by provision of knowledgeable Geosafe staff on an as needed basis under a technical assistance contract. Lastly, the paper identifies a continuing financial involvement between the parties as an important element of effective technology transfer.

INTRODUCTION

The purpose of this paper is to review the processes employed in the transfer of the ISV technology originally from the DOE's PNNL to Geosafe, and subsequently from Geosafe to ISVJ. A general technology transfer model is presented, and the two technology transfer experiences are contrasted relative to it. The following summary description of the ISV technology is presented to help the reader relate to the type of technology being transferred, and the type of business Geosafe is involved in.

The ISV technology was an outgrowth of the joule-heated melter vitrification technology developed by PNNL in the 1970s and 80s for the immobilization of high level radioactive waste. At that time, vitrification had been recognized worldwide as the best available means to immobilize heavy metal radionuclides; and PNNL was DOE's reference vitrification laboratory. In 1980, PNNL melter vitrification experts were given DOE discretionary funds to do proof-of-principle testing on the ISV concept. The initial test was so successful that DOE's Hanford Field Office immediately challenged PNNL to develop a means of vitrification that could be applied in situ to soil sites that had been previously contaminated with TRU waste. Since the 1980 invention (and 1983 patent), the ISV technology has been developed to be broadly applicable to site remediation and waste treatment applications involving a full range of hazardous, radioactive, and mixed contaminants present in soil, wastes, other earthen materials, and debris.

The ISV technology involves the in situ electric melting of earthen materials for several possible purposes, including: 1) thermal destruction/removal of hazardous organic and inorganic compounds, 2) permanent immobilization of hazardous and radioactive heavy metals within a high integrity vitrified product form, 3) conversion of waste materials into recycled products, and 4) production of high integrity vitrified masses for various civil engineering applications.

The ISV process involves placement of an array of electrodes (usually 4) a short distance into the media to be treated. A melt is initiated at the surface between the electrodes, and as electrical power is passed through the melt, joule heating occurs, causing the melt to grow outward and downward as long as application of power is continued. Geosafe employs a mobile, large-scale system capable of applying 3.5 MW of power to a melt. This system has been employed to make individual melts as large as 1,400 tons in mass, and approximately 40-ft in diameter by 22-ft deep.

The high operating temperature of the ISV process (1,600-2,000C) results in the pyrolytic destruction of organic contaminants. Heavy metals are typically immobilized by chemical incorporation into the high integrity vitrified product that results from the melting process. Volume reduction on the order of 20-50% is typical for most earthen media applications. The vitrified product typically possesses outstanding physical, weathering, leaching, and biotoxicity properties. These properties for the ISV product are typically superior to those of ex situ melter products because of the effects of fluxant additives which are necessary to lower the melt temperature in ex situ melters.

The ISV process and its attendant vitrified product may be the most technically preferred and cost effective technology alternative in cases where: 1) a combination of organic and heavy metal, or hazardous and radioactive contaminants must be treated, 2) onsite and in situ treatment is desired, 3) the site contains non-homogeneous soil conditions and/or debris, 4) maximum treatment effectiveness and permanence are required, and/or 5) high volume reduction is desired. The reader interested in more information regarding the ISV technology is referred the authors and specifically to the following two references (1)(Thompson, 1995).

Geosafe provides four basic ISV-related products/services to the site remediation and waste treatment markets, including: 1) applicability analyses and cost estimates, 2) treatability testing and demonstrations, 3) technical assistance during remedial design, site preparation, and site restoration, and 4) onsite vitrification services. Figure 1 shows Geosafe's large-scale ISV equipment being operated at the Wasatch Chemical Superfund Site in Salt Lake City.

REVIEW OF ISV TECHNOLOGY DEVELOPMENT AND COMMERCIALIZATION

The ISV technology was invented and proof-of-principle tested in 1980 by PNNL at the Hanford Site. Initial process exploration was performed until 1983, when the program emphasis moved toward a large-scale equipment design and demonstration basis. The initial application interest was DOE's TRU-contaminated soil sites; a successful pilot-scale demonstration on Pu-contaminated soil was performed in 1983.

By 1986, a large-scale (100 ton/day) mobile ISV system had been designed, constructed, and operational acceptance tested. This enabled performance of the first radioactive large-scale test at Hanford's 200 Area during 1986. Approximately 120 tests and demonstrations were performed at engineering-, pilot-, and large-scale between the years 1980 and 1990. Many of these tests demonstrated the applicability of the technology to a

full range of hazardous, radioactive, and mixed contaminants. This range of capabilities strongly interested the non-DOE marketplace. Geosafe was established in 1988, primarily to address the non-DOE markets that were developing in response to CERCLA, RCRA, and TSCA regulations.

Fig. 1

It should be noted that the nature of the DOE ISV technology development program emphasized rapid equipment development and demonstration as a means of quickly evaluating the potential of the technology. While this approach certainly demonstrated the potential of the technology, it did not allow time nor funds for adequate definition of the underlying science and technology needed to support commercial application of the technology. This became obvious after Geosafe attempted to initiate commercial operations at large-scale; and it became necessary for Geosafe to spend substantial time and money on "backfilling" the base science and technology needed to translate the "laboratory-based" experience to the commercial arena. This translation was completed in 1992, and Geosafe initiated its first large-scale commercial work in 1993. Since that time, Geosafe has performed more than 50 large-scale ISV melts, and has demonstrated the broad capabilities and reliability of the technology.

Fig. 2

Figure 2 summarizes the technology development and commercialization chronologies since 1980. The reader interested in more detail in this area is referred to the ISV commercialization case study presented by the Geosafe authors at Waste Management '95 (3).

ISV TECHNOLOGY TRANSFER

Technology transfer involves passing necessary rights, information, and knowledge, regarding a technology, from one party to another so that the receiving party may effectively employ the technology. There are many ways that technology transfer can be accomplished. At one extreme, transfer may be accomplished simply by licensing a patent to a knowledgeable recipient. At the other extreme, effective technology transfer may require a more extensive effort and a long-term relationship between the transferring and receiving parties. As prior employees of Battelle Memorial Institute, the Geosafe authors were involved with technology transfer activities dating back to the 1970s, primarily from the point of view of the transferring party. In that role they have experienced the difficulties involved in locating and generating interest in a potential technology recipient. As Geosafe employees, they have seen the technology transfer process from the technology recipient's point of view. These experiences have led to a technology transfer model that includes eight (8) basic elements, as follows:

1) Provision of license rights to patent(s), technical information, know-how, and future improvements
2) Provision of full technical information regarding the technology, including process and equipment specifications and a historical project database
3) Provision of know-how related to technology test and demonstration capabilities
4) Provision of know-how related to use of the technology in commercial production
5) Provision of experienced technical and business development staff members
6) Provision of continuing technical, business development, and environmental industry assistance

7) Provision of financial and/or investment support
8) Assumption of an ownership interest by the transferring party in the receiving party.

Transfer of the ISV technology has occurred two times, and is in the process of being performed a third time. The original transfer was from DOE's PNNL (operated by Battelle) to Geosafe, starting in 1988. The second major transfer was from Geosafe to ISVJ starting in 1995. Preparations related to transferring the technology to Australia are currently underway. Figure 3 relates the first two technology transfer processes to a time line and to the commercial status of the technology. Each of these technology transfers are discussed individually below, relative to the technology transfer model listed above.

Transfer from DOE/PNNL to Geosafe Corporation Battelle invented the ISV technology for DOE in 1980. A very fundamental U.S. patent was issued in 1983. DOE also filed for and obtained ISV patents in the major industrialized countries of the world. After issuance of the U.S. patent, DOE announced that nonexclusive rights to use the patent were available to interested parties; to Geosafe's knowledge, there were no respondents to that offer. With hindsight, the authors believe that the early development stage of the technology, and the nonexclusivity of available license rights, contributed to the lack of applicants in response to DOE's offer. Subsequently, Battelle applied for and was granted partially exclusive rights to the technology in 1986. The rights were partially exclusive in that they did not include rights to the radioactive field of use. Radioactive rights were granted within a few years, making Battelle's license exclusive in all fields of use, worldwide. In exchange for these rights, Battelle had to commit to preparation and implementation of a strategic business plan leading to commercialization of the ISV technology. This was completed in 1987. Battelle's plan called for the establishment of a separate company for commercial application of the technology; Geosafe was so established in 1988.

As the world's largest contract R&D firm, Battelle held extensive experience at that time in the field of technology transfer. Many technologies were transferred at that time by licensing patent rights, provision of technical information, and provision of technical assistance to licensees as required. Battelle's strategic analysis of the opportunities for the ISV technology, and the nature of the developing site remediation marketplace, caused them to make an extraordinary commitment to the commercialization of ISV, including provision of key technical and business development staff, and initial capitalization of the new company (Geosafe), in addition to exclusive worldwide sublicense rights, technical information, and continuing technical assistance.

Fig. 3

This transfer of technology from Battelle/PNNL to Geosafe resulted in a licensee that had a full and working knowledge of the technology from technical and business development points of view, and had a direct path for advanced technical assistance as needed. Recognizing that the key staff from Battelle did not have significant environmental remediation industry experience, Battelle further increased the chances of success for its offspring by employing a management team that had prior successful experience in the industry.

It is important to recognize that this transfer of technology involved the transfer of a "laboratory developed and demonstrated technology", but not a "commercially viable production technology". It was believed at

that time that it would be but a short step to translate the laboratory technology into a fully functioning production technology. That belief proved to be in error, and Geosafe found it necessary to invest significant time, money, and effort into producing a commercially viable technology. Had Geosafe been unable to obtain additional capitalization during this period, this technology translation need could have been fatal to the technology transfer and commercialization effort. It is recognized that it is very difficult to accurately predict the effort needed to translate a laboratory technology into a production technology. The importance and need for such translation should be a major consideration in technology transfer efforts.

The transfer of technology from Battelle/PNNL was substantially completed by 1992, when Geosafe's capabilities became strong enough in the ISV technology field to minimize the need for further technical assistance from Battelle/PNNL, except for longer-term R&D needs. As would be naturally expected, the child rapidly gained knowledge and experience from its technology translation efforts and large-scale field activities, making it stronger than the parent in the transferred technology. In fact, collaboration between the two organizations today often involves "reverse" technology transfer, as Geosafe provides technical assistance to Battelle/PNNL in support of its ISV Program being performed for various DOE interests.

Transfer from Geosafe to ISV Japan

Geosafe's sublicense involves worldwide rights. Since its inception, Geosafe has received more than 200 inquiries from foreign organizations regarding the possibility of sublicensing the ISV technology. Such inquiries were handled in a manner consistent with the state of the technology, and Geosafe's perceived need to firmly establish ISV within the U.S. marketplace before taking it abroad. Most inquiries were "blind" (i.e., based on little knowledge of the ISV technology and its status), and were motivated by foreign firms searching the U.S. literature for technology acquisition opportunities.

Many such inquiries also came from Japan, which during the past 5 to 7 years, has been developing its environmental remediation and waste treatment markets. One very different line of inquiry came to Geosafe through the Japan Research Institute, Limited (JRI). JRI had assembled a consortium of companies that were interested in exploring ISV's potential for the Japanese marketplace. At that time they neither requested, nor were ready to seek a sublicense to ISV. Rather, they proposed a time of working together to evaluate the technology and its potential application within Japan. That approach held significant interest to Geosafe; and in 1990, cooperative efforts were undertaken. Membership in the Japan ISV Consortium varied with time; typically there were about 8 member companies, including JRI, a major trading company, a major chemical industry firm, and several construction companies (Japan's remedial action contractors).

For the following four years, Geosafe performed exploratory tests related to the Japanese "condition", at its test site in Richland, WA. Testing was performed in several key market application areas (e.g., LLW facility remediation, contaminated soil remediation, industrial waste treatment, concrete D&D waste treatment). In addition to the U.S.-based testing, the annual program involved performance of demonstration tests in Japan to confirm and demonstrate to others that the U.S. test results would be the same for Japanese soil conditions. The Japan ISV Consortium would arrange

for "field days" (typically two consecutive days) in conjunction with the demonstration projects for purposes of informing potential clients and regulators about the ISV technology. Often test melt products (vitrified monoliths) from U.S. testing would be shipped to Japan for display during such demonstration field days. JRI and the Consortium were very effective in developing market and regulatory awareness within Japan in this manner. Television and printed media coverage was also present during the field days.

In addition to the technology side of the exploratory and evaluation efforts performed by the Consortium, they also worked extensively in the regulatory and marketplace areas. They were able to obtain partial financial support from the Japanese Ministry of International Trade and Industry (MITI) to support their efforts. In 1994, MITI contributed about $5 million toward the design, construction, and testing of a stationary batch type ISV treatment system as part of an economic stimulation project in Japan. That system is shown in Fig. 4.

After the several year evaluation process, a majority of the Consortium members decided that an appropriate opportunity existed for ISV in the Japanese marketplace. The Consortium then proceeded to request and negotiate a license from Geosafe for the territory of Japan. That license was finalized, and ISVJ was formally established in Tokyo during May, 1995.

Fig. 4

COMPARISON OF TECHNOLOGY TRANSFER EFFORTS

Significant differences exist between the transfer of ISV technology between Battelle/PNNL and Geosafe, and between Geosafe and ISVJ. Table I presents the elements employed in both transfers, and points out the primary differences. Most notably, the Geosafe-ISVJ transfer involved transfer of a fully developed, commercially proven technology; whereas the Battelle/PNNL-Geosafe transfer involved transfer of a laboratory demonstrated technology. This situation, at the time of the Battelle/PNNL to Geosafe technology transfer, meant that Geosafe had to bear the risk of the time and expense of translating the laboratory technology into a commercial production technology. This was not the case of the transfer between Geosafe and ISVJ. In this case, ISVJ received a fully developed commercial technology and did not have to withstand the risks that Geosafe had to when it received the technology from Battelle/PNNL. This difference provided ISVJ with much greater certainty that the ISV technology could be immediately applied on a commercial basis within Japan.

Another significant difference between the two technology transfer cases lies in the area of technology deployment know-how that exists within key Geosafe staff members. As mentioned above, the Battelle/PNNL to Geosafe transfer involved the employment of experienced Battelle/PNNL staff members as key staff of Geosafe. This type of know-how transfer has not been done in the Geosafe to ISVJ transfer, primarily because two different countries and cultures are involved, and because of the distances involved. It is recognized, however, that the transfer of know-how to the new company is a crucial ingredient of the technology transfer process. Therefore, as part of the license agreement between Geosafe and ISVJ, Geosafe has committed to provide onsite technical support as needed to support the project development, planning/design, staff training, and performance of initial projects, until such time that ISVJ no longer requires such assistance. The agreement requires that Geosafe technical

staff approve all operational plans and equipment designs prior to commencement. The agreement also requires the participation of Geosafe personnel, onsite, at an agreed upon level during initial operations. In this way, Geosafe will ensure that the needed know-how is present during ISV operations.

Table I

The provisions described above also address another very important consideration of technology transfer; that is the need to ensure that the technology is not misapplied. The ISV technology is not a straight forward extension of an existing technology (e.g., joule-heated melters); rather it is fundamentally different in most aspects of its operation. There is a significant amount of underlying, ISV-specific science and engineering knowledge that is necessary to properly apply the technology. And it is possible to misapply it. Therefore, clear establishment of an acceptable operating "envelope" is a crucial element of the transfer process. And of course, it is of utmost importance to both parties that the technology not be misapplied due to the repercussions that could result in both the U.S. and Japanese marketplaces. The license agreement between Geosafe and ISVJ specifically addresses these concerns.

A last significant difference between the two transfer processes also partially relates to the above needs. In the case of the Battelle/PNNL to Geosafe transfer, Battelle became the primary shareholder of the new company. This guaranteed the kind of close, continuing relationship that is very helpful for effective technology transfer. It is noted, however, that Battelle is not in the business of operating subsidiary companies, but rather has invested in Geosafe as part of the technology transfer process. It is expected that Battelle's share in Geosafe will decrease as additional capitalization is obtained from environmental industry sources to support Geosafe's growth. Geosafe has also become a significant shareholder of ISVJ, but not as a primary investor. This investment was not necessary to provide initial capitalization to ISVJ, but rather it provides benefits to both Geosafe and ISVJ. It allows Geosafe to participate in the growth and success of ISVJ; and it guarantees Geosafe's attention to the needs of ISVJ.

CONSIDERATIONS FOR THE IMPLEMENTATION OF PARTNERING AGREEMENTS FOR TECHNOLOGY TRANSFER RELATED TO DEPARTMENT OF ENERGY PROGRAMS

Terry A. Kuykendall
Parsons Engineering Science, Inc.

ABSTRACT

The Department of Energy (DOE), and the DOE national laboratories in particular, have developed numerous processes and technologies that have the potential to be of practical use to both the government and

commercial market sectors in areas such as environmental remediation, waste management, applied physics, remote handling, etc. For effective commercial application, these technologies must be transferred to private enterprize for further development, tailoring for specific functions and uses, and full development and targeting of potential markets. This transfer will require the skills, interfaces, and business relationships of a consortium of organizations with appropriate specialized experience and expertise.

In order to develop and implement effective technology transfer programs, it is beneficial for the DOE site or laboratory to enter into partnering arrangement with engineering/technology firms, universities and academia, private industry, other government agencies, and specialized business entities to support the identification, development and transfer of emerging technologies developed and/or adapted by a laboratory or research and development (R&D) organization which can be applied to address ongoing or future needs for environmental management.

The concept of partnering represents a long-term commitment among the involved organizations for the purpose of achieving specific business objectives by maximizing the effectiveness of the resources of each participant. This relationship requires change in the traditional business and working relationships to a shared culture without regard to organizational boundaries. This relationship must be based upon trust, dedication to common goals, and understanding of the individual expectations and goals of the partnering team members.

A typical partnering arrangement for DOE technology transfer should accommodate the following goals:

Development and transfer of technology from the DOE operations, laboratory, and/or R&D environment to business entities within the private sector (commercialization);

Implementation of an arrangement to involve (to the extent practicable) entrepreneurial organizations such as small businesses, small disadvantaged businesses, woman-owned businesses, and collegiate universities and organizations;

Identification of areas of potential ongoing and/or follow-on research in support of the DOE and private/commercial sector requirements.

These objectives will be achieved by establishing defined roles and responsibilities of the member organizations of the partnering arrangement, and by emphasizing the strengths and relevant experience of the team as a unit. The partnering relationship will serve as a business venture, and will conduct research, development, and transfer processes in terms of a defined project management and earned value accountability system.

The key elements of the partnering agreement are: long term commitment; equality among partnering members; a mutually supportive relationship; encouragement of innovation; a commitment to continual improvement; insurance of continuity of resources; and the promotion of a `win-win' atmosphere.

The ultimate measure of success will be the demonstrated improvement of the ability of the consortium to identify currently available technologies useful to the private sector, and the expediting of technology transfer available for commercialization.

The technology transfer process must address the interrelationships and organizational dynamics necessary to bring a developmental technology through the development process into a marketable condition. Since the

transfer of DOE technology to the private sector currently is a developmental process, there is no patent guidance for this process. The development of a partnering arrangement between DOE and a consortium of organizations with complementary skills can lead to an orderly and efficient mechanism for introducing DOE technologies to the common industrial market.

OVERVIEW OF REQUIREMENTS

The goals of for a technology transfer program are to apply business principles to technical development in order to increase the return on investment to a higher ratio, avoid unnecessary costs and expenses, expedite the process of technology transfer directly to the common market, and to implement of effective cost and financial controls to demonstrate earned value and value added.

The technology transfer process must implement technology development and demonstration of `lessons learned' to improve the understanding of available and emerging technologies. In order to identify, develop, and transfer technologies to the private sector for potential commercialization, specific process elements and related responsibilities must be addressed by the team, such as basic research, applied research, pilot/bench scale development, technology demonstration, technology transfer, and commercialization.

The process of technology development, implementation and transfer must involve the identification of problem or need and a related candidate remedial technology (or technologies). The technology may be a process, procedure, equipment and/or system that meets a specific need and allows the user to accomplish the desired results in a more efficient, cost effective, and/or safe and environmentally preferential manner than existing methods and/or techniques.

The development of the candidate technology may require basic and/or applied research, testing and implementation of a process or equipment, or the adaptation of existing processes, systems, or methods. To assure that a technology is cost effective and addresses the appropriate application, several stages of analysis and implementation will be conducted. Each stage requires unique talents, capabilities, and experience from the partnering team members. The team must reflect optimum utilization of the appropriate allocation of resources and expertise without regard to the personal preferences of the individual team members.

PARTNERING OBJECTIVES

Partnering is a long term commitment between organizations for the purpose of achieving specific business objectives by maximizing the effectiveness of the resources of each participant. This relationship requires change in the traditional relationships to a shared culture without regard to organizational boundaries. This relationship must be based upon trust, dedication to common goals, and understanding of the individual expectations and goals of the partnering team members.

The partnering arrangement among team organizations should be structured to accommodate the following goals:

Development and transfer of technology from the research/national laboratory environment to business entities with the private sector (commercialization);

Identification of areas of potential ongoing and/or follow-on basic research in support of the Department of Energy (DOE) and private/commercial sector requirements; and

Implementation of an arrangement to involve (to the extent practicable) small, disadvantaged, and/or minority organizations, including Small Businesses (SBs), Small Disadvantaged Businesses (SBDs), and Historically Black Colleges, Universities and Minority Institutions (HBCU/MIs). These objectives can be achieved by establishing defined roles and responsibilities of the member organizations in the partnering arrangement, and by emphasizing the strengths and relevant experience of the team as a unit. The partnering relationship should serve as a business venture, and should be used to conduct research, development, and transfer processes in terms of a defined project management and earned value accountability system (e.g., as per DOE Order 4700.1).

A partnering agreement should not be construed as a contractual agreement. Partnering does not create legally enforceable rights or duties. Partnering does not replace legal contracts; it is a mechanism to implement contracts. Partnering should not be perceived as a `quick fix'; it cannot be implemented without the total commitment of all of the involved parties.

The key elements of the partnering agreement are: long term commitment; equality among partnering members; a mutually supportive relationship; encouragement of innovation; a commitment to continual improvement; insurance of continuity of resources; and the promotion of a `win-win' atmosphere. Success will be based on:

- Business-driven objectives;
- Dedication to total organization as part of the strategic plan;
- Top-down organizational commitment;
- Willingness to accept other/alternate ways and concepts of conduct;
- Agreement to equality among team participants;
- Commitment to invest resources for future returns;
- Ability to relinquish control and back away from specific details;
- Acknowledgement of risks and planning for risk management; and
- Mutual trust in the skills, intentions, and contribution of team members.

The ultimate measure of success will be the demonstrated improvement of the ability of the team to identify currently available technologies useful to the private sector, and the expediting of technology transfer available for commercialization.

IMPLEMENTING A PARTNERING AGREEMENT

Technology transfer and cooperative R&D programs typically have been met with skepticism, disagreement on partnering terms, and with controversies over topics such as ownership of intellectual property. These barriers to must be overcome if a partnering arrangement is to have any opportunity for success. Since the track record so far for commercialization of technologies has been spotty and erratic, precautions must be taken to ensure accomplishment of specified goals.

The partnering agreement is not without some concerns and issues that must be resolved. These issues and concerns include:

- Protection of proprietary information;
- Licensing of products and technology;
- Fair sharing of risks;
- Obtaining and maintaining total commitment to the relationship;
- Creation of dependencies on partnering members;
- Inherent limitations of the competitive market strategy; and
- Difficulties with the integration of organizations with differing cultures.

The primary focus of the arrangement will be for the partnering organizations to assist each other in the development of technology that can be optimally packaged for implementation and transfer to the commercial sector. The team members must have the commitment to identify areas of further development and needs for new basic research as a source of business development for the technology. This cyclic relationship will provide promotion of a continuing and ongoing partnership that will provide not only technology transfer, but will establish the basis for the team to become a long-term contributor to private industry.

PERFORMANCE REQUIREMENTS AND EXPECTATIONS

The development and transfer of technology must focus on the major obstacles to progress that have existed with previous efforts involving national laboratories and R&D organizations. The team must emphasize problem/solution-oriented technology development to support specific client and market sector needs. The partnering program must implement a management structure that involves the team members, customers, regulators, and other stakeholders. This up-front involvement will be instrumental in the establishment of effective communications with internal and external stakeholders, and the conduct of technology development and implementation in an open and interactive fashion. The early buy-in of stakeholders (and potential intervening organizations) will streamline the transfer process, thereby reducing costs and schedules.

The goals of this program must be to apply business principles to technical development in the following areas:

Increasing the return on investment to a higher ratio;

Avoidance of unnecessary costs and expenses;

Expediting the process of technology transfer directly to the common market; and

Implementation of effective cost and financial controls to demonstrate earned value and value added.

Also, partnering is a vehicle for concepts such as Total Quality Management and innovative thinking for the development of technologies. Expected benefits include improved efficiency and funding utilization, and continuous improvement of quality products and services.

The primary team members of a partnering agreement are the supplying organization (e.g., the national laboratory) and the design/engineering firm. Academia will be included to provide additional resources and support for technology development. Small businesses will be represented on a case-by-case basis by companies identified specifically for the selected technology development and transfer application.

THE TECHNOLOGY DEVELOPMENT/TRANSFER PROCESS

The process of technology development, implementation and transfer must involve the identification of problem or need and a related candidate remedial technology (or technologies). The technology may be a process, procedure, equipment and/or system that meets a specific need and allows the user to accomplish the desired results in a more efficient, cost effective, and/or safe and environmentally preferential manner than existing methods and/or techniques.

The development of the candidate technology may require basic and/or applied research, testing and implementation of a process or equipment, or the adaptation of existing processes, systems, or methods. To assure that a technology is cost effective and addresses the appropriate application, several stages of analysis and implementation will be

conducted. Each stage requires unique talents, capabilities, and experience from the partnering team members. The team must reflect optimum utilization of the appropriate allocation of resources and expertise without regard to the personal preferences of the individual team members.

The technology transfer process must implement technology development and demonstration of `lessons learned' to improve the understanding of available and emerging technologies. In order to identify, develop, and transfer technologies to the private sector for potential commercialization, the follow process elements and related responsibilities will be addressed by the team:

Basic Research

This preliminary effort involves the investigation of identified technologies which may not be directed at a specific problem or need, but have potential for application in one or more target areas. The focus in this area will be on the accumulation of knowledge, with an understanding that some concepts of applicability are necessary. The instigation of a relationship with a private engineering organization, along with the connections to private industry, will allow technology researchers to evaluate the implications of results and the potential technology applications. This area is primarily the focus of the national labs; academic institutions may be utilized to supplement laboratory resources.

Applied Research

This effort involves the definition of specific problems or problem types, and the proposal of candidate technologies to solve these problems. Evaluation of the needs of private industry and DOE programs will provide access to field problems to which research can be applied. The engineering firm may support the national laboratory as required in the coordination of investigations into industry and DOE requirements. Academic institutions may play a role in the development of research applications.

Pilot/Bench Scale Development

This is the proof-of-principle phase. The feasibility of a process for application to a specific problem is the basis for this process element. Identification of potential implementation problems and resolution of technical issues typically are accomplished at this stage. The national laboratory and the team engineering firm will participate here in a coordinated effort with academia and a business interested in commercialization.

Pilot/bench scale testing will involve the identification of performance metrics, evaluation of the technology status, benchmarking and baselining of technology, analytical testing, and comparative analysis to define the utility of the candidate process and/or equipment.

Technology Demonstration

At this stage, the candidate technology will be applied to a `real world' problem in the field. Procedures will be developed to document the process, and tested with the expectation that the technology can be fully implemented with the incorporation of the results of the demonstration. This step will involve the preparation of drawings, procedures, and other documents required for consistent and reproducible operation, and may include ancillary issues such as safety, training, quality assurance, and permitting. The engineering firm will have a major role in this area for coordination of activities with the technology developers and the implementing organization (e.g., small businesses).

Technology Transfer

This is the establishment of the ways and means to prepare the technology for introduction into the commercialization process. This will involve documentation of demonstration results and specifications, and extrapolation of potential and possible applications of the technology within the commercial/private industry environment. The laboratory and the engineering firm will coordinate this transitionary phase with the technology developers and implementation organizations, and may include potential end-users.

Commercialization

This step requires that the process or equipment be defined, developed and packaged for specific commercial applications, and that the product meets safety and regulatory standards for commercial. Necessary permits and licenses must be in place to assure compliance. Primary and secondary markets should be identified and developed for potential commercial application of the processes.

It will require a dedicated, well-planned, and cooperative effort to move technology into the private sector. The team engineering firm will be instrumental in working with the partnering members to target commercial industries and to present technologies in the most marketable perspective.

The engineering firm must take a lead role in this process phase, with the support from academia and technology vendors (e.g., small businesses or other organizations that will make the technology available to the public) for commercialization implementation. The partnering team also will be responsible for identifying areas of possible related research, development, and analysis as a feedback loop for future efforts.

ROLES OF THE PARTICIPANTS AND PARTNERING AGREEMENT

The integrated partnership must include defined roles and levels of responsibility for the initiation, evolution, and completion of each technology transfer project. The following sections define a proposed sharing of responsibilities:

National Laboratory/R&D Organization

The national laboratory will contribute a large array of facilities and resources not available in the private sector, a mutidisciplinary staff, and a history of the development of science and engineering technologies that may be developed to serve national needs in areas such as environmental restoration and waste management. The team of dedicated scientists, technologists, and engineers will provide a cooperative source of superior resources for technology development.

The national laboratory would have the primary responsibilities for:

- Conduct of basic research
- Conduct of applied research
- Provision of scientific/technical support
- Participation in pilot/bench-scale testing
- Provision of testing facilities
- Coordination with user facilities

Architect/Engineering Firm

The team A/E firm should bring an established credibility in the DOE complex for design, evaluation, and demonstration of engineered systems and technology. Successful A/E companies add an extensive network of DOE, DoD and private industry contacts, and can promote the conversion of concepts into directly applicable technology for the commercial marketplace. These firms have experience which can provide opportunities

for research and development in addition to access to ongoing remediation projects where new technologies may be implemented, and can identify areas with potential for future research.

Due to the nature of the architect/engineering business, the A/E team member will have historical and current experience in the establishment and deployment of full-service teams to comply with client requirements. The engineering firm can take the lead role in the integration of the team, interfacing of team elements, and the commitment of mutually-beneficial participation for all partnering members.

The primary contributions of an A/E firm to the partnering arrangement will be:

- Conduct of business planning
- Development of financial feasibility analyses
- Integration of team members and elements
- Conduct of market surveys
- Provision of project management
- Conduct of engineering/design support
- Implementation of technical optimization
- Integration of systems configuration
- Conduct of regulatory analysis
- Preparation of permitting and licensing requirements
- Preparation of technical procedures and specifications
- Identification of new needs and opportunities for laboratory programs

Universities and Academic Organizations

Universities and academic organizations should be selected to the partnering team that have a nationally respected reputation and that provide progressive programs in the promotion of engineering and technology development. Universities typically have dedicated faculty and well-developed facilities to support a partnering arrangement. The university also provides access to an engineering student body that can be dedicated to performance, and that is eager to participate in the development and implementation of leading-edge technologies.

The main focus of participation by academia will include:

- Participation in pilot/bench-scale testing
- Preparation of training programs and teaching aids
- Participation in faculty exchange programs
- Provision of co-op/graduate students for research
- Coordination of technology access from other labs
- Investigation of technology transfer from/to other organizations
- Conduct of literature surveys and information searches
- Preparation of technical reports

Small Businesses

Targeted, focused small businesses are the most effective means of making quick decisions on technology transfer, and should always be considered as potential partners. These small businesses provide an entrepreneurial and action-oriented culture that can serve to identify and act on opportunities and to reduce cost and save time through the implementation of innovative ideas. These companies may be equipment vendors, technology implementation specialists, and/or consultants within the DOE culture, as appropriate for the specific technology transfer venture.

The small businesses will be responsible to:

- Support implementation of technology
- Provide needed technology innovations
- Participate in technology demonstrations

Coordinate small business innovative research funding

SUMMARY OF THE PARTNERING PROCESS

The proposed concepts of a partnering agreement combines national laboratories, engineering firms, and academic institutions as the committed long-term team members, with supplemental small and/or specialty businesses selected as appropriate for each technology demonstration and transfer project. The national laboratory efforts will be concentrated in the front end of the process, where technology identification and development are key elements. The academic institution will provide supplementary development and innovation support, and will assist in receiving technology from the laboratory and preparing the technology for commercialization. The team engineering firm will provide the necessary coordination, management, and engineering/design to promote the success of an effective and beneficial partnering relationship.

48-8

ROADMAP PROCESS FOR COMMERCIALIZATION AND USE OF EMERGING CHARACTERIZATION AND MONITORING TECHNOLOGIES

P. W. Wang
T. A. Zachry
M. S. Anderson
J. B. Paladino
U.S. Department of Energy
Ames Laboratory

ABSTRACT

A roadmap process designed to facilitate acceptance of emerging technologies by users and commercial vendors has been developed for use by the U.S. Department of Energy (DOE) Characterization, Monitoring, and Sensor Technology Crosscutting Program (CMST-CP) to transfer its portfolio of technologies. The CMST-CP technology transfer roadmap consists of six main sections: needs assessment, identification of technologies for transfer, a managing-technology-for-development (MTD) process, a technology de-risking process, a technology verification (and/or certification) process, and a "hands-on" technical assistance process. Through the use of this roadmap process, many barriers that impede acceptance of new technologies have been identified and mitigated.

INTRODUCTION

Many contaminated sites exist within the U.S. as a result of nuclear weapons production activities during the past 50 years. According to the 1995 Baseline Environmental Management Report (1), the life-cycle cost estimate to clean up these contaminated sites ranges from $200 to $350 billion in constant 1995 dollars, with a midrange estimate of $230 billion. Over 90% of this total cost will be incurred during the next 40 years, with the remainder lasting to the year 2070 for operation of a few large waste treatment facilities. Because of significant uncertainties, many assumptions were made to derive this estimated range. While the estimate is continually being revised and can be expected to decrease based on newly available data, the nation's contamination problems remain great in scope as well as costliness.

The significant uncertainties cited in the report relate to the lack of characterization of contaminated sites, the technical risk associated with remedial solutions, public and regulatory acceptance of "effective" technologies, and future land use decisions, to name just a few. The

report further states that only one-fourth of the known 10,500 hazardous release sites has been fully characterized. Assumably, substantial reductions in the cost and duration of cleanup operations can be realized by implementing "effective" characterization and monitoring technologies. However, new technology is rarely used in U.S. Department of Energy (DOE) cleanup activities (2). The lack of acceptance of new technologies primarily results from an inadequate amount of technical information, insufficient stakeholder/regulator involvement in decision making, and a lack of teaming between technology developers and users.

The mission of the Characterization, Monitoring, and Sensor Technology Crosscutting Program (CMST-CP), a technology development program within the Office of Science and Technology
(OST) of the DOE Office of Environmental Management (EM), is to provide needed characterization and monitoring solutions in the following key problem areas, hereafter referred to as the Focus Areas:

- contaminant plume containment and remediation;
- high-level waste tank remediation;
- mixed waste characterization, treatment, and disposal;
- landfill stabilization; and
- facility transitioning, decommissioning, and final disposition.

The annual CMST-CP Technology Summary reports, available from 1993-1995 (3,4,5), detail the program's portfolio of technology development activities and their progress.

The Office of Technology Integration, within the OST, is responsible for developing and implementing roadmap processes that lead to the successful use of developed technologies to address environmental problems as well as commercialization for economic benefit. One such roadmap process has been followed for commercialization and use of emerging technologies developed under the auspices of the CMST-CP.

TECHNOLOGY TRANSFER ROADMAP

The CMST-CP technology transfer roadmap, shown in Fig. 1, consists of six main sections: needs assessment, identification of technologies for transfer, a managing-technology-for-development (MTD) process, a technology de-risking process, a technology verification (and/or certification) process, and a "hands-on" technical assistance process. The development of each technology within the CMST-CP portfolio is closely analyzed and scrutinized in accordance with the criteria established within these sections to maximize the probability for successful use and commercialization. A summary description of each section is provided below.

Fig. 1

Needs Assessment

This section encompasses needs identification, validation, and market study. CMST needs were recently identified through site visits conducted by the five Focus Area teams working with individual Site Technology Coordination Groups (STCGs). In addition, CMST needs published in the 1993 edition of the Technology Needs Crosswalk (6) report were validated through listed user contacts and were prioritized according to their assessment of the urgency and cost-savings impact of new technologies.

A market study report describing current and potential markets for chemical sensors and fieldable analytical instrumentation will be completed by February 1996. This report will be used, as the primary informational material for discussion, in the workshop and forum on

chemical sensors for environmental applications to be held in conjunction with the 1996
Pittsburgh Conference. Further market studies are scheduled, and will focus on process monitors and controls and possibly geophysical measurement techniques and data integration tools. In general, these market studies contain several elements: review of commercially available technologies, market estimates and forecasts, and identification of gaps where technology development is needed as well as prioritization of that development.
These market studies along with the customer-focused needs assessment will be used as a tool to assess the value of each technology as perceived by customers (government and private sector). The evaluation of baseline technologies and identification of specific performance characteristics affecting purchase and usage decisions by customers provide an important validity check of the needs assessment results.
Identification of Technologies for Transfer
This section involves coordinating resources and compiling databases to help identify technologies that are ready for transfer. Reports of federally funded R&D activities are becoming increasingly accessible, and many organizations sponsored by federal programs are spearheading efforts to provide on-line access to database information. In the CMST area, these resources include the Technology Summary booklets (3,4,5), the Technology Catalogue, EnviroTRADE and ProTech services, the CMST Technology Catalogue, and others. The CMST Technology Catalogue, an effort headed by Applied Sciences Laboratory, Albuquerque, New Mexico, in collaboration with the CMST Technology Transfer project office at Ames Laboratory, documents information on performance and cost of performance of 58 CMSTs. These informational materials are presented on the Internet at the address: http://cmst.ameslab.gov/cmst/homepage.html.
In addition, two versions of a "Technology Solutions" brochure have been produced. Each contains a different summary list of technologies available for transfer and their potential applications, with one targeting environmental restoration operations and the other waste management operations.
Managing-Technology-for-Development (MTD) Process (7)
The MTD process categorizes technology development into seven maturation stages (or gates): basic research, applied research, exploratory development, advanced development, engineering development, demonstration, and implementation. The criteria and requirements at each stage are clearly defined. Maturation stage information is necessary for a planned and systematic advancement from conceptualization through implementation. It is also required for resource allocation and decision making on levels of private sector involvement, user commitment, and regulatory/stakeholder involvement. This integrated planning tool is designed to address the funding gap or "valley of death" issue that occurs prominently at and after the engineering development stage. By teaming with technology developers, customers, stakeholders, and regulatory bodies, and by clearly defining the commitment required from each at individual maturation stages, an orderly hand-off process can succeed. This model has been adopted for use by the OST.
Technology De-Risking Process
This process involves providing financial support for beta-site testing of "developed" technologies to facilitate their acceptance by customers. It is applicable when a customer has specific technology performance and

cost requirements, and a technology developer can provide the needed solutions. The technology must be beyond the advanced development stage (see MTD process described above) and the prototype must be accompanied by well documented performance data. An implementation plan must be furnished by the customer describing how the technology will be used once it meets performance and cost requirements. This funding is jointly applied for by the developer and customer, and is intended to cover, on a cost-sharing basis, expenses associated with infrastructure support incurred by the customer and the equipment use, testing, and training expenses incurred by the developer. The CMST Technology Transfer project office has developed an application process and acceptance criteria, and has secured funding to support the de-risking of four technologies. This pilot activity is in the early stages and has received three applications which are listed in Table I. Two are being evaluated, and one has been funded and testing has begun.

Table I

Technology Verification (and/or Certification) Process

This process is designed to gain acceptance of a technology by a wide base of customers. Among the many barriers affecting customer acceptance, two formidable ones are: the robustness and completeness of performance data sets, and varying requirements from site to site. Many documented performance data are site-specific and on occasion are obtained under best-controlled conditions. These data sets lack completeness because of the uncertainty of whether they can be reproduced under different test conditions or sample matrices; they lack robustness because of an inadequate level of quality assurance/quality control (QA/QC) data management.

Many state regulatory authorities, federal departments (Department of Defense, Department of Commerce, and DOE), and regional and national Environmental Protection Agency (EPA) offices are teaming to develop working models to address technology performance verification and reciprocity issues. One such model was implemented for the RCRA and Other Heavy Metals in Soils Demonstration. This activity was jointly sponsored by MSE, Inc., the prime contractor for the DOE Western Environmental Technology Office; Sandia National Laboratory, a technology verification entity under contract to the EPA Consortium for Site Characterization Technologies (CSCT); and the Ames CMST-CP and Technology Transfer projects office. Four technology developers participated in the field demonstration activities during the week of September 25, 1995, in Butte, Montana. These developers, their technologies, and the assayed metals are listed in Table II.

Table II

Split samples were archived and sent to two EPA CLP laboratories for confirmatory analyses. The final evaluation report, scheduled to be issued by the CSCT in March 1996, will not only detail the performance (and cost of performance) of demonstrated technologies against individual developer or vendor claims, but also comparatively evaluate these field performance data with results gained from using baseline, laboratory EPA CLP methods. The performance of the four technologies under differing matrices and test conditions will be documented in accordance with a well defined QA/QC data protocol.

The CMST Technology Transfer project is pursuing the opportunity to participate in the recently announced "Rapid Commercialization Initiative," a coordinated effort between the Department of Commerce,

Department of Defense, EPA, and DOE. In addition, verification activities dealing with continuous emissions monitoring technologies and fieldable technologies for the detection of volatile organic compounds (VOCs) and radionuclides in groundwater are being planned. Progress toward these planned activities will be presented at the conference.

"Hands-On" Technical Assistance Process

This process is designed to bring the best-available technological solutions to DOE sites and to assist users with implementation. Such assistance encompasses assessing site problems, researching best available technologies for solving problems, providing on-site technical services, linking site personnel with vendors, helping make equipment/instruments available for testing, devising test plans, and providing training support to site personnel.

Two approaches are used in this process. The first is to market technical assistance services directly to DOE site managers and contractors. A case study showing how the CMST-CP worked with the Westinghouse Defense Waste Processing Facility (DWPF) exemplifies this method. During a visit to the DWPF in Aiken, South Carolina, in July 1995, CMST-CP and DWPF site personnel identified the need for 20 technologies that could potentially reduce the life-cycle cost of high-level waste processing operations. Of the 20 technology needs, eight could be met through further technology development; the remaining 12 needs could be met with existing technologies. To solicit the needed technology development, the Tanks Focus Area and the CMST-CP jointly issued a Call for Proposals. Five proposals were subsequently selected and awarded. In relation to the 12 technology needs with ready solutions, the CMST-CP requested detailed information about functional and operating requirements, waste matrices, and physical requirements (size, weight, power consumption, shape) from DWPF personnel. A technology solution package for each identified need will be created after adequate information is received and assessed.

CMST-CP personnel also visited the Argonne National Laboratory site to investigate the VOC and radionuclide contamination problems at the 317/319 waste sites. Further progress relating to these activities will be presented at the conference.

The second approach is to partner with environmental firms to collaboratively provide hands-on technical assistance to DOE sites. Currently, environmental firms are contracted to perform many of the tasks described above at DOE sites. By closely teaming with these firms and site personnel, the CMST-CP can incorporate its broad knowledge about the merit of emerging technologies into the planning process for developing effective technological solutions, which environmental firms and site personnel can then implement. This approach is in its infancy stage; many follow-up activities are expected to develop.

CONCLUSION

The CMST-CP technology transfer roadmap process identifies and mitigates many barriers that impede acceptance of new technologies. Completeness and robustness of technical information can be achieved by following a well developed QA/QC data management plan as an integral part of a field demonstration guidance plan. The technical performance and costs of new technologies are evaluated and verified against vendor claims and baseline technologies under real-life field conditions by working closely with regulatory bodies and technology developers and users. The resulting field performance and cost information can then be furnished to potential

customers who are responsible for making characterization and remediation decisions.

The "valley-of-death" funding gap is justifiably identified as one of the main barriers to transferring technologies successfully. The CMST-CP approach of pairing technology developers with users as well as providing beta-site testing support and hands-on technical assistance is aimed at mitigating this issue by awarding limited funding support to leverage large resources from other sources including site operations and technology developers and users. Two notable successes include field testing the Sandia robust hydrogen sensor for use in Hanford high-level waste tanks and the teaming activities with the Tank Focus Area and DWPF site personnel. While the funding gap issue remains largely unresolved, a process to use limited resources to achieve the highest return is being developed and practiced.

APPLICATION OF COMMERCIAL NUCLEAR PLANT WASTE MINIMIZATION PRACTICES TO DOE FACILITIES

Heatherly Hicks Dukes
Westinghouse Savannah River Co.

Jerry Hettinger
Pennsylvania Power & Light Co.

ABSTRACT

This paper examines the need for, and feasibility of, an aggressive waste minimization and volume reduction program at the Savannah River Site (SRS). Commercial nuclear plants have been wrestling with the high costs

of radioactive waste disposal for several years and have developed proven programs that may be beneficial for DOE nuclear facilities as well. Though the cost of radioactive waste disposal is typically lower at DOE sites than commercial nuclear plants, dwindling budgets for government projects require closer scrutiny of costs.

It was concluded that significant cost savings could be easily achieved by implementing selected commercial nuclear industry's innovative strategies, techniques, and technologies for eliminating radioactive waste. Analysis of the implementation cost of Commercial Strategies indicates a clear cost benefit with implementation costs typically recovered within the first year.

Acknowledging that the private sector has set the standard for waste minimization, SRS is partnering with private enterprise to lead Savannah River and the rest of the DOE Complex to the cutting edge of waste minimization technology and practices.

INTRODUCTION

The end of the Cold War and shrinking Federal budget has led the DOE Complex to look for innovative means to improve the quality of existing programs while cutting costs. Each DOE site's ultimate survival depends on an aggressive, results-oriented approach to getting more done with less, while protecting the health and safety of workers and the public. Eliminating waste must become a state of mind for every site initiative (1).

The challenge of surviving in a global economy has forced the private sector to develop methods for working smarter and producing more with less. The commercial nuclear industry has developed innovative strategies, techniques, and technologies for eliminating and reducing waste. Acknowledging that the commercial industry has set the standard for waste minimization, the Savannah River Site (SRS) has sought out leaders in the waste field to ensure the best practices and technologies are implemented throughout the DOE Complex.

SRS is a 300 square mile multi-facility DOE nuclear site that includes a fuel processing area, several labs, five reactors, two fuel reprocessing canyons, and several disposal facilities. This site is located on the southwestern border of South Carolina adjacent to the Savannah River and has been operated for several decades producing Special Nuclear Materials for the nation's defense programs and rare isotopes for non-defense applications such as research and space programs.

There are numerous DOE sites that have one or more facilities that are similar in nature to SRS' facilities. The waste minimization and volume reduction programs that are cultivated at SRS could be easily implemented at other DOE sites.

ESTABLISHING THE USER GROUP

To begin learning what techniques the commercial industry is using to minimize their waste, several SRS representatives were asked to form a team to tour two commercial nuclear plants, which were Susquehanna Steam & Electric Station and Beaver Valley Power station. The SRS group had a cross section of organizational lines and functions with representatives from Solid Waste, Radiological Controls, major SRS Waste Generating Organizations, and the Department of Energy (DOE). After two days of walkdowns in the commercial plants and discussions on their programs, the SRS representatives came back with many ideas on how to reduce waste and save money.

To implement programs consistently across the SRS site requires careful planning due to the variety of facilities with vastly different radiological environments. It was decided that the original representatives that went to the commercial plants would form a User group to ensure the best waste minimization and volume reduction programs were implemented for the site. Several smaller task teams were formed as necessary to resolve specific implementation details to make the programs work for the entire site.

Several other commercial plants were visited after the User Group was formed to ensure that the programs being developed at SRS included the major waste minimization practices being utilized by commercial plants in the United States.

BRING IN THE TROOPS

While visiting Susquehanna, a consultant was analyzing the plant's waste generation for further improvements in their waste minimization programs. Susquehanna found that contracting a waste minimization expert to review their program brought a different range of experience and insight than the personnel who worked with the programs on a daily basis.

At the time of the SRS visit, Susquehanna was in the process of cost cutting. Susquehanna's waste cost at Susquehanna included both waste processing and disposal costs (with disposal costs being the largest portion by far). Since Susquehanna is a part of the Appalachian Compact, they have a projected disposal cost in excess of $700 per cubic foot. Susquehanna had established three teams to address the waste reduction strategies. The three teams were to address non-radiological waste, wet radiological waste and dry active waste (DAW) reduction respectively. This was the same focus that the SRS visit was investigating.

Susquehanna had talked to other utilities and implemented many of the obvious waste reduction methods by early 1995, but still lacked the focus on details. At this point, the Susquehanna teams arranged to have an EPRI assistance visit to help identify some of the not so obvious minimization and reduction methodologies. The EPRI assistance visit coincided with the SRS visit to Susquehanna and benefited both the Susquehanna and SRS personnel.

Susquehanna received the recommendations from the EPRI team in June and has been implementing these over the past several months. The recommendations have proven to be effective in reducing the DAW generation in the last outage by nearly one half. These efforts helped Susquehanna become competitive in a deregulating utility environment.

SRS had not had a detailed waste minimization assessment performed by anyone from the commercial industry and decided to seek input from a consultant that had analyzed numerous nuclear waste minimization programs. A detailed assessment may seem costly, but if numerous waste minimization techniques can be incorporated to a waste program, it will compensate for the initial assessment cost many times over.

The SRS Solid Waste department contracted Environmental Resources and Services (ERS) Corporation to assist the major Low Level Waste (LLW) generators in evaluating and characterizing their existing LLW generation, minimization, processing, and disposal practices. The contractor was also tasked to identify a wide variety of potential mechanisms for reducing waste volumes and associated costs. Each facility's waste composition was analyzed to determine where the biggest waste reduction efforts should be concentrated. Figure 1 shows one facility's waste composition breakdown. After several facilities were

analyzed, major waste patterns became apparent that affected most facilities across the site. These waste patterns were targeted for the initial reduction effort since they would give the most cost benefit for the site.

The contractor stressed that the best waste programs incorporate the following strategies in the given order: Management Support, Source Reduction, Recycling, Volume Reduction, and Disposal. Each of these strategies have been incorporated at SRS. The contractor provided a detailed report on various programs that would eliminate the highest volume waste patterns at the facilities evaluated (2).

Fig. 1

Several representatives from Susquehanna also visited SRS for similar walkdowns and discussions that had taken place at their plant. It was thought the commercial partnership would be a "parasitic relationship and a one-way exchange of information" (from commercial utility to SRS). However, this turned out not to be the case. In fact, Susquehanna visitors felt that they brought back with them a sample of one of the best waste tracking programs that they had been exposed to and plan to implement a similar program. This reciprocal visit to SRS confirmed to the participants that this is a win-win relationship since both companies' common ground is in source reduction and back end treatment of radioactive waste.

MANAGEMENT SUPPORT

According to the EPRI report that Susquehanna uses, "Solid Low Level Waste Management Guidelines", visible management support for waste minimization is the foundation for any waste reduction effort. By visible, this means visible to the employees so that waste minimization becomes a team effort. In the commercial industry, the companies with the best waste reduction programs also have the most visible management support for the effort (3). This was also stressed in the report, "Low Level Waste Characteristic Study", which was written for SRS after studying our waste programs (4).

To heighten SRS Management's waste awareness and to increase their support for waste minimization, several User Board representatives gave presentations to the senior staff over a period of several weeks. Also, an Incentive Fee milestone for reducing the site's waste by 40% was set with an award fee of $1,285,000. Senior Staff immediately recognized the advantages of a strong waste minimization program and are supporting efforts to meet the Incentive Fee milestone.

The establishment of the User Group also increased the visibility of management support for reducing waste. Several key waste managers and representatives were participating in this group. At the division level, LLW Reduction Committees were formed to implement the waste reduction programs that the User Board determined to be the most cost beneficial. Waste reduction goals were turned in by the divisions to the site and tracked to ensure progress toward the Incentive Fee milestone of a 40% waste reduction.

A waste minimization training package, that included a video, was developed by SRS Site Training group. This training will be given to the majority of the waste generators on site and emphasizes source reduction practices. This training was developed after viewing several waste reduction tapes from specific commercial power plants who were recognized in the industry as having excellent waste management programs.

GOING FOR THE GREEN

In April of 1995, the procedure for controlling materials in radiological areas was revised to more clearly reflect what the DOE Radiological Controls Manual had intended. One significant change allowed equipment/material (non radiological materials) stored or used in Radiological Buffer Areas (RBAs) be released without a Radiological survey if the owner/custodian/user believed there was no potential for contamination. RBAs are maintained at Clean Area limits which are the following: tritium <1000 dpm/100 cm2, Beta-gamma <200 dpm/100 cm2, and alpha <20 dpm/100 cm2.

The site was considering a program for releasing low potential waste from RBAs when the User Group visited Susquehanna and previewed one of their source reduction programs: Green is Clean. At Susquehanna, their Radiological Control Areas are similar to DOE defined RBAs. Susquehanna segregates their potentially clean waste from contaminated waste by placing the clean waste into Green is Clean receptacles. Green is Clean waste is placed on a conveyor where a gamma monitor scans the waste for release. Susquehanna saves an estimated $500,000 per year as a result of implementation of the Green is Clean program.

Since SRS RBAs are maintained "clean", waste that the owner/custodian/user believes has no potential for contamination can be thrown into Green is Clean receptacles or taken directly out of the RBAs and thrown away as sanitary waste. Radiological Controls (RC) personnel perform surveys of the RBA areas and Green is Clean receptacles to ensure Clean Area limits are being maintained. Green is Clean waste that is removed from the specially marked receptacles is shredded before being disposed of as sanitary waste to ensure radiological markings are defaced. A percentage of the waste is surveyed either before or after being shredded by specially trained personnel to ensure that contaminated material has not been accidentally placed in a Green is Clean receptacle. Incoming Green is Clean waste is specifically tagged with the name of the waste packager, date, and facility from which the waste originated. This allows proper tracking if contaminated material is found in the Green is Clean waste. To date, no waste has exceeded the Green is Clean radiological limits.

Currently, Green is Clean has been implemented in Excess Facilities and Reactor Fuel Storage Division which contains eight facilities and four different radiological environments. 330 cu-ft per month of Low Level Waste (LLW) is being re-directed to Green is Clean for a yearly savings of $160,000. The cost savings far exceeds the implementing cost of the program which was < $10,000. SRS will be implementing this program sitewide in the upcoming months for an estimated annual LLW avoidance of 25,000 cu-ft and savings of $1,000,000. The Green is Clean program is the highest priority on the User Group implementation schedule. This is considered a source reduction program and the implementation costs are inconsequential, whereas the cost savings are tremendous.

WASH IT

While touring the commercial power plants, washable waste bags and tarps were observed being used as a recycling technique. Plant waste was being gathered into washable bags and taken to a waste segregating station where the waste bags were then reclaimed by laundering. Tarps were being used for staging high contamination work that use to require plastic coverings. Even though SRS has not decided to initiate a centralized waste segregating station, launderable bags and tarps were immediately recognized as a potential large waste savings since the site uses more

than 100,000 radiological bags and 200,000 square feet of plastic for transporting radioactive material.

To implement the use of launderable bags, various sized bags were designed to transport a large variety of materials, such as: radiological vacuum cleaners, hot tools, and damp launderable mops. Specialized launderable bags were specifically designed for the removal of 5'x 5'x 16' racks used to store irradiated fuel. The racks are typically lifted out of the basin and double wrapped in plastic, but the launderable bag allowed the rack to be placed right into the bag, zippered and ready to go in about ten minutes. The racks were then transferred to another part of the facility for volume reduction and the bag sent to the laundry for reuse. In all, 14 racks were removed for a waste minimization of 76 cu-ft and total waste cost avoidance of $ 3,780, which does not include the savings from the reduced manpower hours required to prepare the racks for transfer. Another type of bag has been designed to transport fuel casks from one facility to another. The waste savings on this project alone will be a minimum of 4000 cu-ft, plus the savings from numerous man-hours being eliminated for crane manipulation of the cask and wrapping.

Tarps are available to replace plastic being used to protect floors during high contamination work or for wrapping materials for transfer. The site's facilities are located several miles apart in some cases and material must be transported by truck or rail. Historically, the items being transferred were double wrapped to prevent wind damage. The plastic was thrown away as LLW once the item arrived at its destination. By using the washable tarps and bags, a waste minimization of 40,000 cu-ft is estimated once the entire site utilizes these launderable items.

Launderable bags and tarps that have been designed for SRS radiological work are featured in a catalog that can be viewed on the site computer network. An inventory is maintained so that launderable bags and tarps can be utilized immediately by the many facilities at the site.

The commercial industry has also converted to washable mops and rags. SRS uses 450,000 atomic swipes per year for general area smears, absorbent material, and decon cleaning which converts to 4,500 cu-ft of waste per year. By utilizing washable rags instead of atomic swipes, a cost savings of $180,000 can be realized. The same can be said for mops which SRS uses to a tune of 13,379 per year and is responsible for 3,000 cu-ft of LLW. By switching to launderable mops, a cost avoidance of $100,000 can be realized. Currently, five facilities have implemented the use of launderable rags and mops and are estimating a waste minimization of 700 cu-ft annually.

If SRS implements a full launderable program, a total of 98,000 cu-ft of waste can be eliminated (4). In one division where the launderable program has been implemented, the implementing costs were <$40,000, with an annual cost savings is $268,074.

Washable protective clothing (PC) is used throughout the industry, however, the quality of the clothing greatly affects the viable lifetime. At the many plants visited, various types of PCs were observed that seemed superior to those used at SRS. At SRS, a poly/cotton PC is used that has had some shrinkage problems and a looser weave than the ones observed in the commercial plants. Currently, several commercial protective clothing vendors have submitted samples of their wares to SRS for testing. A task team will evaluate the results and procure a more durable PC so that unusable PC waste can be reduced. The PC task team is also reviewing the radiological limits that require PCs to be thrown away

instead of being laundered. The SRS radiological restrictions for sending PCs to the laundry seem to be more restrictive than some DOE sites and all commercial nuclear plants, even though many of the plants are using the same laundering company. If the radiological laundry limits are raised, many PCs can be laundered instead of becoming LLW before they are worn out. In two months alone, more than 16,000 sets of protective clothing were discarded in the trash and lost to one facility. At 2 cu-ft and $20 per set, this one example represents $320,000 in replacement costs and another $1,472,000 in disposal costs (4).

REUSE IT

A prefabricated containment program has been implemented at SRS as a source reduction and recycling technique. Glovebags have been used extensively by the Navy and pre-fabricated huts have been used throughout the commercial industry. In the past, huts at SRS were hand-built out of scaffolding, plastic, and tape for each job. Once the job was completed, all the plastic and sometimes the scaffolding, would be disposed of as LLW. When hand-built huts are used outdoors for an extended period of time, the walls and seams must be maintenanced and retaped many times to maintain its integrity. The site shifted toward prefabricated huts because they were more easily installed and dismantled and can be reused many times. The outdoor huts can be reused at least five times (one month intervals) before they are considered too weathered and the indoor huts can be reused indefinitely. All the seams are heat sealed, so the use of tape is eliminated.

The site is moving toward the increased use of glovebags since they contain contamination to a smaller area than huts and allow the workers to wear less protective clothing. By containing the contamination to such a small work area, an insignificant amount of waste is produced when compared to work performed without containments.

In the past, procurement delays caused many projects to forgo using containments. To eliminate this problem, a central issuance station has been established where containments are stocked so that pre-fabricated huts or glovebags can be readily available as radiological work evolves. The time and effort to set up the issuance station was initiated since the cost savings associated with the use of pre-fabricated containments is approximately $10,000 per use when compared to hand-built huts. Approximately $20,000 in man-hours were spent setting up the issuance station and catalog but over $1,000,000 has already been saved by using prefabricated containments from this centralized location.

REDUCE IT

As the commercial power plants face eventual decommissioning and dismantlement, numerous technologies have been developed to volume reduce the radiological waste produced from this effort. SRS has large volumes of legacy waste that will also need to be volume reduced. A centralized location was established having three major decontamination technologies: CO2 Blasting, Vacuum Grit Blasting, and Kelly Vacuuming.

For low to moderate decontamination efforts, CO2 Blasting and Kelly Vacuuming will be used. The CO2 Blaster works by impelling carbon dioxide pellets against the material surface causing the pellets to sublimate and lift the contamination to a high flow air stream and eventually to a HEPA filter. CO2 blasting is very effective on removing transferable contamination and contamination fixed in an oxide substrate or painted surface. CO2 blasting is also very effective on softer surfaces, such as lead bricks or computer key boards.

Kelly Vacuuming uses a contained super heated water stream and a vacuum system. The super heated water flashes to steam when it hits the contaminated surface and lifts the contamination from the substrate to the vacuum system. This method is especially effective on concrete and porous surfaces.

For aggressive decontamination efforts, the Vacuum Grit Blaster is used. The Vacuum Grit Blaster uses metal grit and a contained vacuum system to blast fixed contamination from metals and concrete.

The above methods may not be used in all cases due to impracticality or reduced cost benefit. For volume reduction of items, a large metal shredder and shearing system is being procured for use in the latter part of 1996.

At this time it is not possible to accurately estimate how much LLW will be reduced due to the new technologies since the equipment can be used to: reduce contaminated area square footage, clean individual pieces of equipment for salvage, clean equipment for repair with less waste generated, and shred equipment for better use of disposal space. A 5,000 cu-ft reduction in waste disposal is a conservative estimate for the first two years.

BURN IT

SRS is in the process of starting up an incinerator facility after reviewing the incinerators used by the commercial power plants which have a volume reduction ratio of 99:1 for their DAW waste. SRS has determined incineration of waste will elongate the life of our burial vaults by several years. To ensure that the incinerator will have feed material after startup, SRS is converting many current waste items to incinerable materials. One of the biggest changes has been converting poly-vinyl chloride (PVC) waste bags to polyethylene waste bags. Another big ticket item has been converting PVC plastic used for wrapping waste to materials that can be incinerated. For waste that can be converted to items suitable for incineration, a reduction of 100,000 cu-ft can be saved from taking up space in the on-site burial vaults.

CONCLUSION

At this point it should be noted that if each of the above mentioned programs is fully implemented at SRS, the waste reduction estimates are not additive. To illustrate this point, implementing the Green is Clean program takes away waste that could be replaced with launderables. Implementing the launderable program will eliminate waste to be incinerated. For the different sites within the DOE Complex, implementing a chosen few of the mentioned programs may be more cost effective than implementing all the suggested programs. Programs with low implementation costs should also be considered for initial waste minimization efforts. The programs mentioned here are not the only ones being considered for SRS. Other programs such as Contamination Area Rollback, 100% Recycle Zones and Second Sort programs are also being considered for implementation at a later date but may be better choices for some sites as their initial waste minimization initiative. In almost all cases, source reduction programs should be the initial consideration for each site.

Due to the similar radiological environments and regulations that each DOE site shares, waste programs could benefit by incorporating the SRS strategies that better emphasize Management Support, Source Reduction, Recycling, and Volume Reduction. Even though many of the DOE sites do not have the disposal costs that the commercial industry has, it is obvious

that tremendous savings can be achieved by implementing a few waste minimization techniques and technologies. Through our partnership with the utilities, each DOE site will have the opportunity to become more cost effective by reducing waste generation volumes.

A NEW TECHNIQUE FOR COVERING THE FINANCIAL RISK OF A WASTE MANAGEMENT PROGRAM

P.L. Kunsch
D. Emmery
ONDRAF/NIRAS
Place Madou 1 PO Box 24/25
B-1030 Brussels
Belgium

ABSTRACT

This paper presents a new financial technique developed to assist a nuclear waste agency in its funding strategy.
Such an agency has a major commitment to cover the totality of the costs generated by the waste entrusted to it. Most of the time, however, planning under uncertainty makes this task difficult. Provisions set aside in application of the "(Waste) Producer Pays Principle" may prove insufficient when it comes to completing the necessary technical programs, sometimes in a remote future.
To hedge against the threat of involving future consumers or tax-payers in the payment of past or present liabilities, adequate and robust financial techniques must be provided.
Such an approach is therefore valuable for all parties involved, namely agency, waste producers and general public.
The main lines of the approach are described in this paper. The basic idea is to have each waste producer committing himself to pay an agreed price for the future use of the services or facilities provided by the agency. The calculation of the price uses modern risk theory for financial decisions.
The paper describes in detail both aspects of how to calculate the price charged to the waste producers and how to invest the funds collected herewith.
It shows how the three main sources of uncertainty in a waste management program can be substantially reduced using the described approach:
- systematic reduction of the waste arisings in the course of time;
- wrong assessments of costs due to adverse trend evolutions, fluctuations or technical scenario changes;

funding strategy.

In conclusion, the paper provides information on the practical implementation of this technique by a nuclear waste agency.

GENERAL BACKGROUND

The fundamental principle for financing the Belgian radioactive waste program is that those who produce the waste should pay for all services to be performed ("Producer Pays Principle").

ONDRAF/NIRAS, the Belgian Agency for Radioactive Waste and Enriched Fissile Materials has the mission to collect radioactive waste and to fulfil all necessary steps till its safe final disposal.

According to the above principle, the agency works at cost price with complete financial transparency with respect to the producer. For that purpose the agency has established a financing mechanism on the basis of fees charged on each volume unit of waste delivered, in order to ensure complete financing of all the operations to be performed. For disposal operations the fees are paid into a fund which is interest bearing.

The accurate determination of the fees is not an easy task, considering the large technical and financial uncertainties, particularly for operations to be performed in a remote future.

Good modelling of the waste management system is therefore required to determine accurate fees which limit the risk of insufficient financing becoming a burden for the future community.

A new technique is presently being developed at ONDRAF/NIRAS which will hopefully reach this aim of reduced risk while respecting the fundamental principle of financing. Although in its present form, it is primarily tailored to meet the direct needs of ONDRAF/NIRAS, this approach may be useful for other radioactive waste agencies. In the following sections, we first describe the traditional approach and its drawbacks. We then sketch the new technique and review its practical application.

SUMMARY DESCRIPTION OF THE FINANCING APPROACHES

For a better understanding of the reasons that have induced the agency to review its approach, it is necessary to describe the traditional approach and its drawbacks.

Model of Traditional Actuarial Calculation

The traditional system of financing the various stages in radioactive waste management can be described as follows:

Calculation of the Unit Fees at Cost Price

A reference program is developed. It includes:

The waste removal schedule per year.

For reasons imposed by the concern for financial conservatism, the volume of waste considered does not include waste generated by the decommissioning of nuclear facilities (power plants and others) owing to the major uncertainties affecting the volumes produced. These uncertainties concern both the volumes and the moment on which the waste is collected and hence invoiced by the agency.

This schedule is therefore prudent from the financial point of view, but probably quite realistic as far as participation in the medium term is concerned.

The technical scenarios describing the waste management operations planned.

The calculation comprises the three following steps:

an economic calculation made on the basis of hypotheses on the various cost items expressed in constant francs of the year under consideration.

an actuarial calculation made on the basis of hypotheses of financial expenses and proceeds. This method makes it possible to calculate a unit cost price per m of waste, fixed for each management operation. The receipts and expenditure balance each other at the end of the operation.

sensitivity analyses, made on the basis of the reference program (schedule and technical scenarios) and of the financial hypotheses. These analyses make it possible to calculate the uncertainty margins added to the unit cost prices to form the per-unit-fee applicable to waste quantities.

The assumptions behind this calculation are the following:

a. The costs related to the services can be estimated with sufficient accuracy. For long-term operations like disposal, knowledge of these costs becomes more detailed with time and as industrial experience is accumulated for those services that are not yet operational.

b. The fee income can be estimated with sufficient accuracy on the basis of removal schedules planned in the long term for the whole of the Belgian program. Knowledge of the program also becomes more detailed with time. The increases or decreases in value of the invested assets are added to - or deducted from - the fee income.

c. The uncertainties related to expenditure on the one hand and to the schedules on the other hand can be evaluated satisfactorily by means of sensitivity analyses. An overall contingency margin is obtained.

d. The financial risk is reduced to its reasonable minimum by a judicious choice of the discounting rates. The financial margin takes account of the residual risk. Detailed Asset-Liability-Management-studies are performed to verify the adequacy of investment strategies of provisions and funds.

e. The distribution of costs between producers is based on a technical calculation of keys (schedule + scenarios), not taking into account uncertainty about actual programs.

Contractual Relationships

As far as contractual relations are concerned, every effort is made to negotiate open-ended contracts with (a) liability clauses to be included in the event of unforeseen costs; (b) clauses concerning the annual notification by the producer of any modifications to his production program; (c) clauses concerning fee adaptations (= cost price + contingency margins) made by the agency, which take into account interdependence in time and with regard to the other producers.

Drawbacks

This approach has shown some important drawbacks which call for a major revision. The main drawback relates to the high sensitivity of the unit fee with respect to the underlying assumptions of the reference program. Large fluctuations are the result. Although the frequent review of cost prices entails in principle high flexibility and, as a consequence, a limited risk of insufficient means, practice has shown that things are much more complicated. The basic hypothesis underlying the model is that the market, represented by the waste producers, would accept any price. This proved to be wrong. Indeed, commercial companies cannot easily accept practically unpredictable changes of price. Therefore, the traditional approach is rather fragile and perhaps unable in the long term to reduce the risk of insufficient coverage of future liabilities. This observation has triggered the need for a more robust approach, which the agency calls "reservation of capacity ". It is sketched below.

Model of So-called "Reservation of Capacity"

Calculation of Costs Attributable to the Producers

The differences with regard to the actuarial calculation, which is clearly "financial" in its approach of time, are considerable. This new model is indeed more "economic". It is more static, hence more prudent and robust in its way of anticipating and handling the time-related uncertainties which can be significant for certain stages of radioactive waste management.

This model has major consequences for the economic studies:

as far as the waste removal programs are concerned, the detailed removal schedule becomes purely indicative of an average distribution in time around a center of gravity. The producer firmly announces the total quantities - not revisable downwards but possibly upwards -, the "capacity" scheduled for removal of his waste.

This method makes it possible to distribute the costs in an objective way among the waste producers, and to determine the full "capacity" needed for the waste management operations;

as far as the technical scenarios are concerned, the detailed cost schedule becomes purely indicative of an average distribution around a "center of gravity", in the same way as before.

Replacing detailed schedules for quantities and costs thus avoids the main pitfall of the actuarial approach, described in section 2.1, which is very sensitive to any change in timing.

Moreover, the uncertainties no longer appear a posteriori in the sensitivity calculations, but are taken into account a priori considering systematic and stochastic uncertainties for each cost item.

The calculations are based on the following principles:

a distinction is made between "fixed costs", independent - within certain limits - of the quantities removed, and "variable costs", proportional to the quantities actually removed in the future;

the fixed costs are distributed among producers according to the "reservation of capacity" principle. Each producer makes a binding minimum commitment to cover his part, regardless of the future fluctuations of his actual program. This commitment takes the shape of an irrevocable guarantee on behalf of the producer.

Each cost item, besides being fixed and/or variable, reveals certain specific uncertainties:

systematic uncertainties, often linked to the lack of conservatism of the project engineer who tends to underestimate the cost driftsa, but also arising from differentials with regard to the economic evolution (measured by inflation or PCI), which are evident in certain activity sectors, for instance in the building trade or in the raw materials industryb;

Systematic factors are taken into account in certain cost items, when it clearly appears that the engineer's assessment is an underassessment of realistic costs, or that a drifting growth can be expected

(1) Average of the realistic cost item =

"Engineer's assessment" x systematic drift factor

stochastic uncertainties, linked to the imperfection or inaccuracy of the a priori knowledge of the actual cost at the time of its occurrence. This type of uncertainty can be represented in different ways, according to the type of analysis performed:

Rectangular: a range around the average value given in (1) and for which a sufficient confidence level can be given (90% of the cases are in this range);

Gaussian: the standard deviation of a gaussian distribution the average of which is given by (1);

Distribution: another distribution, possibly multimodal or asymmetrical, to be specified, centered around an average value (1).

Certain uncertainty distributions can be correlated with each other, for instance the cost of engineering and the personnel costs. Ignoring these correlations amounts to adding uncertainties in a too conservative manner. Consequently, sufficient attention is paid to the identification of uncertainties evolving concurrently.

A global uncertainty factor to be assigned to the fixed and variable costs of each operation is derived by combination of basic uncertainties.The aim of the calculation is to determine the adequate fee to cover the costs at a high confidence level of at least 90%.

Contractual Relationship

The contractual relationship is basically different in timing and in scope from the traditional relationship. While in the latter, the duration and extent of services are simple assumptions based on the reference program, the former implies a firm commitment of both parties. The contract stipulates in detail the precise request of the producer regarding waste management, such as waste types, quantities, and operations to be performed.

In exchange, the agency quotes a price valid for a minimum time period of 10 years. It includes the fixed costs with uncertainties, incurred whatever the actual quantities of waste to be handled.

The fixed part of the price represents a contractual guarantee to be paid by the producer regardless of his actual future program. It is interpreted "as share of the use" of resources of the agency, and it is proportional to the quantities agreed on in the contract. The payments are made, as in the traditional approach, by (fixed and variable) unit fees levied at delivery date on each unit of waste. To take into account either interests on invested money or opportunity cost of capital, the fees escalate each year, beyond inflation, by a constant risk free interest rate.

The payments related to the fixed part of the fee come in deduction of the contractual guarantee.

The conditions agreed upon cannot be revised before the term of at least 10 years. Should the producer exceed the originally planned "reservation of capacity", the guarantee is increased accordingly.

At the end of the contractually agreed period, the waste producer is confronted with the decision of reviewing or of terminating the relationship with the agency.

This decision may be either

Decision 1: the producer decides to end his activities. In this case, he completes outstanding payments related to the fixed costs, i.e. the part of the guarantee that has remained unpaid at this time ;

or

Decision 2: the waste producer decides to sign up for a new period. He provides the same information as previously regarding his waste management needs. The agency reassesses the guarantee level, using the information available at the time, and taking into account the new request as well as the past program and payments. To assure the continuity and the most equitable share of fixed costs among all producers, the new request shall in no case be inferior to the total waste program announced in the previous contract.

FINANCIAL RISK HEDGING USING THE NEW APPROACH

The new approach is characterized by a low financial risk taken by the agency, as fixed costs are covered in their totality with a high confidence level. At the same time, it limits the planning uncertainties of the waste producers, as the future payments are completely known or a known function of the actual waste delivery program. The portion not yet paid, is part of the total guarantee which will only become extinct after all commitments have been fulfilled.

In the wording of modern asset valuation theory, the producer buys a "call option" on the price imposed by the agency for handling his waste. This option is implicitly exercised whenever the actual cost exceeds the agreed price.

The agency sells this option and gets the risk premium, which represents the expected value of the excess costsc. Therefore, adequate financial means are available for the agency, whatever the actual waste delivery program will be.

For funds and provisions, excess return beyond the constant risk free escalating rate of the fees provides additional hedging against unforeseen drifts in the costs.

CONCLUSIONS

The new financing approach significantly reduces the risk of insufficient financial means in carrying out the waste management program.

It should be noted that for financing radioactive waste management, Sweden uses a "reservation of capacity" approach, while Finland has implemented a guarantee system for funding means that are not yet available.

In Belgium there is reasonable confidence that waste producers are in favor of a system combining these two techniques. In contrast to the usual net present value approach, it substantially reduces large sources of uncertainties, i.e.,

- systematic increases or fluctuations in costs ;
- changing technical scenarios or revised operation schedules ;
- systematic reductions or fluctuations in waste volumes to be handled by the agency;
- investment policy of funds and provisions.

This increased robustness before large uncertainties, fully benefits to the agency, as well as to the producers themselves and to the public at large. It eliminates unwanted price fluctuations, and the threat of additional payments for past inaccuracies.

Therefore it also fully responds to the requirements of the "Producers Pays Principle" towards the present and future collectivity.

ON-SITE VS. OFF-SITE MANAGEMENT OF ENVIRONMENTAL RESTORATION WASTE: A COST EFFECTIVENESS ANALYSIS

Albuquerque, NM 87185

ABSTRACT

The Sandia National Laboratories Environmental Restoration Project is expected to generate relatively large volumes of hazardous waste as a result of cleanup operations. These volumes will exceed the Laboratories' existing waste management capacity. This paper presents four options for managing remediation wastes, including three alternatives for on-site waste management utilizing a corrective action management unit (CAMU). Costs are estimated for each of the four options based on current volumetric estimates of hazardous waste. Cost equations are derived for each of the options with the variables being waste volumes, the major unknowns in the analysis. These equations provide a means to update cost estimates as volume estimates change. This approach may be helpful to others facing similar waste management decisions.

BACKGROUND

Sandia National Laboratories (SNL), a Department of Energy (DOE) laboratory located in Albuquerque, New Mexico, is aggressively implementing an Environmental Restoration (ER) Project that is planned to be completed in the year 2000. There are currently 157 solid waste management units (SWMUs) identified as candidates for assessment and remediation at SNL's New Mexico facilities and test areas. These sites include landfills, septic systems and drain fields, firing sites and burn pits, outfalls, surface storage areas, underground tanks, and miscellaneous test areas and discrete sites. The waste materials, or contaminants of concern, include hazardous constituents, low-level radiological constituents, mixed hazardous and low-level radiological constituents, and some Toxic Substances and Control Act (TSCA) regulated constituents, as well as sanitary or non-regulated constituents. The total estimated volume of ER waste likely to be generated is 60,800 cubic yards, including 37,000 cubic yards of hazardous, 2,500 cubic yards of low-level radioactive, 3,700 cubic yards of mixed, 5,700 cubic yards of TSCA, and 11,900 cubic yards of non-regulated.

The SNL ER Project is regulated under a Resource Conservation and Recovery Act (RCRA) Hazardous and Solid Waste Amendments (HSWA) permit. As such, there is a specified schedule for the major assessment and remediation activities associated with each SWMU. The relatively large quantities of waste that are to be generated by the ER Project will exceed the waste management capabilities of SNL, which are sized to support only the day-to-day operations. Consequently, the ER Project must develop an independent strategy for waste management to assure that it can meet the HSWA permit schedule and do so with maximum efficiency. A temporary unit (TU) to store ER-generated waste for one year, with a possibility for a one-year extension, and a corrective action management unit (CAMU) to store, treat, and possibly dispose of ER waste over the duration of the ER Project, are critical elements of the SNL ER strategy. The Environmental Protection Agency (EPA) promulgated the TU/CAMU Rule in 1993 specifically to give greater flexibility to owners of large restoration projects that were being constrained by lack of treatment, storage, and disposal (TSD) facilities capable of meeting land disposal restrictions (LDRs) and minimum technology requirements (MTRs). The TU/CAMU Rule provides the means to excavate ER waste without triggering either LDR or MTR requirements because the waste is not considered to be

"generated" if it goes to a TU/CAMU for treatment, storage, and/or disposal.

Once it was determined that a waste management strategy utilizing both a TU and CAMU might offer reduced treatment, storage, and disposal costs as well as an accelerated cleanup schedule, it was decided that analyses should be performed to verify benefits and quantify the potential savings. This paper summarizes the results of an analysis of costs (and savings) for each of four waste management options. A previous study concluded that the availability and cost of off-site treatment and disposal for the estimated volumes of ER-generated radiological, mixed, TSCA, and non-regulated wastes was such that the CAMU could be used for hazardous wastes only, thus simplifying the permitting process. Therefore, the options analysis summarized below includes only hazardous waste volumes and associated treatment technologies in its underlying assumptions. The results of this analysis will be used to determine the optimal solution for managing ER wastes, in terms of cost, under various waste volume scenarios.

COST ANALYSIS

Four discrete options for the storage, treatment, and disposal of hazardous ER wastes were evaluated to assess their cost effectiveness. Option 1 assumes that all hazardous wastes will be sent off site for treatment and disposal at permitted TSD facilities. The other three options consider various combinations of on-site and off-site storage, treatment, and disposal, and thus require implementation of a CAMU. The second option assumes that the CAMU will be used for interim storage only with off-site treatment and disposal. The third assumes that the CAMU will be used for on-site storage and treatment. Non-regulated materials, i.e., treated materials, will be reused as fill and concentrated materials will be sent off site for disposal. The fourth option is similar to the third except that the treated materials are assumed to be placed into an engineered disposal cell in the CAMU. This option is considered important because until treatability studies are completed on SNL wastes, the actual efficiency of selected treatments for the various waste streams (especially those containing toxic metals) cannot be known with enough certainty to safely assure that the "clean" treatment residues will be below levels of regulatory concern. These options are summarized in Table I.

Table I

Transportation by rail assumes that wastes can be bulk stored and aggregated until there are sufficient quantities to ship. Option 1 does not allow for on-site storage, therefore, truck transportation is assumed. Options 2, 3, and 4 provide for on-site storage, therefore, rail transportation is assumed.

Waste Volume Estimates

The hazardous waste can be subdivided into contaminated soil, debris, and personal protective equipment (PPE) as shown in Table II. Debris and PPE are assumed to be sent off site for disposal. Decontamination water will be disposed in the sanitary sewer, if clean, or evaporated on-site. Thus, contaminated soils, which are the major hazardous waste source, are the basis for this cost analysis.

Table II

The principal organic contaminant is trichloroethylene (TCE). Of the 16,300 cubic yards of soil contaminated with metals, 12,900 cubic yards are in a landfill and are believed to be contaminated with hexavalent

chromium. The remaining 3,400 cubic yards are primarily surface soils contaminated with lead. It is assumed that the lead can be recovered in the field, and thus these soils are assumed not to be treated in the CAMU. Of the 8,400 cubic yards of soil contaminated with both organics and metals, 6,200 cubic yards are contaminated with hexavalent chromium and TCE. The remaining 2,200 cubic yards come from sites that will probably be remediated in situ. Therefore, for purposes of this analysis, the only wastes that are considered relevant for evaluating whether a CAMU is economically feasible are 11,800 cubic yards of soil contaminated with organics, 12,900 cubic yards contaminated with metals, and 6,200 cubic yards contaminated with both organics and metals.

Cost Estimating Methodology

SNL's remedial actions are predominantly at the corrective measures study stage. Conceptual cost estimates were thus prepared to compare the total project cost (TPC) for each of the options. The cost estimates assume that ER waste management activities will be performed by a prime contractor who will subcontract specific work elements to specialty contractors. It is assumed that Sandia will provide oversight of ER waste management operations.

A combination of bottoms-up and parametric estimating techniques was used to prepare cost estimates for each of the options. A work breakdown structure (WBS), based on the DOE Code of Accounts, was developed to encompass the range of activities assumed to be required for the four options. The first three levels of the WBS are shown in Table III; however, much of the estimate was prepared at the fourth level. For example, the level below Other Structures (1.2.7) includes a disposal cell, engineered cap, monitoring wells, etc. The WBS and the cost estimates exclude items common to all four options because these costs will accrue regardless of the option selected. Common items include removal of contaminated materials from the sites and the Temporary Unit. Quantities of labor, material, and equipment were estimated based on current hazardous waste volume estimates, a conceptual site plan for the CAMU (Fig. 1), and from discussions with Sandia project personnel. In general, vendors were consulted for the major cost drivers; i.e., treatment, transportation and disposal. In addition to vendor pricing, published cost estimating manuals were used to obtain costs. The Remedial Action Cost Engineering and Requirements System (RACER) was used to estimate costs for the engineered cap and long-term monitoring in Option 4.

Table III

Fig. 1

Options 1 and 2 assume that wastes are transported off site for treatment and disposal. Option 1 assumes that wastes are transported via truck, whereas in Option 2 transportation by rail is assumed. Soil contaminated with organics (and organics with metals) is transported approximately 800 miles to a RCRA landfill for incineration. Incineration disposal is estimated at $600 per ton (direct cost) based on a vendor quote and includes final disposal of the ash. Soil contaminated with metals is transported approximately 500 miles to a RCRA facility for stabilization and landfill disposal. Stabilization and landfill disposal are estimated at $185 per ton (direct cost), also based on a vendor quote.

Options 3 and 4 assume that wastes are treated on site. Soil contaminated with organics (and organics with metals) is assumed to be treated using low-temperature thermal desorption to remove organic contaminants from

the soil. The variable cost quoted for low-temperature thermal desorption is $66 per ton (direct cost). Soil contaminated with metals, including the residual from the thermal desorption process containing metals, is assumed to be treated using soil washing to remove the metallic contaminants. Metallic contaminants adsorb onto soil fines and clays, and the soil washing process separates these finer, contaminated particles from the coarser, uncontaminated particles. A 6:1 volume reduction is assumed for soil washing. The variable cost for soil washing is estimated at $150 per ton (direct cost); however, there is some uncertainty in this unit cost. One vendor quoted a range of between $7 and $500 per ton depending on soil characteristics and contaminants. Treatability studies will have to be performed to obtain more definitive costs for SNL wastes. In Option 3, treated soils are assumed to be non-regulated, and thus are reused as fill. In Option 4, an engineered disposal cell is estimated for disposal of treated (but not below levels of regulatory concern) soils. Option 4 also includes an engineered cap over the disposal cell, four groundwater monitoring wells, and 30 years of groundwater and vadose zone monitoring. The 1/6 concentrated residual from the soil washing process is sent off site for stabilization and disposal in both Options 3 and 4. Indirect costs include contractor's overhead and profit (OH&P), bond, SNL loading factors, escalation, and contingency. Prime contractor's OH&P was applied at the rate of 10% and prime contractor's markup on subcontractors was applied at the rate of 5%. Performance and payment bonds were estimated at 0.75%. SNL loads were based on fiscal year (FY) 1996 spend plan rates issued by the SNL financial organization. The June 1995 DOE escalation rates for Environmental Restoration were used to estimate escalation. Escalation was applied at the rate of 8.74% assuming a schedule mid-point of July 1998 and a five-year schedule for ER waste operations beginning in January 1996. Contingency was estimated for each WBS element based on an assessment of cost risk within the scope of work assumed for the analysis. In general, contingency was estimated at 15% for low-risk elements, and at 50% for high-risk elements. High-risk elements include operating labor, operating equipment, soil washing, and CAMU closure. The overall applied contingency rates are 15% for Option 1, 16% for Option 2, 31% for Option 3, and 30% for Option 4. According to the DOE Cost Assessment Team (CAT) Cost Estimating Handbook for Environmental Restoration, the allowable contingency range for the remediation phase of an ER Project at the corrective measures study stage is 10% to 60%; therefore, the contingency applied to each of the options is at the low end of the allowable range.

Cost Analysis Results

Table IV compares the TPC for each of the four options. Without considering the time value of money (see Sensitivity Analysis below), Options 1 and 2 are the least cost effective. The cost to transport, treat, and dispose of waste off site (Options 1 and 2) is considerably higher than the cost to treat and manage wastes on site (Options 3 and 4). In addition to the relatively lower unit costs of treating and managing wastes on site, Options 3 and 4 also avoid the associated transportation costs. Between Option 3 and Option 4, Option 3 is more cost effective because the costs associated with the engineered disposal cell and long-term monitoring in Option 4 are avoided.

Table IV

SENSITIVITY ANALYSIS

The major variables affecting cost are the volumes of wastes to be managed. Therefore, it is advantageous to have general formulae for estimating the TPC of each of the four options as waste volume estimates are continually revised. The cost estimates for each of the four options (at the given waste volumes) were segmented into fixed and variable cost components, with respect to volumes, and equations were derived such that:

TCn = a0,n + a1,nV1 + a2,nV2 + a3,nV3, where
TCn = the total cost of Option n, n = 1...4,
V1 = volume of organic waste in cubic yards,
V2 = volume of metals waste in cubic yards,
V3 = volume of organic plus metals waste in cubic yards,
a0,n = fixed costs associated with Option n, and
ai,n = the variable cost associated with Vi for Option n, i = 1...3.

Fixed costs include Pre-Title I design, CAMU capital costs (excluding the disposal cell and engineered cap in Option 4), post-construction startup activities, CAMU operating costs (excluding storage and the variable portion of treatment), and CAMU closure. Variable costs include storage, the variable portion of treatment, transportation, disposal, and in Option 4, the disposal cell and engineered cap. Following are the total cost equations derived for the four
options.

Eq. 1
Eq. 2
Eq. 3
Eq. 4

These expressions provide an effective and efficient means of estimating the cost of each option given a change in the volumetric estimate of waste. It should be noted that these equations are applicable only to SNL because the underlying costs are specifically related to the scope of work at SNL. However, the general method used to derive the model can be used by others. It should also be noted that these relationships are valid within an unspecified range for the variables. For example, at significantly higher or lower volumes, fixed costs may be appreciably different because the scale of operations, equipment capacities, etc. will be different. In other words, fixed costs will likely increase or decrease in a stepwise fashion with changes in volume. Similarly, variable costs quoted by vendors for treatment are a function of quantity. Larger quantities typically imply lower unit costs.

Other analyses that can be performed include break-even analysis and net present value. Break-even analysis can be performed in situations where there is a single contaminant of concern. The volume at which the total cost of two options is identical is the break-even volume and is determined by simultaneously solving two total cost equations. At volumes above or below the break-even volume one or the other option would yield a lower cost. Although not reported here, SNL used break-even analysis to determine the volume at which it would be more economical to send wastes off site assuming metals could be remediated in situ.

Net present value (NPV) analysis recognizes the time value of money to determine the most cost-effective alternative. Future cash flows are discounted to the present using specified discount factors. Annual cash flows are discounted to the present by dividing the cash flows, stated in current dollars, by the discount factor, (1 + i)n , where i is discount rate and n is the year in which the cash flows are realized, beginning

with n = 0 for the current year. NPV is equal to total discounted benefits minus total discounted costs in the case of benefit-cost analysis, and is equal to the total discounted cost in the case of cost-effectiveness analysis. The alternative having the greatest NPV, or the least net present cost, is the preferred alternative. The Office of Management and Budget specifies a discount rate of 7% for use in benefit-cost and cost-effectiveness studies performed for the Federal government. Activities for the four options were scheduled over a 5-year period resulting in the allocation of estimated costs shown in Table V. Table VI gives the discounted cash flows using a 7% discount rate. The discount factors used to discount the values in Table V are given at the bottom of Table VI.

Table V

Table VI

The use of present value analysis does not change the order of the alternatives in terms of cost. Option 3 is still the most cost-effective and Option 2 is still the least. However, this will not always be the case. The longer the schedule and the higher the discount factor, the more dramatic will be the effect of discounting. Also, alternatives that require large expenditures early in the schedule, will be less affected by discounting than those that are weighted more heavily later in the schedule.

In addition to cost considerations, other criteria must be considered in the options selection process. The following section addresses the criteria considered by SNL and gives the results of the options selection process.

OUTCOME

In addition to the cost analysis results, the SNL ER Project considered other, qualitative criteria in reaching a final decision on which of the four options to select. The decision-making process involved SNL and DOE technical staff and managers, the regulators and the local public. Both the TU and CAMU are permitted facilities that must go through a public hearing and comment process. Thus, the early involvement of both the permitting agency and the public is an important means for expediting the resolution of issues and thereby reducing the time to obtain the permits. The qualitative criteria included worker and public health and safety as related to each of the four options. On-site and off-site handling and transportation, CAMU operations with and without treatment and disposal, ecological impacts, aesthetics, etc. were considered and ranked as to their relative importance for the ultimate decision, and finally they were weighted (along with cost) to yield a quantitative relative value. The results of this process are shown in Figure 2. Options 3 and 4, CAMU with storage and treatment, and CAMU with storage, treatment and disposal, respectively, were clearly preferred based on the resulting values. These are also the options having the least total costcost was a dominant factor for each of the groups. (For those who may be interested, separate reports are available on the entire options analysis and on the process used to involve the stakeholders. These reports can be obtained by contacting the authors of this paper.)

Fig. 2

As an outcome of the cost analyses and the stakeholder options evaluation, SNL will pursue permitting a full treatment, storage, and disposal CAMU as defined under Option 4. The disposal cell will not be constructed until it is clear that it will be needed. That need could

result if the treated residues, especially for metals-contaminated soil, contain after-treatment concentrations above levels that would allow unrestricted reuse.

CONCLUSIONS

The least cost-effective solutions for managing ER hazardous wastes, given the constraints and assumptions of this study, are those that involve off-site treatment and disposal (Options 1 and 2). The most cost effective solution is a CAMU combining on-site treatment of hazardous soils with reuse of the cleaned soil as fill (Option 3). A CAMU combining on-site treatment of hazardous soils with on-site disposal of treated soils comes in a close second (Option 4). However, the ultimate decision regarding disposition of environmental restoration waste will depend on stakeholders' perception of risk as well as on cost.

The volume of waste to be treated and managed greatly influences the optimal solution. At a relatively low volume of waste, the capital costs associated with the CAMU may not be justified. However, if current hazardous waste estimates are accurate, then a CAMU can indeed be justified under the assumptions of this analysis. As current hazardous waste estimates change with the incorporation of newly gathered data, the total cost equations can be used to evaluate the continued economic viability of the chosen waste management options.

ESTIMATING MANAGEMENT AND DISPOSITION COSTS FOR MATERIALS IN INVENTORY

Tobin L. Freid

Project Performance Corporation

Sterling, VA

ABSTRACT

The Department of Energy conducted the Materials in Inventory (MIN) Initiative to assess the management practices and structures, vulnerabilities, disposition options, and costs associated with ten categories of materials that the Department no longer needs for their original purpose. One of the key findings of the resulting report (Taking Stock: A Look at the Opportunities and Challenges Posed by Inventories from the Cold War Era, (1)) is the Department's lack of sufficient understanding of the costs of managing and dispositioning most of its materials in inventory. Difficulties in estimating these costs arise from a lack of clear organizational structures within the Department to manage materials and a lack of requirements and incentives to promote identification and disposition of materials no longer needed.

The Department is addressing the difficulty in estimating costs by increasing financial and managerial accountability for materials in inventory and expediting disposition of materials.

INTRODUCTION

The Department of Energy (DOE) accumulated an extensive inventory of materials during the past 50 years to support nuclear weapons production and basic energy research. With the end of the Cold War, DOE sites and programs are scaling back and shifting their attention and resources from weapons production to clean-up and restoration. Therefore, the need for certain materials has decreased. The unused materials, if neither managed appropriately nor dispositioned in a timely manner, may cause the Department environmental, worker safety, or public health problems. Such problems could, then, lead to considerable and unnecessary management, and ultimately, disposition costs. It is imperative that the Department re-evaluate its material needs and ensure that appropriate management practices are in place for the smaller and less dynamic material inventories needed for current and future missions.

Several factors contribute to the increased need for the Department to re-evaluate and comprehensively plan its inventories and materials management practices. First, a change in missions has caused slow-down in materials usage, leading to a backlog of materials for which there is no clearly defined purpose. Second, the Department's recent commitment to openness has brought greater scrutiny to environmental, safety and health issues within the Department, allowing more dialogue about vulnerabilities associated with materials. Third, declining budgets are forcing greater attention on all expenditures, including those currently used to manage materials in inventory.

The Department must understand the costs associated with managing and dispositioning materials in inventory because decisions about several of these materials will need to be made during the course of environmental restoration and deactivation activities. Long-term costs for materials disposition may increase unnecessarily if decision makers favor waste disposal over reuse and recycling due to a lack of understanding about current costs.

OVERVIEW OF THE MATERIALS IN INVENTORY INITIATIVE

The Department undertook the Materials in Inventory (MIN) Initiative to improve management, reduce unnecessary costs, and eventually develop disposition options, thereby reducing the amount of materials held in inventory. The Initiative focused on a subset of the Department's materials, referred to as "materials in inventory," which are defined as

materials that are not currently in use, are not designated as waste, and have not been set aside by the Nuclear Weapons Council as strategic reserves (1).

Materials are considered to be "not in use" when they have not been used for a period of one year and are not expected to be used in the coming year. Nuclear materials are considered "not in use" if they are associated with an inactive program as listed in the Nuclear Materials Management Safeguards System (NMMSS).

Hundreds of materials at DOE-owned facilities potentially meet the definition of a material in inventory. The MIN Initiative focused on ten categories of materials as follows:

Nuclear materials
Spent nuclear fuel
Depleted uranium
Natural and enriched uranium
Plutonium and other nuclear materials
Lithium
Non-nuclear materials
Sodium
Scrap metals and equipment
Chemicals
Lead
Weapons components

Teams of Field and Headquarters staff were established for each category of material to gather and analyze information regarding quantities, locations, management practices and systems, vulnerabilities, costs, and disposition options.

The final report of the Materials in Inventory Initiative, Taking Stock: A Look at the Opportunities and Challenges Posed by Inventories from the Cold War Era, was delivered to Deputy Secretary Curtis in December 1995.

SUMMARY RESULTS OF THE MIN INITIATIVE

The Department is currently storing over 820 million kilograms of materials that fall within the scope of the MIN Initiative. It is difficult to assess the total inventory of materials because tracking requirements and management practices for most of these materials vary from site to site and program to program, with no Departmental level of consistency.

Teams evaluated the status of the Department's current plans for disposition including reuse within the government, recycling, sale or transfer, and disposal as waste. Disposition plans for many of these materials have not been made or implemented because barriers exist that inhibit timely decision making. For example, managers face disincentives to declare materials excess and clear responsibilities among programs are lacking. Also, very few of the materials can be considered "assets" and thus sold for profit. In fact, most of the materials will require characterization, processing, decontamination, or repackaging before they can be dispositioned, which, in some cases, will cost as much or more than the material is worth on the market. For example, the Department recently sold 91 million pounds of lithium for about the same amount of money it will cost the Department to prepare the material for sale.

Some savings can be realized from dispositioning materials in inventory. More importantly, some costs, such as re-occurring costs can be avoided by reducing inventories. For example, if the sale of the 91 million pounds of lithium does not proceed as currently planned, the lithium will have to be repackaged in 5-10 years. This repackaging will cost an estimated $20-40 million dollars.

It is essential to move materials in a timely manner, especially as decommissioning schedules accelerate. Some materials, such as chemicals and equipment, lose value as they age. In the case of some chemicals,

safety vulnerabilities increase overtime as the chemicals change form and composition. Some materials become the focus of regulatory attention when they remain on site without a use for long periods of time. Time is also an important factor as sites shut down and must rapidly disposition large amounts of materials at once. For example, the Energy Technology Engineering Laboratory in California is currently faced with getting rid of 30,000 gallons of sodium within 1 year or it may have to be managed as waste which is costly. The site is working with other sites, state regulators, and sodium manufacturers to resolve this issue.

Findings of the MIN Initiative

Taking Stock includes a number of findings, three of which are relevant to cost discussions:

Finding: The Department does not understand sufficiently the costs of managing most materials in inventory, resolving vulnerabilities, and disposal as compared with other management options.

Finding: The Department does not have clear and effective organizational structures for inventory management and disposition for some materials in inventory.

Finding: The Department lacks policies to require or encourage its programs to identify and disposition materials that are no longer needed.

The complete list of findings appears at the end of this paper.

ESTIMATING COSTS

One of the main tasks that evolved during the course of the MIN Initiative was to begin to assess how much the Department is currently, and will likely, spend to store manage and disposition materials in inventory. In most cases, adequate data were not available to make quantitative estimates for materials other than plutonium and spent nuclear fuel. However, important conclusions can be made about the causes and effects of the difficulty of gathering the data.

Methodology and Results

Cost surveys were sent to each site requesting information on management and disposition costs and potential costs to address vulnerabilities for each material. The quality and utility of the cost estimates received in the surveys vary greatly for two reasons. First, the survey responses did not provide the assumptions or calculations used in developing cost estimates, making verification difficult. Second, the survey requested only existing information; sites were not expected to develop new data for this effort. Less than half of the sites were able to respond with existing information, and not all of those sites responded to all questions. A lack of response does not necessarily indicate a lack of costs.

Cost information gathered for the MIN Initiative presents a snapshot in time of overall costs. Nuclear material inventories tend to be static while non-nuclear material inventories tend to be fluid, making cost estimations difficult. For this and other reasons, nuclear materials, such as plutonium, depleted uranium, spent nuclear fuel, and lithium, tend to have more cost information available than non-nuclear materials, such as scrap metal, lead, and weapons components. Plutonium and spent nuclear fuel seem to have the best management cost data because internal and external pressures have increased attention and programs have been established to deal specifically with these materials.

Managing Materials

Management costs of materials in inventory are estimated to be at least $1-2 billion annually. This estimate drops to about $50-60 million when

not factoring in plutonium and spent nuclear fuel costs. This estimate is not all inclusive because some sites reported that costs to store some materials in inventory, such as lead and chemicals, are negligible except when they are actually dispositioned.

The Department spends approximately $1 billion annually on plutonium management activities such as monitoring, safeguards and securities, facility maintenance, performance testing, surveillance, and packaging and storing. This is the largest identified portion of the management costs for materials in inventory. Spent nuclear fuel accounts for the second largest portion of identified costs with approximately $170 million spent annually on activities such as inspections, pool maintenance, safeguards and security, record keeping, and surveillance.

Addressing Vulnerabilities

As with management costs, data associated with addressing environmental, safety, and health vulnerabilities were best for plutonium and spent nuclear fuel. This is due, in large part, to the fact that the Department has conducted extensive studies on the vulnerabilities of these two materials and both have received focused attention from outside the Department.

The Department estimates that it will cost approximately $900 million to address vulnerabilities associated with plutonium. This number includes stabilization activities at Idaho, Oak Ridge, Savannah River, Hanford, Rocky Flats, and Livermore and Los Alamos National Laboratories as recommended by the Defense Nuclear Facilities Safety Board in 1994. The estimate for addressing vulnerabilities associated with spent nuclear fuel is approximately $677 million.

Dispositioning Materials in Inventory

The Department can save money through timely disposition of materials in inventory rather than maintaining these materials for the indefinite future. Over time the Department can reduce overall costs by avoiding the need to build new storage facilities, monitor some materials, and incur routine maintenance costs, though the initial costs for disposition will seem high.

Initial costs will be incurred because many materials will require activities such as decontamination, repackaging, or other services before they can be dispositioned. These activities often result in higher costs than the Department will immediately recover from the sale or removal of the materials from inventory. Because materials in inventory tend to be co-located with other materials, removing them from inventory will not greatly increase immediate cost savings. However, these savings could be realized in the long-term. For example, lead bricks which fit the definition of "materials in inventory" (MIN lead) may be stored in the same building as other shielding materials or may be stored with waste lead that is not considered to be a "material in inventory". If the "MIN" lead is removed, the other lead will still need to be stored and monitored as before.

Difficulties in Estimating Costs

As the teams tried to develop cost estimates for managing and dispositioning materials in inventory, it became evident that the Department does not understand sufficiently the costs associated with most of these materials for a variety of reasons.

Finding: The Department does not have clear and effective organizational structures for inventory management and disposition for some materials in inventory. Various offices within the Department have responsibility for

materials in inventory. In some cases, several offices have responsibility for managing the same material at a site. This sometimes leads to unclear lines of responsibility for managing and dispositioning the materials. At Fernald, six organizations are involved in the management and disposition of uranium. The high number of participants has slowed down the sale of materials and created confusion over which organization has authority over the material.

For some materials it is difficult to say exactly which program office owns them. Sometimes when projects are terminated, materials are "orphaned", meaning that no office is willing to take responsibility for the material. Without one program responsible for the management and disposition of the "orphan" materials, costs are often carried in general site overhead accounts. The lack of clear and effective organizational structures for inventory management and disposition leads to difficulty in estimating costs.

The Department generally does not allocate budget resources by material, but rather does so by activity. Thus, material management costs generally are paid by the sites as an overall maintenance cost, not as part of a project. Because costs usually are not associated with particular projects, programs do not see the costs of maintaining materials. Maintenance activities such as monitoring, storage, moving, and safety precautions are generally paid for out of overhead accounts for the entire site. These circumstances make it difficult to distinguish how much is spent on materials in inventory compared with other materials. Because lines of responsibility are unclear, life-cycle and opportunity costs are often not taken into consideration when making decisions about disposition. Many management costs will stay the same even if the materials go away. Reducing the volume of materials in inventory, however, may make room for other materials and thereby avoiding new storage facility construction.

Even when it is possible to estimate the cost of managing materials, it is often difficult to assign specific costs to materials in inventory. Determining the portion of costs that are attributable to materials in inventory is difficult because materials are often co-located with other materials not covered by this initiative. For example, chemicals meeting the definition of "materials in inventory" (MIN chemicals) are on shelves along with chemicals that are currently in use. When assessing the costs of managing chemicals, it is very difficult to determine what portion of costs to assign specifically to the "MIN" chemicals.

Disincentives to Dispositioning Materials

Finding: The Department lacks policies to require or encourage its programs to identify and disposition materials that are no longer needed. In fact, there are often financial disincentives to disposition materials in inventory. Many materials require sampling, decontamination and repackaging, as well as time and effort to find adequate and appropriate disposition options. Occasionally, preparation of an Environmental Impact Statement or other documentation is required by the National Environmental Policy Act (NEPA) before materials can be dispositioned. Although NEPA processes are necessary to ensure appropriate consideration of potential environmental impacts and stakeholder involvement, they do increase the amount of time and money a program must spend to disposition materials. If a program identifies and begins to disposition an unneeded material, it would bear the burden of the costs of preparing that

material for disposition. These costs could draw funds away from the program's core missions.

Outside factors also may create disincentives for dispositioning materials in inventory. For example, a storage tank emptied during disposition of a material in inventory may contain a "heel" at the bottom of the tank to collect impurities. Under the Resource Conservation Recovery Act, if the tank was emptied, the heel would be designated as a waste. Once designated a "waste" materials often require costly treatment and packaging procedures. However, if the material was left in the tank, the Department would not have to manage the heel as a waste material. Because of the possible redirection of resources from active projects to pay for disposition or preparation of materials for disposition, and the lack of cost impacts on budgets of responsible organizations, Department programs are effectively discouraged from dispositioning materials. Leaving materials in place is often the simpler option with less immediate or fewer obvious budget impacts. This short-term view can lead to greater costs in the long term as aging materials, storage containers, and facilities require additional attention.

IMPLICATIONS FOR THE DEPARTMENT

The findings of the MIN Initiative have important implications across the Department when it is managing materials, decommissioning facilities, and cleaning up sites. For example, if materials are dispositioned as they are removed from their original location, it is easier to certify the contamination and pedigree of these materials. Once materials are placed in storage, often co-located with materials from other locations, facilities, and processes, it is more difficult to certify that a material has not been contaminated in some way. Many of the Department's materials in inventory were placed uncharacterized in storage many years ago. This has lead to higher current management costs than if final disposition plans had been implemented originally. Additionally, it costs less to move a material once than it does to move it twice.

Material characterization is needed for many materials before management and disposition decisions can be implemented. Some materials have not received extensive management attention in the past and have minimal or no records regarding chemical composition or contamination levels. In addition, the Department has experienced a loss of personnel with process knowledge thereby limiting the amount of reliable knowledge available to make decisions.

Many materials are stored in forms and facilities not designed for long-term storage. For example, a majority of spent nuclear fuel is stored in wet storage pools up to 30 years old, that were not designed for long-term storage. Some materials will require new or updated facilities or repackaging if they are left in inventory for long periods of time. For example, scrap metals and lead will both require new storage facilities in the near future if the inventories of these materials are not decreased.

CONCLUSION

The Department is moving ahead to reduce the amount of materials it has in inventory, and thus reduce unnecessary risk and costs. The Department is working to address the findings of the MIN Initiative by taking a number of actions, including the following:

Developing and implementing systems to promote exchange of materials within the Department;

Evaluating options for effective management structures;

Establishing a policy for programs to identify and disposition materials in inventory in a cost-effective and timely manner;

Clarifying Departmental policies which currently inhibit materials disposition due to misinterpretations; and

Developing methodology to identify the costs of managing materials in inventory.

FINDINGS OF THE MATERIALS IN INVENTORY INITIATIVE

Finding 1: The Departments inventories of materials exceed current mission needs.

Finding 2: Inventory information and materials management systems vary greatly across material types and sites.

Finding 3: The Department does not have clear and effective organizational structures for inventory management and disposition for some materials in inventory.

Finding 4: The Department lacks policies to require or encourage its programs to identify and disposition materials that are no longer needed.

Finding 5: Policy and legal barriers hinder disposition of materials in inventory.

Finding 6: The Department does not understand sufficiently the costs of managing most materials in inventory, resolving vulnerabilities, and disposal as compared with other management options.

ABSTRACT

Support costs make up a significant portion of total costs in the Department of Energy (DOE) Office of Environmental Management (EM), according to preliminary data from the 1996 Baseline Environmental Management Report (BEMR), the 1995 BEMR, and other studies of EM support costs. (DOE uses the term "support costs" to represent costs that would be considered "overhead costs" by private industry.) For that reason, reducing support costs is vital to reducing the overall cost of EM activities.

This paper provides general findings on the nature and significance of support costs from the 1996 BEMR and other relevant studies. This paper

also discusses how EM can reduce support costs by properly identifying and categorizing those costs and by understanding their drivers.

INTRODUCTION

Both government and private industry are under increasing pressure to cut costs. The drive to reduce the Federal deficit and agency budgets has spurred DOE and other agencies to seek more effective ways of increasing productivity and cutting costs. Private industry has focused recently on maximizing profits through increases in efficiency and reductions in costs. Overhead is often the first stop on the road to cost reduction because overhead costs tend to make up such a large percentage of total cost (5). (DOE uses the term "support costs" to represent costs that would be considered "overhead costs" by private industry.) Managers in both DOE and private industry are paying far greater attention to such costs than in the past and are developing cost systems that more accurately represent them.

This paper discusses overhead and support costs in general, presents findings from the 1996 Baseline Environmental Management Report (BEMR)a and other recent studies on overhead costs, and suggests more effective ways of both understanding and reducing those costs. The paper begins by defining overhead and support costs in private industry and in EM and discusses the traditional view of overhead and support costs and the problems with that view. The paper then looks at ways of improving our understanding those costs, examines support cost drivers in the EM program, and draws lessons from private sector best practices for reducing the costs of EM program management. Finally, the paper summarizes the results of recent studies of overhead and support costs.

OVERHEAD COSTS IN PRIVATE INDUSTRY

In the private sector, overhead costs are defined as costs not directly related to production or the provision of a service. For example, in manufacturing overhead costs include the direct and allocated costs other than labor and the purchase of materials. Areas generally considered to be overhead in manufacturing include indirect labor, general and administrative expenses, facilities and equipment costs, engineering costs, and materials overhead costs (5). In the hospital industry, to take another example, overhead costs include dietary staff; cafeteria; laundry and linen; plant; housekeeping; accounting; communications; patient accounts; data processing; admitting; hospital administration; public relations; personnel; auxiliary groups; chaplain services; and medical records (Noreen and Soderstrom 1994). These activities are vital to the functioning of the hospital but are not directly associated with the provision of medical services.

Over the last two decades in manufacturing, overhead costs have increased as a percentage of total costs, and "are replacing the direct costs of touch-laborers and purchased materials" in industry as the largest component of total cost (2). This shift is due primarily to the increased use of automation, which decreases the need for direct labor and increases the amount of overhead associated with maintaining and running equipment (5). The concepts of just in time, total quality management, group technology, and flexible manufacturing systems have also reduced the need for direct labor (4). Currently, overhead costs represent between 35 and 40 percent of total manufacturing costs (3,5). Overhead accounts for 70-75 percent of value added in the American electronics and machinery industry (5). The same article indicates that overhead rates of 1000 percent occur in some firms.

EM SUPPORT COSTS

EM defines support costs as direct and indirect costs incurred for activities other than cleanup. Cleanup costs include treatment, storage, disposal, characterization, retrieval, assessment, surveillance and maintenance, remedial action, decommissioning, deactivation, and stabilization.For BEMR, EM categorized support costs into 6 general areas and 29 more specific areas. This categorization was based upon an analysis of current EM budget documents: Activity Data Sheets; Allocable Cost Report; and site budget documents:

1) Management:
 Executive direction
 Management and operating (M&O) contractor oversight
 Management/award fee
 Program management
 Quality assurance

2) Finance and Administrative Services:
 Administrative support
 Chief Financial Officer
 Human resources
 Information services
 Legal
 Training

3) Environment, safety, and health:
 Environment, safety, and health
 Monitoring
 Laboratory support
 Pollution prevention

4) Infrastructure:
 Facilities management, engineering and maintenance
 Logistics support
 Procurement
 Utilities

5) Safeguards and security:
 Safeguards and security

6) Stakeholder, regulatory, and other:
 Agreements Economic development
 Lab-directed research and development
 Media/communications
 Regulatory compliance
 Stakeholder-related outreach
 Taxes
 Technology development
 Other

Recent studies show that support costs make up between 30 and 77 percent of total EM costs:

I. The 1995 DOE Support Cost Review (1995) found that support costs make up approximately 45 percent of total operating costs.

II. The 1995 BEMR found that support costs are approximately 50-65 percent of total EM costs.

III. Data collected for recent EM "workouts" held between EM Headquarters and sites indicate that support costs make up from 30-70 percent of site costs.

IV. Preliminary data from the 1996 BEMR are consistent with findings from these other studies of the EM support costs (Table I).

Although the exact definition of support activities varied somewhat from estimate to estimate, it is clear that support costs are a large component of total cost in EM.

Table I

PROBLEMS WITH THE TRADITIONAL VIEW OF OVERHEAD AND SUPPORT COSTS

Traditional cost accounting methods, used both in EM and in private industry, base estimates of overhead costs upon volume-related measures such as direct labor hours or machine hours. Overhead costs are assumed to vary in strict proportion to direct labor or machine hours. In other words, overhead costs are assumed to increase by 100 percent if direct labor hours are increased by 100 percent. Traditionally, accountants have even viewed direct labor hours as the cause or driver of overhead costs:

[Traditional] efforts base overhead burden rates [costs] on direct labor, materials, or machine hours. The problem with this approach is that the driving force behind most overhead costs is not unit output or direct labor. Overhead costs do usually correlate with unit output, but that does not mean that unit outputs "cause" overhead costs. In fact, acting as though they were causally related leads managers to concentrate on output measures or on direct labor rather than on the structural activities that determine overhead costs. (5)

Recent analysis has shown that there are two major problems with the above assumptions for estimating and understanding overhead costs:

There is only a weak relationship between overhead costs and direct activity. Noreen and Soderstrom (1994) found that a 100 percent increase in direct activity, such as labor or machine hours, would only cause a 25 percent increase in overhead costs. Data from the 1995 and 1996 BEMR support that analysis. 1995 BEMR data indicated that a 100 percent increase in treatment, storage, and disposal costs would cause less than a 15 percent increase in support costs. Preliminary 1996 BEMR data shows that a 100 percent increase in treatment, storage, and disposal costs will cause only a 20 percent increase in environment, safety, and health (ES&H) costs. Thus, estimates of overhead costs cannot accurately be based on direct activity levels.

More importantly for this paper, even if there was a relationship between overhead costs and direct activity level, direct activities do not cause overhead costs. For that reason, the common assumption that the way to reduce overhead costs is to reduce direct costs is false. Understanding the real cause or causes of the need for an overhead activity is the first step towards reducing its costs. The next several sections discuss ways of more accurately identifying those causes and more effectively reducing overhead costs.

IMPROVING OUR UNDERSTANDING OF OVERHEAD AND SUPPORT COSTS

The principles of activity-based costing (ABC) and Total Cost Management (TCM) shed some light on overhead costs. ABC, an extension of traditional cost accounting, uses multiple cost drivers to assign costs to products, recognizing that labor-based cost systems often do not capture differences in resource consumption by products. The basic premise of ABC is:

Demand for a product leads to activities of production.

Activities of production consume resources.

The amount of resources consumed is determined by the levels of the drivers.

TCM, as described by Ostrenga (8), is "a business philosophy of managing all company resources and the activities that consume those resources. Managing costs in a TCM environment means focusing on activities and the events, circumstances, or conditions that cause or 'drive' these cost-consuming activities."

Thus, ABC and TCM advocate, first, understanding the cause or driver of all costs and then reducing costs by working to change these drivers. For BEMR, EM has collected information on the drivers of support activities. Other recent EM studies and reviews have gone a step further, assessing ways to reduce support costs based upon a growing understanding of cost drivers. The remainder of the paper will provide results from these recent studies and suggest ways to reduce support costs.

EVALUATING EM SUPPORT COST DRIVERS

Several EM studies, the Support Cost Review and the Program Management Analytical Team, have recently examined the causal factors driving support costs. The Support Cost Review indicates that a large portion of support cost are driven by two factors:

DOE orders and requirements; and

The current guidelines laid out for contractor management.

From a detailed analysis of these drivers, the Support Cost Review concluded that significant costs savings could be achieved through the consolidation of DOE and contractor management practices and modification of low value DOE orders. In the former case, the review found that the separation of contractor and DOE planning and budgeting activities complicated the ES&H management process. Removing that separation would result in significant cost savings as ES&H costs comprise 11 percent to 38 percent of total cost (Table I).

The Support Cost Review attempted to evaluate the relative costs and benefits of current DOE ES&H orders and identified three examples of the cost savings achievable by reexamining and modifying current DOE requirements.

National Environmental Policy Act (NEPA): A categorical exclusion is effectively an exemption from the NEPA process granted to certain activities that, by their very nature, have no impact on the environment. Current orders require that categorical exclusion determination for NEPA be conducted at headquarters. The Support Cost Review suggests that this function be delegated to the Operations Office level and conducted by M&O contractors. Such a change would significantly reduce the number of reports required to confirm that an action is not subject to NEPA compliance.

Radiological Control Manual (RCM): Although acknowledged to provide excellent guidance for the safe handling and control of radiological material, RCM guidelines place a burden that brings little benefit on sites with low risk of radiological exposure. Support costs could be saved by revising these guidelines to exempt low risk sites.

Safety Analysis Reports (SAR): Finally, the Support Cost Review found that SAR preparation often places an undue burden on sites where reports were irrelevant, and that a graded approach acknowledging differences in risk levels would be more appropriate.

Fundamentally, the review found that the basic intention of these DOE orders, achieving an acceptable level of worker safety, is not being achieved efficiently. Modifying these orders would allow sites to achieve

these goals more cost effective. As discussed earlier, BEMR found that ES&H costs do not change much as treatment, storage, and disposal costs change. This may be due to the fixed nature of the compliance burden. If so, the removal of some DOE orders should have a significant impact on ES&H costs.

DETERMINING THE COST EFFECTIVENESS OF SUPPORT COSTS

Overhead costs in the private sector are often reviewed by potential customers, suppliers, or partners as a check on the real cost of producing a product or service (4). This interaction leads firms to adopt industry best practices. In the absence of such interactions, the Office of Environmental Restoration Program Management Analytical Team (1995) conducted a benchmarking study comparing program management of EM activities to program management for similar projects in the private sector. The intent of the study was improve the process for conducting program management, an essential support function, by identifying and adopting private sector best practices.

The Team found that private sector program management costs were approximately 40-80 percent lower than those in EM program management which range from 6 percent to 21 percent of total costs (Table I). The reason for this difference, the team concluded, was that program management in the private sector focused on work directly related to the speedy completion of projects and that EM program management did not. Thus, the study shows both that EM program management can be improved by greater focus on those activities that speed the completion of projects, and that benchmarking can lead both to a better understanding of cost drivers and to lower cost.

CONCLUSION

In summary, recent studies on overhead and support costs in EM, other federal agencies, and private firms show four things:

I. Overhead costs are the single largest component of total cost in nearly all industries and government agencies, accounting for more than 35 percent of total cost. Thus, understanding and controlling these costs is key to controlling overall costs.

II. Historically, little attention has been focused on overhead costs. It is only recently that the "hidden factory" of overhead costs has been scrutinized.

III. ABC and TCM indicate that understanding and managing cost drivers is a key to controlling costs. It is clear that there are many overhead cost drivers other than direct activity level.

IV. EM has begun to perform several analyses that allow a better understanding of overhead costs. We believe that similar analyses should be continued and that management based upon these findings could lead to future cost reductions.

LIFE CYCLE COST AND RISK ESTIMATION OF ENVIRONMENTAL MANAGEMENT OPTIONS

David Shropshire
Michael Sherick
Lockheed Idaho Technologies Company*

ABSTRACT

The Lockheed Idaho Technologies Company (LITCO) Economic and Systems Analysis program has developed a life cycle cost and risk estimation process to evaluate Environmental Management options for the United States Department of Energy. The evaluation process is demonstrated in this paper through the comparative analysis of two alternative scenarios that have been identified for the management of the alpha-contaminated mixed low-level waste that is currently stored at the Idaho National Engineering Laboratory (INEL). The two scenarios that are evaluated are a Base Case and a Delay Case. The two scenarios are realistic and based on actual data, but are not intended to exactly match actual plans currently being developed at the INEL. The paper includes a general description of each scenario, along with major assumptions that were made to support the analytical process.

Life cycle cost estimates were developed for both scenarios with the use of the System Cost Model. The resulting costs are presented and compared. Life cycle costs are shown as a function of time and also aggregated by pretreatment, treatment, storage, and disposal activities. Although there are some short-term cost savings associated with the Delay Case, the cumulative life cycle costs are shown to eventually become much higher than the costs for the Base Case over the same period of time, due mainly to the storage and repackaging necessary to accommodate the longer Delay Case schedule. Similarly, life cycle risk estimates were prepared using a relatively new risk analysis methodology that was developed for the INEL Environmental Management Integration task and has been adapted to the System Cost Model architecture for automated, systematic cost/risk applications. Relative risk summaries are presented for both scenarios as a function of time and also aggregated by pretreatment, treatment, storage, and disposal activities. The relative risk associated with the Delay Case is shown to be higher than that of the Base Case. Finally, risk and cost results are combined to show how the collective information can be used to help identify opportunities for risk or cost reduction, and highlight areas where risk reduction can be achieved most economically.

INTRODUCTION

A life cycle cost and risk estimation process has been developed to evaluate various Environmental Management options for the United States Department of Energy (DOE). The Economic and Systems Analysis program, based at the Idaho National Engineering Laboratory, has been sponsored by

the Office of Waste Management, Office of Planning and Analysis (EM-35) and the Office of Science and Technology, Office of Technology Systems (EM-53).

Lockheed Idaho Technologies Company's (LITCO's) Economic and Systems Analysis (ESA) program has developed a systems engineering process for analysis of waste management problems. The process is based on the engineering analysis that LITCO has provided on the Waste Management Programmatic Environmental Impact Statement, Site Treatment Plans (STPs) as required under the Federal Facility Compliance Act, and support for the Baseline Environmental Management Report (BEMR). A risk methodology was also developed by the Idaho National Engineering Laboratory Environmental Management Integration Program. The combination of cost analysis and risk analysis capabilities has allowed the ESA program to address EM alternatives from new perspectives.

LITCO's Economic and Systems Analysis program has developed an extensive knowledge in waste management facility cost development, engineering model design, and risk applications. This knowledge, which was initially developed to support EM-30, has now been additionally focused on EM-50 initiatives to identify cost-effective and reduced-risk alternatives. The ESA studies will be used by EM to gain a greater understanding of the opportunities for cost reductions and provide a quantitative means for comparison of DOE policy options.

The benefits to EM-50 have included:

Providing a baseline for comparison of Technology Development alternatives,

Providing a method to communicate results on new technologies to EM-30,

Providing a bridge between an "Average Site's" approach and site-specific applicability,

Helping to identify needs for technology development,

Providing a basis for prioritizing opportunities for risk or cost reduction.

The benefits to EM-30 have included:

Better focused Technology Development supporting key EM-30 policy options,

Better understanding of the costs and benefits of advanced technology options,

Better integration of a strategic planning basis,

Consistent methodology enabling comparative analysis of waste management alternatives,

Better understanding of cost implications for various complex-wide configuration options.

The need for cost/risk integration has been identified by the DOE. The DOE considers risk and life cycle costs in establishing program priorities. The ESA program has developed a tool called the System Cost Model (SCM) which has facilitated the cost/risk analysis of complex EM alternatives. The SCM allows analysis of various technology processing options for mixed low-level waste (MLLW), low-level waste (LLW), and transuranic waste (TRUW)--both mixed and non-mixed. The use of the SCM has helped LITCO integrate the requirements of EM-30 and EM-50. The two models which have been developed to support cost/risk analysis are described as follows:

System Cost Model (SCM) - The SCM was initially developed for EM-35 to support sensitivity analysis of waste management costs for the BEMR. The SCM produces complex-wide life cycle costs for treatment, storage,

disposal, and transportation of MLLW, LLW, and TRUW. The SCM also includes a database of site-specific waste management information including: waste inventory volumes and generation rates, treatment processing schemes, existing and planned facilities, site-specific cost factors and labor rates, and schedules.

System Cost Model - Risk (SCM-R) - The SCM-R has been developed to a conceptual level for EM-35 to support cost/risk evaluations. The SCM-R is an add-on to the base SCM. The fundamental risk methodology is based on the work done by the Environmental Management Integration Program (EMIP) at the INEL. Approximately 1000 simplified risk assessments were produced for the EMIP. The SCM-R will produce simplified relative risk assessments to show baseline life cycle risk, worker and public risk, waste disposal risk, and waste transportation risk. All categories of waste, from spent fuel to low-level waste, can be accommodated, as can all types of waste (radioactive, hazardous, and mixed). The method is based on the fundamental equations of risk (e.g., as used in CERCLA risk assessments). The risk calculations are based on the product of probability and consequences. The equations are broken down into risk elements, e.g., inventory quantities, toxicities, confinement barriers. Look-up tables provide values to be used for each risk element.

COST/RISK STUDY

This paper includes a specific cost/risk study demonstrating the use of the SCM and SCM-R tools. The study provides a life cycle cost/risk evaluation of the trade-offs of using long-term storage prior to treatment versus treating with existing technologies and minimizing storage. The study is based on actual INEL waste stream data and can be considered representative of the type of analysis that could be performed at any large DOE site. However, since some of the assumptions used are hypothetical, this study is not intended to accurately reflect current INEL plans. Rather, the study is meant to demonstrate a unique cost/risk analysis capability using realistic input parameters.

The purpose of the study was to compare the magnitude of the costs and risks for long-term storage versus the current planning basis. These options show the costs and risks associated with delaying treatment until new technologies are available. The study also shows how both costs and risks can be evaluated in one analysis. The remainder of this paper includes a description of the alternatives, assumptions, cost and risk results, and key study conclusions.

Alternative Descriptions

Two alternatives were defined for this cost/risk study:

1) Base Case Scenario - The Base Case Scenario is comprised of the INEL BEMR treatment, storage, and disposal configuration and the 1995 Mixed Waste Inventory Report (MWIR) waste stream data. The Base Case scenario used a treatment schedule based on the STP.

The waste is retrieved from earthen-covered storage. Retrieval will be followed by receipt and inspection of the waste at the Stored Waste Examination Pilot Plant (SWEPP), which includes an open, dump, and sort module to determine which treatment the waste form will receive. Also included are pre-treatment handling and storage. All necessary pre-treatment facilities are assumed to be in existence at the INEL; therefore, no construction costs are included until the year 2025, when existing facilities are assumed to become obsolete and new storage is constructed.

This case utilizes incineration followed by grouting for the particulates, sludges, and some of the debris. However, most of the debris will be treated by first shredding the waste, which is then treated by thermal desorption followed by grouting. Other solids and particulates will be treated by a polymer stabilization. Disposal is assumed to take place in an onsite engineered disposal facility.

2) Delay Case Scenario - The Base Case Scenario was revised to show the effects of long-term pre-treatment waste storage.

Treatment and disposal for this case are identical to the Base Case with the only change being that the treatment and subsequent disposal occur fifty years later. The treatment and disposal facilities required for the Delay Case are considered to be nonexistent and will require construction. However, no post-treatment storage is required for this case since the treated waste goes directly to disposal.

In addition to pre-treatment storage, the waste will be overpacked as it is received and inspected based on the assumption that current containers are not adequate to support another 50 years of storage. SCM does not have an "overpack" module, however, in order to provide costs to adequately reflect the overpacking, the receiving and certification module costs were artificially increased to account for the activity. After the waste is retrieved (complete in the year 2015) and overpacked (complete in the year 2039), it is stored until treatment is available in the year 2047.

General Assumptions:

The specific waste management system defined for this study was the INEL alpha MLLW. For the sake of simplicity in modeling the INEL alpha MLLW, the initial risk analysis was limited to five waste matrix categoriesa. The total alpha MLLW inventory at the INEL is characterized by 12 waste matrix codes. However, the five waste codes chosen for this demonstration model represent 97.7% of the volume of waste to be treated at the INEL. The five waste codes chosen for this model are: S 3110, S 3120, S 5110, S 5300, and S 5400.

The costs reflect DOE-built and operated facilities required for the alpha MLLW inventory. Since treatment facilities for this waste do not currently exist at the INEL, new facilities will be required. The alpha MLLW will be treated based on the requirements of the Resource Conservation and Recovery Act. The treatment window for the inventory is assumed to be 19 years in duration (same for both cases).

These cases assume that the alpha MLLW inventory is disposed of onsite in an above-ground engineered disposal facility.

Scheduling Assumptions for the Base Case

For the Base case, all construction of treatment facilities starts in 1996, with treatment to commence in 1999. The SCM was allowed to build all treatment required.

Scheduling Assumptions for the Delay Case

Retrieval of the waste will occur over 19 years. After the waste is retrieved, it is received, inspected and assayed at the SWEPP facility over a 19-year duration that ends in 2017. As the waste is assayed it is overpacked and then placed in storage. Overpacking operations will be complete in 2039. Existing storage capacity for the retrieved and overpacked waste is not sufficient, so SCM will be allowed to construct storage facilities as required.

Waste storage continues until 2065. SCM will construct new facilities and decontaminate and decommission (D&D) the old facilities as required during the extended storage period.

Construction (for three years) is followed by treatment, which commences in 2047 and completes in 2065.

COST RESULTS

Life cycle cost estimates were calculated for the two INEL alpha MLLW cases using the SCM and based on the assumptions and case descriptions outlined above. The total life cycle costb for the Base Case was estimated to be $1.25 billion (B), while the total life cycle cost for the Delay Case was estimated to be $2.79 B.

Figure 1 shows a comparison of the cumulative costs for the two cases over time. The Base Case includes higher up-front costs because all needed treatment, storage, and disposal facilities are constructed immediately. However, the cumulative costs for the Base Case level out after the last facility is decommissioned in the year 2024. Because of the much longer operational time frame, the cumulative costs for the Delay Case surpass those for the Base Case in the year 2032 and are ultimately over twice as high.

Fig. 1

Figure 2 shows a comparison of the costs for the two cases broken down by waste management function. The four waste management functions included in the SCM estimates are pre-treatment (including pre-treatment storage), treatment, post-treatment storage, and disposal. Most of the cost difference between the two cases shows up in the pre-treatment category. This is due to the increased cost of pre-treatment storage required for the Delay Case. The higher costs associated with the Delay Case are due to the construction and operations of the necessary storage facilities. The Delay Case costs also include overpacking activities and D&D of two existing storage facilities, neither of which are necessary for the Base Case.

Fig. 2

RISK RESULTS

The relative risk was calculated for both the Base Case and the Delay Case. The annual relative risk for each case is presented in Fig. 3. These risk profiles should be considered preliminary because the basis for the annualized risk calculations is still under development. The output depicts the annual relative risk change as the alternative is implemented. The output represents the total risk of all steps involved in managing the waste, from initial storage through retrieval, handling, treatment, and disposal. The beneficial effects of treatment on the annual risk are evident by the decreasing risk. These effects are primarily attributed to placing the waste in a less-mobile physical form.

Fig. 3

The relative risk was further defined by summary-level treatment, storage, and disposal risk statesc. The illustration in Fig. 4 indicates that the process steps contributing the most to the total time-integrated risk are pre-treatment storage and long-term disposal (>500 years).

Fig. 4

A refinement of the output shown in the previous figure is the breakdown of the relative risk by state (equivalent to module). This output discriminates which specific processes are contributing the most risk for the alternative. For the Base Case alternative, the relative risk is greatest in the front-end module for storage. In treatment, the majority

of the risk is dominated by the open, dump, and sort and the incineration module. The disposal risk is driven by the failure of the engineered barriers in the period beyond 2499 in the module.

COST/RISK ANALYSIS

The individual cost and risk results provide insights to the highest cost and risk modules. This information is valuable to determine general areas of emphasis. In addition to these results, the costs and risks were integrated to provide new insights into cost-effective risk reduction opportunities. Two techniques were developed to analyze the cost/risk results:

1) Normalized Product technique - which can be used to guide technology development prioritization and risk mitigation activities,

2) Marginal Alternative Comparison technique - which discriminates risk/cost performance between alternatives to support further system optimization.

These innovative techniques were developed for the purpose of leveraging the cost and risk data to gain insights into areas of greatest cost savings and risk reduction potential. A description of the methodology for the techniques is included below. The costs and risks from the Base Case and the Delay Case scenarios were also analyzed using these techniques.

1) Normalized Product (NP) technique - The NP technique was used to evaluate the system components to determine the greatest opportunities for combined risk and cost reduction. The NP places cost and risk on a normalized scale so that a unit of risk is related to a unit of costd. The higher values on the NP scale are indicative of the modules/states with the largest relative risks and costs as compared to the processes with the smallest products of cost and risk. The technique helps prioritize where funding should be directed to affect the largest potential risk reduction and cost savings. This technique was applied to the Base Case and Delay Case scenarios and the results are summarized in Fig. 5.

Fig. 5

Results using the Normalized Product technique: The results indicate that the greatest opportunities for risk and cost reduction are in the Delay Case. The marginal changes for cost and risk were highest for pre-treatment. Proportionately, the marginal cost decrement was almost five times that of the risk. This would indicate that the Delay Case has significantly higher costs and some associated increase in relative risk. The results also show an opportunity for improvement in both cases for disposal.

Risk mitigation could include (but is not limited to) reducing the number of years of pre-treatment storage, producing a less-mobile waste form, destroying organics, reducing worker exposure in characterization and packaging processes, and improved final waste form.

2) Marginal Alternative Comparison (MAC) technique - This technique is used to discriminate differences in risk and cost between alternatives. The MAC technique helps an analyst understand trade-offs and sensitivities between risk and costs6 from different waste management options (technologies, scheduling, etc.). This technique can be used to help answer questions like:

- Does risk decrease proportionately with increased costs?
- How much does risk increase if costs are cut?

The technique provides a comparison of the normalized cost and risk data from the alternatives. The fractional change in normalized risk (of one alternative compared to another) is compared to the fractional change of normalized cost (between alternatives). The resulting marginal risk per unit of cost is a measure of the potential effectiveness of an improved alternative in reducing risks and costs. This technique can be used to analyze technology and operational effectiveness for pre-treatment operations, treatment, storage and disposal. A comparison of the Delay Case to the Base Case using the MAC technique is presented in Fig. 6.
Fig. 6

Results using the MAC technique: The results indicate that long term pre-treatment storage (including additional characterization and overpacking) causes significant cost degradation and additional risk. Post-treatment storage costs are marginally improved if treatment is delayed due to improved throughput between treatment and disposal operations. Treatment and disposal costs and risks show no significant marginal differences.

System Level impacts can also be assessed using these techniques. For example, if an improved new technology can be developed in 10 years (resulting in increased pre-treatment storage) how much better would the technology need to perform to break even with the additional costs and risk from the added storage? The system assessment could also evaluate the marginal differences of using a new treatment technology which produces an improved final waste form for disposal.

CONCLUSIONS

The cost and risks of two alternatives were analyzed using a systems-based life cycle cost and risk estimation process. Techniques were applied to integrate the results from the individual cost and risk studies. The techniques helped to provide insights into areas to maximize effectiveness while reducing risk. The techniques can be used to support many initiatives for EM:

- Define incentives for investment in R&D
- Identify and prioritize Technology Development projects
- Maximize operational effectiveness (sizing of facilities, years of operation)
- Optimize schedule
- Optimize facility siting and configuration

The ESA studies will be used by EM to gain a greater understanding of the opportunities for cost reductions and to provide a quantitative means for comparison of DOE policy options.

SLASHING COSTS AND CHOPPING SCHEDULES: RESTRUCTURING THE CERCLA PROCESS FOR A DOE SUPERFUND SITE*

Albert L. Lamarre
Lawrence Livermore National Lab.

PO Box 808
L-619
Livermore, CA 94551
ABSTRACT
Regulatory document preparation at hazardous waste sites has proved to be costly when complying with the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA). At Lawrence Livermore National Laboratory (LLNL) in Livermore, California, we are devising a methodology that will save millions of dollars and shorten the time to initiation of cleanup while meeting the intent of CERCLA to remediate contaminated sites. In 1994, we completed a Site-Wide Remedial Investigation report that describes the characterization and risk assessment of LLNL's 7000-acre Site 300 experimental test site. The next step in the CERCLA process would have required us to prepare complete Feasibility Studies, Proposed Plans, Records of Decision (RODs), and Remedial Action Implementation Plans for three Operable Units (OUs) containing contaminated ground water. Such an effort would require several years and millions of taxpayer's dollars to accomplish. In close consultation with the State and Federal regulatory agencies, we are creating a model strategy to 1) conduct Removal Actions (landfill capping, buried drum removal, surface drainage control, etc.) in the OUs to remove the threat of future releases to the environment, 2) prepare ground water monitoring plans to monitor the contaminant plumes, 3) prepare contingency plans to address the contamination should it migrate and pose an unacceptable risk, 4) move the ground water monitoring tasks to a pre-existing Site-Wide OU that addresses the site as a whole, and 5) incorporate the Removal Actions into the Site-Wide ROD as completed remedies for the OUs. This process will substitute relatively short documents describing Removal Actions, monitoring, and contingencies for the much longer studies and plans currently required. With this approach, potential sources of future releases will be remediated, low risk ground water contamination will be monitored, human health and the environment will remain protected, and regulatory requirements for RODs will be met. Assuming that our negotiations continue successfully, we will save the taxpayers millions of dollars, expedite the cleanup of the site, and bring the entire process to closure.
INTRODUCTION
Regulatory document preparation for hazardous waste sites has proved to be costly and time consuming when complying with the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) of 1980. At Lawrence Livermore National Laboratory (LLNL) in Livermore, California, we are developing a methodology that we expect will save millions of dollars and shorten the time to initiation of cleanup while meeting the intent of CERCLA to remediate contaminated sites and protect human health and the environment.
Description of LLNL Site 300
LLNL is a nuclear weapons research and development laboratory owned by the U.S. Department of Energy (DOE) and operated for DOE by the University of California. LLNL's Site 300 facility, in existence since 1955, supports DOE's defense mission in research, development, and testing associated with non-nuclear components of nuclear weapons. Site 300 is a 7000-acre Experimental Test Site located about 60 miles east of San Francisco, California, in the sparsely populated Altamont Hills of the Diablo Range (Fig. 1). This Superfund site encompasses approximately

11 square miles of former ranch land; surrounding land is used primarily for sheep and cattle grazing, wind-powered generation of electricity, and off-road vehicle recreation. The closest population center is the San Joaquin County town of Tracy, 8.5 miles northeast. Most of the site is undeveloped, with the developed portion consisting of machine and craft shops, high explosives (HE) firing tables and bunkers, buildings that accommodate HE formulation and machining as well as static and dynamic weapons-component testing, administration buildings, landfill disposal pits, roads, and other associated infrastructure. The site is characterized by rugged terrain consisting of rolling hills and steep northwest-trending valleys.

Fig. 1

Pre-CERCLA Environmental Restoration at LLNL Site 300

Since 1981, LLNL has conducted investigation and restoration of chemical and radioactive contamination at Site 300. The investigations have focused primarily on delineating ground water contamination, but have also addressed contamination of soil and rock, surface water, biota, and air. Prior to August 1990, investigations and remediation were conducted voluntarily under the oversight of the California Central Valley Regional Water Quality Control Board (RWQCB), now a part of the California Environmental Protection Agency. In August 1990, as a result of the ground water contamination, Site 300 was named to the CERCLA National Priorities List, also known as Superfund. In 1992, a Federal Facility Agreement (FFA) was negotiated between DOE, the U.S. Environmental Protection Agency (EPA), the California Department of Toxic Substances Control (DTSC), and the California RWQCB. The FFA defines the scope of work required, coordinates efforts among the FFA parties, standardizes requirements, establishes due dates for deliverables, and ensures compliance. Since late 1990, all environmental investigation and remediation activities have been conducted under the oversight of the three environmental regulatory agencies in accordance with CERCLA and State laws and regulations.

Work Conducted Under CERCLA

An important element of the FFA was the establishment of six Operable Units (OU) for Site 300. The OUs were created based on considerations of geography, hydrogeology, types of contaminants present, and nature of the environmental release. Following CERCLA guidance, the regulatory agencies, DOE, and LLNL jointly established for each OU an enforceable schedule for submittal of CERCLA documents from Feasibility Studies (FS) through Records of Decision (ROD). Figure 2 shows the initial schedule incorporated into the FFA in 1992.

LLNL had conducted initial investigations of the site between 1981 and 1992 that identified ground water contaminated with volatile organic compounds (primarily trichloroethylene [TCE]), tritium, and the HE compounds RDX (cyclotrimethylene-trinitramine) and HMX (cyclotetramethylene-tetranitramine). At the request of the regulatory agencies, we compiled this information into the large, comprehensive Site-Wide Remedial Investigation (SWRI) report, which was completed in 1994. This report also presents the results of a base-line public health assessment. The succeeding FS/Proposed Plan (PP)/ROD documents for each OU were to be based on the remedial investigation results reported in the SWRI.

Fig. 2

As work progressed under the FFA schedule of deliverables, it became apparent that a major amount of DOE/LLNL's restoration program personnel, financial, and time resources were being consumed in preparing lengthy and sometimes repetitive and unnecessary documents. For each OU, we proceeded or were prepared to pass through a cycle of 1) preparing and submitting draft documents to the regulatory agencies, 2) responding to regulatory agencies' comments on the document and incorporating their comments into a draft final document, 3) submitting the draft final document to the agencies, 4) responding to the agencies' comments on the draft final document and incorporating their comments into a final document, and finally, 5) submitting the final document to the agencies for final acceptance. This process was followed to completion for the FS, PP, and ROD documents for one OU, and to date has been completed part way through the cycle for two other OUs. To complete this process, we recently were spending annual budgets of $6-9 million, using the skills and talents of approximately 30 full-time scientists, engineers, technicians, community relations specialists, and clerical and administrative staff members.

Progress toward formal implementation of cleanup of the site has been slow because of the lengthy time required to complete the document preparation requirements before cleanup can begin. However, since becoming a CERCLA site, in two cases we implemented Removal Actions to begin remediation of VOCs in ground water even before acceptance of the ROD for the OU.

CERCLA Restructuring

Early in FY95, LLNL and the DOE Oakland Operations Office recognized that our decreasing DOE budget for environmental restoration was not and would not be sufficient to complete the work obligations required by the FFA. In addition, we were experiencing severe frustration at the length of time required to complete what we considered to be unnecessary regulatory documents. Consequently, at our Remedial Project Managers (RPM) Meeting in April 1995, we proposed an alternative approach to the regulatory agencies. We recommended that the Site 300 team (regulatory agencies, DOE, and LLNL) should stand back and take a serious look at how we had organized the project of environmental restoration of Site 300. We proposed to identify possible ways to meet the goals and needs of all parties to the FFA while, at the same time, save the taxpayers and DOE millions of dollars by moving more rapidly to the clean up phase. We proposed restructuring CERCLA as it applies to our restoration activities.

During the course of three RPM Meetings held in April, May, and June 1995, the Site 300 team considered the following:

For the Pit 6 OU, the FS had already been completed, and the regulatory agencies had approved a natural remediation remedy for TCE in ground water. Additional capping of the landfill still needed to be done.

For the Building 850/Pits 3&5 OU, the regulatory agencies had already agreed that no remedial action was required with respect to ground water other than continued ground water monitoring because 1) no economically feasible method is available for removing tritium from ground water, and 2) the tritium poses no risk to the public. Potential future release sites, however, need to be addressed.

For the HE Process Area OU, the regulatory agencies were amenable to discussing options other than writing FS/PP/ROD documents to address low concentrations of TCE and HE compounds in ground water.

Because the regulatory agencies had already agreed that active ground water remediation was not needed or feasible at the Pit 6 OU and B850/Pits 3&5 OU, we concluded that there was no value in preparing three regulatory documents (FS/PP/ROD) for each OU just to identify and select a No Action remedy (other than continued ground water monitoring). Furthermore, the team concluded that any ground water remediation that may be required at the HE Process Area OU could be accomplished much faster and more economically through judicious use of Removal Actions rather than following the conventional and costly CERCLA FS/PP/ROD process.

Consequently, LLNL and the DOE Oakland Operations Office, in close consultation with the State and Federal regulatory agencies, have created a model strategy for CERCLA restructuring as it applies to three Site 300 OUs: Pit 6, Building 850/Pits 3&5, and HE Process Area. The restructuring provides for:

1) Continued protection of human health and the environment.

2) Conduct of Removal Actions where warranted in the OUs to remove the threat of future contaminant releases to the environment. These Removal Actions will consist of landfill capping at the Pit 6 OU; excavating buried drums in the HE Process Area OU; and landfill capping, constructing a surface water diversion ditch, or digging an interceptor drain at the Building 850/Pits 3&5 OU.

3) Continued ground water monitoring at the OUs to monitor the extent and movement of contaminant plumes. This monitoring will enable us to detect any unexpected changes in location, movement, or concentration of the plumes so that remedial action can be taken if warranted.

4) Preparation of contingency plans to establish criteria and procedures for remedial action in the event the ground water contaminants migrate and pose an unacceptable risk to the public or the environment.

5) Moving the ground water monitoring tasks for each OU to a Site 300 Monitoring OU that encompasses all parts of Site 300 where monitoring only is required.

6) Dissolving the three OUs as discrete entities, thereby removing the need for preparation and submittal of conventional CERCLA documents for these OUs.

7) Preparing a Site 300 Monitoring ROD that will, in part, incorporate the results of Removal Actions performed in item 2. The Removal Actions will demonstrate that remedial actions have been taken at the sites of potential releases in the three former OUs.

This restructuring substitutes relatively short Removal Action Engineering Evaluation/Cost Analysis documents, monitoring plans, and contingency plans for the much longer studies and plans (FS/PP/RODs) currently required by the CERCLA FFA. Two other OUs are well along the conventional CERCLA process, and will continue to follow that path to final remediation. One of these OUs has off-site ground water contamination; the other has high concentrations of TCE in ground water. We must complete our remedial investigation work at the sixth OU before determining its ultimate CERCLA pathway. Figure 3 illustrates our expectation of the final resolution as it applies to CERCLA restructuring of Site 300.

Fig. 3

CONCLUSION

With this approach to CERCLA restructuring of the LLNL Site 300 environmental restoration project, human health and the environment will

remain protected, potential sources of future releases to the environment will be remediated, low risk areas of ground water contamination will continue to be monitored, and regulatory requirements for completion of RODs will be met. Furthermore, this new process will hasten the start of remediation in some cases by 1-1/2 years and reduce costs by millions of dollars. We believe this approach of working with the regulatory agencies to identify mechanisms to streamline the CERCLA process is well worth the effort and should be attempted at all sites where feasible.

WHAT MAKES DECOMMISSIONING SO COMPLICATED?
Martin Lietz
Technischer Ueberwachungsverein Suedwest e.V.
Dept. KS
Dudenstrasse 28
D-68167 Mannheim, Germany
ABSTRACT
In Germany decommissioning has become a long lasting process connected with considerable costs. The reasons for this development are analyzed. Two possibilities are pointed out to save time in the decommissioning procedure; the package solution and the black box solution. Further on the psychological situation of decommissioning is discussed with its impact on the decommissioning process.
INTRODUCTION
While there are no plans in Germany to set up new nuclear power plants, an important nuclear activity is dealing with decommissioning. The decommissioning process itself is governed by the atomic energy laws and is therefore subject to authorization. These legal parameters demand a special licensing procedure.
Our organization, the TUEV-SW, an Association for Technical Supervisory, advises the authorities in nuclear affairs safety. Concerning decommissioning we are producing surveys, to give the authorities a decisive support for the approval.
THE LEGAL SITUATION OF DECOMMISSIONING
In the Federal Republic of Germany all nuclear matters are governed by the atomic energy laws, AtG (1) and by the subordinated radiation protection ordinance, StrlSchV (2). The decommissioning of a nuclear plant, which has been licensed by 7 AtG (1), is subject to authorization too, 7(3) AtG (1). This legal parameter needs a special licensing procedure:
  Decommissioning has to be planned, documents and a safety report have to be made.
  The authorities have to be asked for a decommissioning license putting on the documents and the safety report.
  The documents have to be examined, if they fulfil the requirement of 7 (2) AtG (1), with its main aim to protect life and environment against the danger of radioactivity, whereby the steps to protection must fulfil the state of arts; that means especially, that decommissioning work can be done without the risk of significant radioactivity releases into the environment.
  Decommissioning is licensed by the authorities.

As the decommissioning documents have beside the technical meaning also a legal one, mistakes or inconsistencies have to be corrected. The revision of documents can take a lot of time. If there is any deviation in the decommissioning process, the deviation is also subject to authorization, what may require an additional revision of documents. These facts show, that decommissioning needs a special strategy to avoid time wasting mistakes.

THE TECHNICAL SITUATION OF DECOMMISSIONING

In most cases nuclear plants are very complex systems, therefore decommissioning can not be done in only one step. In consequence of that decommissioning has to be done step by step either progressing from one cell or room to another or progressing from system to system. A nuclear plant, which was shut down, is contaminated in the most areas with a more or less amount of radioactivity. The remaining radioactivity is enclosed in the plant within the same barriers as in time of running. Decommissioning and dismantling means, to open these barriers and it must be the objective that within this opening process there are no significant releases of radioactivity. Appropriate safety measures have to be made for every point of intersection. Therefore methods and procedure of decommissioning and dismantling must be laid down in the documents and in the safety report.

Results from the Legal and Technical Situation for the Decommissioning Process

Consideration of the legal parameters and the technical situation of a nuclear plant, which is to be decommissioned, shows that a move for decommissioning needs, because of its nature, a lot of separate technical measures, which are to be described in the documents and which are to be examined in detail.

The analysis of the licensing procedure leads to the following time schedule:

1) Producing of documents and safety report
 Propose a move
 Putting on documents and the safety report
2) Examination of documents
 Producing of the survey
3) License
 Performance

The three time consuming steps depend from one another:

t (license) = f (Q examination, survey)
t (examination) = f (Q documents)
t (examination) = f (A documents)
(t = time; Q = Quality; A = Amount)

The better the quality of documents, the sooner the survey can be produced and the license be given. If the documents do not fulfil the quality requirements and the amount of documents is very high, the examination needs more time and the license gets more complicated, as it contains more regulations.

Looking for time saving measures in the licensing procedure, the first is, to cut the range of the move for decommissioning from one over all step into several steps. This method has the benefit, that all time consuming steps in the licensing procedure can be finished in realistic time intervals, revisions of documents included.

If two or more independent facts are connected in the move for decommissioning, which do not fulfil the requirements of 7 (2) AtG (1) at the same time, the license will only be given when the requirements of

all systems connected in the move are fulfilled. These considerations just lead to the package solution.

Fig. 1

The package solution: The whole range of decommissioning is divided in several packages. Within a package it should be avoided to connect independent facts or systems, which do not fulfil the requirements of 7 (2) AtG (1) at the same time.

Within the package solution there is an optimizing potential. A system or a part of a system (Sys) foreseen to be dismantled has various points of intersections (poi) to the next one (for instance pipes, medium, power, measuring and control systems etc). These points of intersections must be made safe, especially against uncontrolled release of activity. The system may be enclosed from a volume element (cell, room) from which the number of the points of intersections to the next one are less. There is a relation between the size of a volume element of a system (Vol E (Sys)) and the number of points of intersections. The number of points of intersection are direct proportional to the time, which is needed for the different steps in the decommissioning licensing procedure. On the other hand the size of a volume element of a system, which is to be dismantled, is important for the progress of the decommissioning process itself. There is only a little progress in the decommissioning process, if the volume element has been chosen too small. These considerations lead just to the black box solution. To get much progress in the decommissioning process the size of Vol E (Sys) should be at a maximum, while the points of intersections (poi) should be at a minimum.

Fig. 2

The black box solution: Points of intersections are minimized, while the size of a volume element of a system to be destructed is at a maximum.

The benefit of the black box solution is, that the actual time expenditure of producing documents is minimized, as there are less points of intersections and the safety requirements can be proved by worst case analysis. The examination of the documents can be done quickly by the same reasons. In addition the black box solution is high flexible in the performance of the decommissioning license. With both solutions, the package solution and the black box solution, it is possible to save time in decommissioning process.

THE PSYCHOLOGICAL SITUATION OF DECOMMISSIONING

People like to be creative, that means to built up things, while decommissioning and dismantling is basically non-creative. Therefore decommissioning is done reluctantly from the very first beginning. Beside this negative motivation the decommissioning process is connected with the lost of jobs. So everyone of the personnel of a plant, which is to be decommissioned, tries to save his job. This is additionally contraproductive for the decommissioning process and can lead to a further waste of time. But when a nuclear plant is to be decommissioned never the less the question has to be answered, who should do the decommissioning, the plant personnel, who had run the plant or an extern firm, which is doing decommissioning professionally? The plant personnel has a great specific knowledge about the plant and the incidents which have occurred. This knowledge is very valuable for the decommissioning process. But the above mentioned facts, especially the lost of jobs are standing in opposite to it. A great disadvantage of an extern firm, which is doing decommissioning professionally is, that it has no specific knowledge about the plant. On the other hand the extern firm is only

primarily interested in getting the order. If the order is booked, the decommissioning firm may not be unhappy when decommissioning is connected with delay, as time brings money.
Therefore the question, who should do the decommissioning, can not clearly be answered. In both groups, the plant personnel or an extern firm, there is a tendency to slow down the speed of the decommissioning process. Perhaps a solution with a mixed decommissioning personnel might be useful.

CONCLUSION

The decommissioning process is governed by the atomic energy laws and is therefore subject to authorization. These legal parameters demand a special licensing procedure. To fulfil the legal requirements and depending on the nature of decommissioning process a great number of separate technical measures has to be considered and laid down in documents. These legal as well as technical conditions must be taken in to account to avoid time wasting mistakes. A time saving strategy in the decommissioning procedure could be the package solution, whereby the whole range of decommissioning is divided into several packages. Within the package solution there is an optimizing potential, the black box solution, in which the number of points of intersection is minimized, while the volume of the system or room, which is to be destructed, is at an maximum. If a decommissioner takes this strategy - the package and the black box solution - into account before he starts, he can avoid time wasting mistakes and can reduce the costs.
The decommissioning process is basically non-creative and connected with the lost of jobs. Both facts yield a tendency to slow down the speed of the decommissioning process. This retard-effect plays a part in the composition of the decommissioning team. The plant personnel has the advantage of a great specific knowledge in contrary to an extern firm. This valuable plant knowledge should not be given up. Perhaps this retard-effect can be stopped by a solution with a mixed decommissioning team, consisting of plant personnel and personnel of an extern firm; this could be combined with tailor-made contracts containing stops, where the decommissioning success must be proved.

ABSTRACT
The reactor hall at A-1 Nuclear Power Plant at Bohunice became contaminated as a result of incidents both before and after reactor closure in 1979. In particular, a recent spillage of corrosion inhibiting solution led to wide spread contamination in the hall. Liquid also seeped into storage holes, a trench, and into rooms below the hall. Radiation levels of up to 1 Sv/hr are present in some areas.
A decontamination plan and safety case were prepared by AEA Technology (AEAT) on behalf of Slovenske Elektrarne (SE), the utility responsible for A-1. AEAT were also awarded the contract to manage the project including the supply of specialists and key decontamination and robotic equipment. SE are responsible for providing labor, materials and decontamination reagents.
The work is divided into three tasks:
1) decontamination of the reactor hall where contamination levels are relatively low.
2) decontamination of a specific area in the reactor hall which is highly contaminated.
3) decontamination of the rooms below the hall where contamination levels are very high.
The aim of the project is to reduce contamination and radiation levels to permit decommissioning operations in the reactor hall to resume.
Decontamination of the hall is now complete, together with three cranes and various fuel handling machines. Most work up to this point has been carried out manually, either by industrial mountaineers working from ropes, or reactor staff working from a cradle suspended from an overhead crane. Lower levels were decontaminated by hand from platforms. Reagents were applied by hand and a number of reagents were developed by SE and used with great success.
High radiation and contamination levels in one area have necessitated local containment and remote decontamination methods. An area is now enclosed by a MODUCON temporary containment and decontamination is being carried out using an ARTISAN manipulator working through the containment wall. MODUCON and ARTISAN units were supplied and installed by AEAT.
Decontaminating such a large and complicated facility is a very demanding task, and the high radiation areas are particularly challenging. However, close co-operation between AEAT and SE has enabled the problems to be overcome and the project is now 1 year into the program.
INTRODUCTION
This paper describes the decontamination of a redundant nuclear reactor hall and associated equipment, which has become heavily contaminated over the years. The work is a collaborative venture between AEA Technology (AEAT), UK and Slovenske Electrarne (SE), Slovakia. On successful completion of the work, decommissioning operations will resume.
The Site
The A-1 reactor at Bohunice is a 150 MW heavy water moderated, CO2 cooled demonstration plant of Russian design constructed in the 1960s. It was fuelled by natural uranium metal fuel, clad in a magnesium-beryllium alloy. The reactor hall is large; 70 m long, 11 m wide and 30 m high and has a total internal surface area, excluding equipment, of 6000 m2. It houses the reactor charge face, fuel handling machines, and numerous

other large items of equipment including Equipment for Fuel Treatment (EFT), and is served by three cranes.
Fig. 1
History
The reactor was shut down in the 1976 following a number of accidents and is due for decommissioning. The reactor hall first became contaminated in the 1970s as a result of a reactor accident which ejected a fuel element into the hall, together with 40 tons of active CO2 coolant.
In 1991, a corrosion inhibiting reagent ,'Chrompik', a solution of dilute Sodium Chromate, was ejected from the EFT which resulted in severe contamination of the rig itself. Later 3 m3 of water was spilled onto the reactor hall floor which re-dissolved 'Chrompik' residues and distributed activity over 70 m2 of the reactor hall floor and penetrated two rooms below. Despite some remedial action local radiation and contamination levels remain high.
The Task
In 1993 AEAT found low level contamination was widespread and radiation levels varied from 10 mSv/hr in the upper regions of the hall to many mSv/hr in some areas despite local shielding. Around the source of the accidents, the EFT, maximum levels were around 200 kBq/cm2 loose contamination and over 700 mSv/hr surface radiation. The reactor hall, and its large and complex items of machinery thus represented a considerable decontamination liability.
After site visits and discussions, AEAT was awarded the contract to plan and manage the decontamination tasks at Bohunice. The tasks and objectives are as follows :

To decontaminate the reactor hall and its equipment; to permit normal working with respect to both airborne contamination and external radiation levels.

To decontaminate the EFT rig together with the adjacent floor area, including the mortuary hole covers and service trenches; to levels which permit hands-on working.

To decontaminate the rooms below the reactor hall.

The work was divided contractually into two distinct phases : the Production Phase for issue of the decontamination plan and safety case and the Realization Phase for carrying out decontamination tasks.
PRODUCTION PHASE
The first task was to agree a strategy program, and in particular to prepare a decontamination plan and safety case addressing the issues of access, reducing the risks of recontamination and the principles of radiological protection.
Planning required the collation of data relating to Slovak regulations, the plant, its history and current condition, collaboration with station engineers and site visits including a video survey.
Strategy for Decontamination
The low contamination areas of the reactor hall required simple methods; working from the highest areas down to the floor and finally to the rooms below. Walls and intricate systems of cables and wires, equipment and miscellaneous items would be cleaned manually using application reagents such as foams, pastes and gels.
For heavily contaminated areas around the EFT and the rooms below, the removal of surfaces by remote methods within ventilated zones would be necessary. Size reduction and scabbling or chiselling tools would be needed for cutting service pipes and concrete removal respectively.

Wastes generated from these processes would be put into shielded containers supplied by the station staff and handed over to them for storage and ultimate disposal. Secondary arisings would be estimated and minimized wherever possible.

Risk of Recontamination

Areas of high risk would be enclosed in a temporary ventilated containment. Two were proposed based on the MODUCONTM containment system. Radiological Protection measures would be strengthened by full use of barriered 'zones'. In addition the existing ventilation system would be upgraded and fitted with HEPA filters.

Access

The tops of the walls are 24 m above the reactor hall floor and much of the wall surface is painted and featureless; other areas are festooned with cables and services. The rails for the main cranes are mounted on the tops of the longitudinal walls; other lower ledges support smaller cranes and two refuelling machines. (See Fig. 1). A suitable method for providing access to the wall surfaces, the cranes, refuelling machines etc. was needed. Industrial mountaineers had been used for repainting work elsewhere at Bohunice, and so it was proposed and agreed to use them to decontaminate the walls and equipment high above the reactor hall floor.

Work below 13 m would be carried out from a cradle suspended from the cranes. Work on the lowest areas, including a substantial ledge and rail system, would be carried out from platforms and ladders from the floor.

Work in High Radiation Areas

Areas which had been directly contaminated with 'Chrompik' on and around the EFT and in the rooms below, posed problems of operating in high levels of radiation. Surface dose rates were recorded as high as 700 mSv/hr in places and necessitated the use of remote methods. A telerobotic manipulator, ARTISANTM was selected as the most suitable tool available, capable of carrying out all the processes envisaged in the congested surroundings of the EFT and within a MODUCON containment booth.

The Decontamination Plan

The Plan specified the scope of work, decontamination methods, waste arisings, engineering and material support, timescale and cost of the project. This was supported by a probabilistic safety case which justified the proposed actions by quantifying the hazards, and a quality program describing the management arrangements proposed to control the work.

COLLABORATION

Documentation

The proposal and safety case were duly accepted after constructive comment and revision by the plant Management team and Slovak authorities, agreeing the 2 year program.

Preparatory Work

A number of tasks were completed prior to the commencement of the work, including:

- An inventory of the reactor hall identifying over one hundred items for removal.
- Fitting a filter to the main ventilation system.
- Delivery of a mobile ventilation system for use on a MODUCON booth.
- General cleaning of the main crane and rail.
- The decontamination and painting of the internal hall roof section.
- Modification of an active waste drain from the hall into storage tanks.

Obtaining materials and machines from the UK and local sources including vacuum cleaners and a proprietary decontamination system for routine floor cleaning.

REALIZATION PHASE

Having established the overall strategy and produced a detailed decontamination plan, the next stage required the deployment of AEAT staff and equipment on site to prepare and set up for operations. The staff included a full time project manager and technical specialists in robotics and decontamination as required.

The equipment supplied by AEAT included:

An ARTISANTM remote handling system.

Decontamination equipment (including a vacuum collection unit and foam generator).

MODUCON containment booths.

Preparation

The ARTISANTM system was thoroughly tested both in the UK and in a non-active 'mock-up' at Bohunice, including its capability with regard to access and deployment of tooling. An important task for the ARTISANTM was to remove shielding and scabble concrete trenches and this was successfully demonstrated together with the vacuum recovery of debris. Decontamination tools were demonstrated and training given to SE staff.

Two MODUCON containments were erected; one small booth for handling liquid waste, and another larger facility to contain the EFT. Staff from AEAT set up the containments and ventilation equipment supported by SE operators.

During this phase of the work trials with equipment and reagents were undertaken in the UK to assess their suitability for the envisaged application. This included comparing UK and Slovak reagents permitting selection of local products.

Decontamination

The plan submitted to SE reflected strategic decisions and the work was actually carried out as shown in Table I. Many of the tasks overlapped or ran in parallel to utilize available resources.

Table I

The decontamination techniques and progress are discussed in the following sections.

The Reactor Hall and its Equipment

Significant quantities of dust were visible in the hall on all the horizontal surfaces, including machinery and the large number of miscellaneous items of equipment. Airborne activity levels fluctuated depending on work being carried out, (e.g. crane movement). The use of wet methods on a small controllable scale using foam, gels and pastes were therefore preferred, thus minimizing resuspension.

Although most surfaces (steel and concrete) were painted in an epoxy coating which eased cleaning considerably, cleaning was compounded by the complexity of the equipment and years of grime, particularly on all horizontal surfaces.

Each area was thoroughly considered and detailed working instructions were written by AEAT in collaboration with SE staff who had particular knowledge of the plant.

Detailed working practices and specific reagents were thus agreed for each area, and indeed for the many components within, including a number of chemical formulations developed by the A-1 Decontamination Manager for particular applications.

The areas and type of surface within the hall may be grouped as follows:

- Roof 'containment' constructed from corrugated materials.
- Painted walls including rails/ledges of cranes and equipment.
- Three Cranes comprising countless different components.
- Two re-fuelling machines and two manipulators.
- Floor. Painted steel or covered concrete.
- Many miscellaneous items.

An inventory was prepared of every item of equipment in the hall and a grid reference system was set up which enabled the location of each item, or section of surface area, to be referenced. Each item or area was considered in relation to decontamination technique and reagent, the work time and the radwaste arisings. A dose assessment was made for each job compliant with the dose restraint objective of 15 mSv per year per operator.

Foam reagents were tested on large areas of the walls. There was considerably more grime and grease on these surfaces than expected and the use of degreasing emulsions and gels were found to be more effective and easy to use by the mountaineers.

All horizontal areas were thick with dust and were first suction cleaned to remove dust and loose contamination. Debris interceptors and HEPA filter units were used.

The cranes, re-fuelling machines and manipulators were also coated in years of greasy dust. These were decontaminated by hand swabbing using degreasing foams, gels and pastes to minimize recontamination across the surfaces and the risk of damage.

The reactor hall floor was initially decontaminated with a proprietary steam cleaning unit to minimize the spread of contamination by foot traffic. Mops and buckets are now used for routine housekeeping as this was found more amenable to the complex floor at A-1.

Operations over 13 m were carried out by a team of 'Industrial Mountaineers' who were available locally and who were experienced with working in active areas. They gained access to the high areas of the walls and ledges via defined access routes and worked suspended on conventional mountaineering equipment secured from above. Each man carried with him swabs, sponges and buckets of reagent to complete 1-2 m2, returning to replenish materials from time to time. After treatment, all areas were rinsed by wiping with a dilute detergent.

Fig. 2

Operations between 3-13 m were carried out by teams of SE operators working from a cradle suspended from a convenient crane, using hand swabbing methods and reagents.

The lowest 3 m areas, together with a substantial service ledge comprising pipes cables and a rail, were cleaned from floor level, accessed by ladders where necessary. Wall surfaces were festooned with a complex array of services and pipes and methods using emulsions and abrasive pastes applied by sponge were successful

The other equipment in the reactor hall, over 160 items in all, were also decontaminated by 'hands-on' methods using a variety of reagents.

The Equipment for Fuel Treatment (EFT)

This equipment consists of two heavily shielded cylinders in which canned fuel was drained, cropped and repackaged for transport. The immediate floor area surrounding the EFT contains numerous complicated features such as floor storage holes, and a service trench. The main problem is that of gaining access to the many contaminated surfaces to carry out

decontamination. For example, the dose rate on the bottom of the concrete service trench is 750 mSv/hr, but the trench was filled with 4.5 tonnes of steel shot and covered with large lead bricks. A MODUCONTM containment now encloses the EFT preventing the escape of active dust re-suspended during decontamination operations.

Fig. 3

The ARTISANTM hydraulic manipulator is being deployed through the walls to provide access and to carry out the decontamination operations. All the temporary shielding (lead bricks and steel shot), together with all service pipes have now been removed using ARTISANTM. Lead bricks were picked up individually by ARTISANTM and placed in a basket which was removed by crane through a hole in the MODUCONTM containment for decontamination later. Steel shot was removed by suction using a powerful vacuum unit supplied by AEAT which automatically collects debris (dust/spoil/shot) in 200l drums ready for disposal. This proved a highly efficient process.

Services pipes were cut using hydraulic shear tools deployed by ARTISANTM and later removed and packaged into shielded drums through the Waste Posting Port fitted to the MODUCONTM containment.

Operations continue. Concrete removal by a small scabbling tool with vacuum recovery proved too slow and produced excessive quantities of very fine dust by-passing the debris cyclone and collecting directly on the filters of the spoil collector; causing local radiation levels to rise. Up to 20 mm of concrete is now being removed from the floor using chisels deployed by ARTISANTM. Debris is being shovelled up and deposited in tins for posting out in containers: shielded to minimize dose to operators during handling and storage. When ARTISANTM operations are complete, operators will enter the MODUCONTM to unbolt the EFT for removal to another area for dismantling and decontamination at a later date.

The Rooms below the Reactor Hall

These two rooms are situated one above the other, below the reactor hall floor. The ARTISANTM manipulator will be installed through a shielded access plug in the reactor hall floor to carry out the decontamination of the upper room.

Fig. 4

The lowest room will be accessed through a MODUCON containment booth constructed around a door at floor level. The highly contaminated floors and stairs will be decontaminated by scabbling and chiselling, debris being collected in shielded drums using the vacuum unit. The steel duct will be treated by swabbing with appropriate reagents. Remote decontamination and size reduction will be carried out by ARTISANTM to reduce dose, allowing manual decontamination to follow, using suction cleaning, scabbling and treatment with foams.

SUMMARY AND CONCLUSIONS

As a result of a small number of operational accidents, the plant at Bohunice represented a considerable decontamination liability. Having been awarded a contract to plan and implement the decontamination, AEAT faced a number of technical challenges and responded with appropriately engineered solutions to meet them in collaboration with the local Slovak management.

Selection of methods for a specific task depends on a number of local factors including the resources and the type of waste treatment facilities available. Tasks such as the reactor hall have the potential to produce a very large volume of secondary wastes and it is important

that the most appropriate technology is selected to minimize arisings. Furthermore such large facilities pose special difficulties with regard to decontamination on account of their size, access and, in some cases, high radiation levels.

The resulting decontamination plan and supporting documents have gained the approval of both the customer and the Slovak authorities. The work has commenced and is now one year into the program. The joint AEAT/SE management team, together with the station staff and contractors, have maintained a flexible response to a number of technical and contractual constraints. This teamwork has played a significant part in the success of the work to date.

ACKNOWLEDGEMENTS

The development of the ARTISANTM remotely operated manipulator was funded through the UK Department of Trade and Industry.

Dr D Keltos, (VYZ.o.z, A-1, NPP Bohunice) Slovakia, for specific reagent formulations used in the decontamination of the Reactor Hall and its equipment.

THE JAPAN POWER DEMONSTRATION REACTOR DECOMMISSIONING PROGRAM - LESSONS LEARNED ON OPERATION AND MAINTENANCE OF AUXILIARY EQUIPMENT DURING DISMANTLING ACTIVITIES

Masaki Hagiwara
Shinichi Okawa

Department of Decommissioning and Waste Management
Japan Atomic Energy Research Institute
Shirakata Shirane, Tokai-mura, Ibaraki-ken, 319-11, Japan

ABSTRACT

Dismantling of the Japan Power Demonstration Reactor Decommissioning Program (JPDR) was initiated in December 1986, and planned to be finished by March 1996. During this period of dismantling, several useful lessons have been learned such as use of existing facilities, dismantling tools, and project management. Among these, facility maintenance and operation are two key elements that must be considered for effectively conducting dismantling activities.

INTRODUCTION

The Japan Atomic Energy Research Institute (JAERI) is conducting the decommissioning demonstration project of the Japan Power Demonstration Reactor (JPDR) (1,2). The JPDR decommissioning project has been successfully conducted so far; since March 1994, almost all components have been removed from the project site, and the project is currently in its final stages and is planned to be finished by March 1996. Decommissioning efforts have been focused on demolition of buildings.

The following provides a list of objectives for dismantling the JPDR:

- to demonstrate the techniques developed in Phase 1,
- to obtain experience on dismantling activities, and
- to establish decommissioning database for future decommissioning projects of commercial nuclear power plants.

Various cutting tools with remote operation developed in the early state of the project have been used successfully in dismantling highly-activated components. These techniques were proven to be useful in minimizing radiation exposure to workers.

During dismantling activities, various data on project management have been collected continually and are stored in the decommissioning database (3). In addition, several useful lessons have been learned from the dismantling activities such as use of existing facilities, dismantling tools and project management. Among these lessons, facility maintenance and operation are two key elements that must be considered for effectively conducting dismantling activities.

The lessons learned regarding the maintenance of existing facilities are discussed in this paper.

OUTLINE OF THE JAPAN POWER DEMONSTRATION REACTOR DECOMMISSIONING PROGRAM

Facility History

The JPDR was a prototype nuclear reactor built to gain experience on construction and operation of a light water power reactor and to train engineers in nuclear technology. The plant provided nuclear power generation for the first time in Japan in October, 1963. Since then, training of operators and irradiation tests have been conducted.

In March 1976, the plant was shut down as a result of problems in the cooling system. After a few years, it was decided the JPDR should be used for development of reactor decommissioning technology in consideration of future decommissioning of commercial nuclear plants. Table I provides a list of the major specifications of the JPDR.

Table I

Japan Power Demonstration Reactor Decommissioning Program

The JPDR decommissioning program was initiated in 1981 under contract with the Science and Technology Agency (STA). The purpose was to develop and confirm the appropriateness of these technologies by applying them to actual dismantling activities. The research and development of decommissioning technology began in 1981 and nearly finished by 1986. The mock-up test facility was built in a space neighboring on the south of the JPDR, and several mock up tests of dismantling technology were initiated there.

Dismantling Activities

Actual dismantling began in December 1986 with a planned completion date of March 1996. Figure 1 shows the JPDR facilities before the dismantling started in the ground plan. Among the buildings shown in the figure, the office building, the dump condenser building, and the warehouse will remain after completion of the JPDR decommissioning program. Figure 2 illustrates the schedule of the JPDR decommissioning program.

Fig. 1

Fig. 2

During the first stage of the JPDR dismantling activities, machinery around the reactor in the reactor building was removed to provide necessary space for installation and operation of the large remote-operated cutting tools needed to dismantle the JPDR reactor. The reactor core and the biological shield were then dismantled in the order from inner to outer parts. The major dismantling activities are described in the following paragraphs.

The reactor internals were removed by the underwater plasma arc cutting system. The plasma torch was operated, in most cases by a mast type manipulator having four degrees of freedom. Otherwise, the master-slave robotic manipulator was used for handling the plasma torch to demonstrate and verify its newly-developed robot technology.

The Reactor Pressure Vessel (RPV) was dismantled using an underwater arc saw cutting system, after removing the pipes connected to it. Before

installing the underwater arc saw cutting system, a temporary cylindrical water tank was installed in the space between the RPV and biological shield. The tank was filled with water for cutting the RPV underwater. Following the dismantling of the RPV, the neutron-activated portion of the biological shield was dismantled by using both the diamond sawing/coring and abrasive water jet cutting techniques. First, the diamond sawing/coring technique was performed, followed the abrasive water jet cutting technique which was used to cut the upper and lower half of the projected portion of the biological shield, respectively. The controlled blast was applied to the remaining portion of the biological shield, which was only slightly activated. At first, the layer of 40cm width from the inner surface was dismantled by explosives installed into horizontal holes drilled by workers. The waste was placed into containers for storage. The outer layer of the biological shield was dismantled by both controlled blasting and conventional tools. The concrete from the outer layer is being disposed in the shallow land burial place in a site at the JAERI as the first test case.

OPERATION AND MAINTENANCE OF AUXILIARY EQUIPMENT

Refurbishment of the Entrance Room to Radiation Controlled Area

Approximately 200 workers a day were expected to access the radiation controlled area when the full-scale dismantling began. Therefore, the existing entrance room to the radiation controlled area located in the control building was enlarged. Refurbishment of the entrance room was performed from October 1986 to March 1987, and a temporary control gate was established in the equipment entrance located in the northern part of the turbine building while the existing control gate was under construction.

After construction, the enlarged entrance room was equipped with a reception counter, lockers, changing area, decontamination equipment, whole body monitor and personal dosimeters (alarm pocket dosimeter and film badge).

Existing equipment, such as the water supply, drain system, power supply, and ventilation system, were utilized for the refurbished entrance room. The room was located a distance of about 30m from the waste treatment facility and was interconnected by piping. In 1991, a small-scale liquid waste disposal system was established in the dump condenser building because the existing waste treatment facility was going to be dismantled. Then, liquid waste piping from the entrance room was connected to the new liquid waste system and the piping was extended to 50m through an underground tunnel.

In 1994, a new facility for access to the radiation controlled area was installed beside the dump condenser building. It was designed as an exclusive entrance for the dump condenser building.

Dismantling of the existing entrance room began in October 1994 and was finished in March 1995. Since then, the dump condenser building entrance room was temporarily arranged and used as the entrance for whole radiation controlled areas in the JPDR. However, the temporary entrance room was too small to accommodate several workers, and adequate time was required to access the work sites.

Demolition of major buildings such as the turbine building began in April 1995, and several access gates to the controlled area were established near these buildings, then the route to another part of the facility was closed and the entrance room of the dump condenser building was rearranged as the entrance room.

Utilization of Existing Liquid Waste Treatment System

The original liquid waste system was composed of six waste tanks, two systems of waste filters, a waste demineralizer, and several small tanks. When the JPDR decommissioning program began, three large tanks and one system of waste filter was not in use. In addition to this equipment, two seawater pumps (1,500 ton/hour flow) for condenser cooling system were used for waste dilution when liquid waste was discharged to the ocean.

In the JPDR decommissioning program, acceptable criteria of radioactivity and pH of liquid waste was established, radioactivity was 3.7Bq/cc and pH was 5.8~8.6. Therefore an exclusive filter system was installed when the dismantling work such as plasma cutting of the reactor internals, and removal of the RPV using an arc saw started, in which large quantities of radioactive liquid waste were produced.

The existing liquid waste treatment system was utilized while dismantling of the relatively highly contaminated or irradiated components was performed. Before removal of this system, a small-scale liquid waste system was constructed in the basement floor of the dump condenser building in 1991. The liquid waste system was equipped anew and consisted of three waste tanks and dilution water piping from the water service system. The place where waste tanks were constructed was too narrow for a large tank. Therefore, each tank had a capacity of approximately 1.5 m3, which is only one-tenth the size of former waste tanks.

The new waste tank was completed, but frequency of waste treatment increased as a result of the small tank capacity. Because the new waste treatment system had no filtering device to reduce radioactivity in the liquid waste, it was impossible to discharge even slightly radioactive waste to the ocean. Then, the liquid waste in waste tanks had to be transported to a waste treatment facility (research establishment) in Tokai. Reducing the amount of liquid waste throughout the progress of dismantling, reduced frequency of the waste treatment to twice a month. Figure 3 illustrates the new waste tank.

Fig. 3

Utilization of Existing Ventilation System

Components of existing ventilation system were in full service when the actual dismantling activities were initiated. After removal of components around the reactor and the spent fuel storage pool in 1991, delivery blowers were shut down and exhaust blowers were utilized for the ventilation of the reactor building. In 1993, an exclusive exhaust pipe for the ventilation system of the dump condenser building was remade. After that, other existing ventilation equipment was shut down and temporary blowers were installed by contractors who were dismantling object parts.

Dust and fumes generated by dismantling activities are dissimilar from fumes generated by the maintenance of plant operations. The local ventilation systems and contamination control envelopes were installed temporarily at each working area in consideration of dust and fume characteristics. During the JPDR dismantling project, the local ventilation ducts were connected to the existing ventilation system. The local ventilation system has its own filter so that the influence to the existing ventilation system was very small. However, leakage was observed that resulted in the choking of filters in the existing system, while the chamber-type local ventilation system was in use. The likely cause of the leakage was insufficient air tightness of envelope and local ventilation systems. Because it may be difficult to avoid leakage from a temporary

contamination control envelope, it was determined that the self containment type local ventilation system was more effective than the chamber type.

Utilization of Existing Power Supply

In the turbine building and the dump condenser building when the dismantling project began, there were respective systems for power receiving equipment of 3,300V from the central power station in the Tokai research establishment.

In the mock-up test facility, the 6,600V power supply equipment was installed; it provided three phase 3,300V, 440V, 210V and single-phase 210V/105V for dismantling activities and several tests performed in this facility. When the reactor pressure vessel was dismantled with the underwater arc saw cutting system, 3,300V of power was supplied directly.

In 1987, the exclusive supply system for dismantling work was installed near the reactor enclosure. The power of 3,300V was supplied from the mock-up test facility and provided 220V to several distribution panels in the dismantling sites.

Removal of components and the power supply in the control room and the turbine building, respectively were conducted in 1992. The power supply for the turbine building and others was modified so that the power was provided from the mock-up facility instead of the existing power supply. Figure 4 illustrates the mock up test facility power supply.

Fig. 4

However, the power supply of the dump condenser building was detached from the turbine building power supply and modified to provide the power to remaining buildings, such as the office building, the warehouse, and the dump condenser building.

When the power was provided to the building where the dismantling was performed on the mock-up test facility, some problems occurred. Heavy loads were added to the system; for example, start-up of big ventilation fans, and severe voltage drops occurred, resulting in malfunctioning of monitors and other instruments. The power was sometimes interrupted locally by function of the protection circuit. Because the mock-up test facility power supply was designed for mock-up tests and several cutting machines, the power capacity was not enough for both original use and temporary use. Some rearrangement of ventilation fans start-up processes and changes of protection circuit settings were solutions to these problems.

SUMMARY OF LESSONS LEARNED

Since the entrance to radiation controlled areas basically consisted of existing equipment, refurbishment construction was required several times during dismantling activities. Relatively large amounts of workpower were necessary for refurbishment work; this was an inefficient system. Instead, it may be more efficient to built temporary control gates instead of utilization of existing entrance room.

The existing liquid waste system was used while the components were removed and replaced with small-scale equipment. However, it was too small to treat liquid waste from dismantling activities. Capacity and arrangement of substitute liquid waste systems should be carefully studied.

The contamination control envelope and local ventilation system were used in dismantling work. The duct of the local ventilation system was connected to existing ducts and at times, leakage occurred from the temporary equipment, resulting in choking of filters in existing

ventilation systems. Selection of blowers for the local ventilation system and arrangement of contamination control envelopes are important to avoid problems in existing ventilation systems.

When electric power was provided temporarily from the mock-up test facility, some problems occurred as a result of the power supply shortage. Temporary power supplies must have enough capacity for not only dismantling machines, but also maintenance of facilities after removing existing power supplies.

In the JPDR decommissioning program, auxiliary equipment was dependent on existing equipment. Therefore it was required to separate some components from the equipment in use for facility maintenance. During initial removal of components, a detailed study on the dismantling process was important to avoid any expected problems. Information exchange between dismantling and maintenance groups was indispensable.

CONCLUSION

The JPDR decommissioning program has been successful and is now in the final stages. Many useful experiences and lessons learned on the decommissioning and dismantling activities can be gained. In addition, various data on project arrangement collected in the dismantling activities are stored in the decommissioning database. These resulted from the JPDR decommissioning program and will contribute to future decommissioning of commercial nuclear power plants.

In such activities of dismantling, facility maintenance and operation were inconspicuous but important for effective dismantling activities. Effective utilization of existing equipment was important for dismantling activities. Through the dismantling program, auxiliary equipment was carefully studied in each stage of the decommissioning program. Knowledge from these studies may be useful for future decommissioning projects of commercial nuclear power plants.

ABSTRACT

RedZone Robotics, Inc. and Carnegie Mellon University's Field Robotics Center have undertaken development of an advanced remote worksystem capable specifically designed to meet the challenges of performing a wide range of decontamination and dismantlement operations in nuclear environments. This project is funded by the US Department of Energy's (DOE's) Environmental Management Office of Technology Development through the Morgantown Energy Technology Center. Currently, we are working on the third phase of this effort; having completed the design and fabrication

of the worksystemRosie, we are concluding endurance testing and characterization of Rosie's work capabilities, and commencing enhancement of the system design to ensure suitability for use in a DOE facility decommissioning project.

The Rosie worksystem includes a locomotor, heavy manipulator, operator console, and control system for remote operations. The locomotor is a highly mobile platform with tether management and hydraulic power onboard. The heavy manipulator is a high-payload, long-reach boom used to deploy a wide variety of tools and/or sensors into the work area. rosie's advanced control system, broad work capabilities and hardening/reliability for hazardous duty make it a new and unique capability that facilitates completion of significant cleanup projects throughout the DOE and private sector.

The paper presents a system overview, summarized results from endurance testing, and future plans.

INTRODUCTION

The development of the Rosie worksystem has occurred in three separate work phases. The first phase consisted of gaining a knowledge of the DOE's D&D needs, upgrading a pre-existing worksystem with state-of-the-art technologies and enhanced controls for ease of operation, then undertaking a program to test the system and determine its capabilities and weaknesses. The second phase involved developing a second-generation worksystem (Rosie) to perform D&D operations based on knowledge gained in Phase I. During the third and current phase Rosie is being tested extensively to determine general capabilities to deploy tools and perform decontamination and dismantlement (D&D) tasks, as well as assess reliability and maintenance issues.

The tasks and constraints which characterize D&D applications are essential background in the development of this technology. The environment in which such worksystems must perform D&D operations range from areas in which no worker protection is needed to areas in which human entry is precluded. Dangers can include exposure to alpha, beta, and gamma radiation; uranium, plutonium, and tritium; volatile organics, acids and caustics; mercury; TRU waste, asbestos; and mixed waste. Facilities in which D&D is likely to occur include uranium enrichment facilities (including gaseous diffusion plants, centrifuge plants, and other separation plants); research and production reactors; hot cells, canyons, and vaults; stacks and cooling towers; silos and waste storage tanks; analytical research labs; and weapons production and assembly facilities.

Given the wide range of tasks that must be executed, the hazards present, and the difficulty in predicting conditions or comprehensively understanding task needs, remote technology must be highly versatile and reliable. These worksystems require capabilities to handle a variety of tools, they must combine brute force for heavy work with dexterity for fine manipulation, they must be reliable for extended use in areas where human intervention is difficult or impossible, and they must be adaptable to a range of work conditions and settings.

In the second phase of this project we undertook the design and fabrication of a worksystem specifically designed to meet D&D needs. We discovered in our Phase I study, the requirements for a worksystem are very diverse, ranging from human-scale manipulation tasks to large, industrial-scale equipment removal. While it is impossible to build one system capable of meeting all of D&D needs, we selected a concept capable

of addressing a major segment of tasks for which current technology is inadequate.

WORKSYSTEM DESCRIPTION

Rosie is a mobile robot worksystem developed for nuclear facility decommissioning and dismantlement. Its primary function is to perform a variety of dismantlement tasks remotely by deploying tools, sensors, and/or other robotic equipment in hazardous areas. Rosie's capabilities and system design address the need for durability and reliability in these environments, and enable performance of tasks such as piping and process equipment removal, structural demolition, vessel segmentation, waste handling and transport, and wall/floor decontamination.

The system includes a tethered robot, a power distribution unit (PDu), and a control console for robot operation. The robot consists of two major subassemblies, the locomotor and the heavy manipulator. The locomotor is a hydraulically powered, omni-directional platform with onboard tether management. It provides mobility to transport the heavy manipulator, tools, or other payloads within the work area. The heavy manipulator is a four degree of freedom, high-payload, long-reach mechanism capable of carrying a variety of tools, one or more dexterous manipulators, or any other payload of up to 900 kg (2,000 lb) throughout a generous work envelope. Rosie is a teleoperated system with low-level automation features that facilitate more efficient remote operations and allow a single operator to maneuver and work effectively.

Fig. 1

Locomotor

The locomotor is a mobile platform with specifications as shown in Table I. Its frame is an aluminum weldment which supports wheel modules at each corner. Each wheel module has independent drive and steering motions providing an omni-directional capability.

The front two wheels are mounted on extensions which can change the front wheel tread width from 193 cm (76 in)to 345 cm (136 in). The two rear wheels are mounted on a pivoting beam which allows each wheel 5 cm (2 in) of vertical travel for obstacle negotiation.

Located within the locomotor is the hydraulic power supply, which is a 45 kW (60 Hp) supply, providing 114 l/min (30 gpm) of hydraulic fluid at 20.7 MPa (3,000 psi) for all robot motions. The hydraulic fluid reservoir is located at the front center of the locomotor. Directly behind it is the hydraulic pump and its electric drive motor. All of the control valving for the system is located above the pump and motor, inside the locomotor frame. Filters, an accumulator, and the hydraulic fluid cooling equipment are all located in one of two side enclosures suspended from the frame. The other side enclosure contains all onboard control electronics for the system. At the rear of the machine is the tether reel which can carry up to 53 m (175 feet) of tether (up to 38 m (125 ft) of unreeled tether can be included to extend the vehicle's range).

Table I

Heavy Manipulator

The heavy manipulator is mounted on the deck of the locomotor. It is a four degree-of-freedom mechanism providing a long-reach, high-payload capability for tool deployment. It can carry up to 900 kg (2,000 lb) with a 6,800 Nm (60,000 in-lb) moment load, at a distance of 6 m (20 feet) from the shoulder joint. The heavy manipulator consists of four joints; a waist rotation motion on the locomotor deck, a shoulder pitch, a forearm extension, and a wrist pitch at the tip of the forearm. Each of

the four joints has integral position feedback and is servo-controlled based on operator commands. The configuration of the heavy manipulator is shown in Fig. 2 and its specifications are shown in Table II.

Fig. 2

Table II

Figure 3 shows the tip over load limits of the locomotor for loads at the wrist of the heavy manipulator, with the front wheels fully extended, a 900 kb (2,000 lb) counterweight mounted on the manipulator turret, and the rear pivoting axle in its locked position. These load limits include a 455 kg (1,000 lb) safety margin to accommodate dynamic loads.]

Fig. 3

Feedback

Rosie's operator is provided with a complete set of feedback information to support remote operations. Audio and video feedback are provided from onboard microphones and up to ten onboard cameras. Various other onboard sensors provide full system status and health monitoring. Additional user-specified sensors can be installed to provide remote monitoring of key environmental parameters.

Audio/Video System

The audio/video system takes multiple camera views and microphone inputs from the robot and displays them at the console. Rosie can support up to 10 cameras including the following:

- Four cameras with remote focus, zoom, lights, and pan and tilt motions
- Four cameras with remote lights and tilt motions (fixed focus)
- Two cameras with remote lights (fixed focus)

All cameras are modular to allow easy replacement or relocation in order to accommodate different tooling or task requirements.

System Status/Health

The status and health of the system are constantly monitored by various onboard sensors. These include hydraulic fluid temperature, pressure, and reservoir level. In addition, the voltage levels of onboard electronic components as well as their temperatures are also monitored so that a fault may be detected before it can cause a complete system failure. Control and sensing signals are monitored automatically and error checking is performed to ensure reliable communications.

Position Sensing

All of the remotely controlled motions of the system incorporate position sensing. Locomotor wheel steering and drive motions are equipped with resolver feedback which is utilized by the computer control system to coordinate these motions in several different driving modes. This also provides the operator with a quick means to determine wheel positions. The four heavy manipulator motions (waist rotation, shoulder pitch, forearm extension, and wrist pitch) also have resolver feedback. Again, this allows computer controlled coordination modes and a clear understanding of heavy manipulator position/orientation for the operator. The front wheel extensions incorporate limit switches so that the operator can easily discern whether they are extended; this information is also used by the control system in performing automated initialization sequences. The tether reel has limit switches so that the tether cannot be completely unwound from the reel, or wound on beyond the reel's capacity.

User-specified Feedback

The system has the capacity to support user-specified sensors installed on the robot and transmit their data back to the console. Such sensors

can be used to provide remote monitoring of key environmental parameters, such as radiation levels, ambient temperature, the presence of toxic gases, etc.

Control System

Rosie's control system is comprised of an operator control console shown in Fig. 4 and onboard control system components linked by a telemetry system. Control system functions are distributed across two primary computers (CPU's) one in the console and one onboard the robot. The control console CPU displays status and sensor data coming from the robot, interprets signals from joysticks and other switches, and sends appropriate commands to the onboard CPU. The onboard CPU executes commands from the console by closing motion control loops, acquiring sensor data, coordinating axes, and activating video and other onboard equipment. Both CPUs perform continuous error checking and monitoring of communications between the robot and console.

Using this control system, a single operator stationed at the console can control the Rosie worksystem. Primary system functionslocomotor, heavy manipulator, system power, tether, and camerasare controlled using switches and joysticks on the desk top. Less frequently used functions and status information are accessed through the touch screen. Three video monitors, with quad-splitting capabilities, display the onboard camera views. The operator can select any camera view for any of the monitors using the touch screen controls. In this way, each operator can configure the control console monitors to suit his or her particular preferences. In addition, the views can be changed during operation of the system, as needs arise.

Fig. 4

Control Modes

All axes are servo-controlled enabling precise, variable speed motion control for dexterous positioning either by teleoperation or by computer control. This servo-control allows the computer to coordinate the motions of the locomotor wheels in any of three different steering modes. In addition, the heavy manipulator can be operated in two different control modes. These modes are as follows:

Steering Modes

The locator wheels are controlled in any of three driving modes:

4-wheel steering: Front and rear wheels steer in opposition, allowing a turn of any radius, including a pivot about the vehicle's center.

Crab Steering: All wheels steer in the same direction. This mode is especially useful for tight maneuvering and allows an operator to translate side-ways and work continuously along a wall surface, eliminating the need to frequently back away and reposition the vehicle.

Rotate-about-a-point Steering: Wheels automatically steer to turn the locomotor about a predetermined point. Assigning the tool location at this point allows the vehicle to be repositioned without moving the tool.

Boom Modes

The heavy manipulator can be controlled in either of two modes:

Joint Control allows the operator to individually control each joint on the heavy manipulator at a continuously variable speed.

Coordinated Control allows the operator to steer the endpoint of the heavy manipulator and all four joints are automatically coordinated to achieve Cartesian motion. This control mode is an efficient and intuitive way to control the heavy manipulator and allows an operator to perform

difficult tasks like tracking a wall or floor surface with a single joystick motion.

Power and Telemetry

The power and telemetry subsystem allows power and signals to be transmitted from the console to the locomotor and routed onboard to the various sensors and actuators. A Power Distribution Unit (PDU) located between the console and robot provides a location to input site electrical power needed for onboard functions. A tether is used to transmit all power, control, and video signals to and from the robot. All signals from the console pass through the PDU and are combined with the power and routed into the tether. When operating in a contaminated location, the PDU can be located outside of containment, minimizing the number of conductor penetrations required through containment.

The heart of the electrical system onboard the locomotor is enclosed in a sealed box mounted on the left side of the frame. This enclosure houses transformers, control computing, power supplies, video modulation equipment, and heat exchanger units.

Tooling and Auxiliary Services

A wide variety of tools or dexterous manipulators can be deployed from the heavy manipulator or locomotor deck. Highly accurate variable-speed motion control allows an operator to position tools quickly and perform work tasks effectively. Rosie's work envelope allows floor to ceiling reach with most tools.

Both hydraulic and electric power are available at the boom tip to power tools. As much as 57 1/min of hydraulic fluid at 207 bar (15 gpm at 3,000 psi) and 20 amps of 120 VAC power are available. Any user specified tooling can be deployed subject to powering and payload (up to 900 kg/2,000 lb) constraints, including:

Component Removal	Decontamination
hydraulic pipe sheer	pressurized water
reciprocating saw	CO2
abrasive disk	mechanical scabbler
impact wrench	sealant spray
plasma torch	
Demolition	General Purpose
jackhammer/breaker	dexterous manipulator
pulverizer	dual-arm work system
concrete hole saw	
abrasive water jet	
Material Handling	
wet/dry vacuum	
excavation bucket	
dozer blade	
drum grapple	
cable winch	

SYSTEM FEATURES

The Rosie worksystem incorporates many onboard and offboard features which provide significant benefits in remote dismantling. With construction-grade durability, high maneuverability, and power to spar, Rosie can operate effectively to deploy tools, transport materials, and meet the unexpected challenges of D&D.

Work Capability

Rosie is capable of deploying a wide variety of tools and other payloads throughout a generous work envelope. The heavy manipulator extends to reach 26 ft above the floor and at least 12 ft on all sides of the locomotor. All wheels are independently driven and steered, making Rosie highly maneuverable in tight or cluttered spaces. Front wheels extend for added stability. Rosie can be driven with wheels extended or retracted. The pivot-mounted rear axle provides compliance when working on uneven floors and crossing obstacles. Rosie is hydraulically powered, providing high power density suited to dismantling work; as a hydraulic system, Rosie is intrinsically sealed against contamination.

Reliability

Reliability is essential in environments where manual recovery of failed equipment is difficult, costly, or precluded by hazards. The rugged construction of this system is suited to the abusive conditions of dismantlement operations and it is designed to withstand inadvertent collisions or falling objects. The electrical system is designed with sufficient noise immunity and error monitoring to ensure the reliable communication of control signals between the operator's control console and the robot. Sensors are used to monitor the status of critical components and automatically alert the operator of potential problems. Critical actuation's, such as driving and steering, are functionally redundant each wheel module is individually driven and steered, and sufficiently powered to compensate for limited failures. The wheel drive motions freewheel when unpowered to enable emergency recovery towing. Rosie is a tethered system for guaranteed communications and power for extended work durations. Onboard tether management ensures that the tether is not endangered by being dragged.

Decontamination

In nuclear environments, the ability to decontaminate equipment is critical to allow maintenance, storage, and transportation of equipment without incurring personnel exposure. All onboard components on this system are sealed for pressurized washdown. The system's structures are designed to minimize exposed surfaces and areas where contamination can collect and be trapped. Areas that can't be sealed are left as open as possible in order to facilitate cleaning and washdown.

Radiation Hardening

This system is designed to operate in areas where radiation exposure is present. Materials and components have been selected to reduce the potential for radiation degradation. The robot portion of the system is designed to withstand a cumulative radiation dose of 105 R. Higher levels of radiation hardening are achievable if necessary by shielding of critical electronics and using more radiation tolerant components.

Ease of Operations

Rosie can be used to perform D&D tasks without reducing an operator's efficiency or requiring specialized skills. Automation of low-level functions and other control system features allow a single operator to maneuver both the locomotor and heavy manipulator and to work very efficiently.

All motions incorporate position sensing and servo-control, enabling precise motion control for dexterous positioning either by teleoperation or computer control. High resolution and continuously variable speeds allow an operator to move slowly for fine positioning, or quickly for efficient large motions.

Up to 10 onboard video cameraswith lights and pan/tiltsprovide an operator with effective views for navigation and tool deployment.

Modularity and Maintainability

The system is designed to be as modular as possible to expedite maintenance and deployment of alternate tools. Modularity allows the quick replacement of components or subsystems in order to keep the system in service, and allowing failed components to be repaired offboard and off-line. Critical components in the electrical and hydraulics systems are readily accessible and can be modularly replaced.

SUMMARY OF ROSIE TESTING AND LESSONS LEARNED

Over four months of testing have been performed to date at Oak Ridge National Laboratory using the Rosie worksystem. The goal of this testing was to determine areas requiring refinement or modification and to quantify the system's overall capabilities. Over 100 hours of operations have been logged deploying tooling in concrete demolition and metal cutting exercises. Concrete demolition was performed on more than ten reinforced concrete highway barriers and other pre-cast shapes using a hydraulic breaker tool mounted to the boom tip. Metal cutting tasks have been performed using an abrasive wheel grinder deployed from a master-slave dexterous manipulator mounted to the boom tip. Most testing has been performed outdoors; rain occurred on several occasions (operators were unaffected), and the system was stored outdoors when not in use for several weeks.

Overall, the system performed without failures; some minor adjustments were necessary and several design enhancements have been identified to improve durability and operability. Target areas include:

- improve function and reliability of tether management fairlead.
- add reinforcements to several areas on the heavy manipulator to reduce deflection and weld stress.
- secure hardware and components against long duration vibration loads.
- optimize control console for more efficient, less strained operations (switch and touchscreen layout, joysticks, etc.).
- reduce onboard control system complexity to increase reliability.
- increase hydraulic system cooling.
- upgrade hydraulic valving to improve stability and reliability.

FUTURE WORK

Through endurance testing we have evaluated the system and its ability to perform D&D tasks. Overall, the system performs well and meets the general requirements of D&D applications. Phase III testing will continue to characterize Rosie's capabilities and test enhancements that are currently being added. Testing and enhancement activities are also being focused on fully addressing issues such as decontamination and ease of maintenance. We are also focusing toward specific DOE facility decommissioning projects, including Argonne National Laboratory's CP-5 reactor, and commercialization of this system as a broadly applicable worksystem for hazardous applications.

DECOMMISSIONING OF REPROCESSING PLANTS AT BNFL SELLAFIELD - A PRACTICAL SUCCESS

A. E. Sheil
BNFL
Sellafield, Seascale, Cumbria

ABSTRACT
The BNFL Sellafield site has developed extensively since the start of the first construction in the late 1940's and even without further development there will have been some 120 radioactive plants in operation. The decommissioning of these plants requires a co-ordinated and integrated program. The paper describes BNFL's approach to the challenge, its overall strategies, the constraints and the progress achieved to date using real experience from the 18 decommissioning projects currently underway.

INTRODUCTION

When the current reprocessing programs are complete the BNFL's Sellafield site will have contained over 120 radioactive plants all of which will require decommissioning at a currently estimated cost of almost $9B. A formal decommissioning program was initiated in the early 1980s and has expanded to reach the current level of eighteen plants undergoing decommissioning and a program of work stretching over several decades. The management philosophy needs to ensure the optimum approach both for safety and cost, satisfactory interaction with the regulatory bodies and the effective management of the practical work.

THE SELLAFIELD SITE

Initial work at Sellafield in the late 1940s involved the construction of the two Windscale Pile reactors and the associated plants to cool, decan and reprocess the fuel together with the plutonium and uranium finishing lines and the associated waste and effluent treatment facilities. In the mid 1950s the first of the Magnox reactors came on line and it was apparent that the proposed expansion of the civil Magnox program could not be supported by the existing reprocessing plants. This led to the construction of the Magnox reprocessing plant which came on stream in the mid 1960s together with additional pond storage and decanning facilities, many of the existing waste and effluent plants however continued to be utilized with some capacity enhancements. This philosophy of maximizing the utilization of capital investment has continued and the recently commissioned THORP plant for the reprocessing of oxide fuels utilizes supporting plants from both the original military and Magnox programs. Reprocessing of Magnox fuel is anticipated to continue until the later part of the first decade of the next century with oxide fuel reprocessing continuing some years longer. Additionally there is an accumulation of highly active liquors and medium active wastes (mainly fuel cladding) which needs to be recovered and conditioned ready for ultimate disposal. The site interactions are therefore extremely complex and the decommissioning program both for the plants already shut down and operating plants must be integrated with the operational needs of the site.

OVERALL STRATEGIES

BNFL brings together all its waste and decommissioning liability planning in the Waste Management Review (WMPR) and the Decommissioning Review (DPR). These reviews summarize the strategies and programs together with the associated costs thus allowing optimization on a macro scale and the calculation of the necessary financial provisions. WMPR addresses the waste routing and treatment issues together with interim storage. Its aim is to minimize the overall cost by maximizing the utilization of existing facilities and minimizing the number of new plants needed. DPR recognizes the longer term nature of the decommissioning program, anticipated to extend beyond 2100, and seeks to priorities and program the plant

decommissioning to achieve the minimum discounted overall cost recognizing such factors as plant risk, surveillance and maintenance costs, waste route availability, interaction with other plants etc.. Not surprisingly the more fragile plutonium facilities attract a higher priority for early dismantling than for example the extremely robust reactors. Decommissioning cost modelling techniques (1) have been developed to facilitate this long term programming.

PROJECT STRATEGIES

Once identified within the overall decommissioning program the actual project strategy is developed on a case by case basis recognizing the specific features of the plant any links with operating plant and waste routing. Extensive optioneering involving techniques such as Kipner Traego and value engineering are utilized calling on the extensive knowledge of the plants available on the site and experience on similar projects to ensure the optimum cost and safety effective solution is identified. It would be normal to carry out a HAZOP one study on the preferred option to ensure there are no obvious safety show stoppers before investing engineering effort in further design and planning. Any necessary development work in support of the project would normally be identified at this stage. Although every effort is made to obtain all possible plant data it is frequently necessary to recognize a number of uncertainties and projects often proceed in a number of phases where a scope of work can be reasonably well defined, both for contractual and safety reasons, and would often include the acquisition of further data to allow the next phase of the project to be planned in detail. A project manager is nominated who is responsible for the overall control of the project and normally for the control and safety of the plant, occasionally this responsibility remains with the existing plant operators if decommissioning is being carried out in a section of an operating plant.

INTERACTION WITH REGULATORS

Nuclear licensing arrangements in the United Kingdom include the requirement for the licensee to prepare decommissioning plans and programs. For Sellafield this has been developed into an agreed 15 year Post Operational, Waste Retrieval and Decommissioning program updated annually. For each decommissioning project however there is a more detailed interaction with the regulators which varies depending on the assessed level of risk within the project. The more difficult projects, which include the majority of the plutonium decommissioning, will require an overall safety case, detailed safety justifications for each phase of decommissioning and safety documentation for the construction and commissioning of any major facilities in support of the decommissioning. The overall safety case, which is not particularly detailed and is at a safety strategy level, and the first detailed phase submission would normally be required before work could commence. Further detailed phase submissions would be made at the appropriate time. For more simple projects it may be possible to cover all aspects in one document. Additional justification is required for waste generation and discharge authorizations. Particular attention is paid to projected dose uptake during the safety justification stage and formalized ALARP studies are implemented for most projects. A number of dose rate modelling techniques have been developed to assist the process and they allow rapid assessment of benefits achieved by additional shielding or removal of high sources. It is common for regulatory approval to be given in a number of stages

with agreed 'hold points' where performance to date can be reviewed. Frequent contact with the regulator 'Site Inspector' is normal.

PROJECT EXPERIENCE

Decommissioning has been undertaken at Sellafield since the mid 1950s, primarily to create space for new facilities, but since the start of the formal decommissioning program in the early 1980's six plants have been completely decommissioned, a further sixteen major project phases have been completed and eighteen are currently undergoing decommissioning. The following are brief descriptions from a few of the current projects:

First Storage Pond

Built in the early 1950s to receive, cool and decan the fuel from the original Windscale Piles, and later adapted to handle Magnox fuel from the Calder and Chapelcross reactors, the plant ceased operation in 1963. The plant consists of two open cooling ponds (Fig. 1) with an adjacent building housing twelve decanning bays and six withdrawal bays. The pond still contains some 190 skips containing fuel, isotopes, fuel hulls and a mixture of other wastes. Additionally there is a general accumulation of sludge and debris. Within the decanning bays there are over spill wastes from normal decanning operations including fuel rods, graphite and cladding together with residual material from experimental work for chemical decanning and provision of uranium 'pennies' for pilot reprocessing. Due to the period before decommissioning the building no longer achieved modern standards and following substantial stripping out new ventilation, environmental monitoring and cranage has been installed. Current operations center on the stripping out of all equipment from two decanning bays to allow the installation of the skip washing and sorting equipment. Most of the installation involves operations in up to 18' of contaminated water with extremely poor visibility. The sorting of the pond contents to allow appropriate downstream treatment and disposal is due to commence in 1996.

Fig. 1

First Separation and Head End Plant

Built for the dissolution and chemical separation of the Windscale Pile fuel, including separation of the Plutonium, Uranium, medium active and highly active waste streams, the plant is extremely large being over ten floors (60 meters) high and consisting of four highly active and two medium active cells. The plant continued in operation for the reprocessing of Magnox fuel until 1965 when it was replaced by the Magnox reprocessing plant. The north half was then washed out and permanently shut down but the south side underwent extensive alterations including the removal of metal fuel dissolvers, installation of shearing, dissolver, accountancy and maintenance cells to allow head end operations on oxide fuel utilizing part of the existing solvent extraction plant. Decommissioning of the plant poses a particular challenge due to the height of the cells, absence of in cell cranage, no designed access routes for equipment, varying radiological conditions, limited radiological data and absence of accurate as built drawings. A progressive approach is being taken to the decommissioning with the MAN cell, the least radiologically challenging, being dismantled first followed by the other cells, thus allowing the proving of techniques prior to deployment in the other cells. Typically for older plants the cell ventilation was inadequate by modern standards and a new fully filtered system has been installed to support all decommissioning operations. A waste handling facility (Fig. 2) has been constructed

adjacent to the MAN cell and incorporates automatic remote robotic size reduction, mainly using plasma arc, linked to an integrated control system and 3D modelling. This facility will handles the waste from all the cells. Access for the cell dismantling machine (Fig. 3) has been provided at high level and incorporates a manipulator system, deployed at the various levels in the cell, and a hoist to lower the cut components to the ground floor export link to the waste facility; wherever practicable standard components are used with the main development effort directed to special tooling and an integrated control system which links from a three dimensional model of the cell to the manipulator and size reduction robots and is aimed at minimizing operator fatigue and maximizing productivity.

Fig. 2

Fig. 3

Solvent Regeneration Plant

Built for regeneration of the Butex solvent utilized in the original reprocessing plant the plant is about 30 meters high and consists of six cells two of which were fitted out for the process, two were held in reserve, one was for general shielded R&D and one was for post irradiation examination of fuel. The solvent process performed better than expected and the two spare cells were released for other experimental work. Decommissioning of the first of the solvent regeneration cells is underway. There was no installed cell cranage but there were removable cell top concrete panels provided for initial construction. Optioneering concluded that top entry was the best approach and a size reduction facility incorporating cranage, tooling and access arrangements has been constructed and commissioned on top of cells 1 and 2. Following the provision of a filtered extract system it was possible to complete the removal of the residual inventory, particularly the Butex solvent which poses a significant fire hazard. Dismantling of cell 1 utilizing manual techniques has commenced though the hazard posed by the possible presence of solvent necessitates special precautions to be taken. It is anticipated that Cell 2 will be dismantled utilizing similar techniques but the later cells will require progressively more remote methods. Radiological data is limited for some areas.

Plutonium Purification Plant

Built to purify the plutonium stream from the reprocessing plant the plant is large, being effectively two mirror image cells, four stories high with a brick wall as the secondary containment, the vessels and pipework being the primary containment. The anticipated level of plant containment was not achieved and several leaks (all contained within the cells) and remedial works have led to a very high level of internal contamination. As the cell extract was not filtered the plant was a major contributor to the site aerial discharges and prior to allowing routine man entry for decommissioning it has been necessary to dismantle several feed system gloveboxes and install a new ventilation system, commissioned in late 1993. Following commissioning of the new ventilation system cell entries were possible and these confirmed the predicted extremely high levels of contamination and also discovered localized radiation sources in excess of 15 mSv. Intrusive surveys of the cell vessels is now in progress to assess the amount of residual liquor. Dismantling will be undertaken manually, moving components to a waste handling facility, currently being constructed on the South side of the plant, for size reduction and packaging. All external control, sampling and fuel cabinets

are being progressively removed. As with many plutonium facilities there is the potential risk of criticality and extensive in situ inventory monitoring will be undertaken prior to the movement of vessels to the size reduction facility.

Finishing Line 3

This was the main plutonium finishing line for metal and oxide production from 1963 until 1987. It is constructed in a series of over twenty gloveboxes linked by two conveyor systems and operated through a shielded face. The plant operating life and throughput greatly exceeded design expectations but has resulted in a significant hold up of material, particularly in the concentrate stock tanks, the conveyor systems and the furnaces. Contamination is extensive and radiation levels exceed 10 mSv in several areas. Because of the radiation levels it was intended to utilize remote methods but it quickly became apparent that the extremely difficult access (Fig. 4) and the criticality hazard associated with the high residual inventory would make this approach difficult and costly. Extensive optioneering, modelling and value engineering studies were then applied to optimize the dismantling strategy and in particular the choice of manual in preference to remote dismantling approaches. The manual size reduction is practicable provided boxes are removed from the line and the location chosen for the size reduction facility was that left vacant following the earlier dismantling of the adjacent Co-precipitation Plant (see 3.7). Installation of the size reduction facility and associated tooling is underway. The same method of size reduction will be employed as on the current First Floor dismantling with plasma arc as the preferred tool. Gloveboxes will be isolated and removed from the line to the size reduction facility where plasma cutting and other techniques will be utilized prior to inventory assessment and packing in 200 liter drums. As for B203 there is the need to avoid risk of criticality and again inventory assessment will be needed. In this case however the high background from adjacent plant items precludes high levels of accuracy and gloveboxes will undergo secondary assay once removed from the line. Because of the anticipated inventory additional monitoring of items ready for placement in waste drums will be undertaken to ensure the drum fissile material limit is not exceeded. These techniques are already in use on a number of other projects.

Fig. 4

Fast Reactor Fuel Facilities

The Co-precipitation and Dry Recovery plants associated with the conversion of recovered plutonium and uranium for the fast reactor program have already been totally decommissioned. These plants formed the basis for the development of many of the techniques and equipment needed for plutonium plant decommissioning including in situ inventory assay, containment and decontamination, size reduction, and recirculating suit showers with water treatment. The current operations center on the PFR Fuel Fabrication Facility and the associated Dry Granule Production Plant (DGPP) which provided the mixed oxide fuel granules. The PFR plant converted the granules into pellets which were then loaded into fuel pins and finally assembled into fuel assemblies for shipment to Dounreay. Decommissioning of the final assembly area and pin filling line was completed utilizing manual techniques. The next stage of the project involving removal of all other plant which can reasonably be achieved manually is currently underway. The final phase of the project, the fuel line where the pellets were prepared, is the most heavily contaminated

and will require remote dismantling. Following the earlier development work on Co-precipitation and Dry Recovery plants the PFR project can be termed production decommissioning with a large number of plant items to remove against tight financial and timescale targets. The DGPP plant was initially a pilot facility upgraded to full scale production. The result has been a significant decommissioning challenge in terms of residual inventory and dose rates combined with very restricted access. In addition to the techniques used on other projects it has been necessary to develop a manipulator system to allow remote dismantling of the main part of the plant. Following extensive off site development and training, utilizing full scale mock ups, the machine is now deployed on the plant, this will be moved to the PFR plant on completion of DGPP. Many of the systems are common with the machines being developed for other projects. In most cases the same control, viewing systems, end effect manipulators and tooling are used, the main differences being the deployment platforms.

Other Projects

The above projects represent a cross-section of the decommissioning activities being carried out by BNFL across the spectrum of facilities at Sellafield. Others include the well advanced decommissioning of the Windscale Piles Chimneys, the Magnox Reprocessing Plant Plutonium Corridors and Old Evaporator Cell, several other plutonium plants, R&D facilities and the waste recovery operation on Silos. The refurbishing of the Highly Active Dissolver Cell in the main Magnox reprocessing plant, while not a decommissioning project, involved the decontamination, removal and replacement of the fuel dissolver and associated equipment. The successful application of new and existing technology in this and other very challenging environments at Sellafield over many years has provided a very firm base of experience. This real experience has been a major factor in the success of the overall decommissioning program to date.

TECHNOLOGY AND DEVELOPMENT

The projects described depend on the use of a wide range of technologies and techniques to enable them to achieve their objectives. A substantial Research and Development program (2) was established in support of the Sellafield decommissioning projects in 1989 and has successfully provided important equipment and techniques. Examples of these include the in situ and fixed plutonium inventory assay equipment with significantly increased accuracy and the ability to cope with a variety of isotopic compositions, remote equipment backed up by a range of integrated control, modelling and viewing systems which minimize operator fatigue and improve effectiveness, data acquisition systems including three dimensional imaging, radiation modelling codes allowing the prediction of source data from a limited number of dose rate measurements and advanced decontamination methods which are extremely effective but with near zero discharges. The emphasis of the program in support of current projects is to continually increase effectiveness and reliability recognizing that decommissioning is a production scale operation. Whilst it has been demonstrated that the current decommissioning program can be achieved with technologies available today the development program also supports longer term developments, sometimes involving radical and emerging technologies, but all with the overall objective of reducing the cost of decommissioning in an environment when the constraints in the form of

regulations, dose targets and discharges are expected to become increasingly more restrictive.

WASTE MANAGEMENT

Successful waste management is integral with an ongoing decommissioning program. Waste must be produced in a form either ready for ultimate disposal or readily recoverable for further treatment for disposal. Decontamination, segregation, avoidance of cross and secondary contamination and adequate inventories and records are all important factors. Interim storage for Plutonium wastes from decommissioning has been provided cost effectively within part of a decommissioned plant and provisional agreement for a number of encapsulated waste forms has been reached with UK NIREX, the agency responsible for the provision of the UK disposal facility. Techniques for decontamination to be very low or free release level using near zero discharge techniques together with metal smelting are being developed to further reduce waste volumes.

DECOMMISSIONING COSTS AND ACHIEVEMENT

The technical achievement of projects, whilst in itself of satisfaction to the engineers, must be matched by the ability to predict and achieve financial targets. BNFL has since 1988 assessed long term decommissioning costs for all its facilities, shut down, operating, under construction or planned and this is updated on a regular basis. The ability to forecast such long term costs is required to allow for the financial provision for future liabilities both on a global and plant specific basis. BNFL has developed a detailed plant decommissioning costing model (1) which utilizes plant construction information, known or estimated radiological data to generate decommissioning costs, manpower and material requirements, decontamination effluent arisings, waste volumes and disposal container requirements. The reference data used in the calculations is based on currently available technology and techniques and where available real experience on decommissioning projects or other experimental or forecast data. The model has been used on twenty two major plants at Sellafield, including THORP where the provision for decommissioning is included in the cost of reprocessing. This long term forecast for all BNFL's liabilities has shown a downward trend, matched by a reduction in the parallel long term forecast of waste management costs. The reductions in the latter are very much due to the integrated site approach to the problem. For the current decommissioning projects up to April 1995 BNFL had completed some twenty two projects or major project phases and this has been achieved at 85% of the originally estimated cost. The current program encompasses some 18 decommissioning projects underway and the latest predicted out turn (December 1995) is $179M against an estimate of $206M.

CONCLUSIONS

The decommissioning of the Sellafield site presents an ongoing challenge requiring an integrated and coordinated program. The successful completion of a number of projects and the large number of projects currently undergoing practical decommissioning demonstrate that reprocessing plant decommissioning can be successfully and cost effectively accomplished.

ABSTRACT

In May 1995, the Shoreham Nuclear Power Station became the first large, NRC-licensed, commercial nuclear power plant to complete decommissioning and have its license terminated. The pioneering nature of the project made the Shoreham experience unique, interesting and challenging.

Planning for the decommissioning of the Shoreham plant began in 1989. Radiological characterization of the Shoreham facility and site was initiated in early 1990. Radiological surveys were performed on plant structures, systems, the reactor pressure vessel (RPV), RPV internals, the biological shield wall and the facility grounds.

The decommissioning alternative selected for Shoreham was DECON, i.e., prompt removal of radioactive materials to attain conditions for release of the facility for unrestricted use. Other alternatives, such as SAFSTOR and ENTOMB were evaluated but eliminated because of the desire to make the facility available for re-powering or other industrial uses as soon as possible.

Much of the Shoreham decommissioning work was accomplished through dismantlement and removal of equipment. Field tested and proven processes were used to dismantle plant structures and systems. High pressure water lancing (hydrolyzing) and a variety of mechanical decontamination techniques were used during the course of the project.

An extensive final radiological survey (termination survey) was performed to demonstrate that the residual radioactivity levels had been reduced in accordance with Shoreham release criteria specified in the NRC-approved Decommissioning Plan and the Termination Survey Plan.

The cost and schedule aspects of various decommissioning activities were closely monitored and controlled. As a result, the project was successfully completed on schedule and under budget (about $186 million).

In April 1995, the NRC issued a License Termination Order terminating the Shoreham Nuclear Power Station's license and authorizing the unrestricted release of the Shoreham facility. This brought to a successful conclusion the seven-year long Shoreham decommissioning effort.

BACKGROUND

The Shoreham Nuclear Power Station was located on the north shore of Long Island (Town of Brookhaven, Suffolk County, New York) approximately 50 miles east of New York City.

In April 1965, Long Island Lighting Company (LILCO) made public its plans to build the Shoreham plant. In May 1968, LILCO filed an application with the United States Nuclear Regulatory Commission (NRC)--then the United

States Atomic Energy Commission -- for a permit to build the Shoreham plant. LILCO received a Construction Permit in April 1973.

LILCO applied for an Operating License in September 1975. In December 1984, the NRC issued a license authorizing fuel loading and cold criticality testing. This was followed by a low power license, issued by the NRC in July 1985, authorizing testing at power levels below five percent of rated power. The Shoreham plant operated intermittently at low power levels from July 1985 to June 1987, generating total gross thermal energy of only about 120,000 MWH. At the time of the plant's final shutdown in June 1987, the burnup of the fuel was limited to two effective full power days or 48 Megawatt Days/Metric Ton Uranium (MWD/MTU) compared to approximately 38,000 MWD/MTU for a typical BWR core which operated for its full cycle.

In February 1989, the State of New York and LILCO entered into an agreement under which LILCO agreed not to operate the Shoreham plant and to transfer the plant and certain areas and buildings on the Shoreham site to a newly created State agency, the Long Island Power Authority (LIPA) for decommissioning. The agreement was subsequently approved by the Board of Directors of LILCO, the Board of Trustees of LIPA, and the New York State Public Service Commission. The agreement became effective in June 1989 when LILCO's shareholders voted to approve it.

Although the NRC granted a full power license in April 1989, LILCO never operated the Shoreham plant after the previous five percent power testing period. In fact, LILCO began defueling the Shoreham plant shortly after LILCO's shareholders voted to approve the agreement.

Fuel removal from the reactor to the spent fuel storage pool was completed in August 1989, and by NRC Confirmatory Order issued in March 1990, the Shoreham license was modified such that fuel could not be reloaded in the reactor without prior NRC approval. The license was formally amended to a Possession-Only License (POL) status in July 1991. The transfer of this POL from LILCO to LIPA subsequently became effective in February 1992.

In preparation for decommissioning the Shoreham plant, LIPA entered into a Management Services Agreement with the New York Power Authority (NYPA) under which NYPA was contracted to provide technical and management services for the decommissioning of the Shoreham plant. NYPA in turn hired a number of consultants and contractors to carry out the planning, licensing and implementation of the decommissioning project, and also established a composite project organization utilizing LIPA, NYPA, LILCO and contractor personnel.

DECOMMISSIONING ALTERNATIVES

The current NRC regulations define decommissioning as the removal of a nuclear facility safely from service and the reduction of residual radioactivity to a level that permits release of the property for unrestricted use and termination of the license (1,2).

Several alternative methods of decommissioning are available. These alternatives are: DECON, SAFSTOR and ENTOMB. The terms DECON, SAFSTORE, and ENTOMB are defined as follows:

DECON is the alternative in which the equipment, structures, and portions of the facility and site containing radioactive contaminants are removed or decontaminated to a level that permits the property to be released for unrestricted use shortly after cessation of operations.

SAFSTOR is the alternative in which the nuclear facility is placed and maintained in a condition that allows the nuclear facility to be safely

stored and subsequently decontaminated (deferred decontamination) to levels that permit release for unrestricted use.

ENTOMB is the alternative in which radioactive contaminants are encased in a structurally long-lived material, such as concrete; the entombed structure is appropriately maintained and continued surveillance is carried out until the radioactivity decays to a level permitting release of the property for unrestricted use.

The NRC regulations allow all three alternative approaches to decommissioning, although the ENTOMB alternative is endorsed only with some reservations.

SELECTION OF DECON

The contamination and activation levels were low at Shoreham because of its limited operation. Based on these limited contamination and activation levels, it was advantageous to proceed with the DECON (immediate decontamination and dismantlement) decommissioning alternate. There were several other reasons for the selection of the DECON decommissioning alternative; maximum flexibility in selection of future near-term use of the site; availability of personnel who were knowledgeable about the facility and its operating history; the ability to decommission the facility without significant occupational radiation exposure; the elimination of the need for long-term monitoring, surveillance, and maintenance; predictability of low level radioactive waste disposal options and costs; and the fact that DECON alternative would cause no significant environmental impact.

SHOREHAM DECOMMISSIONING PLAN

In December 1990, LIPA submitted the Shoreham Decommissioning Plan (3) to the NRC. The Decommissioning Plan was prepared in accordance with the requirements of Title 10, Code of Federal Regulations (10 CFR) 50.82. Draft Regulatory Guide DG 1005, "Standard Format and Content for Decommissioning Plans for Nuclear Reactors" was used for guidance in preparing the Decommissioning Plan.

The Shoreham Decommissioning Plan was accompanied by a "Supplement to Environmental Report (Decommissioning)" which was prepared in accordance with 10 CFR 51.53(b) (4). The Supplement reflected earlier environmental analyses prepared by LIPA to comply with the requirements of the New York State Environmental Quality Review Act (5).

In June 1992, after two rounds of questions and responses, numerous discussions and complex legal maneuvers, the NRC issued an order approving the Shoreham Decommissioning Plan and authorizing the decommissioning of the facility (6).

SITE CHARACTERIZATION

Radiological characterization for decommissioning of the Shoreham site was performed in stages during the project. The primary goal of the initial effort was to identify those areas and plant systems which were above the proposed release criteria. This information would define the scope of decontamination and dismantlement activities. The results of the initial site characterization effort were reported by LILCO in May 1990 (7) to support preparation of the Shoreham Decommissioning Plan. It consisted of three main efforts or tasks: 1) determine the extent of areas and plant systems with surface contamination levels above 5000 dpm/100cm2 total or above 1000 dpm/100cm2 removable, 2) identify components and structures in the vicinity of the reactor core with neutron induced activity that exceeded either the above surface contamination limits or the proposed gamma exposure rate limit of 5R/hr

at one meter and 3) to identify the principal radionuclides present in surface contamination deposits and in activated in-situ materials.

The site characterization was performed under the administrative control of a specially prepared Site Characterization Program. The first task was performed using the existing Shoreham survey instruments and radiological survey procedures, supplemented by a written work instruction for field surveys. Survey design and survey methods largely followed the NRC guidance for final (termination) surveys available at that time. The second task consisted of neutron activation analysis of the reactor pressure vessel (RPV), RPV intervals, and the biological shield (bioshield) wall. This task was preformed using the ORIGEN2 computer code supplemented by analytical calculations to estimate isotopic compositions. Dose rates from activated components were determined in the initial characterization effort using the Microshield code. The third task was to identify the radioactive composition in areas of the facility where neutron activated materials were the most likely source of residual contamination. This was performed using the neutron activation analysis results supplemented by radiochemistry analysis of core samples.

Several factors prevented complete characterization at the time of the initial site characterization. These were 1) the presence of fuel in the pool prevented physical access to the Fuel Pool and associated plant systems; 2) the NRC operating license and associated Technical Specifications were in effect, limiting destructive removal of materials to gain information; 3) radiological "interferences" were present in the vicinity of the RPV which prevented accurate surveys of gamma exposure rate from the bioshield wall; and 4) the exact requirements of the final site release criteria were not known.

The initial site characterization effort identified 12 areas (nine plant systems and three structural areas) containing levels above Regulatory Guide 1.86 (8) limits. These were the following:

- Reactor Water Recirculation System
- Reactor Water Cleanup System
- Control Rod Drive System
- Fuel Pool Cleanup System
- Residual Heat Removal System
- Condensate Demineralizer System
- Core Spray System
- Sampling System
- Liquid Radwaste System (partial)
- Dryer Separator Pit (structure)
- Reactor Cavity (structure)
- Radwaste Laydown Area (structure)

Initial estimates of decontamination and dismantlement work scope focused on the nine systems identified above. Ultimately, an additional 15 systems and 13 structures were identified which contained levels above the release criteria. The resulting major additions to the decommissioning work scope included portions of the nuclear boiler system, major portions of the liquid radioactive waste system and the bioshield wall.

DECONTAMINATION AND DISMANTLEMENT

Radioactive materials were removed from the Shoreham facility by two general methods: dismantlement and removal; and decontamination in place. Dismantlement and decontamination activities were confined primarily to the Reactor and Radwaste Buildings, with minor activities in the Turbine

Building. Activated portions of the bioshield wall were removed. Systems and equipment removed included the RPV (except for the bottom bowl) and major portions of the plant systems that were characterized as being radioactively contaminated. Control rods, fuel channels and fuel storage racks were removed intact and shipped directly to Barnwell, South Carolina, for burial. About 25 percent of the piping and equipment that was on site before decommissioning began was removed. The majority of contaminated piping and equipment removed from the facility (more than four million pounds) was sent to an off-site vendor for volume reduction. This resulted in a significant reduction in waste burial volume, from a pre-decommissioning estimate of over 80,000 ft3 (no volume reduction assumed) to 8,350 ft3. The removal of radioactive materials was accomplished through 386 well managed, flawless shipments.

The large majority of Shoreham decommissioning work was accomplished through dismantlement and removal of equipment. Industry accepted and field proven processes were used to dismantle plant structures and systems. Techniques ranged from simple, manually operated power band saws used to cut small bore piping to more sophisticated techniques such as pipe mounted cutting machines which were used to mechanically cut large bore piping. The selected options reflected consideration of the radiological conditions associated with their application.

Many areas, equipment and piping were successfully decontaminated and left in place. This included 15,000 ft. of embedded radioactive waste system drain piping, determined to be slightly contaminated over much of its length. This piping was decontaminated in place using high pressure water. Major structures that were successfully decontaminated included the suppression pool, reactor cavity, spent fuel pool and dryer-separator pit. Decontamination techniques were consistent with those routinely used in the nuclear industry. In-situ high pressure water lancing, and a variety of mechanical decontamination techniques were used.

Segmentation of the Reactor Pressure Vessel and Internals

The RPV and internals were decontaminated to the extent practical while in place by water flushing, and were segmented, packaged and shipped for use by others, or for off-site disposal. The bottom bowl of the RPV was decontaminated by grinding the internal surfaces to remove surface contamination. Enclosed cutting stations with filtered exhausts were for the cutting of contaminated components in order to prevent the spread of contamination.

Segmentation of the neutron activated reactor internals was performed using underwater, semi-automatic plasma arc cutting equipment. The RPV was segmented into shell sections using a platform mounted rotary mechanical cutting machine from inside of the RPV. The shell sections were then cut using oxy-fuel into pieces appropriately sized to permit safe and efficient handling, packaging and shipping. Highly radioactive materials for disposal were loaded into liners for transportation in shielded shipping casks.

Guiding Principles

Certain guiding principles were very effective in controlling overall project cost and schedule. For example, it was recognized early in the project that it was difficult (and costly) to perform radiological surveys of piping and equipment to demonstrate compliance with release criteria. This led to the general practice of removing contaminated systems for volume reduction and burial rather than attempting to

decontaminate and survey them in place. This philosophy was succinctly phrased as: "when in doubt - cut it out."

The second guiding principle was to perform waste processing work off-site whenever possible. Volume reduction (compaction, incineration and metal melting) were very effective in reducing the volume of waste shipped for burial to the low level radioactive waste disposal facility. Radioactive material processing at Shoreham was limited to segmentation of large components for ease of handling and shipping. Volume reduction was effective in reducing the burial volume to about one-tenth of the original estimate. Additionally, off-site waste processing minimized the potential for schedule delays, competition for available work spaces and resources and the likelihood of cross-contamination of clean areas.

RADIATION PROTECTION

The total radiation exposure for the entire project was 3.2 Person-Rem (compared to the initial projection of 187 Person Rem), a significant achievement for a project which employed about 1000 decommissioning workers at its peak.

The radiological source terms at the Shoreham were relatively low. The total Curie content in the facility, excluding irradiated fuel, was about 600 Curies with maximum dose rates of about 200 R/hr found on RPV internals. Such low levels, however, did not preclude a necessary attentiveness to minimizing personnel radiation exposures.

The reduction in radiation exposure was the result of an aggressive "dry run" policy, a strong management commitment and an effective ALARA suggestion program which provided recognition and monetary incentives. Additional techniques and features used to implement ALARA during decommissioning activities included the following:

Flooding of the RPV prior to cutting and removing vessel internals with water level controlled to provide optimum shielding benefits.

Extensive underwater cutting of components. Submerged lighting and television cameras provided continuous surveillance of underwater cutting operations.

Installation of an elevator platform in the RPV for raising and lowering cutting tools and removal of cut components from the pressure vessel.

Utilization of temporary indices on walls, cables and beams to assist crane operators achieve proper azimuthal and elevation alignment for disposition of components in transit.

Installation of a floating fume collection hood with HEPA filtered exhaust over the wet cutting station to preclude the escape of potential airborne contamination during plasma arc cutting.

Rigorously enforced policy of clearing personnel from areas when highly radioactive sources ("hot picks") were moved or transported.

An example of the success of the Shoreham ALARA program is illustrated by the task of packaging and shipping 137 activated Control Rod Blades (CRB). This task involved 35 "hot picks" of liners holding four CRBs each. The liners had dose rates of about 25-50 R/hr on contact. Each liner was packaged underwater and removed from the spent fuel pool and placed in specially made shielded transport boxes. In spite of the high dose rates involved and the extent of physical handling the total exposure was limited to less than 0.6 Person-Rem.

FUEL DISPOSAL

The NRC regulations do not treat spent fuel disposal as a decommissioning activity, nor is the cost of fuel removal and disposal included in the

decommissioning cost estimate. Fuel deposal is considered to be an operational activity. It is, however, necessary to remove the fuel from the spent fuel storage pool before the pool and the associated systems can be decontaminated and the facility released for unrestricted use. Therefore, the disposal of the slightly irradiated Shoreham fuel became critical to the success of the decommissioning project.

After developing several other disposal options, including reprocessing in Europe and on-site dry storage, LIPA reached an agreement with Philadelphia Electric Company (PECo) to transfer the slightly used fuel to PECo's Limerick plant for reuse. The fuel shipments got underway in September 1993 after a series of unsuccessful challenges, including legal actions by the State of New Jersey reaching all the way to the United States Supreme Court. New Jersey attempted to block the passage of the barges carrying the Shoreham fuel through its coastal waters. The fuel shipments were completed three months ahead of schedule in June 1994.

FINAL TERMINATION SURVEY

To prepare for the termination survey, a detailed final survey plan (9) was submitted to and approved by the NRC. The Plan was based on the guidance provided in NUREG/CR-5849 (10). For the conduct of the survey, the facility was divided into 385 separate entities called "survey units." These included areas within the facility structures, outside areas and plant systems. Within each survey unit an average of 265 locations were selected for measurements. A total of approximately 230,000 measurements of direct and removable surface activity and gamma exposure rate were taken in the survey. Approximately 105 samples of soil and bulk materials were also collected and analyzed. The survey covered all the buildings, plant systems and site grounds within the secured area fence, about 20 acres.

The termination survey was conducted in parallel with decommissioning activities, and was carried out in four major phases. A Termination Survey Group was established within the decommissioning project organization, which had at its peak 74 people including 40 survey technicians. Survey measurements began in January 1993. A site back out plan was developed to allow the survey to proceed in parallel with fuel shipments and decommissioning activities. Innovative survey techniques and tools (e.g., pipe crawlers fitted with instruments for embedded piping surveys) were developed and employed. The cost of the survey was approximately $12.3 million.

The Final Termination Survey Report (11) submitted to the NRC demonstrated that all 385 survey units (and hence the facility) satisfied the release criteria. The confirmatory surveys performed by the NRC verification contractor, the Oak Ridge Institute for Science and Education (ORISE), concluded that Shoreham was ready for unrestricted release.

CONCLUSION

As the Shoreham decommissioning project was nearing completion, two public meetings were organized (December 1994 and March 1995) to inform the public about the Shoreham decommissioning activities and the results of the final radiological surveys. Although public participation at these meetings was somewhat limited, the meetings received wide coverage in the media.

The order terminating the Shoreham Operating License (12) was issued in April 1995. After allowing 20 days for the public to voice any opposition

and file a request for a hearing (none was received), the License Termination Order became effective in May 1995.

The lessons learned and insights gained from the Shoreham experience have led to proposals for better decommissioning regulations and guidelines from the NRC, particularly as they apply to prematurely shut down plants (13,14).

The successful completion of the Shoreham project was an important step in demonstrating that decommissioning of large nuclear power plants can be achieved at predictable cost and schedule. It holds valuable lessons in a number of areas including decommissioning planning, project management, decontamination and dismantling methods, control of radiation exposure, termination survey techniques and spent fuel disposal.

ABSTRACT

Paldiski, Estonia had been the site of an important nuclear submarine training facility for the USSR Navy. The facility included two scaled submarine mock-ups, one delta and one echo class, each containing an operational nuclear reactor. Construction of the facility began in the early 1960's with the first training submarine (Unit #1) going critical in 1968 with a 70 MWt reactor. A second training submarine (Unit #2) was added in the early 1980's and went critical in 1983 with a 90 MWt reactor. Unit #1 was refuelled and retrofitted with upgraded steam generators in 1980. The two reactors were operated into 1989. Both training submarines were housed within a single building in a common high bay area. Auxiliary site facilities included a liquid waste processing facility; storage buildings for solid and liquid radioactive waste; a central facility ventilation center; cooling towers; a cooling water pump facility; a central heating plant; a radioactive laundry facility; and a radiochemical laboratory. In 1994, as part of the negotiated Russian troop withdraw from Estonia, Russia agreed to defuel and safe store the reactors prior to 30 September 1995, when control of the site was transferred to Estonia. The spent fuel from the reactors was transferred under Russian control to Russia in October 1994. Russian preparation for safe storage of the two reactors included dismantling non-active components, systems related to reactor operation, and some of the associated auxiliary facilities. Russia also constructed two concrete sarcophagi around the remaining hull sections containing the reactor vessels. This work was completed prior to mid-September 1995.

An international expert group was established in early 1994 at the request of the Estonian government. This group is known as the Paldiski International Expert Reference Group (PIERG). The purpose of PIERG is to promote the safe and timely decommissioning of the Paldiski nuclear facility by advising Estonia on technical, legal, organizational, financial, waste management, and radiation safety matters related to the decommissioning activities. Utilizing the resources of PIERG, a

Conceptual Decommissioning Plan has been developed for the site. This plan has been reviewed by the IAEA and Estonia and accepted for implementing as funding permits. The Conceptual Decommissioning Plan is now the basis for ongoing work and planning of future site activities.

BACKGROUND

Paldiski is located approximately 50 km south-west of Tallinn, capital of Estonia. Paldiski had been an important military base and submarine harbor for the former USSR since 1939. In the early 1960's construction began on a land-based training center for nuclear submarine crews of the Soviet Navy. In 1968 the facility with a 70 MWt training nuclear reactor (Unit #1) was commissioned, Unit #2, rated at 90 MWt, went critical in 1983. Unit #1 was refuelled once in 1980. The reactors with all shipboard auxiliary systems were situated in scaled submarine hulls located in the high bay area of the Main Technological Building. Both reactors were shut down in 1989.

After Estonian re-proclamation of independence in 1991, the withdrawal of Russian troops from Estonia territory, closure of the Paldiski training center, and decommissioning of the reactors became a subject of intense negotiations between Estonia and Russia. Ultimately, an agreement on the decommissioning of the Paldiski Training Center was signed in July 1994. According to this agreement, Russian experts removed non-radioactive and classified components of the facility and prepared the site for turnover. The Russian Federation officially transferred ownership and control of the site to the Republic of Estonia on 26 September 1995. The agreement (1) on transition of the Paldiski facility has the nature of a political treaty and technical aspects of the agreement are non-existent or leave considerable margins of interpretation to concerned parties. This had caused difficulties with the planning of decommissioning work as control of the site remained with Russian authorities who's decommissioning activities were performed with limited involvement or supervision by international or Estonian observers.

Normally, the operator is responsible for all aspects of the safe decommissioning of a reactor including preparation of the decommissioning plan and its submission to the regulatory body for approval. In the case of Paldiski, the situation is unique as the reactors were owned and operated by an organization in one country while located in another. The consequence of this has been that the turnover of the site and related documentation has been hampered by multi-national politics.

SITE DESCRIPTION

The site occupies approximately 22 hectares (~9 acres) and consists of the Main Technological Building (MTB) and 8 relevant auxiliary facilities which are: a Liquid Waste Treatment Facility (LWTF), a Liquid Radioactive Waste Storage (LWS), a Solid Radioactive Waste Storage (SWS), a Ventilation Facility, a Laundry Facility, a Radiochemistry Laboratory, Cooling Towers, and a Boiler Facility. The site plan is presented in Fig. 1.

Fig. 1

SITE STATUS, PHYSICAL AND RADIOLOGICAL DESCRIPTION OF THE SITE

Main Technological Building (MTB)

The MTB consists of the high bay area containing Units #1 and #2, two spent fuel storage pools (only one used), processing rooms for primary and secondary coolant water, and an annex of offices. The operational data of the reactors is presented in Table I.

Table I

The reactor fuel was removed and shipped to Russia in October 1994. As part of preparing the site for transition, Russia removed non-contaminated and secret equipment and dismantled the submarine hulls except the sections associated with the reactor vessels. Cast concrete sarcophagi were built by Russia around these remaining hull sections. A preliminary radiological characterization by a US Department of Energy team in 1995 (2) determined that the radiological situation of the MTB is reasonably good with only limited areas of contamination e.g. a spent fuel storage pool and some associated rooms.

Liquid Waste Treatment Facility (LWTF) and the Liquid Waste Storage (LWS)

Liquid radioactive waste is stored in the tanks of the LWTF and LWS facilities. The LWTF contains the equipment used for treatment of the contaminated waste water generated on site. Equipment includes evaporators, flocculation tanks, ion exchange columns, six receiving tanks (total capacity 1020 m3) and two tanks for holding water prior to discharge.

The LWS consists of six tanks (total capacity 2400 m3). These tanks were originally intended as a final depository for processed/concentrated liquid radioactive waste. Four of the six tank at the LWS are now empty and have been decontaminated. The remaining known liquid radioactive waste on site is presented in Table II.

Table II

Radioactive contaminated areas and systems were observed during a preliminary survey of the LWTF. The highest radiation readings recorded were in the vicinity of the ion exchange columns. Detection of slightly contaminated water in pipe chase areas in the basements of the LWTF and LWS indicate leakage from the tanks or plumbing. This will only increase the volume of waste to be decontaminated because in addition to the liquid waste there is now increased areas of contaminated concrete. Recently, 14 additional liquid radioactive waste holding tanks were discovered on site. At present, no information is available on their contents.

The Solid Waste Store (SWS)

The SWS consists of a concrete structure divided into 10 compartments. The top of the storage consists of concrete slabs, or poured concrete with removable plugs all of which have been covered with a layer of crushed gravel and asphalt. This facility was originally intended as a final repository for the radioactive operational waste from the site. The Russian Navy has stated that only three compartments were used and described the contents of the three compartments as:

No 1 - 8 steam generators and a circulation pump from Unit # 1 replaced during the refuelling operation in 1980, contaminated equipment, and miscellaneous contaminated material.

No 4a - Protective clothing and sealed beta sources

No 5 - 20 irradiated control rods, high level radiation sources, contaminated equipment, and miscellaneous contaminated material.

All the waste in the SWS has been disposed without any conditioning and packaging. The Russian Navy has stated that the total activity of the waste in the SWS is about 3.7 TBq.

Laboratory Building

The laboratory building is a three floor building containing offices, health physics training rooms, environmental and radiochemical laboratories, and instrument calibration facilities. Preliminary

radiological characterization by a US Department of Energy team in 1995 indicate that contamination is limited and very low level.

Laundry Facility

The laundry facility is a two floor building that processed all site laundry. The upper floor was reserved for non-contaminated clothing and the ground level for contaminated protective clothing. Prior to site turnover, Russian personnel performed a release survey of the facility subsequently releasing all equipment and piping as scrap metal. Results of surveys performed in the emptied building in 1995 by a US DOE team appear to support the Russian survey data.

Ventilation Facility

The ventilation facility provided off-gas capability to all reactor operation facilities on site. Connected were the Main Technological Building, the Laundry Facility, the Liquid Waste Treatment Facility, and the Laboratory Building. All building off-gas passed through a single stage HEPA filter before discharge up a 100 meter stack. US and Russian survey data of the HEPA filter enclosures do not indicate radiation levels above background. Russian personnel reported that the filters had never been changed during the entire operating life of the facility and no records exist indicating filter integrity testing. It is believed that the filters are either completely intact or have long since disintegrated. Investigations are planned in the future. Work areas within the facility are not contaminated.

Vehicle Decontamination Garage

This facility is only mentioned here. It was designed for vehicle decontamination in the event of a nuclear accident. It was never used for any decontamination purposes serving instead as a vehicle maintenance garage and for supply storage.

INTERNATIONAL CO-OPERATION, THE PALDISKI INTERNATIONAL EXPERT REFERENCE GROUP - PIERG

Preparations for transfer the Paldiski site from Russian to Estonian control revealed that Estonia lacked the necessary technical and financial resources to adequately manage and safely decommission the Paldiski facility. To properly manage the facility, in the near term, international assistance would be necessary.

Even at the moment of regaining independence, Estonia recognized that it would ultimately inherit the Paldiski facility. Realizing that in-country nuclear expertise was non-existent, the Estonian government initiated an international campaign aimed at garnering assistance and support for the management and decommissioning of the Paldiski site. The IAEA and numerous Nordic region countries and organizations were approached for assistance. At the initiative of the Swedish Minister of Foreign Affairs, and after consultations with other concerned countries, a meeting was held in Stockholm in January 1994 which was the beginning of an active international engagement on the issue of decommissioning the Paldiski facility. At a later meeting the Paldiski International Expert Reference Group (PIERG), was established with participation of Estonia, Finland, Germany, Russian Federation, Sweden, USA, IAEA and CEC. Later Denmark and France joined the group.

The objective of PIERG is to promote the safe and timely decommissioning of the former Soviet Union Nuclear Training Center at Paldiski by advising and assisting the parties participating in the decommissioning work on technical, legal, organizational, financial, waste management and radiation protection matters. Part of PIERG's charter is to appoint task

groups to deal with a specific project or technical issue. These task groups currently consist of:

Group Task

- C1 Future Uses for the Paldiski Site
- C2 Conceptual Decommissioning Plan
- C3 Site Radiological Characterization Plan
- C4 Conditioning of Liquid Radioactive Waste
- C5 Radiological Worker Training
- C6 Control Rods and Solid Waste Packaging Options
- C7 Workshop on Radioactive Metal Recycling
- C8 Site Plan and 3D-CAD Modelling
- C9 Comprehensive Site Health Physics Program
- C10 Site Management Plan
- C11 Conditioning of Remaining Liquid and Semi-solid Waste in LWTF and LWS
- C12 Interim Waste Storage Facility Development
- C13 Conceptual Development of an Estonian Final Repository

The C1 Task Group produced a report which was presented and accepted by PIERG. The C2 Task Group produced a Conceptual Decommissioning Plan (3) which was peer reviewed by the IAEA (4) and accepted by Estonia and PIERG for implementation. The Conceptual Decommissioning Plan is a dynamic document and is continuously being updated as new information and resources become available.

The Finnish government using the services of IVO International Ltd., Finland, took the lead for the C4 Task Group and began treatment of liquid radioactive waste in January 1995 (5) using their transferable liquid waste treatment system NURES (Nuclide Removal System). By August 23, 1995 when this project was completed over 760 m3 representing 80% of all radioactive liquid waste on site had been processed. In preparation for the next phase, IVO has carried out characterization of the tank sludges and made preliminary cost estimates for the sludge conditioning.

The Swedish government, coordinated through the Swedish Radiation Protection Institute and using the services of SKB and Studsvik, two Swedish nuclear companies, has taken the lead in the C1, C2, C7, C8 and C10 - C13 Task Groups. These activities include funding and leadership of PIERG; engineering plans for development of an interim waste storage facility utilizing an existing site building; a hands on workshop on materials recycling; development of an accurate site plan and 3D model; and most recently, an offer to collaborate with the US on characterizing the waste in the SWS and to package the waste later this summer.

The President of the United States committed the U.S. Department of Energy to participate in a technical co-operation program with the Republic of Estonia. The scope of the co-operative program included a technical site assessment and establishment of a technical agreement with the Estonians on decommissioning facilities. The Department of Energy's action plan was developed around the President's commitment and with the goal of empowering the Estonian government to safely and effectively manage and decommission the Paldiski site with a minimum of foreign assistance. A primary goal of DoE's involvement has been to demonstrate and transfer US technology. The US has the lead role in the C3, C5, and C9 Task Groups and is participating in the C2, C6, and C11 Task Groups. Several US technical teams visited Estonia during 1995 and performed a site characterization to determine the location and extent of radiological and other hazardous material contamination. The teams were

composed of personnel from the Idaho National Engineering Laboratory (INEL), Los Alamos National Laboratory (LANL), Remote Sensing Laboratory (RLS) and Grand Junction Project Office (GJPO) have had extensive involvement. The teams have obtained direct radiation measurements in addition to performing a limited sampling program; conducted a limited structural analysis on the buildings; and evaluated the presence of non-nuclear hazardous materials on site. An airborne multi-spectral and radiological overflight was performed to map the status of the site and the peninsula on which it is located. Airborne data was acquired that will permit an environmental impact analysis of the site and surrounding peninsula from hazardous material insults. These data will be processed in early 1996. A specialized radiation and hazardous material training course was provided for the Estonians that would be working at the Paldiski site. Participating in the training course through a co-operative agreement with the IAEA were members of Latvian and Lithuanian radiation safety organizations. At the request of the Estonian government, DOE provided a resident technical consultant from B&W Nuclear Environmental Services, Inc. In addition to providing technical assistance on radiation safety, radioactive waste management, and facility management, the resident technical consultant functions as a local coordinator for DoE's initiatives ensuring that logistical requirements are handled with a minimum of delay and that cultural differences are respected.

In early 1996 a DOE team will perform a specialized radiological characterization of the site solid waste storage facility. This facility contains 10 concrete bunkers of which 3 are known to have been used. Un-inventoried waste includes unpackaged irradiated control rods, steam generators, industrial radiography and high level calibration sources, and other mixed radioactive wastes. Utilizing specialized gamma imaging equipment the team will generate visual and radiological images of the waste as well as spectrally analyze the waste. It is also planned to radiologically image the reactor compartment hull sections. This work will be co-operatively performed with Sweden. Discussion are underway with Finland to co-operatively evaluate the remaining radioactive liquids and tank bottoms.

ESTONIAN DECOMMISSIONING ACTIVITIES

As stated earlier, Estonia had no in-country expertise to utilize for the management and decommissioning necessary at the Paldiski site. In 1995, in conjunction with international assistance, the Estonian government established a wholly owned company, AS ALARA, Ltd, for the purpose of managing the Paldiski site and associated decommissioning activities as well as being responsible for all radioactive waste within the country. In addition to Paldiski, Estonian organizations generate radioactive waste from industrial, medical, and research activities. ALARA's staffing is currently at 15. There is a Manager of Technical Operations and four health physics specialists as well as staff maintenance and security personnel. The President of ALARA has over 40 years management experience in the North American energy industry at nuclear and non-nuclear facilities. ALARA management has decided that staffing will be maintained at a custodial level with contract personnel being utilized as needed. The technical consultant provided by the US DOE is working with ALARA personnel to develop a comprehensive site health physics program and provide training in survey and decontamination techniques. As ALARA's

staff gains expertise it is envisioned that ALARA will offer its technical expertise throughout the Baltic region.

THE CONCEPTUAL PALDISKI DECOMMISSIONING PLAN

To assist the Estonian government with the planning of decommissioning activities at the site a PIERG task group (C2) prepared a conceptual decommissioning plan. The Conceptual Decommission Plan took into account technical and non-technical conditions/constraints which included:

- site control by Russia until 30 September 1995;
- ongoing international co-operation (PIERG);
- absence of a clear Estonian policy on decommissioning and waste management and lack of relevant legislation;
- shortage of technical and financial resources and significant uncertainties on when these resources will become available (e.g. final repository for long-lived decommissioning waste).

Due to these factors, decommissioning based on immediate decommissioning and unrestricted site release was not realistic. As a result of the submarine reactor compartments being sealed within sarcophagi other decommissioning alternatives for the reactor vessels were not elaborated on by the task group. The Task Group C2 considered that from a technical and radiological point of view decommissioning activities should be initiated without delay as resources permit.

An aspect of designing and construction of the reactor enclosures should be that eventual dismantlement and decommissioning should be facilitated. At Paldiski, the reactor sarcophagi were designed and constructed by the Russians without co-ordination with Estonia. The approach followed by the Russians appears to maximize long term integrity rather than facilitate eventual decommissioning.

An element of developing a safe enclosure strategy is that physical/radiological surveillance and maintenance requirements are minimized. This requires that the extent of active areas be minimized and a passive configuration reached. This was addressed in the Paldiski Conceptual Decommissioning Plan. At the completion of decommissioning activities for safe storage all residual radioactivity will be confined in a stable form at the Paldiski site. A safe storage strategy requires a robust, durable structure to safely contain radioactive materials for long periods. The MTB appears to offer suitable characteristics for long term storage of the reactors and radioactive wastes. Investigations are underway to establish the suitability of converting the Main Technological Building into a long term monitored waste storage facility. This will solve the problem of where to store the radioactive waste generated as the contaminated buildings on site are decommissioned. In addition,this will provide ALARA a facility for waste storage that arises from other in-country generators.

The Conceptual Decommissioning Plan proposes a decommissioning strategy for the site to be implemented by Estonia. Work to improve and further refine the decommissioning plan continues as resources and relevant information become available. The Conceptual Decommissioning Plan has therefore served to provide a good starting point for development of a Site Management Plan and a Detailed Decommissioning Plan.

The highest priority of the decommissioning plan is the prevention of the spread of radioactive, non-radioactive, and hazardous material to the environment as well as the minimization of waste volume. Treatment of non-radioactive wastes will be coordinated with other environmental restoration projects underway on the Pakri peninsula where Paldiski is

located. Site specific procedures are being established for the treatment, packaging, and storage of the radioactive materials. A radioactive waste management plan for wastes arising from decommissioning activities at the site has been developed and is shown in Fig. 2. The final waste management plan will be approved in accordance with regulatory requirements imposed by the Estonian regulatory body. At present, Estonia has no national radiation regulations. Draft regulations are currently under considered by the Government for passing into law.

Fig. 2

The Conceptual Decommissioning Plan proposes that decommissioning work be split into 12 primary work packages:

- Infrastructure and documentation
- Radiological characterization and survey of contaminated systems, equipment, structures, buildings and the site grounds.
- Characterization and solidification of all tank liquids and sludges in tanks in the LWS and the LWTF
- Converting the MTB into an intermediate waste store
- Laboratory
- Laundry
- Ventilation Center and the Stack
- Decommissioning of the LWS
- Decommissioning of the LWTF
- Active pipes and ventilation ducts in the ground
- SWS
- Restoration of the site

A Site Management Plan is being developed which divides these activities into short, medium and long term actions. The short term action program during 1996 - 97 covers decommissioning and restoration work that are urgently required from radiological and environmental point of view. More extensive and costly work packages are envisaged during the medium term period from 1998 and continue 3 -5 years. The long term action program will carry out daily operations and supervision of the facility. The configuration of the site after the medium term period depends on the selected intermediate waste storage option, if buildings on site are utilized for other purpose, or if they are decommissioned. Figure 3 illustrates an alternative to the interim waste storage facility being located in the Cooling Water Pump Building for waste storage and decommissioning the Main Technological Building. The sarcophagi are shown as free standing buildings. The size of the fenced part of the site has been reduced.

Fig. 3

CONCLUSION

Lack of Estonian in-country nuclear expertise is requiring the involvement of foreign experts to a greater degree than a decommissioning project would normally necessitate. It is desirable to involve the Russian experts who hold knowledge in the design and construction of the reactors and auxiliary buildings as well as the operation of the reactors and the auxiliary systems at Paldiski. This is especially important during the development of the detailed decommissioning plan. Western and European technical experts are providing valuable assistance with the decontamination and decommissioning planning of the facility and with the development of the necessary site operations infrastructure.

Establishment and funding of AS ALARA, Ltd. by the Estonian government

demonstrates that they are aware of the difficulties to be encountered at Paldiski and are ready, willing, and prepared to meet them.
With international assistance, ALARA has organized and begun staffing. Development of a decommissioning plan has provided a goal to work toward and a vision of the future. With international assistance, ALARA is developing a long term site management plan and a comprehensive health physics program. ALARA's staff, with these tools and interaction with their international colleagues, is quickly developing the skills required to manage the site today and begin decommissioning activities as they move into the twenty first century.

ABSTRACT

Atomic Energy of Canada Limited is proposing to build the Intrusion Resistant Underground Structure (IRUS) facility for the disposal of low-level radioactive waste at Chalk River Laboratories, CRL, Ontario, Canada. IRUS is a near-surface repository that is to be constructed above the water table on a sandy ridge. IRUS will consist of a concrete containment facility for the waste, including a reinforced concrete roof and multilayer earthen cover to both warn and impede intruders, and to prevent the infiltration of rain water and snowmelt. Sorbing backfill will surround the waste packages in the repository. The roof covering the facility will be fabricated of very high quality cement, but the roof will gradually lose its integrity. Once roof failure begins, an increasing portion of the vault will become wet and start to degrade, and the contents of the waste packages will begin to leach downward into the underlying aquifer and eventually return to the surface environment. The

transport of radionuclides away from the facility by advective flow has been modelled mathematically. Some radionuclides may never migrate more than a few meters from the facility before they are sorbed to soil or decay radiologically. However, some of the more mobile radionuclides, such as 3H, 36Cl and 99Tc may be transported downslope through the subsurface aquifer and surface in a wetland, known as Duke swamp. This presentation reports estimates of the total annual dose rate to a resident human through several particular pathways. Several of the pathways investigated as part of this wetland scenario are not realistic or are highly unlikely, such as drinking water from the wetland. These predictions were included as part of the scoping or bounding calculations required for a complete assessment. The highest to lowest dose rates by radionuclide are ranked in the order 3H > 14C = 237Np > 239Pu > 94Nb > anaerobic99Tc > 36Cl > 234U > aerobic99Tc. The most important internal pathway is through ingestion of vegetation; 14C and 237Np are the radionuclides giving the greatest dose rate. The most important external pathway is through groundshine from 94Nb.

INTRODUCTION

In temperate environments, particularly in glaciated areas demonstrating considerable topographic relief, performance assessments of waste disposal facilities may require wetland pathways. This presentation describes an assessment of the human dose consequence from dissolved radionuclides that have been transported in groundwater from a radioactive waste disposal facility and discharged into a wetland. We present here how we interpreted the physical environment and groundwater flowpaths, calculated radionuclide residence time in the wetland, developed the human and animal exposure pathways to be modelled, constructed a simple model, and treated special nuclides and pathways to carry out the assessment. The calculated endpoints are the total annual dose rate to a resident human. AECL is proposing to construct the IRUS facility as part of the strategy to manage its low-level radioactive wastes (LLRW). This facility for the near-surface disposal of a portion of the LLRW currently managed at CRL is now in the licensing phase. A safety case bringing together the key elements of facility design, site characteristics, waste form and inventory and performance assessment is in advanced stages of preparation. The analysis presented here resulted from a Features Events Processes Scenario (FEPS) analysis applied to the IRUS project (1).

The IRUS facility is a robust engineered containment structure for packaged wastes. The packages are surrounded by sorbing backfill inside the structure consisting of a 1-m thick concrete roof and concrete walls with a permeable bottom of sorbing buffer. Several cover layers above the roof both warn and impede intruders, protect the concrete roof from freeze-thaw cycles, and prevent the infiltration of rain water and snowmelt (Fig. 1). Although the roof covering the facility will be fabricated of tailored high quality concrete, the safety analysis assumes infiltration through the roof can begin at 500 a. Once infiltration begins in sections of the vault, the contents below will become wet and start to degrade, and the contents of the packages will begin leaching through the backfill and buffer and out the permeable bottom into the groundwater below.

Fig. 1

The proposed site for IRUS is above the water table on a sandy ridge above a coarse sand, large-volume aquifer that discharges into a small

wetland called Duke swamp. The transport of these radionuclides away from IRUS by advective flow has been estimated using mathematical models. Many of these radionuclides will be retarded by sorbing to the solid particles of the buffer, backfill and aquifer. Some may never migrate more than a few meters from the facility before they decay. However, some of the more mobile nuclides, such as 3H , a special cation, and the anions, such as 36Cl, 99Tc and 129I, may reach the wetland.

The Physical Environment, Groundwater Flow Path, and Residence Time in the Wetland

Using water table elevations, physical characteristics and hydrology data of the drainage basin, we sketched in an area of the wetland that would receive the downslope subsurface groundwater flow from the IRUS facility. A rock ledge lies along the west side of the wetland, and there is a drainage basin divide across the middle, near the "thumb" position on the east side (Fig. 2). These features will confine the discharge to a narrow band of wetland along its eastern edge. The sandy aquifer at this discharge location is 3 m deep. The wetland volume receiving the discharge of radionuclides is defined to be 60,000 m3 (400 x 50 x 3 m). This assumption regarding the size of the receiving compartment is not important, because the volume of water flushing it controls mixing in the compartment, and the consequence.

Fig. 2

The flux of radionuclide entering the swamp is simply the total radionuclide (Bq/a) leaving the upslope aquifer, as estimated with the NSURE3 performance assessment code (2), and a correction for radiological decay. We assumed that this activity mixes instantaneously in the wetland compartment. The total concentration in the receiving volume, Ct in Bq/m3.a, is then

Eq. 1

The activity that enters the wetland will be associated with both the water and the peat solids. The ratio between these two constituents in the receiving volume is expressed using the volumetric moisture content of the peat, q in m3water/m3peat, and the peat dry bulk density, rb in kg/m3 dry peat. So the total volume is

Eq. 2

We assumed that the swamp is always saturated, and that the moisture content, q, is 0.9 m3/m3 and the dry bulk density, rb , is 300 kg dry peat/m3peat. The moisture in the peat can be converted from a peat volume, W, to a peat weight basis, W' , through the bulk density, where

Eq. 3

A fraction of each radionuclide reaching the wetland will be associated with the peat solids (having been sorbed through processes such as chemical exchange and complexation) and the remainder will be dissolved in the water. The partitioning of the radionuclide between the peat and the pore water was estimated through the solid/liquid partition coefficient, Kd (Bq/kg solid)/(Bq/m3water) (3). The radionuclide concentration in the peat, Cp in Bq/kg dry peat, was determined through the relationship:

Eq. 4

The radionuclides, dissolved in the water, that flow through the wetland volume will eventually leave and flow down Lower Bass Creek (Fig. 2). An annual flow of water is defined using the downstream weir data, which yield an average of 2.04 x 105 m3/a over the last 7 years. Assuming the porosity of the modelled wetland compartment is 90%, 54,000 m3 of this

volume (0.9 x 60,000 m3) is water. The loss of dissolved radionuclides from the wetland through advected water, Cl in Bq/a, is expressed as
Eq. 5
Turnover rate in the wetland volume is 26% (54,000/204,000 = 0.26), or 26% of the water in the volume is replaced with clean water annually. However, since pipe flow along conduits of old trees and other differential decomposition patterns is quite common, it is more likely that a smaller percentage of the creek flow passes through the contaminated portion of the wetland each year. We define a fraction, f, that passes through the wetland in order to estimate dilution. We redefine Cl as Clf,
Eq. 6

The fraction 0.2 is the site hydrologists estimate of the correct dilution and the 0.1 value is a conservative lower bound. Both the annual flow and the fraction of water flowing through the wetland are held constant over time. The total concentration remaining under this assumption of quasi steady-state conditions is then
Eq. 7
The varying annual nuclide flux entering the wetland compartment is used to recalculate the concentration of radionuclide in the water (Cw) and the peat (Cp), using equation (4). The concentrations Cp, Cw and Ct are then used in the dose rate calculations in the subsequent sections to assess the human and environmental impacts.

EXPOSURE PATHWAYS

A set of exposure pathways was developed based on the primary dose rate calculations for the IRUS safety case, that had been made with the NSURE assessment code (2), and the need to provide scoping or "bounding" calculations for the disposal assessment. We also drew on extensive experience from analyses for high-level waste disposal (4). The pathways considered for humans resident near the wetland were 1) human ingestion of unfiltered drinking water, used as an upper limit for wetland water use, 2) human ingestion of vegetation grown on contaminated peat of the wetland or on peat brought to a garden to ameliorate the sandy soil, 3) human ingestion of game that drinks water from the wetland, and 4) human ingestion of game that eats vegetation from the wetland. Various combinations of dose rates via these pathways can be produced by simple addition of the individual pathway values, for example, humans eating vegetation grown on contaminated soil and game that drinks swamp water. All direct contamination activities associated with the wetland involve terrestrial activities; no aquatic pathways such as fishing or swimming have been included because there are no fish, and the wetland is not amenable to swimming.

If the humans import peat from the wetland to condition garden soil, the root zone uptake is influenced primarily by the concentration in the imported peat; we conservatively assumed the root zone (top 30 cm) is completely composed of peat. This amelioration technology is well known for use in heavy clay soils to enhance root penetration, and in sandy soils to enhance water holding capacity (5). This calculation is not only conservative, but can be used as an upper bound. We assumed that the residents also hunt game and meet some (44%) of their meat requirements from game. The game animal most likely to drink and browse from Duke swamp is a moose, so we used the water and vegetation ingestion requirements of a moose. Since the home range of a moose (5 km2, (6)) is

much larger than Duke swamp, we used a fraction describing the area of wetland to the area of the moose's home range to stipulate the proportion of browse taken from the wetland. However, we conservatively assumed the moose comes to the wetland for all of its drinking water.

COMPARTMENT MODEL CONSTRUCTED FOR SCOPING CALCULATIONS

The radiological dose rate calculations were carried out for each of the four pathways using the equations of the CALDOS model (7). The equations are of the form:

Dose Rate = Concentration x Rate of Intake x Dose Conversion Factor.

Input Inventory

The time-dependent source flux of radionuclides out of the sandy aquifer downslope of the IRUS facility over 50,000 a, were generated from the SYVAC3-NSURE assessment code (2,8). Microsoft EXCELTM was used to fit a function with fixed time steps to the NSURE output which had variable timesteps. Time steps of 10 years were used to provide enough detail to describe the aquifer fluxes for 50,000 a after the onset of roof failure began at 500 a. In the case of 3H, the time steps were changed to 1 year due to its rapid release. The Duke Swamp assessment was performed for radionuclides that had either a large initial inventory, characteristics that render them mobile in the environment, a long half-life, or high radiological toxicity. For this assessment, the selected radionuclides are 3H, 14C, 36Cl, 94Nb, 99Tc, 234U, 237Np and 239Pu. Technetium and U are subject to more retentive soil behavior under low chemical redox potential, typical of geochemical conditions in low lying wetlands and bogs. Dose rates from 99Tc were calculated twice, once for aerobic conditions and again for anaerobic conditions. All radionuclide independent and radionuclide dependent parameters were tabulated in the full report on this study (9), along with the values used, their units and their source.

Major Pathways

A simple compartment model was constructed using STELLA software to calculate the human consequences from the four defined pathways. Radiological decay was included; however, ingrowth of daughters was not. The pathway equations solved are presented in more detail in Sheppard et al. (9).

Other Pathways and Special Radionuclides

Soil ingestion is primarily important for those radionuclides with high Kd values (3,10). Dose to humans from inadvertent ingestion of soil from hands and soil adhering to plants, Ds, was calculated for 94Nb, a strong gamma emitter with a high Kd. The dose rate (Sv/a) for the soil ingestion pathway is calculated as:

Eq. 8

External pathways, such as standing on contaminated ground or using water for bathing, could increase the dose consequence to a resident. Human external dose rates from bathing were calculated for 94Nb, the radionuclide most likely to produce such a dose. The dose rate (Sv/a) from standing on contaminated ground or from groundshine (Dg) was calculated as:

Eq. 9

The dose rate (Sv/a) from immersion (bathing) in swamp water (Di) was also calculated for 94Nb using:

Eq. 10

Calculation of the dose rate to a resident human from 3H used a separate model based on the isotopic dilution of 3H with stable H, an approach

often referred to as a specific activity model. This calculation was also performed for a resident moose and given in more detail in the full report (9). The simple specific activity model gives an upper limit on the dose rate. It is assumed that all of the water in the body is tritiated and multiplies the ratio of the water in the body to the body mass by Cw to give Bq/kg body mass. This concentration in the body is then multiplied by the internal dose conversion factor for tritium (2.9E-8(Sv/a)/(Bq/kg soft tissue) (7), to give an annual dose rate (Sv/a).

RESULTS AND DISCUSSION

Concentrations in Peat and Swamp Water for Comparison with Background Soil and Drinking Water Levels

Total concentrations in peat (on a dry weight basis) and in the swamp water were calculated for comparison to federal and provincial background soil and drinking water standards (Table I), and for use in non-human biota dose rate calculations to be reported elsewhere.

Table I

Dose Rate from Individual Internal Pathways

The individual pathway maximum dose contributions are shown with the time of the maxima for 20% interception of the aquifer flow to Lower Bass Creek (Table II). The internal pathways responsible for the largest human dose for 94Nb, 234U, 239Pu and 99Tc aerobic is drinking unfiltered water directly from the wetland. The next most important internal pathway for these radionuclides is from eating vegetation grown in the wetland or in a garden with peat imported from the wetland. This vegetation pathway delivers the highest dose rates from 14C, 237Np,36Cl and 99Tc anaerobic. The maximum dose rates result from large dose conversion factors and large inventories of these nuclides. The meat ingestion pathway plays a minor role in the dose from all of these nuclides.

Table II

Total Dose Rate

Total dose rate from the four pathways are summed to provide an estimated time-dependent total dose rate for all radionuclides (Fig. 3). Differences in Kd, radiological half-life and radionuclide flux discharged from the aquifer influence which radionuclide is most important at a given time. The total dose rate for 94Nb includes the extra external pathways of groundshine, soil ingestion and immersion in water. Although external exposure pathways are generally unimportant for most radionuclides, groundshine represents a significant portion (67%) of the total dose rate for 94Nb. Groundshine for the other retentive radionuclides is less important, because their dose conversion factors are five orders of magnitude below that of 94Nb. The dose rate from ingesting soil contaminated with 94Nb is 1.4% of the total, and immersion in water (bathing) accounts for only 0.02% of the total dose rate from 94Nb. The aquifer flux inventory ranks the radionuclides from largest to smallest peak inventory (at different times), in Bq, as:

3H > 14C > 99Tc > 36Cl > 94Nb > 237Np > 239Pu > 234U

The total dose rate prediction ranks the doses from largest to smallest as:

3H > 14C = 237Np > 94Nb > 239Pu > an99Tc > 36Cl > 234U> ae99Tc

Fig. 3

The earliest and largest dose rate (8.1E-6 Sv/a) comes from 3H peaking at 22 a after roof failure in the 20% case. The next largest dose rate for this flow case is at 1600 a from 14C (Fig. 3). The peak dose rate for

237Np in this case comes through at 2300 a and the next largest dose rate is from 94Nb at 20,290 a, primarily through the groundshine pathway.

CONCLUSIONS

The most important pathway for dose consequences to a resident of Duke swamp, based on these calculations, is through the drinking water pathway. However, it is highly unlikely that someone would take all their drinking water from a wetland and not process or filter it in some way. The results from human ingestion of untreated swamp water and garden vegetables grown on imported peat from Duke swamp are more than conservative estimates, they are upper bounds. Both 14C and 237Np are important radionuclides for human ingestion through plants/vegetables. The total dose rate for the 20% case, from contaminated vegetation is 2.3E-6 Sv/a at 1600 a for 14C and 1.4E-6 Sv/a at 2300 a for 237Np. The peak dose rate from 3H occurs well before the end of the 100-year period of institutional control of the site. Humans will not have access to Duke swamp during this period. The only radionuclide to give a significant external dose in this case is 94Nb (1.2E-6 Sv/a) at 20,000 a, and this is primarily through the groundshine pathway.

ACKNOWLEDGEMENTS

We thank Bill Selander for helping us define the scenario, Doug Killey for the hydrological information on Duke swamp, Steve Wilkinson for biosphere parameter values and Fenella Lane for the NSURE aquifer flux input data. We appreciate the helpful comments of C. Macdonald and G. Bird (Atomic Energy of Canada Limited) and J. Cook (Savannah River Technology Center) on a draft of this paper.

A GENERAL VIEW OF AN ORIGINAL PERFORMANCE ALLOCATION COMPUTER TOOL: OASIS

P. Thorner
ANDRA

ABSTRACT

Following the law of Dec. 30th, 1991 (2), ANDRA has established a work schedule until 2006 in order to propose a feasibility assessment for HLW deep disposal, based on R&D studies in two underground laboratories. In the first phase, performance for each disposal subsystem has to be defined. For this early process, a specific general assessment tool is needed: OASIS.

OASIS is a deterministic mass transport simulation software which relies on simplified modelling of the pathways. The system (from source to biosphere) is represented by a multi-1D network where hydraulic properties of each branch come from input data. The system is built by associating modules containing elementary transfer functions. The overall physical validity of OASIS needs to be supported by external studies which can rely on more sophisticated and more specific 2D or 3D codes.

OASIS also contains a calculation assistance called "study generator", whose role is to prepare sets of input data (fixed, variable or probabilistic) and to extract relevant values from the resulting blocks. All these operations are defined by the user in a object-oriented approach. The program also provides a user-friendly interface.

An unrealistic but illustrative situation has been chosen as an example to show OASIS capabilities. Simple, mono and bi-parametric studies can be performed as well. The purpose of this type of analysis is to give inputs to performance allocation, using a radiological impact criterion. OASIS is able to perform a great number of these calculations with very low CPU times.

OASIS is now in an ongoing development process where models are versatile and continuously adapted to specific needs. Future versions of the program will contain higher-level functions in order to keep the treatment or the results at a certain degree of simplicity.

BACKGROUND

The field of work for ANDRA has been defined by the law of dec.30th, 1991. It is specified that ANDRA has to give the results of a 15-year research and development work about the feasibility of a deep geological disposal of HLW by the year 2006.

Several milestones have been identified during this period ; the first one, 1997, will correspond to a first selection of main disposal concepts. Efforts are developed within this phase to define the awaited performance of the repository, in terms of functional requisites. This process is called "Performance Allocation", and must be an iterative process. It is related to the results of site investigations and should provide input to the definition of underground laboratories programs and R&D studies prioritization. Technical and economical aspects are

considered for this global process, but the basic criterion to define performances is safety.
The Basic Safety Rule RFS III-2-f specifies the overall safety objectives, principles and functions to be considered. During the Performance Allocation process, the general performance requirement is translated into lower-level specific requirements. This is done for any of the considered scenarios.

DESIGNING THE FACILITIES

The ANDRA approach for long-term disposal design is based on a simple logic: ask "What" you really need in terms of safety before asking "How" to carry it out technically. This principle leads to identify the main function the system has to perform. For the disposal, this function is the long-term annual dose limitation under a regulatory level.
This function is divided into lower-level functions which can be associated to concrete technical solutions. Except for the basic design principles given by the RFS III-2-f, all the disposal systems (the "How") follow the low-level functional requirements (the "What"). Basically, this means that the main task can be achieved by performing several little tasks which form the general specifications for the disposal design.
The requirements from each low-level function must be quantitative. This corresponds to the Performance Allocation, i.e. calculation of a performance level and confidence bounds for each function. It is a systematic and necessarily iterative process.
The only way to define those individual performances is to use simulation. The system is modelled by including all the design data available at that time. Then, through the simulations, the individual performance can be defined in order to achieve the main goal of the system, i.e. not exceeding a dose limit.
Simple and generic performance allocation can be carried out sometimes by hand-made calculations dealing with orders of magnitude. But when iterative, numerous and precise results are necessary, computation is the only answer. To do this, we have designed a new software: OASIS.

WHAT IS OASIS?

OASIS is a multi-purpose scientific software that has been developed by ANDRA for the specific need of long-term disposal safety studies. Rather than a classic scientific code, OASIS must be considered as a toolkit that helps engineers to perform advanced studies. The main features of this software are the following:

OASIS is a software that simulates transport of any quantity (activity, mass, heat) inside any physical system. These systems are based on network modelling, to simplify system representation:
Fig. 1

It is based on a general modular approach: every subsystem such as faults, waste canisters, seals, or biosphere in the case of a disposal, forms an individual module that can be assembled with any other to reproduce the network. This feature allows us building any physical system where a quantity is transported. There is a specific physical system for each release scenario, each underground facility, each waste type and each site.

Each module uses simplified modelling to obtain low CPU times and to keep some coherence with uncertainty levels. In addition, simplified models bring the user to an easier understanding of the system behavior.

Actual models for deep HLW disposal rely on analytical zero or one-dimensional schemes.

OASIS is associated with a general validation process which is geared to build confidence in the models. OASIS needs to be supported by a phenomenological approach mainly represented by 2D or 3D numerical codes. These programs are an intermediate step between OASIS and experimental results. They focus on a limited number of physical aspects but they provide a very detailed modelling of these specific processes. The physical analysis has two main goals: providing input data to OASIS (replacing a non-modelled process by equivalent data or tables) and helping to assess and justify modelling hypothesis inside OASIS.

OASIS provides a study generator, to establish various calculation modes easily. More than for classical calculations, this feature is designed for sensitivity and uncertainty analysis. Deterministic and probabilistic analysis are available (probabilistic here means random sampling of input data, Latin Hypercube Sampling Monte-Carlo for example). According to the user's demands, the generator builds data sets, runs all the needed simulations and then extracts the relevant results for decision-aid processes.

A user-friendly interface is also included so that access to information (data, models and results) is possible without special computing knowledge. From the user's point of view, OASIS appears like an object-oriented software: a physical module, a transported element, a calculation mode with its parameter ranges or a graphical result are specific objects that can be defined independently. That means that several objects from the same type can be defined simultaneously during just one calculating session (more than one calculation type on a system, for example). The user can do any association between objects, as shown further.

OASIS relies on well-known computing solutions such as UNIX, FORTRAN or C. No "exotic" languages or operating systems in order to guarantee long-life for the software. A complete Quality-Assurance process is associated to the development cycle.

HOW IS IT BUILT?

The main technical features of OASIS form the basis of a particular internal structure divided into 5 levels. This structure and some other characteristics have been patented in 1994:

Level 1 contains all the basic modules. It is a model database filled with individual simplified models. In our case, each of the following components are placed inside a specific analytical module: source term, buffer material, disposal architecture, geological media, special geological features or biosphere. Each module contains its own numerical default database (values and uncertainties) related to each of the model parameters.

Level 2 contains the network modules. They are used at each node of the transport network as flux interface between level 1 modules. In an underground hydraulic system, these modules can divide the flux going into parallel pathways or sum it where different pathways converge. These modules are necessary to build the multi-1D approach.

Level 3 contains the scenario generator. This step provides time dependency for the multi-1D network, in order to represent a complete scenario with its event logic. Behavior of the studied system is totally described at this stage. The three first levels are called the

"calculation kernel" and provide results similar to those from classical scientific codes.

Level 4 contains the study generator and has been described. Its instructions come either from the level 5, or from hand-made data sets provided independently. These data sets must be formatted in a specific language especially developed for that purpose, the LSE (from french "Langage Spcifique aux Etudes"). This choice allows running the code independently from level 5, starting from any remote text terminal.

Level 5 contains the user-friendly interface. It is a graphic facility where every instruction coming from the user is translated in LSE. Level 5 can be run independently from the rest of OASIS (to prepare data sets or to analyze old results) or simultaneously (classical use).

PHYSICAL MODELLING CONSIDERATIONS

This chapter provides more detail on levels 1 and 2 and on the validation process for the deep disposal application.

The source term module is a flux or concentration emitter which considers the following options:

- Direct contact between waste and the following media.
- Presence of a hydraulic buffer between wastes and the media.
- Immediate activity release from waste.
- Time-dependent activity release.

Waste matrixes, overpacks and solubility limits are considered in the module. The flux or concentration signal is calculated depending on the model option.

The engineered barrier and the features of the geologic media are associated to transport modules. There are modules for different phenomena:

- Pure advection.
- Advection-dispersion.
- Pure diffusion.
- Sorption and chain decay are also considered.

These modules exist for various 1D geometries: cartesian and axisymmetric. Boundary conditions can be chosen between flux, concentration or flux/concentration relation at the input or at the output.

The biosphere corresponds to a module with a conversion factor per radionuclide.

These informations form a model database. The connection between these modules allows building a large number of pathways for scenarios.

In consequence, each pathway is a sum of physical hypothesis which need to be evaluated by validation exercises. An example for validation is presented on Fig. 2:

Fig. 2

A specific combination of modules with OASIS (source with advective-dispersive geosphere) has been compared to a 2D numerical code, DIMITRIO (finite-element code developed by the French Atomic Energy Commission). An initial 2D simulation has been performed to define equivalent 1D hydraulic characteristics, by identifying the main flow tube (length and water travel time) and by performing a sensitivity study on the main parameters. The resulting hydraulic values have been entered for the OASIS 1D transport model. The figure shows that differences between 1D and 2D are acceptable, even if retardation is changed.

This result shows a part of the validity field for the 1D hypothesis, but it remains very specific. This example has to be completed by many other numerical comparisons, to explore the limits of the models.

HOW TO USE OASIS?

OASIS is implemented on an UNIX workstation and has been developed with standard and portable techniques. A PC version may be developed in the near future. In the case of the HLW waste disposal, the main classical steps to perform calculations with OASIS are the following:

- Define the study name.
- Choose the physical modules in the database. Choose the right boundary conditions, geometry, physical processes for your scenario.
- Link the modules in order to build the multi-1D network.
- Choose radionuclides to be transported. These can be fission products or actinides. Chain decay can be defined afterwards considering any nuclide.
- Define one or more calculation objects. Each calculation object contains the study type (reference, sensitivity, probabilistic), calculation techniques (deterministic, mono or bi-parametric, probabilistic), reference values for fixed parameters, intervals for continuously variable parameters and several general-purpose parameters (min and max simulation time, result filters,...).
- Define graphical results (results can be activity or dose rate, concentration at any point,..). Each object contains all the operations to be done on the results before plotting: curve maximum , means or standard deviations, linear combination of curves, curve intersections with specific levels, etc... All the graphic features must be defined at this stage.

All this is supposed to be done with the help of the user-friendly interface: the mouse is widely used. It is also possible to work without a graphic device: then the user has to write or modify a LSE data file where all the above steps can be found in a special format.

A study managed with OASIS induces few constraints. There is no need to do the operations in a monolithic one-way process: excepting some common-sense operations (like defining a module before modifying its data), many operations can be done independently or done by iterations. Calculations may be performed before defining the treatment of the result.

AN APPLICATION WITH OASIS

The following application deals with the HLW disposal. It is an illustrative example of the type of calculations performed within the Performance Allocation phase. The aim was to determine performance of the safety functions in a disposal so that dose rate does not exceed a fixed limit. A strongly degraded, unrealistic and simplistic situation has been chosen. This has been done to identify the effects of various functions potentially involved in radionuclide containment. It also permits to have simplified models and easily readable results.

Let us consider no engineered barrier and a geosphere hydraulically short-circuited. Waste packages are supposed to be enclosed in an overpack with a finite lifetime, which performs a retardation function. After this period, all the overpacks are supposed to fail simultaneously. When this failure occurs, the waste matrix starts releasing radionuclides at a certain rate. Then, the nuclides reach the biosphere almost immediately with an additional limitation for the low-solubility ones: they are supposed to precipitate near the source, after their release. Three functions can be identified easily:

Flux limitation by the waste matrix release rate.
Flux limitation by retarding the release with the overpack lifetime.
Flux limitation for low-soluble nuclides with the low hydraulic flow.

The first question is "What performance do we need for each function (associated to a specific subsystem) to ensure that dose will not exceed the limit?". During each calculation, the function is supposed to operate alone: the remaining functions are absent or operating at very pessimistic levels.

Figure 3 provides the answer for the second function: lifetime of the overpack. This function relies on radioactive decay. The first and the third functions are taken at a pessimistic level (high). This graph is obtained by performing mono-parametric calculations with many different overpack lifetimes. Then, the maximum relative dose per radionuclide is extracted from each result and plotted in the [dose rate vs overpack lifetime] performance graph.

Fig. 3

The intersection of each performance curve with a horizontal dose limit gives the performance level required from the function for each radionuclide (cumulative dose can also lead to a specific performance). Care must be taken for chain actinides, whose contribution can increase and then decrease with performance: the relevant intersection is the last one in that case (on the right hand of the graph). By evidence, overpack lifetime (or retardation) seems to be much more relevant for short-lived elements than for long-lived or end-of-chain actinides. The absolute result is the performance value for each radionuclide, the relative result is that it might be more interesting to count on retardation for some radionuclides rather than for others (a matter of feasibility). This work can be done for the two other functions.

The second question is "What should the performance of two functions be if their contribution to safety was simultaneous?". This is done by performing bi-parametric calculations on the following parameters: overpack lifetime (retardation) and waste matrix release rate (limitation).

The following figure (Fig. 4) shows a network of iso-dose curves. These curves are obtained by plotting the previous performance graphs with many different release rate values. For each of these graphs, the intersection of the curves with a dose level provides the retardation value. Then, this retardation value associated to the release rate value of the graph form the [x,y] coordinates for the iso-dose graph. Each curve corresponds to four different levels of relative dose: R, R/2, R/4 and R/20.

Fig. 4

The area below an iso-dose curve is a zone where every combination of the two parameters leads to a dose exceeding the limit. The upper area represents all the parametric combinations leading to a dose under the limit: this zone can be interpreted as "acceptable". By evidence, the lower the dose limit, the higher the performance of both parameters must be.

This graph also shows that reducing the dose level might be done in an optimized way. At places in the graph where curves have a horizontal tendency, it seems to be more convenient to increase the waste matrix performance rather than the retardation performance. In that case, lower dose levels seem to be reached easier. The opposite observation can be made in places of the graph where curves have a vertical tendency. In

complement, the other zones show that joint performance increasing of both parameters seem to be the fastest way to reduce biosphere impact. These conclusions are given without taking care of any cost or feasibility aspects, but the main purpose of these graphs is to provide designers with all the relevant performance limits in terms of safety. It is possible to agree with any optimization of the disposal, as long as the system behavior remains inside these safety boundaries.

OASIS allows performing these calculations and many others very easily and with low CPU. The last graph (the bi-parametric one) needed 2,000 simulations of the base case to have all the necessary values. The order of magnitude of the whole calculation time was a few dozens of seconds.

THE FUTURE OF OASIS

The development of OASIS is an ongoing process which will provide the software with features designed to take into account the growing complexity of the calculations. These features can be the following:

- Consideration of time dependence for models: treatment of complex scenarios.
- Inverse techniques for problem resolution.
- Consideration of scenario probabilities - risk approach.
- More complex and complete modules, calculation modes and result treatment.
- Alternative resolution methods (semi-analytical, Laplace's transform, numerical).
- Extension to non-radioactive products migration (e.g. chemical).
- Links with an independent database managing system, like ORACLE.
- Implementation of OASIS on a network, possibly on PCs.
- 2D or 3D models if necessary (much later).
- Visual simulation of mass transportation (visible evolution).

THE INFLUENCE OF INVENTORY DISTRIBUTION ON THE SAFETY ASSESSMENT OF THE ABADIA DE GOIAS REPOSITORY

Francisco Luiz de Lemos

Brasil

Terry Sullivan
Brookhaven National Laboratory
Upton, NY, USA

Sophia Teh Whei Miaw
IAEA-International Atomic Agency
ABSTRACT
Due to an accidental breakage of a Cs-137 radiotherapy source, September 1987, 40.1 Tbq of waste was generated in Goiania, Brazil. All of this waste will be disposed of in a Low Level Waste Repository. The proposed repository is above grade with a soil cover. It is 60 m in length, 20 m wide, and 5 m deep.
An analysis of the influence of inventory distribution is conducted using the BLT computer code. BLT (Breach, Leach, and Transport), is a two dimensional finite elements code, that calculates container degradation (Breach), radionuclide release from the wasteform (Leach), and migration of radionuclides to the facility boundaries (transport).
Two cases are considered: a) the concentrations of Cs-137 in the near field, and b) the concentrations of Cs-137 at a well 100 m down gradient from the repository.
INTRODUCTION
In September 1987, an accidental breakage of a Cs-137 radiotherapy source generated 40.1 Tbq of waste near Goiania, Brazil. During the decontamination work, the waste collected in several different types of packages and removed to an interim storage facility near Goiania city (1). The waste occupies 2650 m3 and is stored as follows (1):

- one package containing the remaining source,
- 90 concrete containers,
- 16 cylindrical carbon steel containers with a volume of 5.7 m3,
- 987 rectangular carbon steel boxes with a volume of 1.7 m3,

Both types of carbon steel container have a wall thickness of 6.35 mm. The waste is 90% soil, rubbish and scrap, 8% paper, plastic and clothes, and 2% organic material. The distribution of waste within the containers is such that 62% of the activity is contained in 1.7% (45 m3) of the volume. Also, 92% of the inventory is contained in 20% of total volume (503 m3).
The proposed repository is above grade with a soil cover. It is 60 m in length, 20 m wide, and 5 m deep (2), see Fig. 1a. The bottom of the repository is 4 m above the aquifer. For most subsurface facilities, the ground water pathway is largest contributor to dose (3). This is particularly true when the distance of the aquifer is small, as is the case at Goiania. Therefore, the basis for comparison for this report will examine release from the repository Other pathways, such as run-off, may be important but are out of scope of this paper.
In most performance assessment, it is assumed that the inventory is uniformly distributed within the facility. This is not the case at Goiania. The non-uniform distribution of waste at Goiania requires an analysis if the potential releases from the repository based on the actual distribution of wastes. For comparison, potential releases will also be estimated for a uniform distribution of wastes. The analysis will be conducted using the BLT code (4). The impact of non-uniform inventory distribution within the repository will be assessed and if significant differences in potential dose occur, recommendations on waste emplacement will be made.
Fig. 1
METHODOLOGY

For this analysis the BLT (Sullivan, 1989) computer code is used to estimate ground water concentrations. The BLT code, is a two dimensional finite elements code, that calculates Breach (container degradation), radionuclide release from the wasteform (Leach), and migration of radionuclides to the facility boundaries (Transport).

BLT reads an input file with information pertaining to the system geometry, water flow, container degradation, waste form leaching, and contaminant transport. This information is used to predict the time-dependent movement of radionuclides through the trench for a single radionuclide species. Wasteform release may be modeled based on three processes: diffusion, dissolution, and rinse.

As a preliminary calculation, complete failure in the engineered barrier as well as in the containers is assumed to occur instantly. Therefore, the infiltration velocity is equal to the containers rate, i. e., rainfall - evapotranspiration (Vz= - 1.9 e-6 cm/s, i. e., 60 cm/yr.)

The finite element mesh used to simulate the disposal facility is presented in Fig. 2.

Fig. 2

The cross section analyzed is the transversal one A-A, see Fig. 1-b, because it provides a shorter radionuclide migration path to the border of the repository.

The initial condition for all the 252 nodes is zero concentration, and the boundary conditions are zero mass flux entering the upper edge of the region and zero concentration at the bottom, leading to a maximum release.

Due to the large number of waste containers it will not be possible to model each of these containers individually. Some containers will be lumped together to form a representative wasteform/container system. Different arrangements of these representative groups will be analyzed. The waste containers are divided into three types that are represented in the waste containing region.

Type 1 is the metal box, type 2 represents the concrete container and type 3 represents the source container.

In total, there are 15 containers containing elements.:

Elements 187,188, 199, 200, 201, 212 represent type 1 containers,
Elements 121, 122, 123, 160, 161, 162, 186 represent type 2 containers,
Elements 213, 214 represent type 3 container.

In the initial stage of the assessment, it is assumed that all containers fail instantly at closure of the facility, t=0. Refinements to the analysis will consider different failure times for each container type. The release from the waste forms is assumed to be controlled by the rinse process which gives instantaneous release of all the inventory. This is the most conservative assumption that can be made about release from the waste form.

For the simulation which considers non-uniform distribution of wastes within the repository, the type 1 containers have 69 Ci per container, type 2 have 69 Ci per package and type 3 have 93 Ci per package. For the uniform distribution case, all containers have 72.3 Ci per package.

In the BLT code, the repository was modeled with 4 different material types:

1) undisturbed soil
2) concrete-engineered barrier
3) backfill-compacted soil
4) wasteform-mixture of cement and bentonite

Site specific data was available for the distribution coefficient in the undisturbed soil. Estimates of other material properties are based on typical literature values.
The properties used are as follows:
Table I
Preliminary Results
For preliminary calculations, it was considered as a first step that the entire inventory is distributed over the packages, and after that, a non-uniform distribution of the waste. In the following table are presented the concentration peak with the corresponding times.
Table II
From Table II, there is not a great difference neither between peak concentrations nor between the times of peak concentration for the two cases (uniform distribution of wastes versus non-uniform). The very short time for peak concentration was due to the high infiltration velocity corresponding to a complete failure of barriers, and the short distance to the aquifer (4 meters).
Well Scenario
For the well scenario, it is considered a well 100 m down gradient from the repository. The finite element grid for this case is shown in Fig. 3.
Fig. 3
It has been considered only two material types: the undisturbed soil and waste/concrete. Also, different soil Kd values have been analyzed (5). According to reference (5), the soil Kd values are greatly influenced by the Cs molar concentration, and therefore the well concentration will be function of the Cs molar concentration. The expected average value for Abadia de Goias soil Kd is 430 cm 3/g, for a molar concentration of 1e-08. The distribution coefficient of the site soil values have been determined by the batch method. Table III shows some values for well concentration versus soil distribution coefficient Kd. These concentration have not been influenced by the wastes distribution.
Table III
From Table III, to exceed a ground water dose of 4 mrem/yr. from the ingestion of 2l/day of contaminated water, it is needed to insure that the ground water concentration does not exceed 1.1e2 pCi/l.
CONCLUSIONS
A preliminary investigation into the influence of inventory distribution within the Abadia de Goias Repository has been conducted. As a comparison, releases to the near field have been determined for two cases, i. e., uniform and non-uniform wastes distribution within the repository. The distribution of wastes was found not to influence peak concentrations greatly.
For the well scenario, the analysis has shown that for the conservative assumptions (instant barrier failure and total release of the inventory), the distribution coefficient of the aquifer would have to be less than 50 cm3/g . The measured distribution coefficient for the site is approximately 430. Therefore, the expected doses are far bellow the standard.
For the well scenario, the analysis has shown that for the conservative assumptions (instant barriers failure and total release of the inventory), the distribution coefficient of the aquifer would have to be less than 50 cm3/g in order to have a ground water concentration above the limit of 4 mrem/yr, for a water consumption of 2 l/day.

However, if all the waste was instantly released, the concentration would be less than 1e-9 molar in the disposal facility and therefore, the expected doses at the well are far below the standard limit.

ABSTRACT

The Performance Assessment for the LANL Low-Level Radioactive Waste (LLRW) Disposal Facility, Area G, is on-going. A detailed review of the inventory data base records and the existing models for source release led to the development of a new modeling capability to describe the liquid phase aqueous transport from the waste package volumes. Inventory is sorted into four release form categories and screened in a comparison of leachate concentrations to the drinking water limit. Percolation through the disposal unit is prescribed in an independent surface water balance model incorporating site rainfall statistics. Waste package types and the disposal unit matrix have independently specified solubility limits and solid-liquid phase partition coefficients, or Kd values. Analytic solutions for inventory limited release of each nuclide in each of the four different waste package release forms are computed. Isotopic contributions are summed over elements to limit the waste package liquid phase concentrations to the elemental solubility limits. Time dependent

releases from the waste packages for each nuclide which may be inventory or solubility limited are specified as model output which is provided as the source term to the unsaturated transport model. The waste package efflux is distributed over the 2-D unsaturated zone model grid points corresponding to the cross-sections for 5 representative disposal units within the mesa top. Results show the Area G release is dominated by the inventory in the 'rapid release waste form' (Kd = 0), which percolates from the waste packages over 5-100 years and from the disposal unit over 50-1000 years. Nuclides in waste package categories with larger Kd values are released proportionately slower. Uranium and thorium are the main nuclides of concern released as solubility limited nuclides from the 'historical inventory' at Area G. The analytic models provide an efficient means to explore the sensitivity of the results to variations and uncertainty in the model parameter values.

INTRODUCTION

A preliminary draft of the site Performance Assessment (PA) for the Los Alamos National Laboratory (LANL) low level radioactive waste (LLRW) disposal facility at Area G has been completed 1) as required per DOE orders. A detailed review of the inventory data base, records and existing models for source release led to the development of a new modeling capability 2) to describe the liquid phase aqueous transport from the waste package volumes. The code output, a time dependent afflux to the disposal unit volume (as detailed in App. 3B to Ref. (1), is provided as input to a sophisticated 2-D unsaturated flow model 3) for subsequent transport within the disposal unit and throughout the vadoze zone.

The Area G disposal facility is located on the top of a narrow finger-like mesa composed of volcanic tuff (Bandelier Tuff), deposited in stratigraphic layers of ash and solidified volcanic flows. Waste disposed at Area G is placed into pits excavated in the volcanic tuff, crushed in place, and backfilled with the native crushed tuff to about 30% waste package and 70% tuff by volume. These disposal operations are evolving to minimize future disposal volume, and to assure stability of emplaced waste.

Disposal operations at Area G began in 1959 and disposal inventory is established in a detailed electronic data base dating back to 1972. (Disposal for operations prior to that date is recorded in log books currently being transcribed to a new data base.) Nuclide quantities are associated with 50 waste codes, which characterize the physical and chemical form of the waste.

ANALYSES

These waste codes were sorted into four waste package release categories, based on preliminary modeling efforts which indicated the release characteristics of concern. The four release categories include rapid release (with compartment release time of one year, and with solid-liquid phase partition coefficient, Kd, set equal to zero, taking no credit for solid phase reabsorption), soil (Kd for Bandelier tuff at neutral pH), concrete/sludge (Kd for concrete at pH=12, and corrosion associated with metal waste forms (with compartment release time of three hundred years, and with Kd=0).

Of the 60 inventory nuclides listed with half-life greater than 5 years, 30 were screened out in a 'leachate screening', and 30 were followed in detail by the source release model. The leachate screening compared the total inventory concentration in the disposal unit moisture to the

drinking water concentrations that result in 4 mrem/yr at the standard ingestion rate. Of the 30 nuclides followed in detail, 15 were decay chain parents, with 48 non-secular equilibrium decay chain products evolved self-consistently.

Geochemistry for the waste packages was evaluated in terms of the equilibration coefficients, Kds, and elemental solubility limits, Csl, interpolated from the literature by Longmire (4). Yucca Mountain Kds (5,6) were used as best estimates for Kds in tuff and as conservative estimates in soil, justified by a favorable comparison of water chemistry between Bandelier and Yucca Mountain tuff samples (4). Solubility limits for tuff (7) were applied to all waste packages except waste in concrete/sludge, where values taken from the literature (8) were applied. A program to evaluate site-specific Kds under field conditions is underway at Los Alamos. This will include five key nuclides in several Bandelier Tuff stratigraphies and over a range of water chemistry.

Percolation calculations were run with a modified version of the SPUR code (9) which does a detailed water balance at the surface. Results for the base case closure cover, 90 cm of crushed tuff, 10 cm soil and a thin gravel-mulch seeded surface, showed an average of 4 mm/yr percolation from the disposal unit bottom (10). Recent results with revised crushed tuff hydrologic properties show an infiltration rate of 5.5 mm/yr. The statistical analysis shows the average percolation rate is for a highly skewed distribution composed of 80% values equal to zero. The implications on the source release model of the actual distribution rather than the average value are under investigation. A range of infiltration model parameter variations were evaluated to account for evapotranspiration including rooting depth and leaf area index, and for run-off including surface slope and other factors important in the surface water balance (10).

The waste release model is based on a compartment representation of the package afflux, and depends upon package size, percolation rate or Darcy flux, retardation coefficient, and moisture content. The physical and conceptual flow models are shown in Fig. 1, where the concentration and flux symbols are defined. An analytic solution for waste package afflux under inventory-limited conditions (everything which is not solubility limited) is evaluated for each nuclide in each waste package type (or release category). This is described in detail elsewhere (2) with the result for the waste package liquid phase compartment concentration, Cw, written as

Eq. 1

with

Eq. 2

The compartment subscripts are shown in Fig. 1, and the l values are 'compartment clearance rates' derived by a control volume integration of the continuity equation defined in terms of the compartment area, A (horizontal planar area), volume, V, Darcy percolation rate, q, dissolution velocity, u, moisture volumetric content, q, and retardation coefficient, R, related in the usual way to the solid-liquid phase partition coefficient, Kd, as R = 1 + rKd/q.

Using this time dependent concentration, the waste compartment afflux, Gw, is

Eq. 3

Nuclide contributions to the same element, including ingrowth from decay chains, are summed to compare to the elemental solubility limits in each

waste package type. Waste package concentrations for each nuclide of the solubility limited elements are partitioned to the contributing nuclides. The solubility limited waste package afflux for a nuclide is

Eq. 4

where Csl is the elemental solubility limit and fsli is the fraction of the solubility limit which is contributed by that specific nuclide. This fraction is assumed equal to the nuclides contribution to the elemental solubility limit at the time when that limit is first exceeded. Solubility limited effluxes continue until the solid phase waste package concentration is depleted to the point the water phase concentration can no longer exceed a solubility limit, and subsequently the waste package is depleted at the inventory-limited release rate (2). An algorithm of how the solubility limits are tracked over nuclides, elements and waste package types is included as Table I.

Table I

Fig. 1a

Fig. 1b

The release model was tested extensively as described previously (1,2). The analytic models described above were supplemented with numerical modeling in two areas. One, the ingrowth of progeny nuclides which can have transport properties different from the parent nuclides makes the analytic solutions to the compartment model impractical. Ingrowth of progeny is calculated numerically in a simple implicit scheme which implements the compartment governing equations with the added complexity of progeny ingrowth. This was used in the present modeling effort to account for 'daughter-product' ingrowth which could contribute to the solubility limit within a waste package. From the perspective of nuclide transport in the site PA work, ingrowth within the packages was considered negligible, and ingrowth was modeled within the disposal unit and in the unsaturated zone within the 2-D unsaturated model (3) because that code has had more extensive QA and verification.

A second numerical modeling effort examined the compartment solutions where the waste package afflux feeds a one-dimensional (vertical axis) representation of the disposal unit. In this case, release from the disposal unit is controlled by the vertical gradient at the disposal unit bottom which evolves consistently along the vertical axis from waste packages homogeneously distributed throughout the disposal unit. This work confirmed that the global or compartment model results were reasonably accurate compared to results with 1-D profile effects in the disposal unit (2).

RESULTS

Figure 2 shows the concentrations verses time inside the waste package matrix. The solid concentration, Cs, is uncorrected for readsorption in the solid phase and corresponds to the case where Kd = 0. The actual solid phase concentration corrected for readsorption inside the waste package and assuming a nuclide with Kd = 0.5 is shown as 'Csmod', based on a governing equation derived elsewhere (2). Csmod decays over the time scale for 'rapid release' to an equilibrium plateau at a fraction, (rmKd/q/(1+ rmKd/q)), of the original solid phase concentration. It then decays to zero over the time scale for percolation from the waste package, along with the waste package liquid phase concentration, Cw. If this nuclide becomes solubility limited, the Csmod concentration is needed to accurately track the solubility limited release through the solubility limited release duration.

For the 'historical inventory' (1988 to the present) and site conditions at Area G, most nuclides are found to be inventory limited. An important result observed from the source release model is that for inventory limited nuclides, it is the component of inventory which is considered to be 'rapid release' which dominates the afflux function of time. All other release forms effect slower release rates which therefore reduce the afflux peak in time. The eventual peak in the aquifer concentration is determined by this release model modified by translation and dispersion during transport through the unsaturated and saturated zones.

Fig. 2

These concepts are illustrated in Fig. 3, which shows the inventory release, Ci/yr, as a function of time for four of the plutonium isotopes in the Area G inventory. The peak release rate for each nuclide is dominated by the 'rapid release' (Kd = 0) waste package source term which occurs at about 3-5 years. Contributions to each nuclide from the other waste package release forms have relatively slower release rates due to effects of solid-liquid partitioning and readsorption (Kd > 0), and are seen in the figure as the 'bumps' which occur later in time from 200-10,000 years. Because these release rates are so small, the contribution from these waste package types to the peak release rate is small even if their inventory is comparable to that in the 'rapid release' category.

Fig. 3

For the Area G inventory and site conditions, the only nuclides which contribute significantly to dose and are solubility limited are uranium and thorium. Uranium is depleted at a solubility limited rate which is sufficient to reduce the concentrations to an inventory-limited release at about 5000 years, after which the source decreases rapidly to negligible levels. This is illustrated in Fig. 4 for three isotopes of uranium. As in the inventory limited case in Fig. 3, there are contributions from multiple waste package types. The most inventory is in the 'rapid release' form which is solubility limited until about 5000 years. Imposed on top of this is a contribution from another waste form (concrete/sludge) which is also solubility limited but is depleted at about 500 years. Most of the uranium in this form is U-235, so only that isotope is noticeably influenced by the second waste form.

Fig. 4

The thorium solubility limit is so small that the release remains solubility limited effectively for all time. Plutonium is close to the solubility limit and would become solubility limited under slightly increased disposal concentrations.

Uncertainties in the results are examined via parametric examination of the input variables, and will be discussed in some detail (1,2). Variability due to transient percolation effects is currently under investigation. Spatial variation in percolation rate or percolation differences within the disposal unit matrix verses within the waste package itself are being evaluated.

CONCLUSIONS

The results of a site Performance Assessment depend critically upon the source release model and its input data. The maximum concentrations in the time dependent afflux from the waste package will be integrated over the disposal unit volume and then translated through the vadoze zone and diluted in the aquifer while being modified slightly for dispersion and diffusion during the aqueous phase transport. Thus, it is a modification

of the time dependent source release which will determine the receptor location concentrations and ingestion dose.

DEVELOPMENT OF A RISK-BASED APPROACH TO HANFORD SITE CLEANUP

W. Andrew Hesser

In Memory of
William G. Stillwell
Pacific Northwest National Laboratory

ABSTRACT

In response to a request from Mr. Thomas Grumbly, Assistant Secretary of Energy for Environmental Management, the Hanford Site contractors developed a set of risk-based cleanup strategies that 1) protect the public, workers, and environment from unacceptable risks; 2) are executable technically; and 3) fit within currently expected annual funding profile.

These strategies were developed because 1) the U.S. Department of Energy and Hanford Site budgets are being reduced, 2) stakeholders are dissatisfied with the perceived rate of cleanup, 3) the U.S. Congress and the U.S. Department of Energy are increasingly focusing on risk and risk-reduction activities, 4) the present strategy is not integrated across the Site and is inconsistent in its treatment of similar hazards, 5) the present cleanup strategy is not cost-effective from a risk-reduction or future land use perspective, and 6) the milestones and activities in the Tri-Party Agreement cannot be achieved with an anticipated funding of 1.05 billion dollars, or less annually.

The risk-based strategies described in this paper were developed through a systems analysis approach that 1) analyzed the cleanup mission; 2) identified cleanup objectives, including risk reduction, land use, and mortgage reduction; 3) analyzed the existing baseline cleanup strategy from a cost and risk perspective; 4) developed alternatives for accomplishing the cleanup mission; 5) compared those alternatives against cleanup objectives; and 6) produced conclusions and recommendations regarding the current strategy and potential risk-based strategies.

This analysis produced a framework and a set of tools that are available for dealing with changes to anticipated funding levels, changes in risk cleanup standards, and Congressional initiatives and inquires. The tools include land-supply curves, cost profiles, risk profiles, mortgage-reduction curves, and minimum operations costs. This paper describes the methodology used to develop mortgage-based, risk-based, and land-based cleanup strategies and how these strategies differ in terms of the work to be performed, its sequence, and the resulting end states.

Some of the principal findings are:

A 50 percent reduction in the cost of cleanup must be immediately achieved and sustained to meet existing commitments and schedules with the project budget. This reduction would require significant savings from some combination of privatization, productivity enhancements, and regulatory relief.

The Hanford Site committed, nondiscretionary costs necessary to maintain safe operations are estimated to be 500 to 700 million dollars annually.

The value of alternative future land uses should be balanced against the cost required to achieve the cleanup levels necessary to enable those uses. Achieving unrestricted use of all Hanford Site land is not

economically feasible given the expected annual funding profile of $1.05 billion (or less) and the limitations of cleanup technology.

Four decisions are critical to any risk-based strategy due to their huge costs and risk implications. These decisions are 1) retrieval/treatment versus in-place disposal of tank waste, 2) retrieval/treatment versus in-place disposal of solid waste, 3) entombment versus removal of major facilities and reactors, and 4) treatment and restoration versus restricted access to groundwater.

If a risk-based strategy is adopted for specific waste materials, the following would apply.

Nuclear Materials. Near-term risks associated with these material would be given priority in the near-term. Given the lack of a national policy for ultimate disposition of these materials, the Hanford Site strategy must plan to manage them safely and efficiently for an indefinite period. An overall strategy for providing long-term, low-cost storage for nuclear material should be developed and implemented.

Tank Waste. The resolution of tank safety issues and prevention of release of contamination would be given priority. Tank waste disposal and related activities would be delayed, pending the determination of the best solution and the resolution of higher-priority cleanup activities. In-situ disposal of tank waste would be the preferred option. Technology for in-situ disposal should be developed.

Solid Waste. A consistent set of standards must be developed and applied for management of solid wastes. In general, buried solid wastes would not be retrieved and stored solid waste would be disposed in-place.

Environmental Contamination (groundwater and soils). Groundwater treatment with present technology is not cost effective and would not be pursued. Access and use restrictions and monitoring would continue while natural processes work to restore the groundwater and technology is developed. Contaminated soils would be capped, covered, and disposed in-place. Environmental restoration activities would be prioritized by benefit per investment dollar.

Facilities. Major facilities would be used for waste disposal and entombed in place. Reactors would be entombed in place. Ongoing mortgage-reduction activities would continue. Other mortgage-reduction activities with high benefit to cost ratios would be accelerated.

The innovative methodology developed in this paper has considerable merit and is recommended for use in development of a Complex-wide cleanup strategy. Hanford managers are applying the results, especially in guidance to contractors for prioritizing the FY96 multi-year program plans and in taking new positions on key decisions, such as cleaning up to less-than-residential standards and treating waste in place instead of retrieving it.

INTRODUCTION

The Hanford Site is at a crossroads. Budgets have been cut substantially and more cuts are expected in the future. The Department of Energy (DOE) is being scrutinized by the U.S. Congress, the Defense Nuclear Facility Safety Board, and the National Academy of Science. Challenges have been made to the Hanford Federal Facility Agreement and Consent Order (Ecology, et. al 1994) (Tri-Party Agreement), and stakeholders and the public are dissatisfied with the rate of progress of the cleanup. Hanford site contractor personnel met with the Assistant Secretary for Environmental Management, Mr. Thomas Grumbly, in December 1994, to discuss the impact of budget cuts on current Hanford Site activities.

During that meeting, Mr. Grumbly requested a risk-based strategy be developed for the Site for the entire cleanup period. Acting on this request, a multi-contractor team from Westinghouse Hanford Company, Pacific Northwest National Laboratory,a and Bechtel Hanford, Incorporated was established to prepare a risk-based cleanup strategy. This paper briefly describes some of the results of that effort, which is formally published in a Pacific Northwest Laboratory Report, Development of a Risk-Based Approach to Hanford Site Cleanup.

Scope of the Study

The team first had to determine the scope of the effort and the elements of a cleanup strategy. The scope of the cleanup mission included those processes that:

Reduce or maintain the health, safety, and environmental hazards to acceptable levels;

Convert hazards to safe, stable forms;

Maintain or disposition existing materials, facilities, and waste inventories; or

Restore the land to enable future uses.

A cleanup strategy is a set of statements that describes the actions that must be taken to accomplish the cleanup mission. A strategy describes the sequence and priority of cleanup activities and the amount of resources that will be applied to those activities over the cleanup period. It specifically describes 1)what will be done, 2)when it will be done, and 3)what the result will be.

Assumptions and Requirements

The development of a risk-based strategy was based upon the following assumptions:

Funding for cleanup would decrease from current levels to about $1.05 billion dollars annually, beginning in fiscal year 1998. Funds could be moved across major program lines.

Regulatory waivers or modifications, including statutory changes, could be obtained, if necessary to execute the strategy.

The Tri-Party Agreement could be renegotiated, if necessary.

All aspects of the current cleanup Hanford Site Strategy could be changed, if warranted.

Given these assumptions, we determined that any cleanup strategy was required only to: 1) protect the public, workers, and environment from unacceptable risks; 2) be executable technically; and 3) fit within the anticipated funding profile. It specifically was not required to meet regulatory requirements.

Then, considering these assumptions and requirements, the approach followed by the study team was to identify the funding available to pay for cleanup activities, determine the highest risks at the site, and build a program that attacked the highest risks first--within allowable funding.

Minimum Safe Conditions

As a first step, we determined how much of the Hanford budget was "nondiscretionary," that is, necessary to protect the public and workers from exposure to stored materials and waste. In this context, minimum operations were defined as "those surveillance, maintenance, and support costs required to control existing material, waste, and facilities in a safe, stable condition." No remediation, stabilization, or disposal costs were included, and new activities required to comply with regulatory agreements would not be completed at the minimum operation funding level.

However, current routine reporting activities necessary to satisfy public and worker safety regulations for surveillance and maintenance were embedded in minimum safe operations estimates.

We determined that Hanford Site nondiscretionary costs to maintain minimum safe operations to be in the range of 500 to 700 million dollars per year. The difference between the committed, nondiscretionary costs and the anticipated budget constraint of 1.05 billion dollars annually represents the funding available to make progress in cleanup. That means the DOE has about 350 million to 550 million dollars annually available to apply to cleanup.

Note that over time nondiscretionary costs would be reduced as "mortgage-reduction" activities were completed. However, some costs would increase due to further deterioration of facilities and associated growth in surveillance and maintenance costs. For study purposes of building the risk-based strategy, we considered a point estimate of minimum safe operations costs of approximately 600 million dollars per year (in current dollars). Next we had to determine what the greatest risks were.

Determination of the Highest Risks

Environmental, worker safety, and public health risks were analyzed to determine their impact on cleanup activities. Risk is the potential of a hazard to cause both immediate and long-term harm to a receptor. It is the product of (1)the consequences resulting from a receptor being exposed to a hazard and (2)the likelihood of an occurrence. A graphical representation of the parameters used in the risk analysis is presented in Fig. 1.

Fig. 1

The harm or consequences to a receptor are related to the hazard source in terms of the quantity of material and its toxicity, form and dispersability. The likelihood of release is related to the available energy sources, release processes, and functioning barriers. Pathways by which a receptor can be exposed to hazards are air, soil, groundwater, and surface water. Since risk occurs over time, we considered 1) current state, 2) the remediation phase of cleanup, and 3) the post-closure phase.

We examined four categories of risks over these three periods. The risks were:

Near-term release hazards with potentially large consequences where release of radionuclides and chemical contaminants could occur through the current or remediation phase. Although these hazards have potentially large consequences, they are relatively unlikely.

Work place hazards associated with all aspects of worker activities.

Long-term hazards where harm to the public results from the transport of radionuclides and chemical contaminants through the groundwater slowly over very long time periods (even hundreds or thousands of years).

Ecosystem hazards where harm results from chemical and radionuclide contamination of plant and animal life and from physical disruption of natural habitats. Hazards to cultural, archeological, and historical resources are included in this category.

Near-Term Release Hazards

Conservative unit risk factors were calculated for an average member of the public, assuming current population distribution and also assuming a calculational receptor 500 meters from the source. These factors were based on inhalation exposure and external exposure from material deposited on the ground. All major facilities were evaluated against the

US DOE Nuclear Safety Policy Criteria of 2x10-6 latent cancer fatalities per year for members of the public.

The largest Hanford Site contributors to the risk to an average member of the public are (not in any particular order): the N fuel stored in the K Basins, the cesium and strontium capsules stored in the Waste Encapsulation and Storage Facility, the debris in the 324 B cell, and the high-level waste in the underground storage tanks. The plutonium in the Plutonium Finishing Plant also represents a significant contributor to the public risk, primarily because of the amount of plutonium and its toxicity.

Work Place Hazards

Key sources of work place hazards include the old reactors, canyon buildings, support facilities, Kbasins, and N reactor. During remediation, the key hazard sources include deactivation and final dispositioning of the old facilities, new facility construction, and cleanup actions involving liquid wastes, buried solid wastes, contaminated soils, and special nuclear materials. Exposures to workers are controlled on an individual basis through procedures, training, and protective equipment. Often, managing worker risk is reflected in increased costs.

In general, it is recognized that it is necessary to increase worker risk (and some public risk) in the short term to achieve a reduction in long-term public and environmental risk. A key decision for managers is whether such increases in worker risks are worth the overall benefit in the long term. Some of the most important results of the work place hazard analysis are:

Overall, worker risks are relatively large compared to public risks, perhaps two to four orders of magnitude greater.

Industrial hazards, especially construction of large facilities, are generally greater risk to workers than routine radiological exposures.

Facility transition can be viewed as work place hazard "mortgage reduction" similar to cost mortgage reduction, in that increased worker risk is the price to be paid for longer-term public and environmental risk reduction. Deactivation of retired facilities results in long-term reduction in worker risks. This means cost-mortgage reduction efforts (e.g., transitioning facilities such as PUREX and the Fast Flux Test Facility) provide risk reduction as well as cost reduction.

There is a fundamental tradeoff between leave versus retrieval policies for tank wastes, buried solid wastes, contaminated soil, and liquid disposal sites. Worker risk is generally greater for retrieval activities than for alternatives which treat the waste in place, such as in situ vitrification and disposal.

Entombment has lower worker risk and is preferred over demolition of old canyon and reactor facilities.

Long-term Release Hazards

The objective of remediation of much of Hanford's wastes is to prevent long-term releases to the public and the environment that exceed acceptable levels. The principal exposure pathway of concern is public consumption of groundwater and contamination of the Columbia River. In the past, airborne and surface water exposure routes were significant, but these have declined substantially with the end of the production mission.

Our study focused on those contaminants of greatest concern, both hazardous chemicals and radionuclides, and three exposure effects: 1)

excess carcinogenic incidence from exposure to radionuclides; 2) carcinogenic incidence from exposure to hazardous chemicals; and 3) non-carcinogenic adverse health effects from hazardous chemicals. Unit exposure factors were calculated for a residential scenario with exposure only through the use of contaminated groundwater. Carcinogenic effects were determined assuming exposure to the peak concentration over the lifetime of the exposed individual.

The summary results of the analysis of long-term risks are:

Long-term release hazards through the groundwater pathway are dominated by seven long-lived, mobile constituents: C-14, Tc-99, I-129, Np-237, carbon tetrachloride, nitrate, and uranium.

Potential contributions from tank waste, buried solid wastes, and existing environmental releases are roughly of the same order of magnitude.

The long-term release hazard posed by existing low-level waste burial grounds is roughly two orders of magnitude higher than that posed by the pre-1970 unsegregated buried waste and the post-1970 retrievably stored transuranic waste. The policy of retrieval of transuranic and suspect transuranic wastes is questioned.

For tank waste, roughly one-fourth of the tanks contribute more than 99% of the long-term release risk. Also, the residual contamination following retrieval and the contamination from prior tank leaks place a floor below which risk cannot be reduced without some form of in situ treatment.

Ecosystem Hazards

We reviewed prior studies and analyses for results that would be applicable to the development of a risk-based strategy. We learned that the isolation of Hanford and its restricted access has resulted in a habitat that is relatively undisturbed. However, the potential for adverse ecosystem impacts from remediation activities is substantial, especially from physical disruption of the ecosystem by soil and waste evacuation and construction of new facilities. Like worker risk, there are tradeoffs for some environmental management activities between near-term damage to the environment and longer-term reductions in public risk.

Elements of a Risk-Based Strategy

Considering the risks described above, we developed a cleanup strategy based upon a single objective: carry out those activities which are the most effective from a risk-reduction perspective, while ensuring the risks are reduced to acceptable levels for the public, workers, and environment. Four considerations are primary: 1) near-term releases which pose an unacceptable risk to the public, workers, and ecosystem will be prevented; 2) workers will be protected from unacceptable hazards; 3) the ecosystem and cultural resources will be protected during remediation; and 4) the Site will minimize long-term releases that might affect the public and ecosystem.

The key elements of the Risk Strategy are:

All reactors would be entombed as permanent disposal sites.

Liquid and solid waste sites outside the central plateau would be capped, covered, and disposed in place.

The central plateau would be a permanent waste disposal site for entombed nuclear facilities, liquid and solid waste disposal sites (capped and covered), and pre- and post-1970 transuranic waste and tank waste (both of which would be disposed in-place). Access to the central

plateau would be controlled indefinitely, and access to groundwater would be controlled for the foreseeable future.

Spent nuclear fuel and special nuclear materials would be removed from current locations and placed in interim storage in the central plateau, pending final disposition.

Facilities outside the central plateau would be dismantled, as appropriate, or consolidated to reduce operations and maintenance costs.

Groundwater would not be treated, and public access would be controlled.

Execution of a Risk-Based Strategy

Execution of this strategy would result in 1) nuclear material consolidated and stored on-site pending final disposal, 2) liquid tank waste disposed in-situ, 3) solid waste disposed in-situ, and 4)major facilities entombed in place. This strategy would leave the environmental contamination in place, but capped and covered, as necessary.

The costs to implement the Risk Strategy would be considerably lower than the costs to implement the current baseline strategy because much of the waste would be disposed in-place. Assuming a 10 billion dollar in-situ cost of disposal of tank waste and nine billion dollars for environmental restoration, the total cleanup cost is estimated at 44 billion dollars--saving perhaps 20 to 30 billion dollars as compared to the current strategy. Figure 2 illustrates the funding profile over the next 75 years.

Recall that a strategy must say what will be done, when it will be done, and what the result will be. Figure 2 addresses the second part of the strategy. Adoption of the risk-based strategy described above means that first priority would be given to preventing near-term, potentially catastrophic releases. Thus, removing the spent fuel from K-Basins and stabilizing underground storage tanks would be given high priority. So would cleaning out the 324 building B cell, cleaning out the Plutonium Finishing Plant, and moving the cesium and strontium capsules to a more stable storage as soon as practical.

Second priority would be given to mortgage-reduction efforts which also reduce worker risk. Facility transition of PUREX, N reactor, Fast Flux Test Facility, and others would be funded as soon as possible.

Fig. 2

As money becomes available from the first two priorities, priority would be given to tank waste disposal, solid waste disposal, and, especially, environmental restoration work. Technology for groundwater treatment would be funded, but not current pump and treat activities.

Of course, all support activities needed to execute these programs, e.g., landlord, would be funded at those levels needed to carry out the above functions.

Adoption of a Risk-Based Strategy

Adoption of a risk-based strategy like the one described in this paper (and it is only one of several strategies which could be considered "risk-based") would require regulatory modification and relief, including renegotiation of the Tri-Party Agreement. It would significantly impact the ultimate use of the land and would considerably increase the waste left in the ground at Hanford. Many of Hanford's stakeholders, especially the Environmental Protection Agency and the Washington State Department of Ecology may oppose such a strategy, and certainly it could not be adopted without their involvement and approval.

Despite local opposition, however, the Department of Energy and Congress may support a risk-based strategy because it is financially affordable while still addressing the highest risks. But if it is to be adopted, the DOE and its regulators should begin negotiations now, before an increasingly skeptical Congress reduces funding and limits options. It is also important for DOE Headquarters to understand the significant implications of adopting risk-based (vice compliance-based) strategies for the Complex. While it sounds good to Congress and others, our study indicates that adoption of a risk-based approach to cleanup is a major change from the current way of doing business.

ABSTRACT
The National Academy of Sciences' review of geological issues related to the technical suitability of the proposed Ward Valley, California site for a low-level radioactive waste disposal facility has important, broadly applicable generic lessons for situations where a scientific panel is on the critical path for a specific project which is governed by a body of existing law and regulation. This paper will describe these generic lessons and offer recommendations for avoiding pitfalls at the interface of science and public policy to the end that the proper role of independent scientific panels in controversial siting cases may be better defined and implemented.

INTRODUCTION

In a paper presented last year at Waste Management '95, we reported on the National Academy of Sciences/National Research Council's (NAS) review of the proposed low-level radioactive waste (LLRW) disposal site at Ward Valley, California. ("The National Academy of Sciences as 'Science Court': Review of the Ward Valley Site by the Board on Radioactive Waste Management.") In March, 1994, Secretary of the Interior Bruce Babbitt requested the Board on Radioactive Waste Management (BRWM) of the National Research Council to review the "earth sciences concerns" in a critical report on Ward Valley written by three geologists, the so-called "Wilshire Report." (The scope of the review was later expanded to add two environmental issues, revegetation and protection of the desert tortoise, a threatened species). Release of the Academy's report was delayed until May, 1995, several months after Waste Management '95. Therefore, last year's paper was limited to discussions of the scope of the NAS study, the committee's procedures, political antecedents to the Secretary's request, and several issues raised by the Academy's review procedures

including charges of bias made by Ward Valley opponents about the composition of the review committee and the Academy's response to those charges. Other issues identified were uncertainty as to the role of the U.S. Nuclear Regulatory Commission's regulations in the deliberations of the committee and the Secretary's failure to say how the Academy report would be used in the federal administration's decision-making on the State of California's request to purchase 1,000 acres at Ward Valley from the U.S. Bureau of Land Management for use as the site of the Southwestern Compact's regional LLRW disposal facility. It was also noted that the Academy's review process had encouraged the U.S. Geological Survey to accelerate completion of a report on characteristics of the unsaturated zones at Beatty, Nevada and Ward Valley and had stimulated the U.S. Nuclear Regulatory Commission (USNRC) and the Idaho National Engineering Laboratory to review estimates of the amounts of plutonium expected to be disposed of at Ward Valley over its thirty-year operational life. (The new estimates are considerably lower than earlier estimates and also considerably less than experience at old disposal facilities.)

HIGHLIGHTS OF THE ACADEMY REPORT

With the release of the NAS report on May 11, 1995, ("Ward Valley -- An Examination of Seven Issues in Earth Sciences and Ecology"), it is now possible to summarize and analyze its findings and to comment on the role of the report in the ongoing Ward Valley land sale (federal government to the State of California) and project development processes. The NAS report lays to rest charges by Ward Valley opponents that the disposal facility will pollute the Colorado River. ("...we believe it highly unlikely that significant amounts or radioactive material from the site would reach the ground water or the Colorado River.") The findings of the Academy report are consistent with decisions made in September, 1993 by the California Department of Health Services to certify the Environmental Impact Report and to issue a license to US Ecology, Inc. to construct and operate a LLRW disposal facility at Ward Valley.

At the news conference in Washington, DC at which the Academy report was released, George A. Thompson, Professor of Geophysics at Stanford University and Chair of the NAS Committee to Review Specific Scientific and Technical Aspects Related to the Ward Valley, California Low-Level Radioactive Waste Site made an opening statement which included the following summary conclusions.

"...the committee concluded that the potential transfer of contaminants through the unsaturated zone to the water table is highly unlikely. In the report we discuss a number of aspects of this potential transfer, and in none of these cases could we find a likely mechanism that would allow contaminants to reach the water table." "...even if all the plutonium at Ward Valley reached the river at the same rate it was disposed of, effects on the river-water quality would be insignificant relative to the background radiation levels currently found in the river. In other words, it would be well below accepted regulatory health standards. And I would emphasize again that we believe it highly unlikely that significant amounts of radioactive material from the site would reach the ground water or the Colorado River."

In responding to charges of committee bias in the selection and composition of the committee, Professor Thompson noted:

"In the past year, we have come under fire -- indirectly in most cases and directly in some -- for having conflicts of interest on the issue of

whether or not low-level nuclear waste should be stored at Ward Valley. It is certainly very true that most of us have been called upon in the past for advice pertaining to the implications of geologic processes for the safety of nuclear power plants and the disposal of radioactive wastes. For this very reason -- our scientific knowledge and experience with these issues -- we were asked to participate in the study. In order to properly evaluate the geologic and hydrologic issues under question at Ward Valley, it was immediately apparent that scientists with expertise on these specific issues would be needed.

"The committee was assembled by the National Research Council after having received names of experts from a range of organizations, including the Committee to Bridge the Gap, a public-interest organization that opposes the low-level waste site at Ward Valley. I should also note that the Research Council did not solicit suggestions for committee members from industry or organizations in favor of siting the waste facility at Ward Valley.

"Having said that, most of us at one time or another have received research funding from the Department of Energy, which as you know, was not the sponsor of this study, but is the primary agency for administering the federal government's nuclear weapons facilities. And several of us at one time or another have conducted or reviewed studies for the Nuclear Regulatory Commission or have worked for private industry on nuclear power and radioactive waste issues. One would be hard pressed, in fact, to find an expert on radioactive waste, or on hydrology and geology issues surrounding radionuclides, who has not lent their scientific expertise to industry or to government agencies."

In his summary statement, Professor Thompson touched on the fact that two of the seventeen members of the committee filed dissenting points of view in the report appendices:

"Two committee members dissented from the general conclusion regarding the potential transfer of contaminants through the unsaturated zone. One of them, Professor Oberdorfer, is here with us today. Their points of view can be found in Appendices E and F in the report. They emphasize the remaining uncertainties about the movement of water through the unsaturated zone, and as a result they were not willing to judge the likelihood of contaminants reaching the ground water as highly unlikely. In addition, the second dissenter, Dr. Mifflin, took a somewhat different view on the issue of revegetation at the site, which I'll discuss in a moment. On the other points in the report, these two members joined with the committee consensus."a

Professor Thompson noted that one of the committee's recommendations is for "ongoing data collection and continued evaluation." Some Ward Valley opponents have seized upon this recommendation to argue that additional data must be taken prior to transfer of the Ward Valley site to the State of California. But this was not the view of the committee majority:

"The entire committee agrees that additional analysis needs to be done. The majority of the committee believes that this could be done during construction and operation of the site. Ongoing review of the site, we feel, would build scientific assurance, credibility and public confidence in the monitoring program."

STATUS OF THE WARD VALLEY LAND SALE AND POSSIBLE CONGRESSIONAL ACTION

As of February, 1996, the Interior Department has not yet sold the Ward Valley land to the State of California. Last May, Interior Secretary Babbitt announced his intention to go ahead with the land sale -- but

with conditions. Some, but not all, of his proposed conditions are based on recommendations of the NAS report. A summary of those recommendations and of California's responses to them is attached to this paper as an appendix. California Governor Pete Wilson has objected to the Secretary's proposed conditions as intruding upon California's regulatory authority. In particular, Interior has insisted that it have a perpetual enforcement role with respect to the conditions and has demanded that the conditions be enforceable in court. California has argued that such a role for Interior is not appropriate for two reasons: one, USNRC, not the Department of the Interior, is the responsible federal agency which exercises oversight of Agreement State radiological health and safety programs, and, two, Interior lacks the necessary expertise. The state has also asserted that, as a regulator, it has available administrative remedies sufficient to assure safe operation of the disposal facility without resorting to litigation. Interior's response in an October, 1995 press statement was that "...the agreement must be binding and enforceable..." because "trust us will not suffice..."

The U.S. Department of Energy, responsible under the Act for providing technical assistance to the states for development of LLRW disposal facilities, has taken a very different view than that of the Department of Interior with respect to the state and federal roles in assuring safe disposal of LLRW. When requested by California Senator Barbara Boxer to assign a National Laboratory to undertake soil tests recommended by the NAS, Energy Secretary 'Leary declined unless the state decides it needs, and requests, analytical services "unique to the Department of Energy." "We believe the State of California, in its licensing role as authorized by the Nuclear Regulatory Commission, should determine how to implement the National Academy of Sciences' recommendation." The Academy report recommended that additional testing be done during the operational life of the disposal facility. Senator Boxer asked that the testing be done before sale of the Ward Valley land to the State.

Following release of the Academy report and Secretary Babbitt's decision to impose conditions on the land sale, negotiations between the California Department of Health Services and the Department of Interior took place. By September, it was clear that the state and federal governments were at an impasse. In September, California Governor Pete Wilson asked Congress for relief. In letters to Senator Frank Murkowski (R-Alaska), Chairman of the Senate Energy and Natural Resources Committee, and to Congressman Don Young (R-Alaska), Chairman of the House Resources Committee, Governor Wilson asked that Congress convey the Ward Valley site to California by statute. The Governor's request was considered and approved by both policy committees and a Ward Valley conveyance provision was included in the Budget Reconciliation Act approved by the Congress but vetoed by the President in December, 1995. The President's veto message includes a reference to Ward Valley which says that legislative conveyance of the land would be "without public safeguards." The President has been misinformed. All requirements of federal and state regulations will apply to disposal of low-level waste at Ward Valley along with the state's 130 license conditions. The fate of both the federal budget and the Ward Valley conveyance provision are uncertain as of February, 1996.

OBSERVATIONS

The Academy's Ward Valley review was on the project critical path for fifteen months from March, 1994 to May, 1995. While the NAS report was

pending, it was clear that the federal government would not act to sell the Ward Valley site to California. Indeed, a reasonable political interpretation of events is that the report was requested because the administration wanted to delay a decision on the State of California's application to purchase the land for the site. In a sense, the Administration's insistence that NAS "recommendations" be elevated to the equivalent of regulations (along with additional conditions invented by Interior), enforceable in the courts by Interior and perhaps by third parties as well, has kept the NAS review on the critical path delaying administrative action by the federal government to sell the land to the state.

At the time the NAS accepted Secretary Babbitt's request for a review of the issues in the Wilshire report, a license for the Ward Valley project had already been issued by the legally responsible state agency. Furthermore, the license and EIR certification were in litigation in state court. It appears that the Academy was not aware of these facts regarding the status of the project, and, equally disturbing from the point of view of predictable process, it is not clear that it would have made any difference to the Academy had it known this status. Litigation on the license and EIR certification was completed on January 18, 1996 when the California Supreme Court denied opponents' petition for review of an Appellate Court decision (October, 1995) upholding the license and rejecting all opponents' claims.

Both the California Department of Health Services and Cal Rad Forum urged the Academy's Ward Valley review committee to utilize the USNRC's regulations for LLRW disposal (Title 10 Part 61 of the Code of Federal Regulations) as the framework for their inquiry. This recommendation drew a chilly reception. When this same recommendation was made on December 15, 1994 to the BRWM at a meeting in Irvine, California, the response was that the Board does science, not regulations. It is only one of several ironies associated with the federal government's handling of the Ward Valley land transfer that the Department of the Interior has attempted to elevate the Academy's recommendations to the status of regulations. By entering a politically controversial siting case late in the game, and utilizing a review framework different from the legally applicable standards applied during license application and judicial review, the independent scientific advisory panel placed the licensee, other project proponents, and the state regulatory agency in a difficult situation. Under these circumstances, the project was subject to two, possibly different, standards of review, one established by statute and regulation, the other established ad hoc by the scientific panel.

Some have argued that independent scientific review can enhance public confidence in the scientific validity of a controversial technical project. However, this benefit can be limited in situations where the scientific issue of safety is not what really motivates opposition. It is an observation of the authors that opposition to LLRW disposal is often really a surrogate for opposition to the use of radioactive materials.

RECOMMENDATIONS

Independent scientific panels can play an important role at the intersection of science and public policy. This role is more appropriately undertaken early in a process when public policy is being formulated generically and regulatory standards to implement that policy are being considered, or in early review and evaluation of data, rather than later, after legal regulatory standards have been adopted and

applied in specific cases of license application review. Certainly, to undertake independent scientific review after a license has been issued and is in judicial review is to risk serving the promoters of delay. Independent scientific groups should be wary of situations where they may find their review on the critical path of a specific project or where their work effectively constitutes an appellate review competing with the courts.

With respect to specific projects, and from a structural point of view, independent scientific advisory panels can work most effectively if they are advisory to the license applicant or to the regulatory agency rather than to agencies outside of the legally established regulatory framework. This will maintain political accountability with those organizations to whom responsibility and authority have been assigned by law.

While it is often argued that additional scientific review will allay the fears of the public and political leaders in controversial decisions, science can only inform, but it cannot make, decisions legally reserved to the political leaders. A surfeit of science is no substitute for political will.

When called upon to resolve controversy that is essentially political, scientific groups would do well to heed the advice of Hippocrates (Epidemics, Book 1, Chapter 11): "First, do no harm."

Summary of California's Response to National Academy of Sciences' recommendations

Recommendation: Install monitoring stations in both the unsaturated zone and saturated zones to supplement the site characterization database as well as to expand the baseline data for operational and post-closure monitoring.

Response: The state plans for operational and post-closure monitoring programs are consistent with this recommendation.

Recommendation: Make Cl-36 determinations and add three groundwater monitoring wells (for a total of eleven) to planned monitoring program.

Response: The recommendation will be incorporated into programs for monitoring for water content, water potential, tritium, groundwater levels, vertical hydraulic gradient, groundwater quality, etc.

Recommendation: Avoid conditions that could cause lateral flow in and surrounding the disposal trenches.

Response: The state has already required US Ecology to remove shallow caliche layers under each of the perimeter berms during construction in order to disrupt the lateral continuity of the caliche layers and prevent lateral flow.

Recommendation: Re-initiate formal consultation with the U.S. Fish and Wildlife Service on the desert tortoise.

Response: Such formal consultation has already begun and will be completed within a few weeks.

Recommendations: The NAS Committee made several recommendations concerning investigational and action levels for unsaturated zone monitoring.

Response: An already established license condition requires the licensee to develop investigation and action levels for the unsaturated and saturated zone monitoring programs, and the Environmental Monitoring Report establishes the investigation and action levels for tritium. Operational procedures approved by the state address potential accidental releases and appropriate remedies during the operation of the disposal facility. Performance assessments of the postclosure period indicate that

off-the-shelf remediation plans are not needed, rather, there is sufficient opportunity to develop and implement remedial measures specifically for any actual, post-closure release of radionuclides, should an unlikely event occur. These existing and proposed requirements fully address the committee's recommendations in this area.
Recommendations: Give significant emphasis to the design and performance testing of the trench cover demonstration units and the revegetation program.
Response: The state agrees that significant emphasis be given to the trench cover demonstration program, and many of the specific recommendations of the committee, such as testing of irrigated and non-irrigated areas, are already in the state plans. However, the state opposes a general research and development program (and an increase in the number of trench cover demonstration units) because of the increased amount of land that would be impacted by such a program.
Recommendation: Establish an independent third-party review group as a means of increasing the level of public confidence in the program.
Response: The process already laid out provides ample opportunity for all interested and affected parties, as well as the general public, to participate in an open and timely manner. The state's periodic evaluations of the site monitoring data will be publicly available. The state will continue to seek independent peer review on specific issues or concerns, including those mentioned by the NAS committee.
Recommendation: Monitor the stability of the site surface, specifically for erosion, ponding, and any subsidence of trench covers, and take appropriate maintenance actions.
Response: The state has always planned to take such actions, with monitoring to continue for at least 100 years after the site is closed, and the state will continue the monitoring and maintenance activities for as long as there is an observed need for such activities, even beyond the 100 year period if necessary.
Recommendation: Incorporate an engineered slope and lined channel for conveying storm water around the west, north, and south sides and corners of the flood protection berm.
Response: The state prefers to allow any infrequent runoff to spread across the existing, shallow alluvial surface for removal by evapotranspiration rather than to create and area of concentrated flow and potentially concentrated infiltration, as the synthetic liner would fail over time.

Chem-Nuclear Systems, Inc.

ABSTRACT
Development of disposal sites for low-level radioactive waste is a complicated legal, regulatory and public sector process. Development of the low-level radioactive waste disposal facility to support generators in Illinois and Kentucky is well under way. Significant progress has been made to re-engineer the siting development process capitalizing on prior lessons learned and a recommitment from Illinois state leadership assuring the future success of the program. Comparisons of why this new process will succeed are the major focus of this paper. Specific changes in approach from the previous process including changes in the Illinois Management Act (Management Act), creation of the Illinois Low-Level Radioactive Waste Siting Task Group (Task Group), new roles for the Illinois State Geologic Survey and Illinois State Water Survey (Scientific Surveys) and the Illinois Department of Nuclear Safety (IDNS), a new contractor reliance approach and increased confidence on the "science" are the major contrasts between the previous process and the new process currently underway.

INTRODUCTION

Prior to 1980, all nondefense low-level radioactive waste (LLRW) generated in the U.S. was shipped for disposal to six commercial LLRW facilities, including the LLRW facility near Sheffield, Illinois. By 1979, only three of these disposal facilities were still in operation. The facility near Sheffield was closed in 1978 following a refusal by the NRC to grant a license for an expansion of the site. The remaining facilities were located in Nevada, Washington and South Carolina. Following a series of packaging and transportation incidents at each of the sites, the governors of those states took steps to reduce the volume of waste coming into their respective states and put pressure on Congress to create a more equitable system for disposal of national LLRW.

In response, Congress passed the Low-Level Radioactive Waste Policy Act (Policy Act) of 1980. This act established a federal policy that each state should be responsible for providing disposal of commercial LLRW generated within its borders by 1986. The Policy Act also encouraged the formation of interstate compacts to manage LLRW on a regional basis.

In April 1980, then Governor James Thompson signed an executive order creating the Illinois Department of Nuclear Safety (IDNS). The mission of this newly created department was to protect the public health and safety of the Illinois citizens from the potential hazards of ionizing radiation.

By 1985, it was apparent that no state or compact would be able to meet the 1986 deadline for LLRW disposal, so Congress passed the Low-Level Radioactive Waste Policy Amendments Act (Amendments Act) of 1985. This new act extended the deadline for providing final LLRW disposal to 1996 with interim disposal provided by 1993. The act further established a system of milestones and penalties for the states and compact to meet.

Between 1984 and December of 1992, the Department followed a LLRW management system which included a siting process, public participation plans, community benefit plans, research studies to develop siting criteria, contractor qualification and hiring process, and development of licensing regulations compatible with federal guidelines. The reasons the first process failed was that the initial process was bounded by weaknesses in the Illinois Management Act, dependance on the Department to serve as both site promoter and site regulator, and attempts by the Department to accelerate selection and licensing of the Martinsville

site. As determined by the Illinois Low-Level Radioactive Waste Disposal Facility Siting Commission (Siting Commission) after its 72 days of hearings, the Department's rush to judgement suggested that politics appeared to take the lead over science in the selection of the site. A thorough evaluation of the failed process would need to be undertaken and changes made for any new siting process to succeed.

From January 1992 until late summer 1993, the Department along with its contractor, and major waste generators reviewed siting processes being developed and siting activities underway in other host states nation-wide. Out of this review grew the newly re-engineered and redefined process being implemented today.

THE ORIGINAL PROCESS

The Illinois Low-Level Radioactive Waste Management Act of 1983, as amended, made the Illinois Department of Nuclear Safety responsible for selecting a site for disposal of LLRW in conjunction with licensing a disposal facility. The Department had developed a program and adopted a schedule to allow the new regional LLRW disposal facility to begin receiving LLRW by 1993. To fulfill this mandate the Department, as shown on the Process Flowchart, Fig. 1, planned to locate several large candidate areas with technically excellent features for disposal of LLRW. To identify from these areas several potential alternative sites. Designate from the alternative sites, a couple of sites for detailed geotechnical characterization and environmental study. Evaluate the results of these investigations and select one site for the development of the disposal facility. The selection of a final site had to meet all of the following criteria as set forth in the Management Act:

Fig. 1

1) The site shall be located so that the public health, safety, and welfare will be protected.

2) The site shall be located in a suitable geologic and hydrological medium.

3) The site shall be located so as to minimize the possibility of radioactive releases into groundwater utilized as public water supplies.

4) The site shall be located outside the boundary of the 100 year flood plane as determined by the Department of Transportation.

5) The site shall be located so as to consider the distance necessary for transportation of low-level wastes and so that the impact on existing traffic flows is minimized.

6) No low-level radioactive waste disposal facility shall be located in or within 1 1/2 miles of the boundaries of any municipality unless approval is given by the governing body of that municipally.

7) No low-level radioactive waste disposal facility shall be located in an area of a county situated more than 1 1/2 miles beyond the boundaries of a municipality unless approval is given by the governing body of that county.

The Department had virtually unlimited authority to pursue this process. It could choose its contractors for the detailed studies, it could choose its siting criteria, it could ultimately choose its own site. As this process began to bog down in technical disputes and semantics, it became apparent the original time table would not be met. The acceleration of the entire process to stay on schedule may have been responsible for untimely management decisions, which, when viewed externally from the process, appeared to call the entire siting process into question.

Following an investigation by the Illinois Senate Executive Committee of the LLRW siting process in the spring of 1990, the Illinois General Assembly amended the Management Act to create the Illinois Low-Level Radioactive Waste Disposal Facility Siting Commission (Siting Commission). The commissions directive was to evaluate the safety and suitability of any site proposed by the director of the Department of Nuclear Safety. In August 1990, the Siting Commission held its first meeting. On October 9, 1992 after 72 days of public hearings and volumes of testimony by all parties involved, the Siting Commission issued its final order relative to Martinsville Alternative Site, "...the Commission finds and determines that the site with respect to a facility of the proposed design does not meet all the criteria set forth in subsection (b) of Section 12 of the Management Act by a preponderance of the evidence." The looseness of the Management Act had allowed the process to become very disjointed, leading to its final end with the Martinville hearings, and Siting Commission ruling.

THE NEW PROCESS

During the spring Legislative session in 1993, significant changes were made to the Illinois Management Act. Among these important changes the establishment of the Illinois Low-Level Radioactive Waste Siting Task Group (Task Group) as well as doing away with original seven criteria. The Management Act as amended (August 1993) authorized a second site-selection process. Responsibility for the initial part of the process, up to site characterization and licensing, was assigned to the following entities: the Task Group, the Illinois State Geological Survey and the Illinois State Water Survey, and the contractor chosen by the Department. This new process set forth decreet steps to follow to ensure a successful conclusion. The Illinois LLRW Siting Process flowchart, Fig. 2, depicts how these steps during this endeavor will proceed.

The Task Group was mandated to assume responsibility for two critical steps:

Fig. 2

1) Development of site-selection criteria for the LLRW disposal facility and

2) Determination of whether three proposed sites meet the site-selection criteria.

The Management Act emphasized the importance of science above other considerations in the siting process by requiring (1) that four of the nine members of the Task Group "shall have expertise in geology, hydrogeology, or hydrology" and (2) that the "[p]rinciple criteria shall relate to the geographic, geologic, seismologic, tectonic, hydrologic and other scientific conditions best suited" to an LLRW disposal facility. The Act also directs the Task Group to consider supplemental criteria, such as "land use, economic, transportation, and any other matter identified by the Task Group as relating to desirable conditions for an LLRW disposal facility."

It is important that the roles of the entities involved in the site-selection process not be confused. In particular, the role of the Task Group in developing criteria for screening the state and narrowing the available choices should carefully distinguished from the role of the Department in licensing the disposal facility and regulating its operation and closure.

Once the Task Group adopts its final set of criteria, the Governor appoints a replacement for the Director of the Illinois Department of

Nuclear Safety who is now removed from the Task Group. These final criteria are then turned over to the Scientific Surveys who apply them to screen the entire state and identify at least 10 locations of at least 640 acres each that appear likely to meet the siting criteria. During this process any volunteer locations presented will be included for evaluation. A written report will be issued to the Task Group identifying the locations within the state.

After the Scientific Surveys identify at least ten or more locations, this list is then passed to the facility contractor, Chem-Nuclear Systems, Inc. (CNSI) who will evaluate the locations and winnow the list to three promising sites. During this process limited intrusive field investigations will be conducted when required. Once three site are identified, the contractor will prepare a report and the Task Group will hold public meetings to discuss the issue of whether the three sites meet the siting criteria. Once concurrence and approval is given by the Task Group that the three sites indeed meet the criteria, they will be passed back to the contractor who will select one site for final evaluation, and will notify the Task Group of the Site selected. At this time, the Illinois LLRW Siting Task Group is abolished, having finished their task. CNSI will then conduct intensive field investigations and site characterization of the selected site. Concurrently, CNSI will prepare a license application for the site. Once this phase draws to a close the contractor will submit to the Illinois Department of Nuclear Safety, Licensing Division its license application for review.

The Department will review the application following the sequences shown in the license application review process, Fig. 3. Once all licensing concerns are addressed, a Notice of Intent to Issue License will be given. The process will now proceed in one of two avenues. First, if there is an objection to the issuance of a license then a hearing will be conducted. During this process a hearing officer will be appointed to preside over an adjudicatory hearing where the burden of proof is on the objector. The hearing officer will recommend to the Director of the Department whether or not a license should be granted. Second, if no objection is forth coming, the Department will issue a license for the construction. During the construction, the Department inspects all phases of work for conformity with the license application. Once construction is completed, the Department will amend the license to authorize receipt and disposal of waste. Where upon LLRW disposal operations begin.

Fig. 3

CONCLUSIONS

Since 1980 a great deal has been accomplished toward successfully siting a LLRW facility in Illinois. The first process failed for several reasons including the Siting Commissions perception that politics and the need for local approval overrode the scientific investigations into site suitability; the Department's dual role of site promoter and regulator; and the apparent rush to meet federally mandated deadlines. A relational chart of the New process and the Original process depicting similar siting activities is shown in Fig. 4. As determined by the Siting Commission after its 70 plus days of hearings, the Departments rush to judgement appeared to caused politics to take the lead over science in selection of the site.

Fig. 4

Illinois, after the failed first siting process and the experience of the Siting Commission, evaluated the short comings of its first process and

set in motion a comprehensive program to ensure the ultimate success for LLRW disposal. This process includes a definitive "road map" for the siting activities. Eliminates the Department from the roles of site promoter; and focuses the Department on its role as regulator. This process also places specific emphasis on scientific discipline, while allowing private enterprise to develop a sound working philosophy for the safe management of low-level radioactive waste disposal in the state of Illinois.

THE NEW PROCESS FOR SELECTION OF A SITE FOR LOW-LEVEL RADIOACTIVE WASTE DISPOSAL FOR ILLINOIS

Paul Corpstein
Tom Blackburn
Chem-Nuclear Systems, Inc.

Ralph Stein
Golder Federal Services, Inc.

ABSTRACT

Chem-Nuclear Systems, Inc. and its technical contractors Golder Associates, MK-Company, and Hanson Engineers have developed a new process for selection of a Low-Level Radioactive Waste Disposal Facility in Illinois. Regulatory framework for the new process are contained in changes to the Illinois Management Act approved by the Governor in 1993. These changes created the Illinois Task Group which adopts criteria, assign's the Illinois Scientific Surveys the responsibility to initially screen the state, gives Chem-Nuclear responsibility to assess locations in Illinois against criteria and select and characterize a site to serve the generators in Illinois and Kentucky for the next 50 years, and allows the Illinois Department of Nuclear Safety to resume its mandated role as regulator of Illinois generators, users, and disposers. The new process concedes the old process to history and starts afresh with many new concepts. Putting the site selection, characterization and licensing responsibility totally in Chem-Nuclear hands allows the company and its contractors to develop an integrated process which will use newly proven technical and analytical processes and will use performance assessment to guide the siting decision process and support the licensing process. Unlike the previous effort to site a facility in Illinois, the new process is clear, unambiguous and explicit in its intent to have science rather than politics as the driver and to incorporate lessons learned from the previous siting effort. This paper describes the new process from Management Act amendment to selection of the site by Chem-Nuclear.

INTRODUCTION

The State of Illinois has dramatically improved the methodology that will be employed to select the site for development of a low-level radioactive waste disposal facility to serve the disposal needs of Illinois and Kentucky. The site selection process developed by Chem-Nuclear Systems, Inc. (Chem-Nuclear), and its project team of Golder Associates Inc., Hanson Engineers Inc., and Morrison Knudsen Corporation is founded on the positive aspects of the lessons learned from the previous siting effort. The basis for the new process will be the utilization of performance assessment modeling and decision analysis methodology to perform Value-of-Information analyses during its five-step site selection process. Use

of performance assessment modeling and decision analysis methodology will lead to a more focused management and refined utilization of resources dedicated to field investigations that will be used in selection of the site for the Illinois Low-Level Radioactive Waste Disposal Facility (ILLRWDF).

BACKGROUND

The site selection process Illinois employed in the late 1980s, during its first effort to identify a site for the development of the ILLRWDF, was a process based on acceptance of the site by the unit of local government (either a municipality if within 1.5 miles or the county if not located within 1.5 miles of a municipality). This process lead to the identification of the Martinsville Alternative Site. The site selected was ultimately eliminated from consideration after the Siting Commission reviewed the site selection process and the technical merits of the MAS and found them to be unacceptable. As a result of this first siting effort, the Illinois Legislature, through the Illinois Department of Nuclear Safety, established a revised siting process to identify a site suitable for the ILLRWDF.

The revised site selection process is substantially different from the previous one that resulted in the selection of the MAS. The major changes embodied in the new process:

Establish a Task Group to develop site selection criteria;

Divide the siting process into two distinct phases;

Removes acceptance of the site by local government; and,

Establishes a process allowing for the acceptance and evaluation of volunteered lands.

Task Group - Formed by the amendment of the Management Act, the Task Group consists of nine voting members, three of whom are State officials (the Directors of the Illinois Department of Nuclear Safety, the Illinois Environmental Protection Agency and the Illinois Department of Natural Resources). Four of the additional members have expertise in the fields of geology, hydrogeology or hydrology. Of the two remaining additional members, one is a member of the public with environmental experience and the other has at least five years experience in local government. In addition, there is one non-voting member.

The Task Group has been given the responsibility to accomplish several important tasks including:

Development (including public review and comment and holding public hearings) of the site selection criteria;

Acceptance of the locations identified by the Scientific Surveys; and,

Conducting meetings on, and approval of the three sites identified by Chem-Nuclear;

After identification of one site for characterization, the Task Group will be abolished.

Site Selection Process - The site selection process will be conducted in two distinct phases. The first, conducted by the Scientific Surveys, will involve Statewide screening. The Surveys will conduct a broad screening of the State of Illinois using the criteria developed by the Task Group. Additionally, the Scientific Surveys will evaluate all lands volunteered against the site selection criteria. The result of the Statewide screening will be the identification of at least ten locations, each of at least 640 acres in size. The results of the Statewide screening and evaluation of volunteered locations will be published in a report and submitted to the Task Group.

The second phase of the site selection process will be conducted by the Chem-Nuclear team. After identification of at least ten locations by the Scientific Surveys, Chem-Nuclear will conduct evaluations, including possible field investigations, of the locations. Upon completion of these evaluations, Chem-Nuclear will select three sites, of at least 640 acres that appear promising for development of the ILLRWDF. In selecting the three sites, Chem-Nuclear will give preference to sites in Locations that were volunteered, unless those sites are clearly less promising than sites in other locations. Chem-Nuclear will then prepare a report fully describing the siting evaluations and submit the report to the Task Group.

Upon receipt of the siting report, the Task Group will conduct public meetings on three sites selected. At the public meetings, Chem-Nuclear will present the results of the siting evaluations. Also during the meetings, the Task Group will receive oral or written information from the public regarding the sites under consideration. Following the meetings, the Task Group will determine if the three sites satisfy the site selection criteria adopted by the Task Group.

Following the Task Group's decision that the three sites meet the site selection criteria, Chem-Nuclear will select one of the three sites for characterization and notify the Task Group of the site selected. Upon receipt of the notification of a site selected, the Task Group will be abolished and all of its records transferred to IDNS.

Public Acceptance - The new site selection process does not require that formal acceptance by the public nor local governing bodies be obtained prior to selecting a site. The new process is based on selecting the premise that site selection should be driven by the technical merits of the sites rather than by the public's or government's acceptance of the sites.

Volunteered Lands - During the new siting process, lands that are volunteered by land owners or units of local government will be given selection preference unless they are clearly less promising than other lands identified as meeting the Task Group's site selection criteria. Lands may be volunteered at two times during the site selection process. The first period for accepting volunteered lands will be within 45 days of the formal adoption of the Task Group's site selection process. The second period will be during the first 90 days of Chem-Nuclear's site selection activities.

IMPROVEMENTS TO SITE SELECTION IN ILLINOIS

Unlike the previous "greenfield" effort to select a site in Illinois, the new site selection process which the Illinois legislature has promulgated and the Governor has signed into law is clear, unambiguous, and explicit in its intent to lay out a process which capitalizes on the issues raised and lessons learned in the previous effort. The new improvements in the Illinois Process explicitly altered inherent conflicts in the Act and will lead to a safe, suitable and environmentally sound site for Illinois and Kentucky generators to use for the next 50 years.

In the new process, the contractor, Chem-Nuclear, plays a significantly enlarged role, the Illinois Scientific Surveys play a new and expanded role, the Department of Nuclear Safety's role is aligned strictly with its regulatory mission, the Task Group is formed, serves, and is abolished and the general public has an opportunity to participate in the process from criteria development to site operations. Figure 1 shows a brief view of the major process milestones divided into six project life

phases. As of February 1996, the project is in phase I and is beginning the process of performing statewide screening to identify 10 or more locations in Illinois which appear suitable to host the LLRW Facility.
Fig. 1
IMPROVEMENTS IN THE ACT
The Illinois Management Act , amended by House Bill 1918 and signed in March of 1993, was streamlined and strengthened to assure that it did not fail to guide the Illinois participants to a successful conclusion in this, the second attempt to develop a LLRW disposal facility in Illinois. Assurance for success, especially in LLRWDF Development processes, can be and is defined as "incorporation of change based on past failures to improve probabilities of success". In Illinois, this is exactly what has transpired and what is being implemented.
The new process concedes the old process to history and starts afresh with several new concepts: The initial process in Illinois put the Illinois Department of Nuclear Safety in a position where it was both site developer and site regulator. In this obviously conflicting role, the Department had to promote, seek, find, market, and regulate the process. In the new process, the Department is a participant until the criteria are adopted. At that point, the Department plays no active role in site selection and is not a process player until Chem-Nuclear submits a license application to them.
The previous Management Act established general criteria that provided minimal technical direction to use to establish a site. Unfortunately, the criteria that were developed under the Act fell short of the technical specificity needed to guide the process participants to find a suitable site. Hence, IDNS, the regulator, had to step up and assume responsibility to develop the site selection framework including specific technical criteria to use to qualify sites. Revisions to the Management Act created the Task Group which has the responsibility to develop the needed technically specific criteria. The process employed by the Task Group as specified in the Management Act to develop these criteria, specifically lays out technical discipline experts to sit on the Task Group, specifies technical areas which must be addressed by criteria and mandates public participation into the entire process.
The Act, as a result of detaching the IDNS from the process, separated the site selection decision from the more rigorous health and safety decisions made during the licensing process. This in fact puts the responsibility to make decisions directly where it should be. The Task Group makes criteria decisions, the Surveys make broad statewide screening decisions, Chem-Nuclear must make precise technical comparisons of sites to selection criteria to find licensable sites, and the Department makes licensing decisions.
The Act dealt the responsibility for statewide screening and broad application of the Task Group's criteria to the State Scientific Surveys. This action eliminated the Department's role in the previously controversial technical part of the process and as well put the State's trusted technical body in charge of one of the most crucial parts of the process. The Surveys will eliminate broad areas in the state from further consideration based on their many years of experience in statewide studies and investigations, and will provide to Chem-Nuclear those areas that appear likely to meet the Task Group criteria.
Another significant change in the Act, is to delegate to the contractor, Chem-Nuclear, the direct responsibility to select a site which it will

have to characterize, defend during licensing and eventually operate. This puts the responsibility to perform directly on the company who stands to capitalize the most from the success of the siting process. The original process had the drawback of putting the IDNS in the role of needing to market the siting. The Department had to try to attract communities to volunteer since a community selected without consent could easily pass a resolution stating that the community did not want the site and they were no longer in consideration. This "promotional" role for the Department was one of the most significant changes in the Act.

A final change that the Act brought about is the removal of politics from the process and the inclusion of the public into all phases of site development, from Task Group proceedings and Scientific Surveys screening to Chem-Nuclear selecting a single 640 acre parcel of land in Illinois to license. This was accomplished by removing local referendum which restricts the ability of a city management to override the wishes of the community, and opened the process to all members of the public, anywhere, anytime.

THE IMPROVED SITE SELECTION PROCESS

The project participants as shown on Fig. 2 each have a defined role as outlined in Section 10 of the Management Act. The new and improved process includes formation of the Task Group, the Task Group developing criteria with which to screen the state, and Chem-Nuclear developing criteria with which to evaluate safety/licensing, environmental, and operational qualifications of the locations determined by the Surveys.

Fig. 2

The Task Group Criteria are intended to serve as a reasonable and objective basis to eliminate certain lands of the state from consideration, to select other lands for siting a disposal facility, and to determine if the three sites offered by Chem-Nuclear are promising for the development of a disposal facility. However, the Task Group Criteria do not address all necessary requirements that the site and disposal facility will have to meet.

Chem-Nuclear will develop additional safety/licensing, environmental and operational criteria to use in selecting three sites from the Scientific Surveys multiple locations. These criteria include Mandatory Criteria , which define characteristics a site must (or must not) have to be licensed; Avoidance Criteria which define less desirable conditions, and Preference Criteria which define desirable conditions. Chem-Nuclear Avoidance and Preference Criteria are comparative in nature and can only be applied to land which meets both the Task Group Criteria and the Chem-Nuclear Criteria.

USE OF PERFORMANCE ASSESSMENT FOR SITE SELECTION AND CHARACTERIZATION

The general practice, in the past, for site selection and characterization of nuclear waste disposal facilities, was to gather as much information on the site and region surrounding the site as possible, analyze the information, and then make a choice of a site. The initial appearance of performance assessment (PA) was usually in a safety report or the license application following the detailed characterization of the site.

This approach to siting underwent a change, starting in the mid-1980's, as part of the site characterization program for a high level nuclear waste site. There were three factors that drove this change: first, the testing program had grown so large that it was too costly and time consuming to perform all the tests that had been identified by the

researchers; second, there was a need to identify those tests that were important to determining whether or not a site was suitable; and third, the period of performance was so long that using a deterministic approach was not suitable in a licensing environment. The combination of these three factors resulted in PA assuming an important role in the siting process. For the Illinois siting process, PA plays a role from the start of siting to both guide the siting process and support the licensing proceedings to help ensure that the testing and data needs are well defined and consistent with what is needed to ultimately site a disposal facility. The Illinois siting program must acquire all the data needed to make a siting decision but without engaging in a testing program that is far in excess of the requirements. PA will greatly assist the project in obtaining only the appropriate data.

PERFORMANCE ASSESSMENT IN THE SITING PROCESS

As noted in the "Improvements to Site Selection" section, The Illinois Scientific Surveys engage in Statewide screening to find 10 or more locations that appear likely to meet the Task Group Criteria. Once this operation is complete, Chem-Nuclear then proceeds to reduce these 10 or more locations to three (3) sites that appear promising for development of a disposal facility. It is during this stage where the locations are being reduced to 3 sites and one of the sites is selected for detailed site characterization, that PA is applied.

APPLICATION OF PERFORMANCE ASSESSMENT

In simple terms, PA is a computational method that models various parameters which are important to determining the suitability of a site and ties the parameters together in a relational manner to predict overall system performance. The important parameters are:

- Disruptive events (human intrusion, earthquakes, etc.) that can affect the disposal site performance;
- Performance of the engineered barrier system;
- Radionuclide transport pathways through the geosphere; and
- Radiation dose at the disposal site boundary.

Initially, following the identification of the 10 or more locations by the Illinois Surveys, the locations will be evaluated using the Task Group and Chem-Nuclear Criteria. However, there are criteria that cannot be evaluated without site-specific field data, especially, criteria related to subsurface geology and hydrologic conditions. It is the availability of these additional site-specific data that will serve as the initial input into the preliminary PA model. The model, however, at this point in the process has only limited field data which can be used for evaluation of the locations. Nevertheless, PA will be used to gain information on the total system performance, and aided by Value-of-Information analyses, will guide the subsequent collection of field data.

VALUE-OF-INFORMATION ANALYSES

Value-of-Information Analyses (VOI) will be used to assist in the design of data collection activities at various stages of the siting program. A VOI analysis explicitly compares proposed testing decisions to ensure that the testing selected offers the value in return of useful data. This technique is based on an iterative PA process where as more data is collected it is added to the data base of the model and the program is run with the enhanced data base. By examining the output and performing sensitivity analyses, it will be possible to identify which activities (data collection) will be most critical to rapid and accurate determination of site and design suitability and provide the greatest

reduction in overall uncertainty, particularly in the overall uncertainty of the preliminary PA results.

DECISION ANALYSIS AND PEER REVIEW

The use of PA and VOI, as noted above, will provide a framework for constructing and implementing the siting program. In addition, PA will provide a basis for selection of sites to present to the Task Group, and ultimately aid in the selection of one site for development as a disposal facility. The PA will provide the decision maker with the probabilities of a particular set of sites or a site having a "likelihood of success". However, PA alone will not necessarily provide a clear path to selection of site(s) since there will be uncertainties associated with the collection of data and the probabilities that a site will perform as predicted for many hundreds of years.

Because of the uncertainties in performance, the Program will use a decision-analysis approach, possibly using techniques such as the multi-attribute utility method where the data on the site(s) is subjected to an elicitation routine to provide additional information on the expected site(s) performance and the "likelihood of success". In addition to a formal decision-analysis approach, the Project will make use of peer review to provide the decision maker with independent evaluation of specific technical issues. The ultimate decision maker on selection of three (3) sites, and subsequently, a single site for licensing, is the Project manager.

Making the Site Selection Decision

The process which Chem-Nuclear will implement to make the site selection decision can be described in general terms as follows: Using an iterative procedure, the 10 or more locations provided by the Surveys will be examined using both non-intrusive and intrusive testing to enlarge and enhance the data base, and with the assistance of PA and decision-analysis, reduce the locations to three (3) sites and ultimately to one site. A typical process is shown in Fig. 3. This figure shows the iterative process as the large land areas, associated with Locations, are successively reduced to smaller areas, then to three (3) sites. A similar process is used as the three (3) sites are reduced to a single site which is then subjected to site characterization and licensing. As the process unfolds, an evaluation is made of the probability that each area/site will comply with the criteria and the licensing requirements. Decision analysis and PA will be used to guide the testing, as well as to identify areas and sites which should be dropped from the list of candidates or retained. This iterative process continues throughout the siting stage of the program.

Golder Associates
ABSTRACT
The New York State Low-Level Radioactive Waste Management Act, as amended, requires that the New York State Low-Level Radioactive Waste Siting Commission (Siting Commission) select a disposal method or methods before selecting a disposal site. The Siting Commission chose to evaluate six candidate disposal methods -- above-grade vaults without an earthen cover, covered above-grade vaults, below-grade vaults, augered holes, a vertical shaft mine, and a drift mine -- in great detail before making a choice. The paper describes the evaluations and comparisons of the six methods, with emphasis on the performance measures of most interest in making such comparisons. The Siting Commission conducted the most detailed comparison of low-level radioactive waste disposal methods to date. In July 1995, it selected covered above-grade vaults, with both a drift mine or a vertical shaft mine as alternatives.
INTRODUCTION
In response to the federal laws on low-level radioactive waste disposal, New York enacted the Low-Level Radioactive Waste Management Act in July 1986 and amended it in 1990. The Act created a Low-Level Radioactive Waste Siting Commission with responsibility for selecting both a preferred method and a site for disposal of New York's low-level radioactive wastes. Under the amended Act, the Siting Commission was required to evaluate alternative disposal methods and select a preferred disposal method (or methods) before proceeding to select a site. The process for method evaluation and other steps in the method selection process are described in some detail in Ref. 1-3. It is summarized in the following paragraphs.
Based on the input received during a public outreach program and the review of previous work by the Commission and others, six candidate disposal methods were evaluated in the disposal method selection process:
- Above-grade vaults without an earthen cover (uncovered above-grade vaults).
- Covered above-grade vaults.
- Below-grade vaults.
- A vertical shaft mine.
- A drift mine.
- Augered holes.

This group of candidate disposal methods covers the full range of major conditions affecting permanent low-level radioactive waste disposal. It also includes the two alternative methods specifically mandated for consideration in the 1990 amendments to the 1986 Act: deep vertical shaft mined disposal and above-ground monitored retrievable disposal (represented by above-grade vaults without an earthen cover).
The Commission evaluated the six candidate disposal methods with respect to the seven evaluation considerations listed in Table I. The relative abilities of each of the disposal methods to satisfy criteria that were formed from the evaluation considerations were assessed. Factors for use in developing criteria and in evaluating the disposal methods are also shown in Table I. This paper summarizes the results of the evaluation and indicates the methods preferred by the Commission.
Table I
In the spring of 1995 the New York legislature reduced the Commission's funding to a point where it was no longer able to operate. Prior to

ceasing operations, the Commission chose the tentative preferred disposal methods (the wording comes from the 1990 Amendments) described here. Presently there are no plans to continue to look for a disposal site in New York.

THE DISPOSAL METHODS EVALUATED

To perform comparisons of alternative disposal methods, the Siting Commission prepared conceptual designs for the six candidate methods. Those conceptual designs were intended to meet design requirements specified in New York regulations and to be of sufficient detail to enable objective comparisons of the six methods with the aim of selecting a preferred method (or methods). In fact, it was often necessary to add more detail to the designs than is typical for a conceptual design, in order to enhance public understanding of how a disposal facility would function. The conceptual designs are described in Ref. 4-5.

Some features are common to all six disposal facility designs. These include features such as buildings for the receipt of waste, the placement of waste in concrete overpacks called modular disposal units (MDUs), and conduct of administrative functions. The designs were based on the receipt of a total of 5.5 million cubic feet of low-level radioactive waste over 60 years. This waste volume corresponds to the most likely or "expected" case described in Ref. 6.

Conceptual designs were developed for generic disposal facility sites with characteristics based on Ref. 7, which provides information about the geology and hydrology of sites that are typical of the non-excluded areas in the State of New York. For the four near-surface methods (i.e., not mines), the generic site characteristics do not have a major effect on the designs, except that generally shallow groundwater conditions limit the depths to which waste can be placed below grade. Designs were prepared for the mine disposal facilities in four geologic media: shale, salt, limestone, and igneous/metamorphic rock. The designs for covered above-grade vaults, below-grade vaults, and augered holes have earthen covers placed over the concrete vaults or holes. Those earthen covers are 7 feet thick and consist of various layers of natural and man-made materials that serve functions such as prevention of water infiltration, prevention of animal and plant intrusion, and support of short-rooted plants at the surface. The conceptual designs were developed to allow comparison of the inherent features of the six candidate disposal methods. The designs were not necessarily optimized and, since potential sites were not known, they will probably be changed considerably if they are developed further. Table II provides information about some characteristic parameters of the conceptual designs. The parameters shown are some of those that were used in the detailed comparisons.

Table II

EVALUATIONS

Comparative evaluations were conducted of the ability of the six candidate disposal methods to satisfy the considerations and factors given in Table I. Both qualitative and quantitative evaluations of the methods were used, depending on the consideration or factor. Some factors were divided into several parts called measures, the measures were evaluated separately, and then the evaluations of the measures for each factor were combined. All evaluations were presented in the visual form illustrated in Fig. 1, showing the relative ranking for each of the six candidate disposal methods. Each ranking also contained a brief statement of the level of uncertainty associated with the evaluations. The ranking

in Fig. 1 is for Factor 5B, Confidence in Licensability. The evaluation for that factor was a qualitative one and above-grade vaults without covers were rated significantly lower than the other methods because they would probably not meet the present New York regulations for low-level radioactive waste disposal. The Siting Commission was unanimous, however, in its view that the most important factor in selecting a disposal method was the protection of the public health and safety; in this regard all but the Uncovered Above-Grade Vaults were rated favorably.

Fig. 1

Figure 2 shows the visual presentation of the relative ranking of the disposal methods for a measure used for Factor 1A, Protecting the Health and Safety of the Public. The evaluation for this measure, potential peak radiological dose to the public after closure, was quantitative. It was the result of detailed dose assessments for the 10,000 years after disposal facility closure, based on the conceptual designs and the generic site descriptions (8). Figure 2 shows that the uncovered above-grade vaults and mines in igneous or metamorphic rocks were estimated to give doses in excess of the limits prescribed by New York regulations. The poor projected performance of the mines in igneous and metamorphic rocks was based on geologic data available for New York. Dose projections for mines in limestone were very dependent on future drilling activities. Since limestone formations in New York are expected to always be overlain by shale or salt (7), no further analysis was made of this measure for limestone mines. Mines in salt and shale were projected to give very low doses.

Fig. 2

The abilities of the six candidate disposal methods to meet all 19 Factors listed in Table I were evaluated. However, not all of the factors or measures used to evaluate factors were found to be helpful in discriminating among the methods. In some cases, the measures were very similar for all six methods. In other cases, the impacts of the methods (for example, radiation doses to the public during normal operations, one of the measures for Factor 1A), while different, were so small that there was no significance to the differences. All of the measures and factors were divided into three categories after the evaluations were completed: those judged to be of little or no value in discriminating among methods, partial discriminators, and major discriminating factors. Table III shows the way the evaluations for the latter category were summarized. A similar table that was prepared for the partial discriminators is shown in Table IV. The entire set of evaluations is summarized in Ref. 9.

Table III

Table IV

SELECTION OF THE TENTATIVE PREFERRED DISPOSAL METHOD

The comparative evaluations were presented at three public meetings in March and April of 1995. The Commission decided not to assign numerical weights to the considerations and factors, or to give numerical ratings representing the abilities of the disposal methods to satisfy the considerations and factors. It was felt that numerical weights and ratings can portray a degree of objectivity that is not always supported by the available data and the level of design detail. Also, use of numerical weights can result in a lack of flexibility that makes it difficult to respond to public concerns. In its selection of the preferred methods, the Commission used a qualitative approach that represented the individual and collective judgements of its members. The

Commission members each weighed the advantages and disadvantages of the methods separately; any two Commissioners could have chosen the same method for somewhat different reasons. Although other methods (such as multi-attribute utility analysis) could have been used to compare the candidate disposal methods, it is believed that the final choice of preferred methods would be essentially the same.

The Siting Commission chose Covered Above-Grade Vaults as the Tentative Preferred Disposal Method. For the major discriminating factors (Table III), the Commission determined that Covered Above-Grade Vaults was rated more favorable for all factors. Covered Above-Grade Vaults would protect the public from radiological impacts (Factor 1A). There is confidence that the construction materials used would maintain their essential physical and chemical properties as long as necessary (Factor 3A). Monitoring to assure compliance with regulatory standards could be conducted without difficulty (Factor 4A). This method would allow for the retrieval of waste, either the entire volume of waste or only Class B and C waste (Factor 4B). The method offers flexibility in siting options; it could be used in a variety of locales and conditions (Factor 5A). There is confidence that the method could meet regulatory requirements and be licensed (Factor 5B). Finally, the projected total life cycle costs for this method compared favorably with other methods (Factor 6A).

The Covered Above-Grade Vaults were also rated more favorable for fifteen of the seventeen partial discriminating factors (Table IV). The only two factors where this method rated less favorable were relative resistance to inadvertent intrusion after facility closure (Factor 1C) and increased truck traffic in the host community because of the importation of materials for construction of the cover system (Factor 7A). Neither of these two factors was considered decisive.

Recognizing the need for flexibility in fitting a method to a site to be determined later, the Commission chose Mine Disposal (i.e., either a Drift Mine or a Vertical Shaft Mine) as an alternative Tentative Preferred Disposal Method. The two mine methods shared many similarities in terms of their design, function, and favorability ratings and can be considered variations of one method. If placed in certain rock media, such as shale or salt, both mine methods rated more favorable than three of the near surface methods for most of the comparative factors in Tables III and IV. A mine in shale or salt performed very effectively to isolate radioactive waste and protect public health and safety and the environment (Factors 1A, 2A, and 3B). A mine in igneous or metamorphic rock of the type typically found in New York was considered to be unsuitable, however, because of the potential for high postclosure peak radiation dose to the public.

The mine methods ranked less favorable than the Covered Above-Grade Vaults for a number of factors that the Commission judged to be important. As can be seen from Table III, the mine methods were rated less favorable than covered above-grade vaults with regard to the ability to monitor compliance (Factor 4A) and, for the vertical shaft mine, the cost of recovering or retrieving all Class B and C waste (Factor 4B). Factor 4B, Ability to Recover or Retrieve Waste, was evaluated separately for recovery or retrieval of all waste and for Class B and C waste only. They were also rated less favorable than covered above-grade vaults with regard to protection of health and safety of workers (Factor 1B), and operational cost sensitivity (Factor 6B). On the other hand, mines were rated more favorable than covered above-grade vaults in terms of their

resistance to inadvertent intruders (Factor 1C) and the amount of truck traffic near the disposal site (Factor 7A). The principal deficiencies in the other disposal methods are described in the following paragraphs.
Uncovered above-grade vaults were considered less suitable because the estimated potential doses to the public after closure indicated that this method may not be able to meet the regulatory performance objectives (Factor 1A); the method is not licensable under current New York regulations (Factor 5B); the vault concrete and reinforcing steel may not last long enough to provide adequate containment of radioactive contaminants (Factors 3A and 3B). This method is not as capable of protecting air, water, and biota (Factor 2A) and it is more vulnerable to earthquakes and other extreme events (Factor 3C).
Augered holes were judged to be less suitable for low-level radioactive waste disposal because they require a much larger land area, making siting much more difficult (Factor 5A); have higher costs as reflected in the present value of the facility (Factor 6A); have higher costs to retrieve or recover wastes in the postclosure period (Factor 4B). They are also less resistant to inadvertent intruders (Factor 1C) and, due to the large site size, have larger nonradiological impacts on land, water, and any nearby community (Factors 2B, 2C, and 7A).
Below-grade vaults were considered less suitable than the methods chosen because of the potential difficulty of finding a site in New York with a water table deep enough to accommodate the conceptual design for this method (Factor 5A); a depth of at least 30 feet is needed. Below-grade vaults were also found to offer less resistance to inadvertent intruders (Factor 1C). The possibility of covered vaults that are partially above and partially below grade was discussed but this approach was not evaluated. Had the method selection process continued beyond selection of a tentative preferred method, an evaluation of this hybrid approach may have been pursued.

FUNDING OPTIONS FOR TRANSPORTATION PLANNING ASSISTANCE TO STATES AND TRIBES

Judith Holm
U.S. Department of Energy

Waste Policy Institute

Audrey Adamson
Science Applications International Corporation

ABSTRACT
The projected volume of radioactive and mixed-waste material shipped by the U.S. Department of Energy is expected to grow significantly in the future as DOE waste management programs are fully implemented. Concerns raised by affected jurisdictions related to DOE transportation activities are carrier qualifications, vehicle inspection, enforcement of applicable regulations, transportation operational procedures, and support for emergency preparedness and response activities. States have requested that DOE provide funds for all transportation-related activities, not just selected shipping campaigns. There are a number of existing mechanisms to fund these activities in affected states, however, most of these take a 'piecemeal' approach. This paper examines current DOE and other federal agency funding for transportation and emergency management planning and explores options for streamlining and rationalizing DOE's approach toward funding states and Tribes.

INTRODUCTION

In recent years there has been an increasing focus on cooperative transportation planning, technical assistance and training between DOE and states, Tribes and local governments affected by DOE shipments of radioactive material. The department recognizes the benefits of coordinated planning and anticipates greater demand for technical assistance and training from host and corridor jurisdictions as DOE's radioactive shipments increase through the next decade (see Fig. 1)a. By one estimate, up to 40 states will be directly affected as either hosts or along the transportation routes. Shipments of material managed by the Office of Environmental Management (EM) constitute a large majority of the projected increase.

The Office of Civilian Radioactive Waste Management (RW), the Waste Isolation Pilot Plant (WIPP) and other EM programs are successfully engaging states, Tribes, local governments, regional organizations, and professional associations in all levels of transportation planning including transportation program development and specific shipping campaigns. The RW and WIPP programs are required, by statute, to provide transportation-related technical assistance and training to state, tribal and local jurisdictions affected by their shipments. Both programs have several cooperative agreements in place with states, Tribes, and regional and national organizations to provide transportation-related planning assistance and training. Other EM programs have used these agreements to channel funds to state and tribal jurisdictions for planning and training

activities related to specific shipment campaigns. States, Tribes and local governments also receive funds through other non-transportation-related DOE and federal agency programs (Federal Emergency Management Agency (FEMA) and the Department of Transportation (DOT)) which indirectly benefit their transportation-related planning and training. States also provide a major portion of emergency preparedness funding through fees or state appropriations.

Fig. 1

Providing assistance to states, Tribes, local governments and other interested parties to support their involvement in general transportation program development and specific shipment planning has paid dividends. The Transportation External Coordination Working Group (TECWG) has helped to build a consensus on what issues DOE must address in developing its transportation programs and is now recognized as a model of public involvement for other non-transportation EM programs. Also, coordinating with affected jurisdictions played an important role in successfully planning and implementing the Cesium-137 Capsule Return Program and the Foreign Research Spent Nuclear Fuel Urgent Relief Program.

Still, recent budget cuts and subsequent programmatic reprioritization have focused attention on the effectiveness and efficiency of the department's transportation-related planning assistance and training efforts. Clearly, some of the arrangements for engaging states, Tribes, local governments and other interested parties in transportation planning are redundant. For instance, several of the RW and WIPP cooperative agreement groups have the same or similar membership and frequent single issue meetings place heavy administrative burdens on all participants. It is evident that DOE is no longer able to fund all transportation planning efforts that have been developed over recent years.

To continue capitalizing on the benefits of cooperative transportation planning, meet the likely demand for greater technical assistance and training generated by anticipated increases in DOE shipments, and reduce administrative and program inefficiency, DOE must develop a more rational and consistent approach to funding transportation planning assistance and training. This paper examines the current method for delivering funds and proposes a more streamlined approach.

CURRENT APPROACH

Funding for planning assistance and training provided by each DOE program to states, Tribes and local governments is based on their program mission. DOE recognizes states have base programs and DOE's responsibility is to assist states in planning and preparing for the transportation of DOE materials. For instance, the WIPP and RW cooperative agreements provide recipient organizations and their members with the funds and training they need to help DOE plan and implement the shipping programs for transuranic waste and commercial spent nuclear fuel, respectively.

Fig. 2

Although other EM offices use the WIPP and RW agreements, funds are also provided only for the material managed by the particular program office. Figure 2 shows the sources and delivery mechanism of funding assistance for planning and training provided by EM programs to states and Tribes during FY1994. A comprehensive picture of transportation-related financial assistance to states and Tribes from all federal sources can be found in Bradbury and Jones (1994).

The current DOE approach is largely a reflection of the legislative, administrative, and organizational differences among traditionally separate and functionally distinct DOE transportation programs. As part of her Strategic Alignment Initiative, Secretary O'Leary has indicated that minimizing DOE's "stovepiping" of programs is a key component of her efforts to increase the department's administrative efficiency. Although transportation programs have long been seen as separate and distinct from various DOE program offices, missions, within the department, their transportation missions are cross-cutting. They involve or affect many of the same people outside DOE (States, Tribes, localities). Moreover, the operational and public safety responsibilities of state, tribal or local personnel are not likely to differ significantly for the bulk of DOE shipments. In addition to the obvious administrative and resource inefficiency of sometimes redundant DOE transportation assistance and training programs, the current fragmented approach also inhibits recipient jurisdictions from pooling DOE assistance with other federal assistance or resources to efficiently plan for and meet the entire spectrum of their public safety needs.

POSSIBLE OPTIONS

There are three basic options for funding coordinated transportation planning, technical assistance and training: national; regional; and "local". Each option has advantages and disadvantages for achieving various aspects of a coordinated approach to transportation planning and implementation.

A National Option

Through a national approach, DOE would continue providing funds for transportation planning assistance to organizations with a national perspective on issues related to the transportation of radioactive and other hazardous materials. Since its inception in 1992, the TECWG has worked with RW and EM to identify and resolve issues in 6 broad transportation-related areas: 1) General Program Planning: 2) Transportation Operations; 3) Emergency Management; 4) Technical Assistance; 5) Training; and 6) Public Information & Education. The group meets twice annually and maintains a rigorous process for incorporating participant input into transportation program development. Individual TECWG members serve as liaisons between the group and their broader organizations. Many TECWG member organizations have significant influence on the course of various issues of concern to DOE transportation programs.

In addition to the TECWG, EM sponsors the Local Government Network (LGN) through a cooperative agreement with the Urban Energy & Transportation Corporation. The network is a loose affiliation of senior local government officials, from around the country, emergency management, fire and rescue, law enforcement, and environmental health officials. Participants in LGN regional and national meetings provide DOE transportation managers with a local perspective on hazardous material transportation.

Like TECWG, LGN participants help shape DOE transportation program development by applying their knowledge and experience towards transportation-related issues such as technical assistance and developing and shaping training. Both groups have been instrumental in developing many of the ideas and issues raised in this paper. They will continue to work with DOE to develop and implement more efficient and effective transportation programs. As groups, neither the TECWG nor the LGN are

directly involved in planning specific DOE transportation actions, although individual members can and have served as valuable contacts for DOE programs and field offices during shipping campaign planning.

A Regional Option

As part of a regional funding option, DOE would continue sponsoring various regional or specific national organizations through cooperative agreements to convene their respective members to address operational and planning issues related to specific DOE shipments. RW currently has agreements in place with the Southern States Energy Board (SSEB), Western Interstate Energy Board (WIEB), The Midwest Office and Easter Regional Conference of the Council of State Governments (MOCSG and ERC) , the National Conference of State Legislatures (NCSL), the National Congress of American Indians (NCAI), the Conference of Radiation Control Program Directors (CRCPD), and the Commercial Vehicle Safety Alliance (CVSA). WIPP has agreements with SSEB, the Western Governors' Association (WGA), the Confederated Tribes of the Umatilla Indian Reservation, the Shosone-Bannock Tribe of the Fort Hall Indian Reservation, and the State of New Mexico.

These regional government organizations provide a neutral forum for discussing issues of regional concern, developing regional response or solutions such as a mutual aid agreements, and moderating between DOE programs and individual states. In addition to funds for administering the cooperative agreement and convening meetings, DOE could provide "pass-through" funds to the states through regional groups for, among other things: 1) DOE trainer "consultations" with affected state jurisdictions; 2) training curriculum development and distribution; and 3) train-the-trainer courses. States would then be responsible for providing training to appropriate local personnel.

There are several drawbacks to working through regional groups. Experience with the Cesium-137 Capsule Return Program and the Foreign Research SNF Urgent Relief Program has shown that obtaining needed authorizations and adding incremental funding to existing agreements can be awkward and time-consuming. Tribal interests are not represented in the current cooperative agreements with these regional groups. In addition, existing cooperative agreements do not represent all the jurisdictions likely to be affected by future DOE shipments. Additional State-by-State or Tribe-by-Tribe agreements would be required. Implementing additional agreements to cover the remaining affected jurisdictions would result in additional administrative costs for both the federal government and the States and/or Tribes. The "pass-through" nature of the regional approach to program implementation may not result in the most effective or consistent application of resources by recipient organizations because potential differences in the interests of the regional groups and the constituents they represent.

A "Local" Option

The "local" or jurisdiction-by-jurisdiction option is the traditional federal approach for directly aiding states and Tribes and is most effective when dealing with a limited number of affected jurisdictions. DOE-EM has experience in direct funding through several cooperative agreements with states and Tribes, and through its Agreements in Principle (AIP) with several states hosting DOE facilities. Other federal programs (FEMA, DOT) providing funds directly to states and Tribes may provide an avenue for DOE to do the same. However, some programmatic control and objectives might be lost.

EM has several cooperative agreements in place with Tribes to participate in environmental monitoring activities, to conduct facility ground water testing, and to participate in a dose reconstruction project. One such agreement with the Confederated Tribes of the Umatilla was used to fund transportation-related emergency response activities as a pilot project.
EM's AIP process provides more than $20 million per year to 13 states for technical and financial support for independent oversight of facility environmental monitoring and emergency response planning. AIPs are funded by EM and administered by DOE field offices located in or near recipient states. Current guidance to participating states emphasizes that AIP funds are for emergency response must be directly related to off-site consequences of on-site emergencies. AIP guidance and procurement procedures would need to be amended to include transportation-related activities. However, it is not clear in every case that the state agency receiving AIP funds is the appropriate recipient of transportation-related funds.
The Federal Emergency Management Agency (FEMA), the Department of Transportation (DOT), and the Environmental Protection Agency (EPA) also are significant sources of planning assistance and training for state, tribal and local governments.
FEMA is responsible for coordinating and distributing federal assistance for emergency planning, preparedness, response, and mitigation for civil defense and peaceful radiological incidents (for both fixed and transport-related), and natural disasters. FEMA has used its Comprehensive Cooperative Agreement (CCA) mechanism to consolidate and channel financial assistance from various federal sources through the governor's office to the emergency management agency in each state. Tribes can participate in CCA programs either through separate cooperative agreements or (at their option) by receiving funds passed through state agreements.b
Currently, 13 programs are funded through the CCA including FEMA's Emergency Management Assistance Program, Emergency Management Training Program and Hazardous Materials Program, and the U.S. Army's Chemical Stockpile Emergency Preparedness Program (CSEPP). Each sponsoring agency governs the content and scope of the specific program while FEMA administers the overall agreements with participating states and provides technical assistance. Thus, each program has different eligibility and reporting requirements to meet specific program and information needs, and each comprehensive CCA is tailored to meet the needs of the state.
The DOT also provides assistance through training and planning grants authorized by the Hazardous Materials Transportation Uniform Safety Act (HMTUSA) of 1990 and through its Motor Carrier Safety Assistance Program (MCSAP). Both states and Tribes are eligible for the HMTUSA grants which are intended to assist in training public sector employees in responding to hazardous material incidents and planning grants for developing, improving, and implementing emergency plans required under Title III of the Superfund Amendments and Reautherization Act (SARA) of 1986. Grant applicants are required to identify fees assessed on hazardous material shipments and the purpose of those fees. The MCSAP program provides funds to assist states in covering costs for roadside inspections, safety compliance reviews, and follow-up enforcement actions.
Transportation-related assistance from the EPA is provided through a competitive grant process designed to improve state, tribal and local emergency planning and right-to-know programs established under SARA

Title III. The grants are focused on geographic areas that have high risks for a chemical accident including transportation intersections and corridors.

By channeling its assistance through an existing federal program, DOE may be able to reduce its overall administrative costs by utilizing established procedures and personnel (both federal and state) experienced in administering assistance programs. Also, this approach would enable jurisdictions to better leverage the assistance provided by DOE against the assistance they receive from other sources and their own resources for routine transportation and emergency preparedness activities. DOE would, however, risk losing some administrative and programmatic focus and program recognition among recipients

Of the existing federal assistance programs discussed here, only FEMA's CCA mechanism has been used by other federal agencies to implement their respective assistance programs. The CSEPP program is an example. A March 1995 General Accounting Office (GAO) report on the CSEPP program found inadequate financial data and management controls by both the Army and FEMA despite an attempt in 1994 to restructure the program's management procedures.c

The GAO report also questions FEMA's plans to replace its current system with Performance Partnership Agreement (PPA) beginning in FY96. According to FEMA the new mechanism will consolidate funding streams into a multi-year performance agreement which will enable states greater flexibility to allocate resources to address their particular hazards. It will also "reduce substantially micro-management and current reporting requirements." In its analysis, the GAO cautions that "CSEPP funds may lose their identity if funds for many programs are awarded to states by functional categories."

Given the GAO's concerns about of the CSEPP program and the fact that FEMA is planning to replace its current system with a new block-grant-type assistance program, channeling DOE's transportation-related assistance through FEMA, at this time, does not appear to be prudent.

A Hybrid Option

To this point this paper has examined the current funding system for transportation-related planning assistance and training and several other options. Each of these options, by themselves, have disadvantages that might jeopardize the effective completion of DOE program office missions. Therefore, we propose a hybrid option. The hybrid option incorporates pieces from all of the other previously mentioned options.

Recognizing that transportation-related planning assistance and training are cross-cutting needs; every DOE program will now, or in the future, require these services and expertise. DOE should maintain these services in a "corporate" level, rather than have each program office develop, implement, and support a transportation assistance and training program. There are several reasons why this makes sense especially in light of the current budget situation. First, external parties have requested that DOE consolidate its training support and provide a consistent approach that can be incorporated into existing state, tribal, and local programs. Second, DOE can no longer afford to maintain separate, but similar, training and assistance for each DOE program office. Finally, from a program management point of view, a "corporate" office is better able to integrate ongoing transportation and training activities throughout the complex and between the field offices and DOE HQ.

After consultation between DOE-HQ program offices, the DOE "corporate" transportation office, and with input from the site programs and DOE support offices, would pool assistance funding and or training for field programs that would be managed at DOE field offices. DOE-HQ maintains its policy and coordination role. As the field offices and the site programs are the people implementing shipping campaigns and interacting with the first responders, state, tribal, and local officials the operational decisions should be made closer to "home." DOE-HQ would continue to work with the TECWG and LGN and the Transportation Internal Working Group (TICWG) to address broader program and policy issues. (The TICWG is the internal DOE working group that brings together program people to discuss transportation issues.) In the near term DOE-HQ would continue to work with the regional groups of states, with an eye towards having them work more closely with the DOE sites (site programs) in the states they represent to address operational planning. See Fig. 3.

There would be an eventual devolution of technical assistance and training to be handled by either the States and/or the DOE sites. In some cases the regional groups can serve as a repository for information and/or trainers. Technical assistance might flow through the DOE operations offices to the States. We refer to the successful Idaho example, in which DOE-HQ provides the materials and the funding to DOE-Idaho and they in turn provide their training, exercises, outreach, and education. At some point we might consider funding states directly, given the legislative precedent seen in the 180 (c) provision of the National Waste Policy Act.

The primary advantage of this hybrid option is that it provides for direct program office involvement in field implementation while providing the field office system with authority to plan and implement shipments. It strongly encourages "corporate" integrated transportation planning, not simply on a program-by-program basis. It also enhances DOE's ability to fulfill program objectives by crafting agreements which focus on the specific technical assistance and training needs in transportation corridors.

Transitioning from the current fragmented approach to the proposed approach will take time. Successfully implementing the proposed option rests largely on the willingness of HQ programs to consent to relatively decentralized program implementation and the ability of all parties to agree upon an appropriate formula for determining DOE program funding contributions. These and other internal DOE issues are being address by the Transportation Internal Coordination Working Group (TICWG).

Fig. 3

CONCLUSION

This paper has presented a variety of funding options for providing transportation-related assistance and training to States, Tribes, and localities. Each of these options has advantages and disadvantages. One is able to argue the merits of pieces of all of these options. However, the expected increase in the number of radioactive material shipments during the next decade and the current budget situation are providing strong incentives for DOE to streamline its fragmented approach to funding transportation planning assistance and training. If done correctly, a more effective and efficient funding and planning process, one that increases the likelihood of a safe, successful and timely movements, can result.

ABSTRACT

Contact-handled transuranic (CH-TRU) wastes will be shipped and disposed at the Waste Isolation Pilot Plant (WIPP) repository in the Transuranic Package Transporter-II (TRUPACT-II) shipping package. A primary transportation requirement for the TRUPACT-II is that the concentration of potentially flammable gases (i.e., hydrogen and methane) must not exceed 5 percent by volume in the package or the payload during a 60-day shipping period. Decomposition of waste materials by radiation, or radiolysis, is the predominant mechanism of gas generation during transport. The gas generation potential of a target waste material is characterized by a G-value, which is the number of molecules of gas generated per 100 eV of ionizing radiation absorbed by the target material.

To demonstrate compliance with the flammable gas concentration requirement, theoretical worst-case calculations were performed to establish allowable wattage (decay heat) limits for waste containers. The calculations were based on the G-value for the waste material with the highest potential for flammable gas generation. The calculations also made no allowances for decreases of the G-value over time due to matrix

depletion phenomena that have been observed by many experimenters. Matrix depletion occurs over time when an alpha-generating source particle alters the target material (by evaporation, reaction, or decomposition) into a material of lower gas generating potential. The net effect of these alterations is represented by the "effective G-value".

Based on existing allowable wattage limits, it is estimated that a large portion (approximately 34 percent) of the CH-TRU waste cannot be shipped. The TRUPACT-II Matrix Depletion Program (MDP) has been established with the objective to investigate the phenomena of matrix depletion to support more realistic, age-dependent effective G-values. The MDP is a cooperative effort involving the U.S. Department of Energy Carlsbad Area Office National TRU Program, the Idaho National Engineering Laboratory, the Los Alamos National Laboratory, and the Rocky Flats Environmental Technology Site. The MDP is comprised of experiments designed to examine the behavior of effective G-values over time for different waste materials and the effects of isotope, agitation, and heating. The experimental data will be evaluated in conjunction with waste container headspace gas sampling and theoretical and predictive modeling to formulate bounding effective G-values for each simulated waste material and time segment. This paper describes the objectives, scope, components and preliminary results of the MDP that are expected to provide the justification for greater wattage limits for CH-TRU waste containers. The increased wattage will ultimately allow shipment of a much greater portion of CH-TRU waste.

BACKGROUND

The inventory of contact-handled transuranic (CH-TRU) waste, currently in retrievable storage at U.S. Department of Energy (DOE) sites, is planned for shipment to, and disposal at, the Waste Isolation Pilot Plant (WIPP). The Transuranic Package Transporter-II (TRUPACT-II) is a reusable shipping package designed for the transportation of CH-TRU waste containers to WIPP. Waste containers are 55-gallon drums, standard waste boxes, and ten-drum overpacks.

The TRUPACT-II was designed in accordance with the requirements for Type B packaging found in Title 10, Code of Federal Regulations Part 71 (1). Upon completion of the design and the required testing, the TRUPACT-II Safety Analysis Report for Packaging (SARP) was submitted to the U.S. Nuclear Regulatory Commission (NRC) in 1989. Based on the analyses presented in the SARP, the NRC issued Certificate of Compliance No. 9218 for the package in August of 1989 (8).

A major transportation requirement for the TRUPACT-II is that the concentration of potentially flammable gases must not exceed 5 percent (by volume) in the package or the payload during a 60-day shipping period after the TRUPACT-II is sealed. Decomposition of materials caused by radiation, or radiolysis, is the predominant mechanism of gas generation during transport.

CH-TRU waste is classified into four major types (I, II, III, and IV) based on chemical and physical characteristics and further subdivided into waste material types (I.1, I.2, I.3, II.1, II.2, and III.1) based on bounding flammable gas generation potential as shown in Tables I-1 and I-2 (8). The gas generation potential of a target material is characterized by its G-value, which is the number of molecular or ionic products (usually gaseous products) generated or consumed per 100 eV of ionizing radiation absorbed by the target material. Each CH-TRU waste container is assigned a TRUPACT-II shipping category, which is based on a combination

of waste material type and the packaging (number and type of plastic layers of confinement) of the waste materials within the waste container. To demonstrate compliance with the flammable gas requirement, theoretical worst-case calculations were performed using G-values to establish allowable wattage (decay heat) limits for each TRUPACT-II shipping category.

The maximum allowable wattage limits for each shipping category and for the TRUPACT-II were based on the initial G-values observed during experiments on the irradiation of materials found in TRU waste. The wattage limit calculations assumed a constant G-value from the time the waste was packaged until emplacement at the WIPP facility. The calculations made no allowance for decreases of the G-value over time, a phenomenon observed by many experimenters (5,6,7,9,10,11,12). Because the majority of CH-TRU waste retrievably stored at DOE sites is 5 to 22 years old, wattage limits based on initial G-values are extremely conservative. Taking into account the existing TRUPACT-II wattage limits, it is currently estimated that a large portion of the CH-TRU waste container inventory cannot be shipped. A joint effort was conducted at the Idaho National Engineering Laboratory (INEL), Los Alamos National Laboratory (LANL), and Rocky Flats Environmental Technology Site (RFETS) to determine the impact of existing wattage limits on the shipability of CH-TRU waste stored at those sites. Of the total volume certifiable CH-TRU waste (i.e., waste that meets the requirements of the Waste Acceptance Criteria for the Waste Isolation Pilot Plant (3)), it was determined that approximately 34 percent of the waste would not be shippable based on its failure to meet the TRUPACT-II wattage limits. Although the effort was performed at the three named sites, the results are applicable to all DOE sites that plan to ship CH-TRU waste to WIPP. The TRUPACT-II SARP contains a Gas Generation Test Plan; however, implementing the plan for 34% of the CH-TRU waste would be prohibitively expensive and time consuming.

All TRU waste will ultimately have to be transported to the WIPP; therefore, a method to provide for its acceptance for shipment in the TRUPACT-II is needed. The solution may lie in determining effective G-values as a function of time and thus more realistic TRUPACT-II wattage limits, primarily by accounting for age-dependence of the waste. A cost-effective method for arriving at age-dependent G-values and revised TRUPACT-II wattage limits is matrix depletion testing.

Matrix depletion occurs over time when an alpha-generating source particle alters the target material (by evaporation, reaction, or decomposition) into a material of lower gas generation potential. The matrix depletion process decreases gas generation by reducing the availability of the target material, thereby resulting in a decrease in the G-value with time. The fraction of energy emitted that is absorbed by the target material varies with time and is related to the short mean free path of alpha particles. When the alpha-generating source is dispersed in or on the target material in a particulate form, it will affect only that target material in a small semi-spherical area around each source particle. Additionally, some energy will be lost in the source particle itself and in surrounding nonhydrogeneous material, such as air, that is not available for the liberation of hydrogen. The net effect of these reactions is represented by the "effective G-value."

Two observations of CH-TRU waste over time support the concept of matrix depletion: 1) a consistent decrease in the effective G-value, and 2)

darkening of plastic surfaces (i.e., charring of the waste matrix). The effective G-value has been found to decrease exponentially with time. In fact, within 2 years the effective G-value for Pu-238 contaminated materials was found to approach an asymptotic value several times lower than the initial effective G-value. Based on the available experimental and empirical results, matrix depletion acts to decrease the rate of flammable gas (specifically hydrogen and potentially methane) generation inside CH-TRU waste containers.

OBJECTIVES AND COMPONENTS

The Matrix Depletion Program (MDP) was established with the objective to investigate the phenomenon of matrix depletion and to arrive at age-dependent bounding effective G-values. The activities under the MDP include matrix depletion experiments, headspace gas sampling and analysis, data management and analysis, and documentation. In order to specify the quality of data from the data collection activities under the MDP, a formal procedure based on U.S. Environmental Protection Agency (EPA) guidance was used in formulating data quality objectives (DQOs). The DOE Carlsbad Area Office (CAO) is responsible for the overall management of the MDP. CAO is also responsible for performing audits of MDP activities at INEL.

In the past, LANL has conducted a number of investigations of gas generation in CH-TRU waste to support the WIPP (10,6,11,12). Recently, a limited number of experiments were conducted to determine the matrix depletion effects of Pu-238 on cellulose and polyethylene (7,9). Because of this experience and the availability of the necessary equipment, LANL will be responsible for conducting the matrix depletion experiments. The experiments were designed to quantify the matrix depletion phenomenon using a variety of simulated TRU waste matrix materials (i.e., polyethylene [PE], dry cellulose, wet cellulose, polyvinyl chloride [PVC]), and solidified aqueous or homogeneous inorganic solids that contain water (i.e., cemented waste forms). The total duration of the MDP will be 2 years, with cylinder sampling occurring every 2 weeks. The sampling frequency was determined by the requirement for an adequate number of samples, so as to ensure accurate statistical analysis. Based on mechanistic arguments, the effective G-values for drums older than 2 years will be similar, but lower than those at 2 years; therefore, the value for 2 years will be conservative for older drums. The experiments will also quantify the effects of agitation and heating. Agitation levels to be used in the study are those that simulate transportation and handling events. The heating temperature is based on the highest values used in SARP analyses (140F 5F). Two isotopic sources of plutonium, a blend predominantly Pu-238 and a second blend predominantly Pu-239, will be used in the experiments because Pu-238 has higher decay heat production that causes many drums in the TRU waste inventory to exceed the established wattage limits and Pu-239 is the primary isotope present in TRU waste. The experiments will comprise 60 test cylinders split up into four groups: normal, heated, agitated, and heated/agitated. These groups are designed to simulate the range of conditions encountered during TRU waste transportation and handling operations. Effective G-values will be calculated for each test cylinder from the raw data derived from the experiments. The effect of each isotope, agitation, and heating will then be evaluated to formulate bounding effective G-values for each simulated waste material and time segment (2).

Headspace samples will be collected and analyzed from a representative sub-population of existing TRU waste containers at ambient temperatures. Samples will be taken from both drum and inner confinement layer. These activities are being performed by the INEL and the RFETS under the WIPP Transuranic Waste Characterization Program (TWCP) (4). Headspace sampling includes the drum headspace and the headspace of inner layers of confinement. In the TWCP, headspace gases of all CH-TRU waste drums will be sampled and certain drums will undergo innermost layers of confinement sampling. QA requirements specific to the MDP are described in the MDP QAPP, which is consistent with the TWCP requirements (3). Headspace gases will be analyzed for hydrogen and methane. The TWCP and MDP are coordinating efforts to make a variety of waste types and drum ages available to the MDP. A total of 740 drums will be examined prior to the completion of the matrix depletion experiments. Headspace gas sampling and analysis will be accomplished in accordance with the TWCP.

Drum headspace gas samples will be collected and analyzed from a limited number of existing TRU waste containers at elevated temperatures. This effort is being performed at the INEL under the TRUPACT-II Gas Generation Test Program (GGTP). The GGTP consists of controlled tests with actual containers of CH-TRU waste to determine gas generation rates under simulated transportation conditions. CH-TRU waste drums of waste types I, II, or III will be selected for testing if the decay heat loading of the container exceeds the TRUPACT-II wattage limit for the shipping category of the container. The drum must also meet other requirements before being tested, including having a fissile gram equivalents (FGE) less than 200 grams, weights less than 1,000 pounds, surface dose rates less than 200 mrem.

Data management and analysis involves several key elements. First, data obtained in each portion of the MDP must be validated to ensure that quality assurance requirements have been met and that the data are suitable for use in the MDP. Second, individual effective G-values must be calculated from raw data collected in the matrix depletion experiments. Third, the individual effective G-values must be summarized appropriately to formulate the bounding effective G-values. Fourth, the experimentally derived bounding effective G-values and drum headspace flammable gas (i.e., hydrogen and methane) concentrations predicted from the bounding values must be calculated and compared with respective actual waste drum values.

As noted above, data collected in matrix depletion experiments will be reduced to formulate bounding effective G-values. This first step involves calculating effective G-values for each sampling time and test cylinder. Second, individual effective G-values will be analyzed and used to formulate bounding values for each simulated waste material and time segment of interest; these values will be 95% upper confidence levels based on matrix depletion experimental effective G-values. A set of bounding effective G-values will be determined for PE, wet cellulose, dry cellulose, and cement for time segments of interest.

Existing mathematical models for predicting gas concentrations in waste containers will be finalized. The models are based on the aspiration model described in the TRUPACT-II SARP and simulate the time-dependent generation of flammable gas within the innermost confinement layer and subsequent time-dependent transport across the various confinement layers of TRU waste containers. The models will then be applied using the bounding effective G-values determined from the matrix depletion

experiments to predict flammable gas concentrations within actual TRU waste containers up to the age of the container when sampled. A theoretical model that simulates matrix depletion effects in an idealized geometry will also be developed to further illustrate the phenomenon. Development of the models will be led by INEL. However, it is anticipated that the model development will be completed with a high degree of collaboration drawing on the expertise from the INEL, the LANL and the RFETS.There will be two types of comparisons made using the bounding effective G-values derived from matrix depletion experiments. The first will compare the bounding values with the GGTP results and the second will compare hydrogen and methane concentrations predicted from the bounding values with hydrogen and methane concentrations measured in the TWCP.

Statistical comparisons will be made of bounding effective G-values derived from the matrix depletion experiments with the measurements from actual TRU waste drums (i.e., TWCP and GGTP) in order to show that the effective G-values from the matrix depletion experiments are in fact bounding. Because of the simulated waste materials used in the MDP, it is expected that headspace flammable gas concentrations predicted from the MDP bounding effective G-values will be greater than measured drum headspace flammable gas concentration at ambient temperatures. It is also expected that the bounding effective G-values measured in the MDP will be greater than the effective G-values calculated from sampling TRU waste containers at elevated temperatures.

In both cases, MDP effective G-values are expected to be greater due to the nature of the target material and the geometry of the cylinder contents. While other non hydrogen-generating materials are present in actual CH-TRU waste, these are not included in the MDP. In addition, the target material will be directly sprinkled with plutonium, allowing it to be embedded in the target. In actual CH-TRU waste, the plutonium is dispersed and not always in such direct contact with hydrogen-generating materials.

Quantification of the time-dependent behavior of the effective G-values (i.e., flammable gas generation rates within waste containers) is expected to support justifications for greater wattage limits for CH-TRU waste. The increased wattage limits will allow for shipment of a much greater portion of certifiable TRU waste without increased risk. Assuming the data justifies an application for higher TRUPACT-II wattage limits, the documentation to support an application to the NRC will be prepared and submitted to the CAO and National TRU Program.

ISOTOPE PRODUCTION POTENTIAL AT SANDIA NATIONAL LABORATORIES: PRODUCT, WASTE, PACKAGING, AND TRANSPORTATION*

A. J. Trennel
Transportation Systems Department
Sandia National Laboratories**
Albuquerque, NM 87185

ABSTRACT

The U.S. Congress directed the U.S. Department of Energy to establish a domestic source of molybdenum-99, an essential isotope used in nuclear medicine and radiopharmacology. An Environmental Impact Statement for production of 99Mo at one of four candidate sites is being prepared. As one of the candidate sites, Sandia National Laboratories is developing the Isotope Production Project. Using federally approved processes and procedures now owned by the U.S. Department of Energy, and existing facilities that would be modified to meet the production requirements, the Sandia National Laboratories' Isotope Project would manufacture up to 30 percent of the U.S. market, with the capacity to meet 100 percent of the domestic need if necessary. This paper provides a brief overview of the facility, equipment, and processes required to produce isotopes. Packaging and transportation issues affecting both product and waste are addressed, and the storage and disposal of the four low-level radioactive waste types generated by the production program are considered. Recommendations for future development are provided.

PROJECT NEED AND BACKGROUND

Nuclear medicine is an expanding segment of today's medical and pharmaceutical communities. Specific radioactive isotopes are vital, with molybdenum-99 (99Mo) being the most important medical isotope. The decay product of 99Mo is the isotope technetium-99m (99mTc), which is the medically useful element in its metastable form. The metastable state of a nucleus is at a higher energy potential than the ground state (1); this property produces gamma rays upon transition that are detected by medical equipment.

Nordion International Inc. manufactures much of the world supply of the 99Mo used for medical purposes in a reactor operated by Atomic Energy of Canada, Ltd. The reactor's useful life is expected to expire by the end of this century. The possibility of this reactor being shut down prompted the U.S. Congress to direct the U.S. Department of Energy (DOE) to provide for a domestic backup source for this essential isotope. An Environmental Impact Statement for the production of 99Mo at one of four alternative sites is being prepared by the DOE. Although the final selection of a site awaits the completion of the National Environmental Protection Act process, Sandia National Laboratories (SNL) has been indicated as the preferred site.

The SNL Annular Core Research Reactor (ACRR) was evaluated as a facility to produce 99Mo (and later other isotopes that can be economically extracted from the process). Medical isotope production at SNL is a new manufacturing venture. Should SNL be selected and the project achieve the manufacturing stage, the SNL facility would serve as a backup to the Canadian supply to provide up to 30 percent of the U.S. market under normal circumstances, with the capability to produce 100 percent of the domestic 99Mo requirement should the need arise.

The DOE has produced radioisotopes for users, both public and private, for decades. In the private sector, Cintichem, Inc., manufactured 99Mo and several other isotopes for a market segment in the U.S. as recently as 1989. The Cintichem process was approved by the U.S. Food and Drug Administration (FDA). Rights to the patented process (and the Drug Master File documenting the process) were acquired by DOE in 1991; DOE proposes to use this process to avoid the development time and expense of qualifying a new process. Ancillary equipment acquired by the DOE included packages for product, wastes, and spent fuel.

The proposed project would fabricate unirradiated targets to Cintichem specifications, followed by irradiation in the SNL ACRR. The irradiated targets (contained in a transfer cask) would be moved to the adjacent Hot Cell Facility (HCF) for processing. At the HCF, the radioisotopes of interest would be separated from the fission product inventory. The short half-life product, 99Mo in NaOH, would then be transported by air to U.S. radiopharmaceutical manufacturers. Fabrication process wastes would be temporarily stored at SNL for later disposal at authorized waste facilities.

THE REACTOR

DOE views SNL's ACRR, HCF, and other associated facilities to be a promising site for this isotope production program (2) for several reasons. The ACRR is a modern facility in an operational state with characteristics that are compatible with radioisotope production. It is capable of being dedicated to continuous isotope production, which is necessary to meet the demands for short-lived medical-use isotopes. The ACRR is collocated with the HCF and both can be modified with relative

ease. The ACRR at SNL is in proximity to excellent air transportation facilities (the Albuquerque International Sunport) for radioisotope shipments.

The ACRR facility includes the reactor and all support systems required for its operation. The reactor core is installed in a large open tank filled with about 10 meters of water to provide both core cooling and radiation shielding. The core is cooled by natural convection in an open water pool, and the water pool is cooled by an external heat exchanger. The current ACRR configuration consists of an annular array of UO2-BeO-fueled elements with an active fuel height of 52 centimeters. The dry, steel-lined, control cavity would be removed from the center of the core to provide a flooded region for target irradiation. Two configurations, one with a maximum of 19 targets and the other with a maximum of 37 targets at a time, are planned. The targets used to form the isotopes would almost completely fuel the reactor. With targets installed, only 180 or 130 conventional fuel assemblies, depending on the target configuration selected, would be required to operate the reactor. With installation of additional heat exchangers or cooling towers, the improved heat rejection capacity would allow the reactor to run at 4 MW. For isotope production, the ACRR would be operated in the steady-state mode at or below 4 MW.

TARGETS AND PROCESSING

Because the ACRR is a pool reactor, targets and fuel elements would be readily accessible for removal. Targets consist of stainless-steel tubes approximately 45 centimeters long and 3.18 centimeters in diameter, containing highly enriched uranium-235 (235U) as a 50-micron layer of uranium oxide (U3O8) electroplated onto the inside surface of the tube. Targets will be irradiated to provide a range of fission products that includes isotopes of molybdenum. Targets irradiated for several days would be removed from the core and transferred (using pass-through ports) to a rack in the adjacent Gamma Irradiation Facility (GIF) pool. A transfer cask would be lowered into the GIF pool and the irradiated target(s) would be loaded into the cask and transferred to the HCF using a manned transport vehicle.

The HCF will be reconfigured to streamline the process of irradiated target processing. One proposed HCF modification is the addition of new steel confinement boxes (SCBs) that would result in safer, more reliable, and more versatile extraction operations. The new SCBs would provide complete process control, including waste minimization and management. The units would collect byproducts from the radioisotope extraction, process the byproducts, and package them into waste containers. Modular design would allow easy replacement of components. Another important addition to the HCF is the Quality Control Laboratory, which is required by the approved FDA procedure.Irradiated targets containing almost 7.4E+14 becquerels (Bq) of fission products would be processed within the SCBs. The desired isotopes would be extracted from the fission product spectrum by chemical dissolution and precipitation procedures. First the noble gases and iodine would be condensed from the target fill gas and the fission products would be dissolved from the inside of the target. Then chemicals would be added to maintain specific fission products in solution and the molybdenum would be precipitated, filtered, and cleansed. Finally, the precipitated molybdenum would be redissolved for shipment to radiopharmaceutical companies.

Although 99Mo is the initial product of interest, iodine-131 (131I) and xenon-133 (133Xe) may also be directly extracted from the processing line as additional medically valuable products. The isotope iodine-125 may also be processed from xenon-124, a nonradioactive isotope of xenon; however, this process requires additional apparatus and would only be explored after sufficient success is achieved in 99Mo processing.

Each target would yield up to 29.6E+12 Bq of 99Mo after discharge from the reactor. The isotopes would be further purified to meet FDA standards. The isotopes would then be packaged and shipped in shielded casks by air freight to radiopharmaceutical companies. Approximately 20 to 25 targets per week can meet all U.S. demand with proportionately fewer targets for the standby level of 10 to 30 percent U.S. demand. The ACRR will have the capability to irradiate up to 37 targets continuously; however, this level would be used only under extraordinary conditions of national need and would place a greater burden on the processing facility.

WASTES

The production program will generate low-level radioactive waste primarily consisting of four types. The first type is a high-activity acidic liquid that will contain the bulk of fission products and unfissioned uranium. The second type of low-level radioactive waste is hardware process stream waste generated from isotope separation and purification. This waste includes copper, stainless steel, glass, plastic, and aluminum. Also generated is soft waste, such as personnel protective clothing and lay down material. The final type of waste is spent resins generated during the operation of the ACRR and GIF pool.

The 99Mo isotope extraction process wastes would account for the majority of the low-level radioactive waste volume generated by the proposed program. The extraction of isotopes from irradiated targets involves a number of wet chemical processes. These production activity chemical processes are benchtop processes that are conducted using small (< 500 milliliter) laboratory containers and other equipment of various forms, typically glassware. Because the isotopes that would be produced are used as radiopharmaceuticals for human use, the extraction process is closely controlled and monitored for contamination by chemical remnants and unwanted radioisotopes. Hence, all laboratory equipment such as glass flasks, tubing, and the like would be replaced after a single use to prevent possible contamination of future batches. This equipment would be placed in small containers (about the size of a one-gallon paint can) that, when full, would be placed in a waste container.

The acidic liquid process solutions that remain after the radioisotopes are extracted contain uranium and other radioactive elements called fission products. These liquid solutions would be neutralized as a final process step, rendering the solution nonacidic, solidified with an agent such as portland cement, and then placed in a waste container. The uranium would not be recovered from the solution nor from the solidified waste because it is not economically feasible to recover it at SNL or other DOE recovery facilities.

The waste container used during storage and eventual disposal for this solidified process waste would have a volume of about 0.21 m3 (55 gallons). The radioactive process equipment discussed above and the solidified process waste may be placed either in the same container or in separate containers, based on operational and disposal considerations.

The filled waste containers would be stored in a shielded area. The solidified process waste would be stored on site for approximately 6 to 12 months, by which time the radioactivity of the waste would have been reduced significantly as shown in Fig. 1. The process hardware waste is expected to have a lower level of radioactivity and thus could be transported to the selected waste disposal site after final packaging at a time that is being determined.

Fig. 1

The proposed program would generate between 24 and 180 containers (similar in size to a standard 55-gallon drum) of low-level waste (both process hardware and solidified process waste) from the isotope extraction process each year. These waste containers would contain no more than 7.4E+13 Bq of radioactive waste when shipped to the disposal site in B-3 waste transport packages. Fission products would be responsible for nearly 99 percent of the activity level. The remaining activity would be mostly from the activation of the stainless-steel target shell.Although solidified process waste shipments could be made to the disposal site as soon as 6 months after generation, the HCF has sufficient shielded storage area to store waste generated by 2 years of maximum (100 percent of U.S. need) production. Table I identifies most of the waste materials and quantities that are known to be included in the extraction process waste stream.

Table I

Past assessments indicate that the wastes produced in the extraction process would not generate radioactive mixed wastes. This means that the radioactive waste would not contain nor be mixed with waste that is considered hazardous according to the Resource Conservation and Recovery Act.

PRODUCT AND WASTE PACKAGING

Table II shows the general characteristics of the three Type B packages that will be used in the Isotope Production Project. The DOT- and NRC-certified Type B (3) package designated for use in transporting 99Mo and 131I is the CI-20WC-2 or -2A (4). The primary difference between the two models is the size and the amount of shielding. Both CI-20WC (Fig. 2) models are steel-encased with wooden outer protective jackets, a depleted uranium shielded cask, and an inner steel containment vessel. The protective jackets are contained within an 18-gauge steel drum. The inner containment vessel is a 7-cm outer diameter by 14.26-cm-long, 416 stainless-steel, gasketed and threaded container. The product packages are certified for 99Mo/99mTc in normal form as solids or liquids with a maximum quantity of material per package of 3.7E+13 Bq, and 131I in normal form or liquids with a maximum quantity of material per package of 7.4E+12 Bq.

Table II

Fig. 2

The package designated for transportation of product waste is the NRC-certified B-3 Type B package (5). The packaging (Fig. 3) consists of a 15.38-cm lead-shielded steel weldment in the shape of a right hollow cylinder with a bottom containing a drain assembly and a recessed, plug-type gasketed and bolted lid. Packaging features include lifting and tie down devices and a drain to the central cavity. The maximum weight of the loaded package is 13,636 kg.

Fig. 3

Spent nuclear fuel shipments are not expected to occur for several years. Such fuel will be stored until DOE designates a repository. When shipments are to be made, the BMI-1 package will likely be used. The package assembly consists of five major components: the stainless-steel enclosed lead-shielded cask, the stainless-steel encased lead-shielded cover and gasket, the radioactive material, internal canister or basket, and a custom matching skid on which the cask rests vertically.

PRODUCT AND WASTE SHIPMENT

Isotope 99Mo decays at the rate of about 1 percent per hour (half-life 66 hr). Consequently, shipment of the product must be expedited to prevent needless decay of the product. Nordion, which is the only North American company presently shipping bulk 99Mo, uses a combination of commercial and chartered air flights.

SNL expects to ship up to 29.6E+12 Bq of 99Mo per processed target and about 6 to 7 packages per week at the nominal 30 percent production level. The 99Mo product will be pharmaceutical quality, and FDA-approved procedures will be used for its production. The 99Mo is expected to be shipped initially on a daily basis to one of three different locations: St. Louis, Chicago, or Boston. Air freight express class of shipments are planned. If a stop is required, the shortest routing time from Albuquerque to the customer city will be preferable. Product movement from the SNL reactor area to the airport transfer point using Kirtland Air Force Base and Albuquerque International Sunport access roads is the preferred route, avoiding public roads. Product quality assurance may occur during the time the product is in shipment.

The primary waste disposal site designated for production and laboratory wastes is the Nevada Test Site facilities north of Las Vegas, Nevada (6). The site is compatible for the classes of waste generated by the production processes, and the site is operational. Two alternative waste disposal facilities are located at the Hanford Site near Richland, Washington. The 200-West Waste Generation Facility is quite extensive and has several current burial sites as well as some older burial grounds that are monitored. A second, alternate site is operated by U.S. Ecology as a commercial facility.

If the waste containers were to be transported by truck, it is most likely that one truck would carry one B-3 package per shipment, because of the weight of the B-3 package. Two packages per truck may be possible; however, depending on the exact payload weight, two packages would likely exceed the maximum gross weight allowed for one truck. The shipments would go directly from the HCF to either the primary site or to one of the alternative sites using the most direct route selected by the motor transport company. Approximately 85 shipments per year will be required. All packaging used to store and transport waste generated by the isotope production processes will adhere to DOT requirements as specified in the applicable parts of 49 CFR (7).

FUTURE DEVELOPMENT

Nuclear medicine is growing in importance and versatility, leading to an expanding market both in the U.S. and worldwide. The need for nuclear medicine will continue to grow as populations increase. New radiopharmaceutical and medical substances are increasing the spectrum of these items available to the medical community. Concurrently, the number of countries acquiring such technologies is expected to increase, perhaps dramatically. A substantially increased demand for radiopharmaceuticals is likely to result.

Future production, storage, loading, handling, and movement considerations of both isotope products and waste should focus on the need for modified or new containers and those that are suitable for automation. Significant benefits can accumulate by minimizing the human element in isotope production operations. Robotics Address As Low As Reasonably Achievable concerns and reduce the possibility of human error. In addition, real-time cask identification survey and real-time radiation survey could be safely and quickly carried out mechanically. SNL's expertise in robotics and automated waste handling should be applied to the Isotope Production Project to increase production, safety, and waste management.

FEASIBILITY STUDY FOR PRIVATE-SECTOR TREATMENT SERVICES FOR ALPHA-CONTAMINATED LOW-LEVEL MIXED WASTES

Robert R. Bloom
Rene R. Rodriguez
Rust Federal Services Inc.

ABSTRACT

Rust Federal Services, under contract to the United States Department of Energy (DOE), Idaho Operations Office, performed a study to develop and evaluate the feasibility of a suggested private sector solution for the treatment of alpha-contaminated low-level mixed waste (ALLMW) stored or produced at the Idaho National Engineering Laboratory (INEL). The feasibility study is an initial step in the potential procurement of privatized treatment services for these wastes.

Rust's derived objective of the feasibility study was to define an optimal treatment system and analyze the feasibility of that system for accomplishing the processing objectives specified by DOE. All aspects of the selected treatment system were addressed in the feasibility study, including technical, regulatory, public involvement, and financial considerations. Two central elements of the study were a technology screening task to select the optimal treatment system and an analysis of the institutional, business, financial, and contractual issues that are likely to accompany the privatization of treatment services for DOE.

INTRODUCTION

As a result of past nuclear defense program activities, a considerable volume of waste containing both radioactive and hazardous contaminants ("mixed waste") has been buried and/or stored at the INEL. Much of this waste is contact-handled heterogeneous material such as paper, plastic (chlorinated and nonchlorinated), cloth, wood, sludges, bulk metal, etc. This waste contains less than 100 nCi/g TRU and is therefore classified as low-level waste. The INEL has approximately 27,000 m3 of ALLMW. Approximately 95 percent of the waste is contaminated with Resource Conversation and Recovery Act (RCRA) hazardous material, and some waste contains Toxic Substance Control Act (TSCA) polychlorinated biphenyls. However, EPA regulations prohibit the disposal of material that contains RCRA constituents directly on or in the land without prior treatment to remove and/or destroy the hazardous constituents. Therefore, treatment of the ALLMW is required to remove or destroy the hazardous constituents (i.e., those regulated under RCRA).

This paper first describes the technical and institutional issues that were considered in developing and evaluating the optimal system for treating the ALLMW. It then addresses the business, financial, and contractual considerations involved in obtaining private sector participation in design, construction, and operation of the selected treatment facility.

TECHNOLOGY SELECTION AND EVALUATION PROCESS

The process used by the Rust team for selecting and evaluating the optimal treatment solution for INEL ALLMW focused on a technology screening and selection task to define the treatment technology system that could most cost-effectively meet all treatment objectives defined in the Feasibility Study Statement of Work (SOW, Ref. 1) for the specified waste streams. This task was followed by an analysis of the regulatory and other institutional requirements and constraints that could affect the treatment facility and its operations. The steps in the technology screening and selection task are summarized below.

Step 1. Identify types and quantities of waste media/contaminants requiring treatment. Approximately 27,000 m3 of wastes are stored at the INEL that meet the criteria for treatment in the described facility. Five ALLMW streams (metals, combustibles, heterogeneous, sludges, and concrete/bricks) account for approximately 94% of the total waste volume. The remaining waste streams, which account for approximately 6% of the total waste volume, include glass, particulate matter, plexiglass, non-metal molds/crucibles, resins, evaporator salts, gloves, scintillation cocktails, radioactive sources, and unknown wastes. The data in Table I is provided to help summarize the volume of each ALLMW waste stream and the relative percent of the total volume that they represent.

Table I

As the first step in the technology screening and selection process, characteristics of these wastes were tentatively identified from information contained in waste profile sheets. Many of the waste profile sheets included only information about the radioactive components of the waste, so information about the hazardous constituents was incomplete or inaccurate. As the project progressed, additional information became available and was incorporated into decisions.

Step 2. Define waste treatment objectives. The following Rust waste treatment processing system objectives were specified in the SOW:

Meet RCRA Land Disposal Restrictions for destruction or removal of hazardous constituents.

Meet waste acceptance criteria provided in the SOW for durability, compressive strength, leachability, resistance to immersion and biodegradation, and radiation stability.

Maximize final waste form durability.

Maximize options for treating a variety of contaminants and/or types of waste.

Step 3. Establish screening criteria for candidate technologies. Two go/no go criteria were identified to immediately eliminate from consideration those treatment technologies that could not support the overall waste treatment objectives. To be considered, an ALLMW treatment technology had to have been successfully demonstrated on at least a pilot-scale basis and had to be applicable to at least 10% of the targeted waste streams.

Subsequently, the Rust evaluation team produced a definitive list of ranking criteria against which to evaluate candidate treatment technologies that passed the go/no go decision point. Each criterion was assigned a weighting factor consistent with the level of importance of that criterion to the overall technology selection process. The five ranking criteria and their respective weighting factors (wf) were:

- Operability/Maintainability/Reliability wf - 5
- Properties of Secondary Waste Streams Produced wf - 4
- Waste Feed Characterization and Pretreatment Requirements wf - 4
- Nuclear Criticality Issues wf - 3
- Permitting Issues and Public Acceptability wf - 2

These criteria were used for two purposes: first, to identify technologies with the highest overall scores for further consideration, and later (in Step 6) to establish relative rankings for each criterion among the candidate technologies.

Step 4. Identify candidate treatment technologies. Using the criteria developed in Step 3, the team identified a list of candidate technologies that met all ranking criteria. The candidate technologies, identified for further consideration by type, are listed below.

Thermal Processes

- Plasma Hearth
- Joule Melter
- Controlled-Air Incinerator
- Fluidized Bed
- Metal Melter
- Vortec Incinerator
- Rotary Kiln

Chemical Treatment Processes

- SOIL*EXSM with Wet Air Oxidation

Decontamination Processes

Acid Rinse
CO2 Blasting
Chemical Rinse

Stabilization/Encapsulation Processes
Polyethylene Encapsulation
Sulfur Polymer Cement Stabilization.

Step 5. Establish treatment system selection criteria. Other criteria deemed important, as indicated by the SOW, were also identified and used as factors for evaluating the candidate technologies. These criteria were:

Versatility/robustness of system (number of waste streams treated, pretreatment requirements)
Waste volume reduction
Operational safety risks (e.g., use of high-pressure systems, waste handling requirements)
Life cycle cost
Final waste form characteristics.

Step 6. Evaluate and rank the treatment technologies using the weighted selection criteria. In this step, applicable waste streams were identified for each candidate technology and each technology was evaluated against the selection criteria for the applicable waste streams. Within each waste stream, a numerical ranking was assigned to each technology versus each selection criterion reflecting the degree to which the technology satisfied the criterion for that waste stream. The numerical values ranged from 3 (high) to 1 (low). The numerical values for each waste treatment/waste stream combination were tallied and reported as a final score. The score represented the applicability of each waste treatment technology to each target waste stream.

Step 7. Define potential treatment system implementation scenarios. No single technology can effectively treat all of the ALLMW that is the subject of this study; a suite of treatment technologies is required. Therefore, from each of the five waste stream treatment technology scoring matrices, the two highest-scoring waste treatment technologies for each individual waste type were identified. Various combinations of the high-scoring technologies were evaluated to predict their effectiveness when used together to treat the total INEL ALLMW inventory. In total, five waste treatment systems were evaluated.

Step 8. Select the treatment system with the best combination of advantages considering all selection criteria, evaluation factors, and implementation scenarios. Using the waste treatment objectives and evaluation criteria defined earlier, the five waste treatment technology systems were evaluated to select the most advantageous overall treatment system. The waste treatment system that was recommended consisted of a plasma hearth process, an evaporation system, a thermal desorption and mercury amalgamation system, and a series of decontamination systems. This combination was selected because of its ability to handle the extremely heterogeneous assortment of waste materials to be treated, as well as the glass waste form produced and other advantages of the plasma hearth technology.

Regulatory Considerations. Because the feasibility study examined every aspect of siting, designing, constructing, and operating an ALLMW treatment facility, it was necessary to define the regulatory requirements and constraints that could impact the facility's cost,

completion schedule, and operations. Plans were developed for implementing:

- A licensing and permitting strategy and schedule
- A public acceptance program
- Waste transportation
- Safety Analysis Report requirements
- Support for National Environmental Policy Act requirements.

In addition, a siting analysis was performed to identify the most cost-effective location for the facility. This analysis considered the public acceptance, licensing, permitting, waste transportation, and safety aspects of building the facility at an on-site (i.e., INEL) location versus an off-site location.

BUSINESS, FINANCIAL, AND CONTRACTING CONSIDERATIONS

As part of the feasibility study, Rust prepared a business plan for developing, constructing, and operating the ALLMW Treatment Facility under a prime contract with DOE. The business plan included a market assessment, an analysis of risks and liabilities, a plan for providing treatment services, contractual performance terms and conditions, pricing, and other contractual considerations.

Rust's ALLMW Treatment Facility would be planned as a turnkey project, design through D&D, performed by a prime contractor. Regardless of whether the prime contractor enters into a joint venture, partnership, or teaming arrangement with other organizations, the requirement for ensuring a reasonable return on investment will exist. Since the majority of the waste that could be treated _s under DOE's jurisdiction, the prime contractor will need DOE's commitment to make a minimum quantity of waste available for processing. The contractor will then establish an equitable return on investment based on that minimum waste quantity. Given this expectation, Rust examined various investment scenarios and concluded that three are most likely to meet the needs of DOE and the contractor, as follows:

Commercial Partnership Model. Rust examined a facility designed, constructed, and operated under commercial-type fixed price contracts, but owned by the government. This investment scenario provides for shared risk between DOE and the contractor, a reasonable return on investment for the contractor, and, potentially, low overall cost to the government. With this alternative, pre-operational costs would be reimbursed as incurred on a fixed-price basis, except permitting, which would be performed on a cost-plus-incentive-fee basis. Operating costs would be recovered through fixed-unit-price processing revenues. The government would own the treatment facility and would obtain treatment services from the contractor on a fixed-unit-price basis under a multi-year performance-based contract.

To maximize the benefits of this contracting arrangement, the terms and conditions should be as definitive as possible to avoid contingencies, the concept of pay-for-performance should be incorporated wherever possible, and incentives should be considered where appropriate.

Privatized Model. Rust suggested that a "totally privatized" investment scenario, where the contractor would pay all pre-operational costs with the expectation of recovering those costs through operation of the facility during the base period of performance, is the preferred approach. This approach would save the government time and money by optimizing contractor performance and requiring only a limited DOE staff (project manager and contract specialist) to oversee contractor

activities. This investment scenario presents some risks that would be borne almost exclusively by the private contractor. These risks would potentially consist of little to no cost recovery until operational start-up, potential increases in the rate of interest on borrowed money, and changes in strategy or objectives, either by DOE or the regulatory community, during the pre-operational period that may adversely affect the contractor's ability to recover pre-operational costs.

However, these risks could be mitigated by inflation adjustments, clear definition of DOE requirements in the contract, and provision for unit price adjustments as necessary. For example, annual reviews of unit prices in relation to interest/inflation rates and state taxes, with unit price adjustments to compensate for increases, would alleviate some risks. Clear definition of DOE requirements in the contract scope will aid in preparing accurate lump sum estimates, evaluating them, and recognizing when changes are necessary and valid.

Government Model. The "government model" would be a conventional cost reimbursable contract with an incentive fee to incorporate the pay-for-performance concept. As in the other approaches, a performance bond would be required. This method would likely result in more competition (i.e., more bidders) due to the virtual elimination of risk for the contractor; the lowest fee; and the lowest contractor-applied contingency. It would involve more oversight and administrative costs for the DOE. It could result in additional contractor cost as additional DOE intervention potentially could occur. The contractor would not have to add substantial contingency for cost of money, regulatory delays, etc. However, DOE would assume the majority of the risk with this approach.

CONCLUSION

Treatment of the ALLMW at INEL can be achieved in the most cost-effective and timely manner by locating the treatment facility on the INEL site and using the plasma hearth process (PHP) technology as the centerpiece of this facility. This facility will cost substantially less than is projected in current government estimates for an ALLMW treatment facility. The "totally privatized" investment scenario would offer the most cost effective treatment services to the DOE by allowing the private sector contractor to cover all pre-operational costs and subsequently recover these costs through operation of the facility during the base period of performance.

NATIONAL MIXED WASTE TREATMENT STRATEGY - AN INDUSTRIAL PERSPECTIVE

Edward E. Wannemacher
Rust Federal Services Inc.

ABSTRACT

The Federal Facility Compliance Act (FFCA) required that each site develop an inventory of its mixed waste volumes and a plan for implementing treatment capacity. These plans identified available capacities of commercial facilities; however, they were unable to predict future commercial facilities since the private sector was generally

unwilling to invest in new facilities without a committed volume of waste. A review of the draft site treatment plans indicates that the DOE will need eighty-seven new treatment facilities to manage its mixed wastes.

Many sites are now considering privatization as an alternative to meeting FFCA requirements. INEL, Oak Ridge and Hanford are expected to release privatization solicitations in late 1995 or early 1996. These privatization initiatives represent the opportunity to serve as a core for a national mixed waste strategy which can potentially save the DOE millions of dollars. By expanding the treatment capabilities and capacities of these three privatization initiatives, the DOE can avoid capital investments at multiple sites. It is expected that this concept could handle 90% of the DOE's mixed waste. The remaining 10% could be managed by transportable equipment mobilized from site to site or to one or more of the privatized fixed facilities.

This paper will expand on this proposed concept and will include an update on the DOE's mixed waste privatization initiatives. It will also provide an industry perspective on how to structure privatization initiatives that will attract industry.

BACKGROUND

The Federal Facility Compliance Act of 1992 established requirements for U.S. Department of Energy (DOE) sites to achieve compliance with the Resource Conservation Recovery Act (RCRA) for mixed wastes. Sovereign immunity was granted until October 1995 to allow the DOE to devise a plan to ensure that adequate treatment capacity would be available. Each site was required to inventory its stored waste and predict volumes for newly generated wastes. Furthermore, it required that each site evaluate treatment options and establish a schedule for treating mixed wastes. These requirements led to each site preparing a site treatment plan for submittal to their respective states or EPA for approval. In general, these plans identified existing treatment capabilities or described technology development and treatment capacity activities needed to achieve compliance. Evaluations of existing treatment capabilities were limited to permitted or planned treatment facilities either operated at a DOE site or within the commercial sector. These activities generated the data required to quantify the volumes and characteristics of mixed wastes. However, the data did not provide an evaluation of private sector capabilities for adding mixed waste treatment capacity. Nor did it provide the market demand information required for the private sector to invest in new treatment capacity. In traditional environmental markets, market demand is largely created by enforcement of regulations. Since DOE sites were operating under sovereign immunity, the incentive or market demand for creating commercial mixed waste treatment facilities was eliminated. Furthermore, since each site developed its own plan, it was impossible to determine the economies of scale that could be achieved by combining waste streams from multiple sites with common characteristics. To achieve compliance, the DOE identified numerous treatment systems at an estimated cost exceeding $7B.

Realizing the need to "do more with less," the DOE began aggressively pursuing privatization for treatment of mixed wastes. Privatization will indeed save monies. However, if the DOE is to benefit from privatization, procurements must be devised that share risk to attract the maximum number of competitors. In general, high risk will result in few

competitors, and thus higher cost to the government. This relationship is depicted below.

Fig. 1

STATUS OF CURRENT PRIVATIZATION ACTIVITIES

In 1995, the DOE moved forward with privatization plans as evidenced by solicitations issued by INEL and Hanford. The following is a summary of the terms and conditions and assessment of the associated business risk:

Table I

RECOMMENDATIONS FOR IMPROVING PRIVATIZATION

Private sector companies are not averse to assuming risk if the risk can be quantified to allow a business decision. For example, our parent company, WMX Technologies, Inc., is aggressively pursuing privatization of POTWs. These opportunities represent large capital investments and risk. However, the main differences between the POTW market and the DOE mixed waste market is that in the former we are guaranteed long term contracts. Liability is shared and rewards match risks. On the other hand, the DOE is priding itself on shifting risk to the private sector. The following must be accomplished to maximize private sector investment and participation in DOE mixed waste treatment opportunities:

- Provide adequate performance specifications
- Guarantee minimum mixed waste volumes - combine waste streams of common characteristics that can be treated by a single treatment train
- Fund initial technology demonstrations so that the private sector can gain information on waste characteristics and treatment technology efficiency
- Change terms & conditions to avoid risk language such as "termination for convenience"
- Allow waste to be treated by NRC & EPA regulations and avoid transfer of DOE orders
- Commit to schedule for delivery of waste
- Shift control to private sector and avoid having cost plus award fee contractor overseeing fixed price contractor

NATIONAL MIXED WASTE TREATMENT STRATEGY

An innovative approach for privatizing mixed waste treatment has been proposed by Lockheed Martin's Center for Waste Management at Oak Ridge. The core of this program is to establish national contracts for mixed waste treatment technologies. This approach offers the benefit of defining market demand for the private sector and allowing the DOE to take advantage of economies of scale that would be realized by combining wastes from multiple sites. In order for this approach to be successful, the DOE must receive cooperation from multiple sites. Furthermore, it will be necessary for the sites to agree on contract terms and have funding available simultaneously. One alternative would be to pool waste management funds from multiple sites and establish a single national contract for treatment technologies. A roadmap must be developed, clearly defining market demand, contract requirements and delivery of waste volumes so that the private sector can quantify risk and potential return on investment. Finally, this roadmap should include a strategy depicting which waste streams will be managed at regionalized treatment facilities and by mobile treatment systems. Regionalized privatization facilities should be procured in a standard fashion.

ALTERNATIVE TO NATIONAL PROCUREMENTS

The DOE does not need a new national procurement initiative to realize the benefits of privatization. Since procurements are moving forward at

INEL and Hanford, a new national procurement would be disruptive. Instead, to avoid redundancy the DOE should attempt to coordinate privatization procurements to ensure inclusion of wastes treatable at other sites. Secondly, standard terms and conditions, performance specifications, and other contract requirements should be structured to ensure adequate competition. By coordinating these large regional privatization initiatives (INEL, Hanford, Oak Ridge), it is anticipated that 90% of mixed waste by volume could be managed. The remaining 10% could be treated using the Oak Ridge model of combining like waste streams and procuring single vendors for each waste type. These technologies could be offered as mobile services for treatment of wastes at individual DOE sites. The services could be mobilized to one or more of the large privatization complexes or set up at a vendor's own site.

CONCLUSION

Privatization of mixed waste treatment can reduce the DOE's cost by at least half. If the DOE develops sensible contracts and defines market demand, private industry will, in the spirit of competition, make treatment capacity available. A national strategy is therefore recommended. The strategy should include privatization of regionalized facilities encompassing the maximum number of waste streams from multiple sites. It should also provide for procurement of niche technologies and services for remaining wastes. If DOE mixed waste privatization efforts are not designed correctly, the DOE will end up with few competitors, thus negating the benefits of privatization. Furthermore, private firms that accept unrealistic risk will run the chance of failure, possibly resulting in default or renegotiation of contract.

Session 55 -- WORKSHOP - REMEDIATION WASTE MANAGEMENT UNDER THE CAMU RULE AND RCRA/CERCLA INTEGRATION

ABSTRACT

The Environmental Protection Agency (EPA) has promulgated regulations governing the creation and designation of Corrective Action Management Units (CAMUs) to add flexibility to the Resource Conservation and Recovery Act (RCRA) corrective action process. In the final rule,

remediation waste is subject to land disposal restrictions (LDRs) and minimum technology requirements (MTRs) in a less limiting way than has been the case under existing regulations. Is the CAMU concept useful? This paper will explore the use of the CAMU concept and practical applications. The implementation of CAMUs will be discussed for each EPA Region and associated states. Currently, a few industrial sites have obtained CAMUs through a Class III permit modification. Details of these permits and discussions of permit applications being finalized will be presented. Draft Order modifications have been finalized for several facilities, and these will also be discussed. Some sites have presented the CAMU as an applicable or relevant and appropriate requirement (ARAR), and the difficulties encountered will be described. The possibility for application at the U.S. Department of Energy (DOE) sites will be detailed. Discussions will include the criterion for designation and "Keys for Success." Applications for CAMUs have been tracked for over two years, and specific projects, both commercial and government, will be described.

CAMU ISSUE PAPER

The Environmental Protection Agency (EPA) has promulgated regulations governing the creation and designation of Corrective Action Management Units (CAMUs) to add flexibility to the Resource Conservation and Recovery Act (RCRA) corrective action process. The CAMU is similar to the Superfund concept of "the area of contamination," in which broad areas of contamination, often including specific subunits, are considered a single land disposal unit for remedial purposes. The CAMU provisions allow for corrective actions that may not be subjected to all RCRA requirements. Rules for CAMUs achieved final status on February 16, 1993 (FR 8658), although the original corrective action rule has not been finalized in its entirety. In the final rule, remediation waste is subject to land disposal restrictions (LDRs) and minimum technology requirements (MTRs) in a less limiting way than has been the case under existing regulations. A summary of the advantages of the CAMU rule are as follows:

Remediation wastes, including hazardous wastes, may be placed in a CAMU without triggering LDRs.

Because of the flexibility in moving and placement of wastes, hazardous waste remediations may be completed in less time than corrective actions subjected to all RCRA requirements.

Cost savings can be realized by avoiding the expense of off-site incineration.

More treatment of waste is expected, resulting in remediation that is equally or more protective than current standards.

MTRs may not apply to CAMUs.

KEYS TO SUCCESS

Is it protective?

Successful CAMU applications should include a clear statement of how the CAMU will be more protective of health and the environment.

What is the timing?

CAMU applications where corrective actions will be completed before March 1997 have a better chance of success.

Is the application complete?

Failure to provide a complete response will cause delays and may jeopardize the decision process.

Fig. 1

CAMU ISSUES

A lawsuit was filed against EPA in May 1993 by the Environmental Defense Fund (EDF), Natural Resources Defense Council, and Hazardous Waste Treatment Council. The lawsuit alleges that the provisions of the CAMU rule are not protective of human health and the environment and that process waste may be mixed with cleanup waste in a CAMU. A settlement is being sought through modifications of the Hazardous Waste Identification Rule (HWIR). The first part of the proposed HWIR was signed November 13, 1995. There will be separate rulemaking for HWIR media with final action anticipated by March 1997. The HWIR is expected to divide contaminated media into two categories: highly contaminated material and less contaminated material. As defined under the rule, highly contaminated waste will be treated under Subtitle C, whereas less contaminated wastes would be exempted from Subtitle C as long as they are adequately managed under a state program.

DISPOSAL OF CURRENTLY STORED WASTES

While stored waste that is not remediation waste (i.e., process waste or other waste not generated as a result of corrective action activities) cannot be disposed of in a CAMU, it is unclear whether currently stored remediation waste could be disposed of in a CAMU. The final rule does not address this issue. A discussion with EPA indicated that it may be possible, although difficult, to obtain approval for the disposal of previously stored remediation wastes in a CAMU. The primary obstacle to gaining approval for the placement of stored remediation wastes in a CAMU appears to be centered on EPA and public concerns regarding the difficulty associated with ensuring that stored, nonremediation wastes are not unknowingly (or knowingly) placed in the CAMU. This concern appears to be strong enough that it is unlikely that facilities will be able to treat and/or dispose of previously stored remediation wastes within a CAMU.

IMPLEMENTATION POLICY

The basis for implementing the CAMU provisions rests in EPA's findings that RCRA Subtitle C requirements, when applied to existing contamination problems at a facility, can limit the flexibility of the decision maker, act as a disincentive to more innovative remedies, and provide strong incentives for leaving wastes in place. The desire to expedite corrective action and achieve reasonable cleanup solutions led EPA to develop the concept of CAMUs in the 1990 proposed corrective action rule. Because corrective action at RCRA facilities often addresses broad areas of contamination containing discrete waste management units, the consideration of a contaminated area as a whole and selection of a remedy that best addresses the entire area of contamination is appropriate. In these situations, EPA believes that the entire area of contamination can properly be considered as a waste management unit.

If the Regional Administrator determines that a CAMU designation should be made, the facility's permit or order must be modified to incorporate the CAMU. EPA intends to implement the CAMU rule in all states in which the Agency currently administers the Hazardous Waste Solid Amendment Sections 3004(u) and (v) corrective action authority. No formal CAMU guidance document exists, and the U.S. Department of Energy Headquarters does not plan to issue amendments or interpretations to the ruling. The tracking of CAMU requests is handled by the regional offices. The status is as follows:

Region I

Remington Arms (Connecticut) established a CAMU under a modification to a consent Order signed by EPA on October 1994. This CAMU is for the soil washing residue.

Region II

The Region does not have a formalized Standardized Operating Procedure (SOP) for CAMU application. EPA has developed a policy that requires initial treatment, a waste collection system, biomonitoring, and triple lining of the landfill.

American Cyanamid in New Jersey finalized a CAMU in December 1993. This was a Class III permit modification. The CAMU was a consolidation of metal sludge from small landfills into a triple lined landfill.

Region III

The Region received the following CAMU applications.

Sci-Tech (formally American Cyanamid) has finalized a Class III permit modification for the use of a CAMU at the Willow Island, West Virginia facility. An existing basin was the designated CAMU and will receive potentially contaminated soil from the Underground Storage Tank removal operations.

Standard Chlorine Superfund Site in New Castle, Delaware, is an operating RCRA facility. EPA, as the lead agency, generated a proposed plan for public comment. The facility commented that the CAMU provision should be considered as an applicable or relevant and appropriate requirement under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA). The Record of Decision did not include the CAMU. It was reported that the facility had selected an inappropriate area.

Region IV

Several facilities within the Region have submitted CAMU applications.

Air Products (Florida) submitted a proposal for a Statement of Basis in which wastes from several areas contaminated with dinitrotoluene would be consolidated into a CAMU and biotreated. This was finalized August 8, 1994. EPA signed this order September 19, 1995.

Southern Piedmont (Georgia) has submitted a proposal for a Class III permit modification for a CAMU that would be used for bioremediation of contaminated soils.

U.S. Electrical Motors (Mississippi) received a CAMU designation as part of the original Part B permit for the facility. The CAMU will be used to store soil excavated during construction of interceptor trenches.

North Carolina granted a Class III permit modification to General Timber on June 5, 1995.

Caven Ham Forestry (Mississippi) has proposed a CAMU for inclusion in the reissuance of the permit.

Region V

Ford Motor Company (Michigan) has a CAMU. Earlier the Michigan authorities had discussed this facility, but EPA had been unwilling. EPA approved the CAMU application after the CAMU Rule. There are approximately five proposals for CAMUs in this region, including Ohio and Indiana.

In Ohio, an earlier petition for a facility in Cincinnati was not granted, but one application is close. A federal site (Fernald) is in the "talking" stages at this writing.

A commercial site is being discussed in Indiana.

Region VI

The Region has adopted a formal SOP to maximize the quality of review for CAMU requests. A regional CAMU Working Group reviews applications at Peer Review meetings led by the applicant's EPA facility manager. The following facilities have received or are pursuing CAMUs.

Louisiana will require consolidation waste to meet a standard other than the best demonstrated available technology.

The W.J. Smith facility in Texas will employ a unique technology.

EPA Region VI is issuing an executive order to WITCO of Louisiana.

Region VII

All states in the Region have expressed favorable interest; however, there are no CAMUs or final applications in this Region.

Region VIII

Regional personnel identified as current policy the expedient approval of CAMU applications where remediation and completion of the corrective action is likely by 1996. The time frames used in this verbal directive coincide with the expected duration of the EDF lawsuit.

The Flying J Petroleum Refinery (Williston, North Dakota) has identified the location of a proposed CAMU in the Corrective Measures Work Plan for the Facility. These work plans have been approved. Two CAMUs are designated at this facility. One CAMU will occupy three quarters of the property. The other CAMU is for lead-contaminated soil being held for off-site shipment.

Union Pacific (Wyoming) had a CAMU designated in the work plans approved by EPA Region VIII on June 30, 1995.

For Rocky Flats (Colorado), there are early discussions concerning a CAMU. Details will be presented in a case study.

Region IX

California reported the following activities.

IT, Vinehill has requested a CAMU designation for a landfill. This landfill has gone beyond the boundaries of the county, and the facility proposes to consolidate the waste into a permanent landfill.

California has prepared an executive order for this facility.California has a two-step process: (1) designation of a CAMU and (2) preparation of an enforceable document.

Region X

Except Alaska, state interest has been favorable. The Region suggested those issues to be identified in the application are: (1) Is it justified? and (2) Will it facilitate treatment?

The Hanford facility in Washington has considered a CAMU application, but decided on a CERCLA designation.

Envirosafe Services of Idaho had a CAMU designated in the RCRA permit. The CAMU is a Titan Missile silo.

Table I

With the exception of Region VI and California, there is little formal guidance for CAMU applications. As demonstrated above, activities vary from Region to Region. The informal applications are presented to indicate the variety in timing of CAMU applications with respect to other corrective action activities.

55-3

INTEGRATING CERCLA AND RCRA TO BETTER MANAGE HANFORD'S ENVIRONMENTAL RESTORATION WASTE

Mark T. Janaskie
US Department of Energy, EM-44

Cloverleaf Building
19901 Germantown Rd.
Germantown, MD 20874-1290

ABSTRACT
The Environmental Restoration (ER) Program at the Richland Operations Office and the Office of Northwestern Area Programs at Headquarters, EM-44, have worked together successfully with regulators and stakeholders to establish a disposal facility at the Hanford site capable of managing Hanford's environmental restoration waste. The Environmental Restoration Disposal Facility (ERDF) is a technically sound, cost-effective, and "environmentally-friendly" disposal facility that is the result of an innovative integration of CERCLA and RCRA requirements. Most importantly, in this instance, the integration of CERCLA and RCRA requirements represents a new paradigm in project management, one that exemplifies the phrase "better, faster, cheaper".

INTRODUCTION
Successfully integrating the requirements of the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) and the Resource Conservation and Recovery Act (RCRA) has led to the establishment of an innovative disposal facility for managing remediation wastes at Hanford. Hanford's Environmental Restoration Disposal Facility (ERDF) is the result of a three to four-year effort between the U.S. Department of Energy (DOE), the U.S. Environmental Protection Agency (EPA), and the Washington State Department of Ecology to construct an on-site facility for managing wastes from Hanford's environmental restoration program. During that time, the three parties considered several alternatives to determine which regulatory pathway would expedite the construction and ultimate operation of the ERDF.
The ERDF is the primary disposal facility for wastes generated under Hanford's Environmental Restoration (ER) program. It is a large-scale expanding landfill, authorized under the CERCLA. Designed and constructed to comply with the technical requirements of the RCRA, the ERDF occupies a 1.6 square mile area on the central plateau of the Hanford site, approximately 200 feet above groundwater. The ERDF includes a double liner and leachate collection system. The initial trench is composed of two cells, each 500 feet wide x 500 feet long and 70 feet deep, and is designed so that it can be expanded in two-cell increments, while still allowing disposal operations to continue. This "expanding trench concept" allowed the DOE to significantly reduce overall project costs by shrinking the initial facility footprint from 6 square miles to 1.6 square miles, while still providing adequate disposal capacity for the restoration program.(1)

INTEGRATION OF CERCLA AND RCRA FOR THE ERDF
The ERDF project is authorized for operation under CERCLA. The project was designated as the DOE pilot project to integrate NEPA values into the CERCLA regulatory process. Authorization of a waste disposal facility under CERCLA, and integration of NEPA values into the CERCLA process, set this project apart from others at Hanford.(1)
The first regulatory pathway considered for the ERDF, in late 1992, was to include the facility as a RCRA land disposal unit in the overall Hanford site-wide RCRA permit, which at the time was undergoing review by the Washington State Department of Ecology. However, there was almost immediate concern among the three parties that this option was unsatisfactory, because in addition to the lengthy RCRA permitting

process, that by itself could take several years, most wastes being placed into the ERDF would likely be subject to the land disposal restrictions (LDRs), and having to treat all of them prior to disposal would be cost prohibitive.

Shortly thereafter, in May 1993, the regulators informed DOE that their preferred regulatory approach for ERDF was going to be application of the newly-issued (April 1993) CAMU rule. The CAMU rule amounted to a more streamlined approach to RCRA landfill design and construction, due to some regulatory relief from the LDRs and minimum technological requirements (MTRs). At this point, the DOE believed that the CAMU Rule was a better alternative than the usual RCRA permitting scheme because at least the CAMU Rule offered the DOE some regulatory flexibility. The terms of NEPA and its state counterpart, the Washington State Environmental Policy Act, were to be addressed in tandem with those of the CAMU. CERCLA was to be addressed, but only to the extent necessary to fulfill the requirements of NEPA. Thus, at that time, the ERDF regulatory package was to consist of a CERCLA Proposed Plan to cover NEPA, a CAMU permit application, and a draft NEPA Environmental Impact Statement.

This CAMU strategy was developed to take advantage of the teaming arrangement between the Washington State Department of Ecology and the EPA. Under the arrangement, Ecology would regulate ERDF as a CAMU under the Hanford Site-Wide RCRA permit, and under the Washington State Environmental Protection Act (SEPA), via the State Environmental Impact Statement (SEIS) process. EPA would provide oversight and issue a Record of Decision (ROD).(1)

However, by the spring of 1994, it became clear that even with the greater flexibility of the CAMU strategy, the approach could not overcome the time constraints associated with the ERDF schedule. Since the CAMU process would still require the DOE to submit extensive geotechnical data and design plans for the facility, similar to following the full RCRA process, it would likely take several years before the ERDF could be approved. There was a very real prospect of missing ERDF's TPA milestone.With Hanford's stakeholders voicing concerns about the lengthy process and potential for a missed milestone, the three parties quickly came to recognize that the solution for getting the ERDF constructed lay in CERCLA's advantages in terms of speed of implementation over the RCRA/CAMU process. With the speedier CERCLA process allowing for the technical requirements of both RCRA and CAMU to be integrated as ARARs, while also integrating NEPA values into CERCLA, the state and the EPA decided that they wanted the ERDF to be designated as a CERCLA facility.

The final CERCLA-only ERDF regulatory package was submitted in September 1994. It included the RI/FS, a Proposed Plan, a NEPA roadmap describing where in the regulatory package the NEPA values were captured, and the ROD, which was issued on January 20, 1995. The public involvement schedule, beginning with the initial siting meetings and finishing with the approval of the ROD, encompassed less then 15 months. This compares to a schedule that normally takes up to three years to complete.

LESSONS LEARNED

The ERDF project is an excellent example of reinventing government, or what the DOE-EM program refers to as "thinking out of the box". From the very start of the project, the major focus was to depart from the conventional thinking that surrounds DOE projects. Changes to regulatory programs and their standards was not considered off-limits. Moreover, when accounting for the ERDF's tight project schedule and impending TPA

milestone, new ideas for expediting ERDF construction were encouraged. With the help and cooperation of the EPA and the State Department of Ecology, as well as Hanford stakeholders, normal regulatory processes were streamlined. By integrating the technical requirements of RCRA and NEPA with the regulatory flexibility of CERCLA, the DOE was able to design and construct the most environmentally sound and cost-effective facility for Hanford's remediation waste. In hindsight, the decision to depart from conventional project management thinking has proven to be a very wise one, especially in light of shrinking EM program budgets. Without this new approach to integrate CERCLA and RCRA requirements, the ERDF would not exist.

At the present time, construction of the ERDF facility is well advanced. It is likely, weather-permitting, that the facility will be completed several months early, and begin receiving waste in July 1996. In any case, the ERDF will be ready for operations on September 30, 1996, satisfying its Tri-Party Agreement (TPA) milestone.

ABSTRACT

A 1,050 acre Corrective Action Management Unit (CAMU) was approved for the Fernald Environmental Management Project (FEMP) by the U.S. Environmental Protection Agency (USEPA) to manage environmental media remediation waste in the Operable Unit 5 Record of Decision, 1995. Debris is also proposed for management as remediation waste under the CAMU Rule in the Operable Unit 3 Remedial Investigation/Feasibility Study (RI/FS) Report, as of December 1995. Application of the CAMU Rule at the FEMP

will allow consolidation of low-level mixed waste and hazardous waste that presents minimal threat from these two operable units in an on-property engineered disposal facility without triggering land disposal restrictions (LDRs). The waste acceptance criteria for the on-property disposal facility are based on a combination of site-specific risk-based concentration standards, as opposed to non-site-specific requirements imposed by regulatory classifications.

The designation of the CAMU was proposed because the Department of Energy (DOE) will manage low-level radioactive waste, hazardous substances, hazardous wastes and/or mixed wastes as remediation wastes pursuant to Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) response actions at this former uranium processing facility. Certain regulations promulgated under the Resource Conservation and Recovery Act (RCRA) were evaluated as applicable or relevant and appropriate requirements (ARARs) for remediation of the FEMP, including the CAMU Rule. Therefore, the CAMU will add a measure of flexibility in order to expedite and improve FEMP remedial actions. Compliance with these ARARs would have increased the cost and time of the remedial projects without providing any additional protective measures.

Specific aspects of remediation will be expedited under the CAMU at the FEMP, based on negotiations with the Ohio Environmental Protection Agency (OEPA) and the USEPA, Region V. Environmental media and other remediation waste that may contain listed hazardous wastes may be managed in the on-property disposal facility that are below the site-specific waste acceptance criteria (WAC). The OEPA, in supporting this concept, has expressed a desire to limit placement of characteristic waste in the on-site disposal facility. Listed waste from any area will not invoke treatment standards because the regulatory status of the waste will change from "listed" to "remediation" waste. For example, if an area of concern is identified through field monitoring instrumentation, then treatment will only be required if the media affected by a source of released contaminants exhibits toxicity characteristic concentrations.

Temporary units (TUs) and existing facilities will be designated under the CAMU in remedial action work plans when needed to facilitate remediation. These standards will allow for more flexibility in using the minimum technology requirements (MTRs) so that existing structures may be used to facilitate remediation.

WHY USE A CAMU?

Historically, joint CERCLA-RCRA guidance dictated that hazardous waste could not be treated or moved out of the designated area of contiguous contamination (AOC) without triggering LDRs or MTRs. The Corrective Action Management Unit (CAMU) Final Rule (58 FR 8658, Vol. 58, No. 29), promulgated on February 16, 1993, provides facilities undergoing RCRA corrective action with greater flexibility to move, treat, and dispose of wastes on site without triggering LDRs or MTRs, thereby encouraging application of innovative technologies and more protective remedies.

If on-property disposal is selected as part of the preferred alternative for a CERCLA site, there are three possible options for on-site management, treatment, and disposal:

1) comply with LDRs and possibly request any combination of the following: a no migration petition, a treatability variance, a treatment and storage facility variance, or a delisting petition; or

2) application of the "CAMU Rule"; or

3) request an ARARs waiver under CERCLA.

Management and treatment of low-level mixed waste (LLMW) at the FEMP was proposed using the "CAMU Rule" because the soil and debris containing hazardous waste are remediation wastes. In addition, the other options cited above under option 1 would prove to be more costly to meet treatment requirements and time-consuming to receive approval for variances, waivers, or petitions that do not improve the degree of protection to human health or the environment.

The "CAMU Rule" can be invoked only if the waste to be managed is a remediation waste (i.e., not part of an "as generated" process). A "remediation waste" is defined in 40 CFR 260.10 [58 FR 8683] as:

"all solid and hazardous wastes, and all media (including groundwater, surface water, soils, and sediments) and debris, which contain listed hazardous wastes or which themselves exhibit a hazardous waste characteristic, that are managed for the purpose of implementing corrective action requirements under 264.101 and RCRA section 3008(h). For a given facility, remediation wastes may originate only from within the facility boundary, but may include waste managed in implementing RCRA section 3004(v) or 3008(h) for releases beyond the facility boundary."

Disposal of hazardous waste constituents during Superfund actions requires compliance with several potential ARARs under RCRA. Once waste is picked up under the CERCLA area of contamination (AOC), or from the RCRA unit, the requirements for waste disposal are triggered. The LDR treatment standards often cause increased cost and time for remediation. For this reason, many facility owners have historically opted to cap contaminated soil in place and avoid triggering waste placement standards. With the promulgation of the CAMU Rule remediation waste can be managed based on protective site-specific standards and at a lower cost to the remediation project.

Compliance with the LDRs presents the most stringent potential waste placement RCRA ARARs. LDRs can be triggered as applicable requirements by "placement" of restricted RCRA hazardous wastes in land-based units. Land-based units include landfills, surface impoundments, waste piles, and land treatment facilities.

CAMU RULE CRITERIA

EPA promulgated the "CAMU Rule" under RCRA to promote the most efficient and cost-effective remediation possible. In the absence of the CAMU Rule, LDRs are triggered when "placement" occurs, as described above. In promulgating the "CAMU Rule", the EPA provided a separate regulatory framework to manage remediation waste, judiciously expedite cleanups, and reduce costs. In this respect, CAMUs can only be used for management of remediation waste, not for "as generated" hazardous wastes from ongoing production processes or other industrial activities.

The CAMU designation criteria are related to the practical necessities of managing remediation wastes on site during cleanup, rather than to the areal extent and the contiguousness of the contamination prior to cleanup. A CAMU can be designated to include the entire facility, but cannot be extended beyond the facility property boundary even if the contamination release has migrated beyond the facility boundary. However, remediation wastes, especially environmental media, can be managed within the CAMU even if they are associated with a release that has migrated beyond the facility boundary.

The "CAMU Rule" also created Temporary Unit (TU) provisions [40 CFR 264.553, 58 FR 8684] that can be applied to treatment or storage of remediation wastes during remedial activities. TUs can be located inside

or outside the physical boundaries of a CAMU; however, like CAMUs they must be located at the facility. The EPA Regional Administrator determines the requirements for siting, operating, monitoring and closing a TU. Like CAMUs, TUs are also not subject to LDRs and MTRs. There is a one-year time limit on the use of the TU which can only be extended an additional year if the wastes have to remain in the unit due to "unforeseen, temporary, and uncontrollable" circumstances.

According to 40 CFR 264.552(c), seven criteria are to be considered to designate and approve CAMUs for purposes of managing remediation waste:

1) Facilitate the implementation of reliable, effective, protective, and cost-effective remedies.

2) Waste management activities will not create unacceptable risks to humans or to the environment resulting from exposure to hazardous wastes or hazardous constituents.

3) Include uncontaminated areas of the facility, only if including such areas for the purpose of managing remediation waste is more protective than management of such wastes at contaminated areas of the facility.

4) Wastes that remain in place after "closure" of the CAMU shall be managed and contained so as to minimize future releases, to the extent practicable.

5) Expedite the timing of remedial activity implementation when appropriate and practicable.

6) Use treatment technologies (including innovative technologies) to enhance the long-term effectiveness of remedial actions by reducing the toxicity, mobility, or volume of wastes that will remain in place after "closure" of the CAMU.

7) To the extent practicable, minimize the land area of the facility upon which wastes will remain in place after "closure" of the CAMU.

FEMP SITE BACKGROUND

The Fernald Environmental Management Project (FEMP) is a facility owned by the U. S. Department of Energy (DOE). The Fernald facility occupies approximately 1050 acres in a rural area approximately 18 miles northwest of downtown Cincinnati, Ohio. The facility was operated for production of purified uranium metal from 1952 until 1989, when operations were suspended. In July 1986, a Federal Facility Compliance Agreement was jointly signed by the U.S. Environmental Protection Agency (EPA) and the DOE to perform site characterization. In April 1990, the EPA and DOE entered a Consent Agreement for cleanup of Fernald as a Superfund site under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA). This agreement has been revised several times, and is now referred to as the Amended Consent Agreement (ACA). In 1988, a Consent Decree was jointly signed by the Ohio Environmental Protection Agency (OEPA) and the DOE, under Clean Water Act and RCRA authorities, that provides for the management of water pollution and hazardous wastes, including closure of hazardous waste management units (HWMUs). This Consent Decree was amended in January 1993, and together they are collectively referred to as the Stipulated Amendments to the Consent Decree.

Several RCRA-regulated hazardous wastes were generated during the production of uranium. Since the shutdown of production operations at the facility, several HWMUs have been identified. Knowledge of releases from the HWMUs will necessitate compliance with RCRA during the remediation of building debris, and soil and groundwater impacted by these releases. All environmental media (soil, groundwater, and sediment) which contain

hazardous waste constituents are anticipated to also be low-level mixed waste (LLMW) due to pervasive low-level radioactive contamination at the FEMP. These remediation wastes will be managed under the provisions set forth by DOE, EPA, and OEPA to designate the CAMU at the FEMP.

The ACA divided the site into the following five operable units (OUs) based upon their location or the potential for similar response actions:

- OU1 Waste Pit Area Waste Pits 1 - 6, Burn Pit, Clearwell
- OU2 Other Waste Units Solid Waste Landfill, Southfield Disposal Areas, Flyash Piles, Lime Sludge Ponds
- OU3 Former Production Area production area and production-associated facilities and equipment
- OU4 Silos 1 - 4
- OU5 Environmental Media soil, groundwater, surface water and sediments, flora and fauna

In accordance with their signed Records of Decision (RODs), OUs 1 and 2 will ship their RCRA-regulated remediation wastes off-site, which will require complying with the RCRA LDRs for acceptance at the off-site disposal facility. In contrast, OU5 will to dispose of material containing hazardous waste constituents in an on-property engineered waste disposal facility, and OU3, in its RI/FS Report, is considering on-site disposal for its material.

IMPLEMENTATION OF THE CAMU AT THE FEMP

The boundaries of the CAMU are designated in the OU5 ROD to coincide with the 1,050 acres of land within the FEMP property boundaries, such that remediation waste from the entire site (CERCLA's definition of "site") can be managed within the CAMU. The CAMU is also designated to include the on-property disposal facility, provided those wastes meet site-specific waste acceptance criteria that are protective of human health and the environment. A map of the Fernald site (Fig. 1) shows the area of excavation, which was determined by the lateral extent of uranium that exceeds the site-specific, risk-based, cleanup level. The cleanup level is based on an 1 x 10-5 incremental lifetime cancer risk for an undeveloped park, as described in the OU5 Proposed Plan and ROD. The Production Area on Fig. 1 represents the anticipated areas containing potential hazardous wastes. The on-property disposal facility will also function as part of the CAMU. Existing structures to be closed during remediation, and TUs under the CAMU Rule, as needed for on-property disposal, will be designated in the appropriate remedial action work plans.

Fig. 1

The seven criteria described above will be met through the selected remedies described in the OU5 and OU3 RODs, respectively. Each criterion above is referenced below in parentheses where each one is addressed. The on-property disposal facility will serve as a reliable method of containment, which will be designed to be effective for 1,000 years [40 CFR Part 192] (Criteria 1 and 4). In addition, the on-property disposal facility will minimize the land area for wastes that remain on-property (Criterion 7). The use of concentration-based WAC for on-property disposal of LLMW constituents will ensure protection to the sole-source aquifer beneath the site, which are determined through site-specific extensive remedial investigations, risk-based calculations and modelling (Criterion 2). Therefore, on-property disposal will be more cost-effective than shipping large volumes of LLMW off-site for disposal (Criterion 1). In addition, the statutory preference for treatment

(Criterion 6) will be met through treatment of those excavated volumes that are statistically indicated to be characteristically hazardous.
The CAMU will expedite remediation by minimizing segregation, analytical testing, and handling time that otherwise would be needed to meet the specific LDR treatment requirements for individual hazardous wastes (Criterion 1).
The use of existing interim status HWMUs and TUs under the "CAMU Rule" during remediation will also expedite remediation because the need for construction of new storage or treatment facilities will be minimized. In addition, the use of these existing facilities and TUs will not cause any additional impact on the environment where soil and groundwater contamination already exist. Application of MTRs, intended to prevent contamination of soil and groundwater, would not be logical for existing facilities/units since the very situation which they are intended to prevent already exists at the site. If TUs are used for the Fernald site, initial analysis within the OU5 Feasibility Study (FS) indicates they might be needed for the duration for soil remediation.
Remediation costs will be considerably reduced by the application of the "CAMU Rule" at the FEMP. OU5 contains an estimated minimum volume of 28,000 cubic yards of soil containing RCRA-regulated constituents. Most of this soil contains constituents that may be from listed wastes, but which are not anticipated to exceed the WAC for the on-property engineered disposal facility. Only small volumes of soil may be statistically representative of characteristically hazardous waste.
OU3 (the former production facilities) activities currently involve decontamination and dismantlement of the structures under a Record of Decision for Interim Remedial Action (IROD); up to 10% of the material removed under the IROD can be disposed at an off-site location. It is anticipated that this will typically consist of radioactively-contaminated building materials which will be handled as low-level waste (LLW). Other wastes are currently being managed in accordance with approved removal actions. Final disposition of the material removed in building dismantling will be addressed in a combined Remedial Investigation/ Feasibility Study (RI/FS) Report and Proposed Plan currently in preparation, leading to a final ROD. The OU3 RI/FS is analyzing three alternatives: 1) no further action (indefinite storage); 2) disposal in an on-site engineered disposal facility; and 3) off-site disposal.
Although some of the resultant OU3 remediation waste material will likely be classified as mixed waste, the implementation of the "CAMU Rule" will impact the level of treatment that will be required for disposal in an on-site disposal facility. The constituents in the material are not expected to exceed the WAC for the on-site disposal facility. If they do, however, the remediation waste material will either have to be treated to meet the on-site WAC, or be treated in accordance with LDR requirements and be disposed of off-site at a permitted/licensed mixed waste disposal facility at a significantly greater cost.
IS THE CAMU FOR YOU?
EPA's intent in promulgating the CAMU Rule was to allow sensible cleanup solutions for existing contamination problems while attaining the statutory standard to protect human health and the environment. Therefore, any site in the process of developing a cleanup strategy for existing contamination should consider using the CAMU Rule as a tool for implementing a potentially more cost-effective remedy. Attributes of a

site that might influence a decision to designate a CAMU include the presence of contaminants at a site that would be regulated under RCRA and/or CERCLA, and where corrective action or remedial action is indicated. In addition, the use of a CAMU would be most appropriate for sites that plan to treat waste on-site so that staging areas, treatment units and existing facilities could be designated for remediation purposes, and especially if the remediation waste may be managed permanently in an on-property disposal facility.

SUMMARY

The use of the CAMU at Fernald is approved by the regulatory agencies via OEPA concurrence and EPA's signature of the OU5 ROD (January 1996). A similar approach is anticipated for OU3's ROD (projected for EPA signature in late 1996). The CAMU Rule is the most appropriate method for compliance during remediation of soil and debris at the FEMP because the substantive requirements under Subtitle C will be met for providing long-term, cost-effective, practical and protective remediation. In this respect, application of the CAMU should be considered at other sites undergoing environmental restoration, regardless of whether it is being conducted as a CERCLA response action (removal action or remedial action) or RCRA corrective action.

ABSTRACT

Across the DOE complex, hundreds of above and below ground storage tanks contain large amounts of high-level waste. The Fernald Environmental Management Project, a site within the DOE complex, contains four, above-ground, domed, concrete waste tanks. Some structural deterioration has been noted in the walls and domes of the tanks, resulting in concerns about leakage of their contents. Waste retrieval for final remediation must begin in 1997.

RedZone Robotics, Inc. and Carnegie Mellon University (CMU) are developing a tethered mobile robot, Houdini, to work inside waste storage tanks in support of the Department of Energy's Environmental Restoration and Waste Management (EM) Program. The development of Houdini is funded by the DOE's Office of Science and Technology through the Morgantown Energy Technology Center. Houdini will first be deployed at Fernald in support of the waste retrieval for final remediation of the K-65 waste silos. Fernald personnel are active members of the development team.

Houdini is a tethered, hydraulically powered, track driven, teleoperated, work machine with an expandable frame chassis that allows it to fit through confined entries as small as 0.57 meters (22.5 in.) in diameter.

The Houdini system performs heel removal, waste retrieval, waste mobilization, waste size reduction, and other tank waste retrieval and decommissioning tasks. It is equipped with an articulated plowing blade and a manipulator with exchangeable end effector tooling. Tooling consists of a gripper, scoop, shear, vacuum suction hose grip, and spray-down nozzle. The system can locomote over and through a variety of waste forms, and can operate fully submerged. An operations trailer houses Houdini's primary operator interface console. Joysticks, switches, and remote-viewing monitors allow the operator to control the system from a remote location. A second, portable control station provides the capability for local operations, on-site debugging, system checkout, and emergency recovery. A navigation system developed at Oak Ridge National Labs (ORNL) provides the operator with feedback on the vehicle's position and orientation inside the tank.

Robotic systems are needed to work inside waste storage tanks in support of the DOE's EM activities. As a technology for supporting the DOE's EM program and in comparison or collaboration with other competing technologies, Houdini provides many benefits. The Houdini system is designed to eliminate or reduce potential public and operational health risks associated with work on DOE tanks. The system provides fully-contained remote operation, reducing the risk of spreading contamination outside of the tanks. Because of Houdini's similarity to bulldozers and backhoes from the construction industry, it provides simple, intuitive, and efficient waste handling techniques. Houdini's transportation, installation, deployment, and removal operations are simple due to its compact size. Houdini's simplicity and operational capability lead to cost efficiency with respect to development, operation, and maintenance. The Houdini concept was developed specifically in response to the needs at Fernald, but is useful at a number of other DOE sites where tank remediation projects are planned. Upon successful completion of the development program, in late 1996, RedZone will make the results of this program commercially available.

INTRODUCTION/NEEDS

RedZone Robotics, Inc. and Carnegie Mellon University (CMU) are developing a tethered mobile robot, Houdini, to work inside waste storage tanks in support of the Department of Energy's Environmental Restoration and Waste Management (EM) Program.a This project is funded by the DOE's Environmental Management Office of Technology Development through the Morgantown Energy Technology Center (METC). Our goal is to develop technology that is useful for in-tank operations throughout the DOE's EM program. The first application of the Houdini system is to support the waste retrieval action planned for the final remediation of the Fernald site's waste silos. RedZone and CMU have discussed potential applications for the system with personnel from several other DOE sites, and have found that the system would be widely useful in the DOE complex for tasks both inside and outside of waste storage tanks. We are tailoring the first implementation of the Houdini system to the specific needs of the Fernald silo remediation. The Fernald application-specific design constraints are primarily interface issues and should not interfere with the utility of the system at other sites.

In addition, DOE personnel at the Oak Ridge National Laboratories (ORNL) have expressed a strong interest in the Houdini system. They have a target application scheduled for mid-1996. This program represents a unique opportunity to develop a new technology that has immediate

application in two CERCLA cleanup actions; the proposed applications at Fernald and ORNL support Federal Facility compliance agreements.

OBJECTIVES/PROBLEMS

The primary application for the Houdini system is to support the final remediation of Silos 1, 2, & 3 at the Fernald Site. Houdini will perform essential missions in support of this final remediation effort that will retrieve waste from the tanks and vitrify it for long term storage.

The CRU4 area at the Fernald site contains 4 above-ground, concrete waste silos. All four domed waste silos are 24.4 meters (80 feet) in diameter, 11 meters (36 feet) high at the center of the dome, with 8.3 meter (27 foot) high vertical walls. Four 0.51 meter (20 inch) diameter manways are evenly distributed around each tank dome at 15 feet from the side walls, at a slant of 17 degrees from horizontal. A fifth 20 inch manway near the center of the dome will be eliminated when a 6 foot opening is created to support the remediation activity.

Some structural deterioration has been noted in the walls and domes of the silos, resulting in load restrictions. No detectable load is allowed on the 6.1 meter (20 foot) diameter center section of the dome. On other dome areas, the maximum live load is limited to 700 pounds including personnel and gear.

Waste material in Silos 1 and 2 is described as K-65 material and has the consistency of toothpaste. The waste is covered with a 0.3 meter (12 inch) thick layer of Bentonite clay to reduce radon emissions from the waste. Material in Silo 3 is a light, dry metal oxide powder similar in consistency to talcum powder. The Silo 3 waste may be compacted near the bottom of the silo. In addition, each silo contains pipes, wrenches, sample bottles, gloves, and other debris that has fallen into the tanks over the years.

The fourth silo is identical to the other three, but was never used for waste storage. It will be used as an uncontaminated mock-up facility to fully test all procedures prior to remediation of other silos. Silo 4 may be partially filled with a surrogate waste material to support these tests.

To enable the waste retrieval operations in light of the dome load restrictions, a superstructure has been constructed over Silo 4. An equipment room situated over the center of the dome is supported by the superstructure. Seals will be installed between the equipment room and the silo dome and a six foot diameter opening will be made in the silo dome directly under the equipment room. Doors in the equipment room floor will provide access to the tank. Controlled entry points, rails, winches, equipment carts, and other mechanisms in the equipment room will support the deployment and retrieval of equipment into the silo.

The primary retrieval method for Silo 1 and 2 waste will be hydraulic removal. A sluicing pump will be lowered into the tank from the equipment room. Water will be added to the waste material and the liquefied waste will be pumped out of the tank. In Silo 3, pneumatic conveyance will be used to retrieve the waste material. The methods will remove the bulk of the waste materials from the tanks, leaving only debris and a waste heel to be removed by other means.

APPROACH/SOLUTION

The Houdini system will be used for heel and debris removal from the tanks, during and after the bulk material removal by sluicing and pneumatic conveyance. In Silo 4, Houdini's capabilities will be fully tested in an uncontaminated environment. The silo will be partially

filled with surrogate waste material and debris that approximates the waste properties in Silos 1 and 2. During bulk material removal, Houdini will be deployed to remove debris material that interferes with the sluicing operation. Using a shearing tool and gripper, Houdini would be deployed to gather debris, size reduce the debris as necessary, and load the debris into a tram bucket for retrieval from the tank. After the bulk waste removal action is complete, Houdini will be deployed to perform waste heel removal and debris collection. To perform the heel removal, a small sluicing pump will be lowered into the tank. Houdini will use its gripper to deploy a water spray nozzle. Water spray will be used to mobilize the heel material and wash it toward the sluicing pump for removal. The Houdini plow blade will be equipped with squeegees on the sides and bottom and will be used to push slurried waste material toward the sluicing pump. The edge of the plow blade can be used to push waste material away from the side wall of the tank to clean the edges of the tank floor. Houdini can also be used to wash down or apply a spray coating to the tank side walls for decontamination.

In Silos 1 and 2, Houdini will be used to support waste retrieval for final remediation in the same modes as described above for the Silo 4 functional test. The radioactive waste in Silos 1 and 2 will be primarily retrieved by sluicing, after which, the waste will be vitrified for long term storage.

In Silo 3, Houdini will support waste retrieval for final remediation in conjunction with the bulk material removal by pneumatic conveyance. Specifically, Houdini will perform debris collection, size reduction, and removal during and after bulk pneumatic conveyance, and perform heel removal by deploying a pneumatic vacuum hose. In addition, Houdini could be used to plow waste material to a central point for pneumatic retrieval. Houdini could also deploy tools to assist in removing compacted waste material from the tank floor.

PROJECT DESCRIPTION/TECHNOLOGY

System Overview

The Houdini system consists of five main components and their subsystems; the vehicle, deployment system, PDCU, control consoles, and tooling.

Vehicle

The vehicle is a hydraulically-powered, track-driven, folding frame machine similar to a small bulldozer. The vehicle can fold to fit through a 0.57 meter (22.5 inch) diameter opening for deployment, and is equipped with a plow blade and a manipulator arm. The plow blade also folds for deployment and can be height-adjusted for plowing various materials at various rates. The manipulator is a Schilling Titan class hydraulic dexterous manipulator, which can deploy a variety of tooling for performing work inside a tank. The vehicle tether is attached to the rear of the folding frame assembly. The tether termination will support the full weight of the vehicle and tooling to enable deployment and retrieval. Two camera and light assemblies provide visual feedback for remote operation. One camera and light unit is mounted on the forearm of the manipulator. The camera is aimed by orienting the manipulator. The second camera unit includes a pan and tilt unit and is mounted on a mast at the manipulator shoulder. A microphone will provide audio feedback to the operator. Navigation system sensors will be installed on the vehicle as part of the navigation system interface.

Deployment System

The deployment system is designed to interface with the superstructure and equipment room above the Fernald waste silos. It is an important part of the Houdini system. First, it provides a convenient way to remotely manage and store the 150 feet of tether that is the lifeline of the Houdini vehicle. Second, it provides the lifting force that is needed to lower and raise the vehicle into and from the tank. Third, it provides a "docking area" where the vehicle can be secured during storage or transport, and lastly, it provides an area where spare parts or tools can be stored when not in use.

Tether Reel

The tether reel is a "spool" looking device that is 48 inches in diameter and 30 inches wide. A flange at each end contains the tether on the drum. Payout of the tether is controlled by a mechanical level-wind system that ensure that the tether does not cross over on itself and tangle. The tether reel is driven by a hydraulic motor with a "power-off" brake in case of hydraulic power loss. The hydraulic motor is sized to allow a pull force of 2000 lb tangent to the reel surface. A payout sensor is used to monitor the length of tether that has been reeled out. The sensor shall also indicate ends of travel (i.e., when the tether is completely in or out). A means of manual retrieval is necessary in case of hydraulic power failure. This is accomplished with an external, battery powered, hydraulic supply and manually operated valve.

Tether

The tether is used to lower and raise the vehicle in the tank and provides control signals and electric and hydraulic power to the vehicle. The tether will be a custom fabrication that includes:

- Strain-relief termination
- Hydraulic supply and return lines
- Shielded-twisted pairs for control and feedback signals
- Mini-coax lines for camera signals
- Shielded-twisted pairs for navigation system signals Conductors for power to onboard valving
- Kevlar braid for structural support (to carry the weight of the vehicle)
- Abrasion resistant coating

Power Distribution and Control Unit

An environmentally sealed and temperature controlled power distribution and control unit (PDCU) will be installed on the superstructure, outside the equipment room. The PDCU includes the electric transformers and distribution/conditioning equipment, the control system, and tether and control system interface connectors. A separate enclosure will house the electrically-powered hydraulic power supply.

Control Console

The operator console provides the operator interface to the Houdini system. The console includes joysticks, switches, a master manipulator, and video monitors for controlling system functions and monitoring system operation.

Navigation System Interface

An interface will be provided to the Position and Orientation Tracking System (POTS) which has been developed at ORNL. ORNL has agreed to make POTS available to this program as Government-Furnished Equipment. POTS will provide accurate feedback on the vehicle's position and orientation inside a tank to enable more efficient and robust controls.

Control Trailer

A control trailer will house the operator control console. The trailer will be a simple mobile, industrial trailer that provides heated and air conditioned real estate for the operator. Tie downs will be provided for securing the trailer against high wind. The trailer will be structurally capable of being moved with the control console inside. The trailer will require 110 volt site power.

Suitcase Controller

A hard-wired suitcase controller will be available to perform system checkout, local operations and provide for emergency operations in the case of console/control computer or telemetry failures between the control center and the deployment system. Switches, buttons, and a single remote viewing monitor will provide for simple operations from the suitcase controller.

Tooling

Specialized tooling will be provided to enable the use of the Houdini system in support of the Fernald waste retrieval plans. The bottom and sides of the plow will be equipped with squeegee blades to provide efficient mobilization of the waste slurry on the floor of the tank. A gripper, shear, and scoop will be provided for deployment from the manipulator. For sluicing operations, Fernald will provide a small pump for heel removal operations; RedZone will equip the pump with a water line, hose reel, and spray nozzle that can be deployed by the Houdini manipulator to spray-wash waste material toward the sluicing pump. For vacuum retrieval operations, Fernald has agreed to provide a hose grip that will attach to the manipulator and enable the deployment of a pneumatic vacuum hose.

APPLICATION/BENEFITS

As a technology for supporting the DOE's EM program and in comparison or collaboration with other competing technologies, Houdini provides many benefits. The Houdini system is designed to eliminate or reduce potential public and operational health risks associated with work on DOE tanks. The system provides fully-contained remote operation, reducing the risk of spreading contamination outside of the tanks. Because of Houdini's similarity to bulldozers and backhoes from the construction industry, it provides simple, intuitive, and efficient waste handling techniques. Houdini's transportation, installation, deployment, and removal operations are simple due to its compact size. Houdini's simplicity and operational capability lead to cost efficiency with respect to development, operation, and maintenance.

Evaluating the merits of the Houdini system for these applications requires comparing it to competing technologies. In comparison to mobile robot systems that are currently available, Houdini's folding frame technology provides a substantially larger work platform which can fit through existing tank openings. As a larger platform, Houdini is more powerful, more efficient, and more capable than other, smaller mobile systems.

Several non-robotic retrieval methods are being considered for use in DOE tanks. These technologies, such as sluicing, pumping, and pneumatic conveyance, are appropriate or preferred technologies for some of the tanks in the complex. As it will at Fernald, Houdini could assist in the application of these retrieval and conveyance methods. In addition, the current design could be applied for use in Oak Ridge's north and south tank farms.

Depending on specific work tasks and application sites, Houdini can be deployed to either complement or replace a long-reach manipulator (LRM) system. Used in conjunction with LRMs, Houdini provides additional or enhanced capabilities inside a tank. In tasks where Houdini is useful instead of LRMs, Houdini will be simpler and less expensive to deploy, operate, retrieve, and decontaminate than LRMs.

FUTURE ACTIVITIES/APPLICATIONS

In addition to the primary application at Fernald, other applications for Houdini have been identified in support of tank waste retrieval operations in the DOE and private sector. Also, several tasks outside of tanks have been identified for which Houdini would be useful.

Oak Ridge North and South Tank Farms

The north and south tank farms at Oak Ridge National Laboratory have a total of 16 domed, cylindrical, single-shelled, underground storage tanks made of Gunite (similar to concrete), ranging in diameter from 20 to 50 feet and equipped with 24 inch diameter manway penetrations. These tanks were used to store laboratory waste and are expected to contain a wide variety of materials, with estimated radiation levels of 1 to 100 R. During 1983-1984 the tanks were emptied through a sluicing method, leaving a heel of up to several feet thick at the bottom. The heel waste must be removed to prevent the migration of waste material out of the tanks. ORNL is under a Federal Facility Compliance Agreement to complete a CERCLA treatability study on the Gunite and associated tanks. The baseline plan for this study includes the evaluation of both vehicle- and arm-based retrieval systems. The current plan at ORNL is to evaluate the Houdini vehicle during this study, and if successful, Houdini might be selected for the final remediation retrieval action.

Other DOE Tank Applications

The Houdini system is useful in a variety of other DOE tank waste retrieval operations. Houdini could be deployed in a tank prior to the major removal action to collect additional information about the waste content and tank interior.

In support of other in-tank work systems, such as long reach manipulators, Houdini could be used to deploy cameras, lights, and sensor systems. The mobile deployment of such monitoring equipment will provide viewing and data gathering flexibility that cannot be achieved by mounting such equipment on fixed masts or on a long reach manipulator.

The long reach manipulator (LRM) systems that are being developed for tank waste retrieval will require a variety of tools to accomplish their tasks. The Houdini crawler could serve as a mobile tool carrier for the LRM, carrying several tools and making them available at the most appropriate location inside the tank.

In support of final tank decontamination and decommissioning, Houdini could deploy tools to scarify internal tank surfaces.

Commercial Tank Applications

Periodic cleaning and inspection of storage tanks in petro-chemical industries are becoming common maintenance procedures. It is likely that these procedures will be required by law in the US in the next few years. We have been in contact with several service providers in the petro-chemical industry, who have expressed an interest in the Houdini system in support of these operations.

Non Tank Applications

Alternate uses currently envisioned for this system include indoor as well as outdoor tasks. In support of buried-waste excavation programs,

Houdini could perform fine excavation and monitoring to assist a larger remote excavator, perform fine excavation to isolate and extract specific objects, and assist removing a drum in one piece. In support of decontamination and dismantling programs, Houdini could be used as a small platform to gain access through tight areas for selective equipment removal and could lend assistance to larger worksystems as a tool-carrier platform, size-reduction system, or waste packaging system. In support of surveillance and monitoring operations, it could perform such functions as monitoring drum storage areas and decommissioned processing areas requiring access to tight corridors. Removal of the tether is possible through the use of a gas-engine or batteries and the interface of a radio telemetry system.

ABSTRACT

This paper describes the design, manufacture, integration, testing, training, and commissioning of 2 Remote Controlled Material Handling System (RCMHS) for the retrieval of approximately 5,600 drums containing solid Thorium waste at DOE's Fernald site. The work was performed by Spar Environmental Systems in partnership with RSI Research under a contract from Fernald Environmental Remediation and Management Company (FERMCO). The RCMHS design and development program presented unique challenges to produce two remotely controlled vehicles capable of inspecting, acquiring, retrieving, and disposing of drum containers containing solid thorium waste. A very aggressive schedule had to be matched with meeting stringent safety requirements and developing systems capable of handling drums ranging in size from 35 to 110 gallons and weighing up to 1300 lb each. The system also had to lift and transport a fully loaded Thorium Overpacking Container (TOC), which is a 6 drum holding pallet and a lid, weighing up to 8,000 lbs when full.

The design concepts were developed at the proposal stage and were adhered to with minimal changes on a fast track program to mitigate risk. The program required that detailed design be completed, materials and parts be manufactured, software written, and the system integrated and tested within 12 weeks from issue of the contract. The RCMHS system was designed around a standard Nissan "Box Car" fork lift truck which was heavily customized for remote control. The vehicle includes a unique Drum and Plywood Handler (DPH) which is a specialized 4 degree of freedom attachment designed to manipulate either drums or plywood sheets, see Fig. 1. In addition the RCMHS is capable of remotely picking up loose material with special purpose clean-up tools.

The two systems have been delivered and commissioned at the Fernald site and are ready for operations inside the drum storage warehouse, Fernald Site Building 69. With 12 site operators fully trained and the system is now being put into service.

Fig. 1

RCMHS GENERAL DESCRIPTION

The Remote Controlled Material Handling System (RCMHS) is a highly modified 8000 lb commercial fork lift truck which provides the capability of handling radioactive thorium waste stored in a warehouse. The drums are stacked tightly together, three tiers high with plywood sheets separating the tiers. To complete the remediation project the RCMHS undertakes the following 5 functional tasks:

1) Normal drum retrieval, through grasping the drums by their chimes;
2) Corroded drum retrieval through grasping and supporting the bottom of the drum or rotating of the drum so that the lid becomes the new base;
3) Plywood separator retrieval, by lifting and clamping the plywood sheets and placing them in a stack;

4) Debris clean up, achieved by the DPH picking up the spillage container and the debris sweeper;
5) Moving Thorium Overpacking Containers and removing / replacing the lid to these containers, achieved with standard forks and sideshifter.

REMOTE CONTROL BASE UNIT

The Remote Control Base Unit (RCBU) consists of the Base Fork Truck, the On Board Remote Controllers (3), the Visual Monitoring System, Hydraulic control modules, hoses, and cables, see Fig. 2 for general overview layout. The Base Fork truck is an 8000 lb capacity, 2 wheel drive, liquid propane gas powered, "Box Car" Fork Lift Truck (Box Car models are approximately 8 inches shorter which gives a tighter turning radius). A three stage mast provides up to 151 inches of lift capability with 6925 lbs at a 24 inch offset from the face of the forks. With 8000 lbs at 24 inches, the mast can be raised to a height of 41 inches in free lift mode; where the carriage rises on the central cylinder but the mast stages remain collapsed. The mast can be tilted from 5 degrees forward and 5 degrees backwards.

Fig. 2

Permanently mounted to the RCBU lift carriage is a side shifter which provides +/- 4 inches of lateral movement and functions as a platform for the mounting of the DPH or Forks. The centre of gravity of the cargo was offset by an additional 3 inches from the front axle of the lift truck as a result of the thickness of the sideshifter being added to the carriage. This added to the weight of the side shifter, approximately 400 lbs, meant that the counter weight at the back of the vehicle had to be supplemented with an additional 600 lbs to ensure the handling characteristics with full load were maintained. The On Board Remote Controller (OBRC) provides local vehicle control for the RCBU hydraulic actuators and camera/ Pan/Tilt Unit (PTU) functions. It also receives and transmits data to the Control console, and provides system health monitoring. The RCBU includes the camera/PTU assemblies and their support frame. The electrical system of the lift truck was modified to include an additional battery for the OBRC to ensure that the voltage levels were maintained during start up. The alternator was replaced with a larger capacity unit to supply the needs for the electronics, lights, camera assemblies, and hydraulic valves. The gear pump that was supplied with the lift truck was replaced with a pressure compensated hydraulic piston pump to reduce the heating effect on the hydraulic fluid.

ON BOARD REMOTE CONTROLLERS (OBRC)

The OBRC controls the RCBU and drum /plywood handler functions through proportional valves, solenoid valves and, pressure and flow regulators. In case of an emergency, the parking brake is automatically activated by the Controllers if the health monitoring system is triggered by a telemetry fault, loss of hydraulic pressure, or electrical power disruption. The fail safe capability of the parking brake is achieved through spring activation with the spring rate being set to provide a an acceptable stopping rate. The OBRC substitutes for the normally human controlled functions on the fork truck such as braking, throttle, gear shifting, parking brake release, mast lift and tilt, and steering. The manually controlled valves were removed and replaced with electrically actuated proportional control valves. The parking brake has a manual release, to allow towing on the RCBU in case of a complete system failure. The main brake is integrated into a single control which is proportionally released as the joystick on the control panel is moved

from the centre position. The brake will not release unless a motion enable trigger (dead man switch on the joystick) is held closed. When mast or DPH functions are desired the RCBU is switched to handling mode. This causes the engine RPMs increase, providing additional hydraulic power for lifting or handling drums. To ensure that the resultant extra engine power is not transferred to the drive train, thus creating an unsafe condition, forward and reverse motion is disabled while in handling mode.

Due consideration of the radiation environment in which the OBRC and RCBU are operating has been made in selecting the electronics and CCD camera systems. In general, commercially available electronic components and CCD devices are capable of sustaining total radiation dosages of the order of 5 kilorad without sustaining damage or degradation in performance. This is roughly an order of magnitude higher than the total dosage expected throughout the operational life of the RCBU, thus avoiding the need for radiation hardened components. The major hazard in the Building 69 is airborne thorium particulate, which presents no hazard to the RCBU components.

Three controllers are utilized on the RCBU. Controller 1 provides the base vehicle functions such as brakes, throttle, gear shifting, mast lift/lower, mast tilt, and sideshift. The second controller operates the Drum and Plywood Handler's solenoid valves. The third controller drives the camera functions (zoom and focus) and pan and tilt motions. The Third unit also handles the communications between the OBRC and the Remote Operations Console controller. The complete Electrical Block diagram for the RCMHS system is shown in Fig. 3.

Fig. 3

DRUM AND PLYWOOD HANDLER (DPH)

The DPH is designed to handle normal drums, corroded drums that could rupture, 4 by 8 foot plywood sheets used to separate the tiers of drums, and with the help of remotely installed tools pickup loose material from the floor. The DPH attachment was based on a "Cascade" 3500 lb rotator/clamp that has been modified to better complete the tasks required of it. The DPH is capable of +/- 168 degrees of rotation. This allows a suspect drum to be carried on its side then placed in its lid on the Thorium Overpacking Container. Hydraulic travel stops limit the rotation so that the internal cable cassette is not over stressed.

The drums are held by two grippers which are mounted on a set of arms. Each arm is driven by a hydraulic cylinder and their motion is synchronized with a hydraulic flow divider. The clamp arms are capable of gripping drums from 20 to 30 inch in diameter,which corresponds to drums of 35 to 110 gallon capacity. Travel stops on the cylinders limit the minimum to maximum gripper openings from 18 to 35 inches respectively. Gripper pressure is maintained on a drum even if the RCBU is shut down by pilot operated check valves. The grippers have 3 pressure settings for closing, low for empty drums (300 psi), medium for loaded 55 gallon drums (650 psi), and high for overpacking drums (800 psi). The load settings can be adjusted to any pressure using the relief valves.

The barrels are held on either side with two large grippers. Each gripper has fifty-five rubber nipples which are pressed onto the barrels to provide both grip and support of the drum chimes. The grippers slide along linear bearings on the support arms to retract the drums over the support plate. The gripper Extend/Retract drive utilizes 1 hydraulic motor on each arm which moves the grippers through a chain/ sprocket

drive. The two grippers are synchronized using a pressure compensating flow valve which keeps their rate within 4 percent of each other. If the gripper plates do get out of synchronization they will equalize at the end of travel hard stops.

The Grippers present a narrow profile when approaching drums, thus allowing the drums to be removed even when they are placed chime to chime. The drums in the stacks are tight to one another, so to remove them, the RCBU approaches the stack at a 60 degree angle to the face. The corner drum is removed first thus producing a wider profile on the adjacent drum. This procedure is repeated along the face of the stack until all the drums are removed. The second row is then removed in a similar manner. When all 8 drums are removed from a plywood separator, the sheet can be taken away to expose the tier below. Limited pushing of the drums can be attempted with the grippers, however, if the drums are heavily corroded this action increases the risk of rupture.

The drums are supported after they are retracted into the DPH with a support plate. Two dual acting hydraulic cylinders provide the support plate with up to 8 inches of vertical travel. The Lift plate is hinged to prevent damage to itself or the tops of drums if the mast is tilted forward during operations.

For tasks of lifting the plywood separator sheets, the support plate is inserted under the edge of the plywood and the RCBU is driven forward so that the plate slides under the sheet. The support plate is raised until it contacts 4 rubber nipples on the under side of the grippers. The rubber securely holds the plywood so that it can be manoeuvred by the RCBU.

The DPH can be removed from the side shifter with quick mechanical, electrical, and Hydraulic connections. The forks can then be installed on the carriage to allow the RCMHS to handle the TOC. The DPH to fork exchange task or the reverse operation can be performed single handedly in less than 5 minutes.

SWEEPER PLATE AND SPILLAGE CONTAINER

The sweeper plate and the spillage container are designed to be remotely installed onto the DPH by driving the support plate into a pocket at the back of the Spillage container. The Sweeper is clamped with the grippers, then lifted out of a tool rack. The sweeper plate can be retracted towards the spillage container using the gripper extend /retract drive. The sweeper preforms two functions, the first is to pull debris into the spillage container and the second is to hold the spillage container closed during transportation to the disposal container. The scoop on the front of the spillage attachment is hinged and will dump automatically due to the force of gravity, if the sweeper is extended away from it.

REMOTE OPERATING STATION (ROC)

The Remote Operating Station is installed into a trailer adjacent to Building 69. The ROC is an operator work station providing two control consoles, the main console is used for RCBU control functions and the other provides control of the cameras and PTUs. In addition, two color televisions provide the operators with the camera views from the RCBU. The operator console features a joystick for RCBU forward, reverse, speed and steering control. A deadman trigger is incorporated in the joystick and if released it will apply the brakes and cut the throttle. The command console features 2 key locks to enable the RCMHS and 10 status warning lights, Fig. 3 shows the warning sensors. Individual switches give the operator control of all the discrete functions in the RCMHS. An

emergency stop button on the console provides the operator with a method of shutting down the system if needed.

A separate console with 2 joysticks is provided for the camera pan and tilt, and zoom and focus controls. This console also houses the supervisor emergency shutdown, for potential hazardous conditions unobserved by the operator.

Hardware safety features are backed up by software interlocks that automatically stop the RCBU if protocols, handshakes, and system parameter set points are violated. The RCBU is stopped by an internal E-Stop which functions similar to the RCMHS Halt.

VISUAL MONITORING SYSTEMS

The VMS is a critical subsystem for the successful operation of the RCMHS under remote teleoperation. The ability to remotely navigate the RCBU within the confines of the building and to safely manoeuvre the RCBU and operate the attachments to inspect, grapple, secure, transport and dispose of drums, separators and loose material, are totally dependent on the visual system. Wide angle lenses give the cameras approximately a 90 degree field and give the operator the ability to see both the vehicle as a reference and work area. To increase the operators efficiency, additional camera views are provided at the work site to give an overall perspective to the operations. Reversing and manoeuvering in confined spaces with grappled payloads is a challenge. The VMS provides the operator with reverse and forward viewing by panning the cameras.

The minimum focus distance required for handling the drums is approximately 5 ft, which is compatible with the minimum focus of the 10:1 zoom ratio lens selected. Each camera has its own quartz halogen flood light which is co-linearly mounted on the Pan and Tilt Unit to provide direct illumination of the work site. The light from the floods is cast over an area which closely matches the cameras widest field.

Since all operations require the operator to discern the position of the RCBU and its tools from the surroundings, visual cues on the mast, DPH, and tools are critical to successful completion of the tasks. The mast height, tilt, and side shift can be seen directly when the left side camera is tilted down. The camera is able to view flat black markers against a bright yellow or orange background. The height of the carriage on the mast is directly shown in one foot increments. For the DPH grippers the end of travel positions for extend/ retract are given with a black stripe.

CLPA MOUNTING ON THE RCBU

The Cameras, Lights and Pan/tilt Assemblies (CLPA) are positioned on the top of the centre stage of the mast. The cameras are positioned approximately 2.5 m above ground level with the carriage operating in the free lift range. When the DPH is raised for third tier drum operations the cameras rise with the centre stage thus maintaining a perspective view. With the two cameras mounted on the same plane, the operator is provided with a perspective to sense depth. The cameras also give a clear sense of the position of the RCBU centre line which is a critical step in alignment for drum handling.

TELEMETRY AND VIDEO COMMUNICATIONS

A hard wired telemetry, audio, and video system provides a total of 500 feet of communications length between the ROC and the RCBU. For operations within Building 69, a 9/32 inch steel aircraft cable is strung the length of the warehouse, approximately 250 feet. The telemetry and video cables are then hung on the aircraft cable with quick connection

hangers spaced every 12 feet for a total length of 240 feet. The remaining cable is used to provide the run between the trailer and Building 69.

To provide the vehicle with lateral movement capability within the building, a cable pulley system is mounted on the right side of the RCBU. This allows up to 30 feet of movement to either side of the aircraft cable. The pulley system also provides some tension to the cable for retrieval behind the RCBU as it moves along the length of Building 69.

REDUNDANT EMERGENCY STOP

The RCMHS is equipped with a Redundant Emergency stop which ensures that even if the primary telemetry link does not respond to the command, a second path will safe the RCBU. The redundant emergency stop operates through a separate set of conductors and when the signal is tripped, a power relay is cut which shuts down the RCBU engine and vehicle controls. When the Emergency Stop is commanded the following occurs:

a) the engine is stopped,
b) the parking brake is activated, by cutting power to the solenoid,
c) the transmission is shifted to neutral,
d) all mast and attachment functions are stopped,
e) the electronics and the video system put in standby.

RCBU MANUAL OPERATIONS

A pendant can be manually attached to the RCBU which allows limited local operations of the base vehicle, mast and sideshifter. This pendant is used to assist the operator in the change out tasks of the DPH to the fork and vice versa or in case of a control system failure.

DESIGN AND MANUFACTURE

Due to the extremely short schedule for the development of the RCMHS it was critical that the design and manufacturing stages be integrated, so that the critical components were fully detailed and in the process of manufacture, while the less critical components were being designed. The design concepts, layouts and detailed drawings were all performed using Autocad.

The Drum and Plywood handler hydraulic hosing and tubing layout had to be undertaken right on the vehicle due to their complexity and short development schedule. The first vehicle became the prototype for the hydraulic arrangement and then this was duplicated onto the second vehicle. A detailed photographic record of the hydraulic layout was kept as a reference for future builds.

The DPH and scoop/sweeper had to be remotely stored and installed with no manual intervention, this meant that each tool required its own custom stand. The stands had to not only support the tools, they also had to provided alignment guides for the visual system. A combination of course visual cue and fine mechanical guides were used for the removal and replacement operations. The visual cues were developed during the initial testing phase of the RCMHS. This process of tailoring the RCMHS system to the actual tasks being performed, optimized the design and reduced the operators time to perform tasks by a factor of 2.

OPERATIONAL PROCEDURES AND TESTING

To reduce the risks that the RCMHS system would be unable to perform the tasks required of it, the operational procedures were developed in conjunction with the layout design and the functional requirements. The control panels functions were defined from the requirements generated in the operational procedures. This parallel design process meant that the

hardware design, system requirements, and the operational procedures were developed and updated co-incidently.

To reduce the risk that the RCMHS System may not function correctly while performing its tasks, a step by step operational analysis was under taken using the Autocad drawings. Each individual function (degree of freedom) for the RCBU was placed on a different layer on the drawing. By selecting individual or groups of layers, specific functions could be checked and procedures verified. As an example, all the mast and DPH layers could be selected and rotated with respect to the front axle of the truck to simulate the tilt function of the mast. This type of action was carried out in discrete steps for all the critical operations for the tasks of picking up drums or the plywood. The drum handling operations were repeated for drums on the top, middle and bottoms tiers in the stacks. The viability of the operating scenarios was validated by this analysis. This analysis of the operating procedures proved to be very useful in the training of the FERMCO site operators. The sketches produced, gave the operators a much clearer visualization of the tasks being undertaken then the written procedures did.

The RCMHS specification called for the vehicle to be able to position a drum within one inch of the desired position. The first time that this test was performed using the complete system, the drum was placed within a half inch. The operator also found that the this was an easy tolerance to meet on repeated tests.

For the drum removal task from the third tier, it was found that the removal procedure could be accomplished within 10 minutes of start. This included the time required to place the drum onto the TOC. Corroded drums were found in the test program to present the operator with no additional challenge as compared to fully intact drums. The large grip area combined with the support plate, resulted in low stresses on the drums so damage was minimized during handling.

Waste pickup using the scoop and sweeper was a task that required the DPH to be very close to the zero degree position. With the scoop level this tool was capable of picking up about 95% of the material on the floor. For the test, the material used was of a fine grain particulate. Since, the thorium waste is congealed, it should be even easier to sweep up than the tests demonstrated.

DELIVERY

The two complete RCMHS systems were delivered to the FERMCO site in September and October of 1995. At the site the vehicles were given a functional test to verify their performance following shipment from Spar. The RCMHS System has exceeded the performance requirements originally set out for it.

FURTHER APPLICATIONS

The RCMHS is a versatile remote controlled platform that can be outfitted with other attachments e.g. a manipulator, so that the system could undertake other types of operations in a hazardous environment. Modifications to the drum / plywood handler can be incorporated to allow grasping of much larger diameter, heavier, or odd shaped objects.

The cable telemetry/video system can be replaced with a Radio Frequency system that would allow the RCMHS to have increased freedom for operations. The base fork lift truck need not be limited to propane power. The option exists to have the RCMHS controllers and attachments placed on electric, diesel, or gasoline powered lift trucks or tow motors.

DRUM INSPECTION ROBOTS: APPLICATION DEVELOPMENT

F. B. Hazen
FERMCO

R. D. Warner
U.S. Department of Energy

ABSTRACT
Throughout the Department of Energy (DOE), drums containing mixed and low level stored waste are inspected, as mandated by the Resource Conservation and Recovery Act (RCRA) and other regulations. The inspections are intended to prevent leaks by finding corrosion long before the drums are breached. The DOE office of Science and Technology (OST) has sponsored efforts towards the development of robotic drum inspectors. This emerging application for mobile and remote sensing has broad applicability for DOE and commercial waste storage areas. Three full scale robot prototypes have been under development, and another project has prototyped a novel technique to analyze robotically collected drum images. In general, the robots consist of a mobile, self-navigating base vehicle, outfitted with sensor packages so that rust and other corrosion cues can be automatically identified. They promise the potential to lower radiation dose and operator effort required, while improving diligence, consistency, and documentation.
The Stored Waste Autonomous Mobile Inspector, or SWAMI, has been supported by the Robotics Technology Development Program (RTDP) and built by the Savannah River Technology Center (SRTC), with assistance from Lawrence Livermore National Laboratory (LLNL). Other systems have been administered by the Morgantown Energy Technology Center (METC) as Program Research and Development Announcements (PRDA's) with OST support. These systems include the Autonomous Robotic Inspection Experimental System, or ARIES, built under contract to SCUREF (South Carolina Universities Research and Education Foundation) by a team from University of South Carolina, Clemson University, and Cybermotion, Inc. Additionally, the Intelligent Mobile Sensing System, or IMSS, was built at Lockheed Martin Space Systems in Denver. Finally, a stand-alone image analysis method entitled Automated Baseline Change Detection (ABCD) system is being developed under a NETC PRDA with Lockheed Martin Missiles and Space in Palo Alto, CA..
The Fernald Environmental Management Project (FEMP) has been an early testing site and has worked extensively with the development teams in an effort to more closely link potential customers to the researchers. This work has included development of site specific inspection procedures and standards, design of a test plan to evaluate the robot's performance, modification of facilities, and the operation and test of the prototypes. To date, only SWAMI has been tested at Fernald, though the IMSS and ARIES are scheduled for testing in 1996. The systems will ultimately be evaluated in a "bake-off", supported by the Mixed Waste Focus Area (MWFA) and organized by Fernald. The comparative test, to be held in about a year, will identify what systems may be ready for commercialization and

which parts of others might best be incorporated into a final commercial product. Early indications are that the application is more challenging than first anticipated, due to variations in lighting, environment, facility and drum layout. These circumstances strengthen the need for identification and integration of the best demonstrated available technologies, accomplished through mutual development and competition of alternate technical approaches.

INTRODUCTION

This paper describes the development of a new application for robotics, waste drum and facility inspection, and the effort to evaluate its utility in the field. The work has been conducted at the Department of Energy (DOE) Fernald Environmental Management Project (FEMP), by the Technology Programs (TP) department of FERMCO, Fernald's prime operating contractor. TP has been a technical facilitator, integrating the needs of end-users and efforts of robot developers. To describe this process, the baseline manual practice and generic technology are first outlined, followed by details of the systems that have been built and the on-going program to test them. Experience to date and plans for completing the program are then presented.

Inspection robots perform drum and facility inspections by visually assessing drum condition and other aspects of the facility and inventory. They identify containers by their bar codes, capture and store their images, and evaluate them for signs of damage through machine vision techniques. Corrosion cues identified can include rust spots, streaks, and blisters. Dents, bulges and tilted drums can also be recognized if special purpose sensor suites are included. Other facility inspections may also be performed, including checking the floor for elevated radiation levels or puddles, measuring ambient gamma radiation, or monitoring environmental factors such as temperature, humidity, and lighting. Inventory checking is another possible application, if a materials database is maintained. By automating the initial inspection of the containers, human inspectors only have to physically verify the small subset of containers reported as 'suspect', or possibly damaged, by the robot. The robot must be conservative in its judgements so that damaged containers are never passed as acceptable, even if this means that some containers that are actually satisfactory are added to its suspect container report. Since the primary purpose of the inspections is leak prevention, and not leak identification, suspect drums are expected to be identified before they result in material releases.

Drum inspection robots have the potential to reduce worker exposure to radiological or chemical hazards present in the waste. Inspection quality will also improve through the use of these devices. Consistent performance and diligence result from the robots unhurried, methodical inspections. For containers stacked four pallets high in a facility, drums at the top and bottom of the stack receive the same treatment as those at eye level. The devices eliminate the need for inspectors to stoop down to scrutinize lower level drums, or climb ladders to properly inspect topmost containers. Demands on human inspectors could then be reduced even as inventory increases. While people will always be required in RCRA inspections, robotics can lower the amount of labor required for the activity. The machines provide timestamped, unalterable documentation of inspection activities and drum condition by archiving images and other findings. This improvement in documentation will be a major attraction to RCRA regulators.

TECHNOLOGY SPONSORS AND DEVELOPERS

Assessment of the potential benefits of the application and the maturity of component technologies led the DOE Office of Science and Technology (OST) to support several efforts to develop drum inspection robots. Each system has similar functions, though they offer different technical approaches. The result is that teams from national laboratories, universities and the commercial sector have been able to participate in an exhaustive search for viable solutions. One such robot is the Stored Waste Autonomous Mobile Inspector, or SWAMI, built by Savannah River Technology Center (SRTC), and funded by the DOE Robotics Technology Development Program (RTDP). Image analysis and inspection reporting were developed by Lawrence Livermore National Laboratory (LLNL). Fernald developed SWAMI's archiving and database access routines.

The Morgantown Energy Technology Center (METC) issued Program Research and Development Announcements (PRDA's) for two other full systems. The Intelligent Mobile Sensing System (IMSS) was built at Denver, Colorado, by Lockheed Martin Aerospace. A prototype demonstration was held in April 1995. The Autonomous Robotic Inspection Experimental System (ARIES) robot has been built by University of South Carolina (USC), Clemson University, and Cybermotion under a contract with SCUREF (South Carolina Universities Research and Education Foundation). It was demonstrated in November 1995. METC has also more recently issued a PRDA with Lockheed Martin Missiles and Space for the Automated Baseline Change Detection (ABCD) system, a novel approach to image analysis that compares subsequent inspection results to identify corrosion cues. The DOE Mixed Waste Focus Area (MWFA) recently launched a follow-on initiative to test systems and integrate the best elements into a final, commercial ready system. This represents a renewed and more comprehensive approach towards application development in this field.

APPLICATION DEVELOPMENT PROGRAM

It has been found that though drum deployment in facilities varies significantly across the DOE complex, the need to inspect drums is very common and a growing challenge. At Fernald, the facilities are not highly contaminated, waste inventory has been plentiful and ambient radiation levels are low. At some other sites, the waste emits significant gamma radiation and thus renders the inspection task more hazardous. This has made the Fernald facilities an appropriate initial test area. The goal of the application development and testing program has been to discover the optimum level automation and functionality, in accordance with user desires, current technical capabilities, and common sense.

The full impact of a new technology is difficult for anybody to predict, including waste facility operators. End-users must learn technology limitations, and developers should appreciate the full range of environmental variability in the field. For the drums inspection robotics program, this started with a dialog between the two groups. Specifications matching technology supply to demand could then be generated. Contacts were made with regulators, a set of tests was prepared, performance criteria for application acceptability were outlined, and facility modifications were determined. As projects progressed it became clear that the amount of variability in the field was greater than had previously been envisioned. Teams then had to redesign to meet performance requirements, leading to modifications of testing program scope and schedule. Priorities for Fernald's waste facilities have since changed and its inventory is expected to be

eliminated in a short time. Other sites have expressed a strong interest, leading possibly to different application requirements. Thus, the testing program has required almost as many iterations at the technical approaches to the application, demanding flexibility and adaptability. Identification of user needs was a first task for all the development teams, and they toured several DOE sites to investigate the need and interest in drum inspection robots. In addition to Fernald, several other sites have expressed interest, including the Idaho National Engineering Laboratory (INEL) and Los Alamos National Laboratory (LANL). At the latter site, previously buried drums of transuranic mixed waste are being excavated and will greatly increase inventory, as no disposal has yet been envisioned. Additionally, Hanford had plans to use automated inspections in a new waste processing facility, and at one point was scheduled to demonstrate the IMSS in their RCRA storage areas. Based on the potential applicability on site and the willingness of FEMP Waste Programs Management (WPM) to give SWAMI a chance to show its potential, a demonstration at Fernald was planned early in the RTDP program.
Ultimately a single demonstration site at Fernald was selected. TS-4 is a translucent, 90 by 450 foot Tension Support (TS) building with a 12,000 drum inventory in regularly spaced aisles. Fernald information has also been shared with the ARIES and IMSS teams. The ARIES project team has since expressed an interest in tests at Fernald, and the IMSS team followed suit after plans at Hanford fell through.
Early activities were focussed on producing guidelines for the development of the ultimate SWAMI system while an initial testbed, SWAMI I , was being developed at SRTC. Toward that end,a site use requirements document was written that outlined the technical requirements for use at Fernald. This included a request for four-high stack inspection of multiple drum sizes, an 'aisle abort' feature, and full accountability of all drums in the facility. It was noted that the robots must achieve a level of robustness in operation and inspection reliability so as to give credence to its potential for daily usage. The document also surveyed the drivers and practice of inspection at Fernald.
A Work Plan was written to inform the local DOE field office and RCRA regulators in Ohio about the intended demonstration and proposed acceptability criteria. The goal was input from the regulators on what tests would constitute a sufficiently strong case that robots were at least as good or better than human inspectors in certain aspects of inspection. A set of tests to be used in the actual demonstration was described. Success criteria were tuned to the ultimate customer's needs and represented achievable though technically challenging benchmarks. The response from the Ohio EPA was that they would have no comment on acceptance criteria until the technology was more mature. However, they did suggest that the accuracy of current inspections should also be assessed.
A Test Plan was then developed, detailing procedures to systematically evaluate SWAMI for suitability of use in the field. Many of these tests were focussed on production-quality machines that are ready to be operated by site personnel. The original test plan subsequently was modified to match changes in technical scope and schedule. The revision focussed on checking a list of 'baseline' and 'plus' performance goals. The attributes separated achievable near term goals for core functions from desirable but nonessential 'plus' features. SWAMI was then brought to Fernald and tested. A demonstration showcasing SWAMI was held in

December 1995. In the last year, the IMSS and ARIES have also had major demonstrations, in mockup drum storage areas. The MWFA is now supporting an effort to consolidate the work that has been performed to date in this research area and identify the best individual solutions to the overall application. The centerpiece, dubbed the "bake-off", is the comparative test of each robot, in the same facility and in short succession. This will not necessarily be held at Fernald. In advance of the bake-off, a new outreach effort is being made to develop a user's group to supplement early Fernald application guidance to the developers. The users will also be asked to help develop the a new test plan, in conjunction with input from the development teams. The bake-off will occur in early 1997. Before the bake-off, IMSS and ARIES will be given the opportunity to bring up their sensor suites for data collection and then test their full systems at Fernald, as SWAMI has done, over the next six months. The bake-off site will be selected based upon the highest level of commitment to end-use, from the user's group.

CURRENT INVENTORY AND INSPECTION PRACTICE

Clearly an important element of the new application is the environment in which the machine will operate and the baseline practice that it is supplanting. Those issues are considered in this section. At many DOE sites, mixed waste has accumulated in part because of the difficulty in disposing of it. At Fernald, operations resulted in the accumulation of over 100,000 drums of mixed and low level waste. Legacy waste from previous operations is likely to have been originally stored in drums. Newly generated waste is now often placed in B-25 containers and larger boxes because of their better packing efficiency. All stored waste is subject to inspection requirements. The requirement for inspection of Mixed Waste inventory and facilities is found in the Resource Conservation and Recovery Act (RCRA). RCRA is enforced at the FEMP by the Ohio EPA. Low Level Waste (LLW) also is inspected regularly. A consent decree with the State of Ohio drives the activity at Fernald. The growth of inventory and inspection demands lead to the program to develop drum inspection robots.

The machines must operate in storage facilities that range from outdoor concrete pads, to former processing buildings, or unheated temporary storage structures. 55-gallon drums are most prevalent, though other sizes are also used, including 85 and 110-gallon overpack containers. They are stored on pallets stacked up to four high, though three-high is typical. Aisle widths of 36" are most common and encouraged by the Occupational Safety and Health Administration (OSHA), though requirements vary amongst facilities and can be as low as 26 inches.

The inspections are intended to prevent leaking by early identification of corroding drums (1). Presently, they are performed visually on a daily basis and on a formal weekly schedule to meet RCRA demands. Drums are always positioned so that the side seam and locking screw for the ring that holds the top down are visible because corrosion has been found to start most frequently along the side or bottom seam. Only the visible portions of the drum are inspected. This has been found to be sufficient and reasonable by facility operators and regulators. Suspect drums are categorized according to corrosion severity, with the levels defined in Standard Operating Procedures (SOP's). The most likely cause of container degradation is rust. Dents in the containers can also potentially breach the container or, more likely, act to raise the internal stress of the container in the dented area, thereby making corrosion more likely.

Blisters usually start inside the drum, and very small defects can result in leaks. As a rule, containment ability is not affected by general external corrosion if only paint and/or minor metal flaking is occurring. Certain drums are much more likely to leak because of corrosive material within them, and these should be checked more diligently. Freeze cycles and high humidity also accelerate container degradation.

GENERIC TECHNOLOGY AND APPLICATION

The three robots are very similar in the function their machines perform. However, each has a distinct technical approach. Indeed, there are some differences in functionality, as well. The attributes that they all share in common include the main subcomponents: Base vehicle, Inspection sensor packages, Off-board operator controls, Data analysis and presentation, and wireless Ethernet communications (between the host and the robot). Individual components and techniques needed to produce these systems have all been field proven, but the integration of the subsystems into a single machine has proven to be challenging. In order to emphasize the approach towards fair and equal consideration of each system in the bake-off, common elements in all three robots are described here before their individual implementations are introduced. Some of the technical issues faced in application are also detailed.

Self-navigating mobile robots used as the base vehicle for these systems have been under development for over ten years and are commercially available, though the requirements for specific applications often cannot be readily met by off-the-shelf equipment. Several commercial systems have been field-proven to not harm people, the environment or themselves. The basic function of the vehicle in this application is to position sensor packages near each drum in the facility so that it can be inspected, and to house the sensors and actuators that comprise the mission package. For this application, additional battery power for the sensors, a reduced size to navigate in aisles and access all drums, and tolerance to temperature extremes are required.

The machines autonomously travel throughout the facility using an internal map of the environment that originates from the standard CAD files. Navigation techniques including dead reckoning, active or passive landmarks, and local features are used to constantly improve the robot's estimate of its position on that map. Obstacle identification capabilities give the robot the ability to find and then navigate around objects and are accomplished by a redundant set of tactile sensors (bumpers) and non-contact laser or ultrasound ranging systems. Most of the vehicles include autocharging systems so that the robot returns to the base station to recharge when necessary. On-board computers are provided as part of the base robot and the level at which external computers interface with them vary amongst manufacturers. In some cases modifying or externally controlling the machine can be hampered by the manufacturer's restriction of source code access.

Variations in drum position, aisle location, lighting, and temperature are amongst some of the environment-driven challenges for this application. Solutions are available but can complicate system design. In real facilities, aisles are frequently created, rearranged and relocated. They are not necessarily all the same length, or width. Whole drum rows are dismantled to access drums at the far end, resulting in changes in drum and pallet location. Multiple size drums are often stored in a single row, and the arrangement of the drums on a pallet varies from size differences and random placement error. Temperature extremes must be

tolerated, since most storage areas are unheated. Some water and ice is also possible. Untended operation is desirable so that the robot can operate when there is less activity in the warehouse. For some machines, night operation is preferred because it reduces the variation and intensity of background light.

Inspection packages on the robots consist of color cameras, strobe light illumination and barcode readers at a minimum. Dents and other topographic features can be inspected by using structured lighting or other methods. With structured lighting, a light emitter such as a laser and a camera that captures the reflected light. The surface can be then be reconstructed using geometric models of the light source, receiver, and ideal drum surface, when the distance from the drum to the robot is known. Multiple sensor packages are used on all of the drum inspection robots to increase throughput since data collection is time consuming. Multiple drum images may be taken to capture corrosion features on the edges of the visible drum surface. The number of images needed is also dependent on the drum size, which can vary in a facility.

Drum center sensors are included in order to position the robot in front of a drum stack. Additional actuators are often used to give the proper standoff for data capture, reposition the cameras for multiple images per drum, and cover more than one level per sensor pod. Supplemental on-board computers are used to control the added equipment and provide an interface to the base vehicle and host workstation. Drums are not necessarily stacked evenly on each pallet, and some systems include fine positioning capability to adjust for offsets either across or along the length of the aisle. Designs must consider the need to inspect all the drums at the far end of dead-ending or dog-legged aisles.

A great deal of data is gathered during robotic inspections. Currently, the robots typically process three or four-high stacks of drums in 60-90 seconds. Multiple images for each drum must be uploaded to the host workstation and commands from the base computer must be received. Wireless Ethernet has been the solution selected by all development teams. The transceivers do not require special frequencies and they support the most common protocols. However, transmission within the stacks of metal drums may be somewhat unreliable. It can usually be improved by moving into direct line of sight with the base antenna. The amount of data transmitted depends on whether images are compressed, if analysis occurs on board, and whether images of non-suspect drums are also retained.

Lighting has a strong effect on the success of image analysis used in the drum inspection application. Images can get overexposed in bright light, sodium lights artificially increase the amount of red in the image, and strobes can create blind spots. Lasers used for dent detection, drum center finding or other purposes are susceptible to wash-out and specular reflections on glossy black drums. Unfortunately, glossy black is a very popular drum color at Fernald. Higher powered lasers can be used but they require special safety precautions that could impede other facility operations. Streaks should not be confused with the handwriting or stencils often found on drums. Red paint on labels or color coding on drum ribs should not be identified as rust. Straps securing top level drums should not be confused with dents.

Special purpose hardware is needed for image analysis. Because of the large amount of data and the sophisticated machine vision techniques used, processing the drum images can be time consuming. Inspection goals

were developed for the SWAMI project and represent a reasonable match between technical capabilities and application requirements. Through additional interviews with expert inspectors and input from the new MWFA drum inspection robotics user's group, these values will be revised prior to the bake-off. The current standards are for rust spots greater than 1/4 inch diameter, vertical discoloration streaks larger than 1/4 inch wide and 6 inches long, and dents larger than 1 inch depth, 1.5 inches wide and 2 inches long. A specification for blisters was not identified at that time. However, blisters as small as 1/8 inch in height and diameter have been found to result in leaks. They are also challenging to identify since they may have both discoloration and/or relief cues that must be successfully detected. For all defect features, false positives are somewhat undesirable but false negatives are much less acceptable.
Base stations for the machines consist of a charging area and one or more host workstations. The robot is operated through graphic-based controls that provide for facility set-up, task inception, monitoring and control, results presentation and archiving of inspection records. To check inventory location records, as well as for mission planning and reports uploading, interfaces to site-wide material databases are often provided. At Fernald, an ORACLE database called the Site Waste Information Forecasting and Tracking System (SWIFTS) is used. Several other sites store their waste inventory records in a similar format. Printers, additional mass storage, and high quality color monitors are also supplied. Some of the development teams have envisioned the development of features to reduce the occurrence of false positives. This would allow insignificant artifact or corrosion features to be ignored on subsequent inspections. For rust spots, if the size increases over a threshold between inspections, the feature would again be highlighted.

SYSTEMS UNDER DEVELOPMENT

Fig. 1

SWAMI

A first SWAMI prototype was demonstrated in a mockup area at Savannah River Site in November 1993 (2). Figure 1 shows SWAMI II as it was demonstrated in December 1995 at Fernald's TS-4. It is a modified HelpMate robot from Transitions Research Corporation. It has automated battery charger docking and sophisticated obstacle avoidance. It also has many enhancements including local aisle following, a system from the University of Michigan for backing out of dead-end aisles (3), a floor radiation survey system, image capture and processing, and wireless Ethernet. An off-board computer is used as the primary interface to the robot, and a separate VME card cage houses electronics dedicated to image processing. The rad survey system uses scintillation counters instead of gas proportional detectors found in previous SRTC robots. It was tested offline but not as part of the integrated system. The on-board supervisory controller consists of three VME based microcomputers that utilize the GENISAS control software from the RTDP to dispatch tasks between a supervisory control system and various subsystems.

Two sensor pods are positioned by a vertical mast on the robot high enough to cover four-high stacks of 85 gallon drums. The pods are offset by the height of two drums so that the first and third drums are inspected before the second and fourth. Each has cameras and strobes for image capture, a barcode reader, and lasers with black and white cameras for dent detection. Two image cameras cover the required field of view while three sets of two lasers and a camera are used for dent detection.

Drum centers in a stack are individually found by a special purpose laser system which then adjusts the position of the sensor pod to achieve optimal height, reach, and lateral offset to the inspected surface by individual linear motions. The lasers are all rated Class 2, which is essentially eyesafe. The pods are attached behind the robot, inspecting only one side of the aisle per pass. They fold so that the robot can spin at aisle dead-ends and then inspect the other side on the return path. If end-of aisle clearance is less that 8 feet, the robot backs out of the aisle and then re-enters backwards so that the other row can be inspected. The data is compressed on-board and transmitted to the base station.

SWAMI off-board equipment includes base station and vision processing computers, printers, and a charging station. The main operation interface for daily system users is called the SWAMI Operator Interface (SOI). Drums to be inspected are selected from a map of the warehouse updated with the latest information from the site's SWIFTS database. Simply by selecting one or more row halves, a mission profile is automatically generated and downloaded to the robot. It also highlights suspect drums that have been found and identifies drums that are out of place as compared to the database.

Images are uploaded and then analyzed on the vision processing computer as they are collected and then uploaded from SWAMI over one of two wireless Ethernet channels. This process starts in the field and continues after the robot has returned to recharge, because of the long time required per picture. The method of rust identification includes color recognition and thresholding, noise reduction and region growing. Streaks are also found based upon their orientation and shape. Structured light data is also uploaded and then analyzed for dents and blisters. The inspection findings are presented through a separate window that prioritizes the drums according to corrosion severity. By selecting a drum with the mouse, a representation of the drum is shown to the operator, with the suspicious areas boxed by the program. Utilities are provided to print out results for physical verification in the field. The images are ultimately stored in a data archive indexed to the SWIFTS database.

Fig. 2

ARIES

The ARIES robot, shown in Fig. 2, was first demonstrated as an integrated system November 1995 in a cold test area mocked-up to match Fernald specifications. Hot testing at Fernald early in the summer of 1996 is planned after additional enhancements are completed. Drums of 55-, 85-, and 110-gallon capacity can be inspected in aisle stacks up to four pallets high. ARIES is the first robot to demonstrate inspection of multiple drum sizes, and the only one to inspect 110 gallon drums (4). It has an autodocking station and is capable of backing and turning around in a 36 inch aisle. Off-board control workstations provide mission planning and monitoring, while wireless Ethernet provides links to on-board computers used for real time mission control and analysis. A power management system, supplemental dexterity package, and a radiation hardening study have also been included.

The machine base is the Cybermotion K3A, redesigned by the vendor to accommodate 36-inch aisles. It navigates using dead reckoning (measuring motion distance and heading changes) and position updates to passive landmarks. The landmarks appear as tennis ball can-sized cylinders

covered with retroreflective tape. The reduced size vehicle still has the synchro-drive system that permits six wheels on three horizontal leg units to each be individually steered and/or driven. This improves accuracy of motion recording by maintaining constant wheel contact with the floor. A Camera Positioning System (CPS) is installed on the robot top and moves four instrumentation packages, one for each level. Its stowed height is 10 feet and at maximum extension it is 16 feet tall. The top three levels are positioned using an extending mast in which one linear motion controls the height of the mast and another controls the separation between pods. The lowest level pod is dropped behind the robot using a mechanical linkage. Each image acquisition subsystem consists of a camera with a strobe lamp above and below it. Both strobes are fired in sequence so that reflections can be subtracted from the image. A laser structured light source projecting five dots against drums is used to identify the drum size, drum center location, and tilting. All the lasers used are eyesafe.

Color processing, using specialized algorithms, incorporates supplemental multi-strobe lighting and differential strobe based structured lighting. The design goal was to detect rust larger than 1/2 by 1/2 inch. With wide angle lenses, this leads to a requirement for two images per 55 gallon drum. The images are stored in a Hue-Saturation-Intensity color representation from which a range of values can be attributable to rust. Dent and streak detection are not currently supported though a solution to blister identification is included. This is done by modeling the blister as a conglomeration of small bubbles protruding from the surface, and then performing a frequency analysis of the image intensity. The images are matched and reconnected for clarity in presenting results to the operator. This is achieved by blanking out all regions judged to not be on the surface of the drum, using the projected laser spots in the drum image to guide the cropping process (5). A single drum is currently processed in six seconds, and the time required to inspect a single four high column and move on to the next is 1 minute. ARIES present throughput is about 2,500 drums per 24 hours.

Robot operation is controlled from a Unix workstation in a portable software environment that has been designed to be scalable to smaller systems for commercialization. However, path and facility simulations that have been developed work best on Silicon Graphics systems. A series of menus guide users or site managers through the facility setup, mission profile, dispatch and monitoring, all activated from the main program. The facility map is derived from an AutoCAD file. A path assembler is used to generate the mission script with location attributes and procedures along a series of linear path segments.

Fig. 3

IMSS

The IMSS was demonstrated at the Lockheed Martin Denver facility in April 1995. Figure 3 shows the machine as it appeared during the demonstration. Hot testing at Fernald in the spring of 1996 is also planned. Unlike the other two robot development teams, Lockheed Martin built a custom designed robotic base (6). The welded frame, steel skinned vehicle is quite narrow and can thus enter aisles as small as 30 inches wide. It has special Mecanum wheels that allow it to move or rotate in any direction including sideways. Obstacle sensors consist of ultrasound range sensors and miniature limit switches set behind the sheet metal so that they trip upon contact. They are hard-wired directly into the power distribution

system. Aisles are expected to remain fairly constant in location and size, for the current system. The waste facility is described as a main corridor and a series of evenly lined pallet stacks that define the aisles between rows. The robot uses its side ultrasound sensors to align itself with aisle ends and to count aisle entrances. 4-5 hours battery life is the maximum obtainable over the full temperature range specified, using a sophisticated set of sealed Nickel-Cadmium batteries that eliminate the explosion hazard from hydrogen off-gas during recharge. At room temperatures, charge capacity is even greater.

Three fixed sensor arrays are mounted on a vertical mast to inspect up to three stacks of drums concurrently. Extensions to four high stacks are also possible. Each sensor suite consists of two ultrasound sensors used to determine drum centers, a barcode reader, two color cameras and diffused halogen strobe for rust inspection, and a class 3A laser and B/W camera for dent and tilt detection. Two vertical parallel axes of motion move the sensor suites left or right so that the optimal standoff distance and angle is maintained. The mast can swing to the front or rear of the vehicle to inspect drums at the end of an aisle. Four camera shots are required on 55 gallon drums in order to meet detectability goals. Tilt axes on the sensor suites allowed full coverage of the drum from its center.

Images are stored in uncompressed format, but only when defects are found. Multiple sensor arrays are used to improve inspection time. Streaks and blisters were not addressed in the first prototype. Dents on the flat cylindrical surface of the drum, as well as tilting and bulging, were detected using the structured lighting system. Some difficulty was reported with glossy black drums in fluorescent lighting, due to the reflectivity of the surface.

The operator interface presupposes that there might be multiple IMSS robots operating simultaneously. Aisles to be inspected are chosen by double clicking on the spreadsheet entry for that row. Rows are assumed to be all the same length presently. Post-mission, a newly compiled defects database is presented with each feature as a separate spreadsheet entry. The workstation communicates with the robot through a wireless Ethernet. They included the concept of a "baseline" mission, in which a defect database is generated. This database can then be consulted so as to reduce false positives by noting already present defects that are not severe. Now the development team will be integrating the ABCD image analysis system with the IMSS which uses a similar type of baseline inspection method.

Automated Baseline Change Detection

The Automated Baseline Change Detection (ABCD) project seeks to develop enhanced analysis capability for autonomous inspection, that could be useful on any of the robotic vehicles described above. The effort got under way in 1994 and will result in a prototype system ready for demonstration in Fiscal Year 1996. The system compares a current inspection image with an archived baseline image. Any change is identified. If further interpretive analysis verifies that the change is benign, then no action is required. If the change is not benign or is not recognized, then human operators are notified. The key to this process is the use of a commercially available system to identify a target label affixed to all drums, compute sensor distance from the drum, and then rapidly and precisely reposition the sensor. Image transformations are

used to match the pose of the newly acquired image to that of the archived baseline.

OPERATIONAL TESTING AND QUALIFICATION

The most important evaluation to be made, and the one that best summarizes robot's effectiveness as an inspector, is the side-by-side comparison of the robot's inspection reports with those generated using existing methods. Thus, during field trials, the waste storage facilities are to be inspected by both the robotic and human inspectors. Accountability for all drums in the warehouse, whether checked by robots or people, is required to guarantee that every drum has been inspected. Throughput and reliability are also very important. All these tests require the machine to be evaluated over as long a time as possible so as to be able to compare machine results against manually generated weekly RCRA reports.

Typically, end-users want to minimize facility changes and developers want to permit facility changes that reduce variability. For SWAMI tests, a moderate set of facility modifications was agreed upon, including the extension of aisle ends and the enlargement of barcode labels. The first test plan, released July 1995, described the full evaluation of SWAMI, its supporting equipment, and the documentation, from the perspective of a DOE site end-user. Its intent was to evaluate a machine nearing production-ready status, outlining ten test methods to evaluate the system from a subcomponent and system level. It called for a Pre-Start Audit addressing basic safety concerns to be completed before other tests are run. A series of offline, or one-time tests were then described, including Safety and Diagnostics, Operator Interfaces, Vehicle Locomotion and Power, Navigation, Barcode Reading and Inventory Checking. During Operator Interface tests, the usefulness and clarity of the controls were to be evaluated as the procedures were simultaneously documented.

It became apparent that intermediate data collection exercises would be necessary before production-quality testing. Other development teams also requested access to the facilities for development purposes. Image data from the warehouses up to that point consisted of video footage and photographs of the drums. Two new types of tests were identified: data collection using individual teams's hand-carried sensor suites, and developmental testing of the robot in the facility, allowing for technical iterations and improvements in the field. The tests acknowledge the value of actual data to the developers. For instance, the design and optics of the camera system, as well as the positioning accuracy of the sensor mast, have a great effect on inspection performance. For the SWAMI project, sensors were brought to Fernald to get better system training data, and this proved very useful in developing algorithms at the laboratory.

In the final SWAMI test plan, radiation detection system tests were removed, others consolidated, and procedures were outlined in greater detail. The final test plan describes two methods to study robot performance over a substantial period of time. The Duration test method compares robotically and manually collected RCRA reports and other key performance attributes, such as the incidence of false positives and false negatives, throughput, and labor requirements with automation. An identification exercise was also included, to compare human and robotic attentiveness. Colored dots were to be randomly placed on visible drum surfaces and then both inspection methods would be compared for completeness of coverage. This test requires additional routines in the

robot's image analysis modules, to separately tabulate the count of dots. The other robot feature requested to support testing is a reporting function to record and timestamp selected internal machine variables such as position, heading, or recent actions.

The Inspection Data Capture and Analysis test method focusses on determining inspection accuracy for each corrosion feature type (rust, streaks, dents, blisters), detectability as a function of feature size and location, and sensitivity to aisle placement or drum color. This is accomplished through the addition of a test aisle in the facility. The test aisle consists of a number of empty drums, some of which, called 'ringers', have intentionally placed defects whose description and location have been documented. These ringers are stored, swapped and moved amongst the population of test aisle drums. Four 'Feature Standards' were also included, one for each corrosion feature type. Graduated sizes of dents, rust, etcetera were created on each, from below to above pre-agreed detection limits. The blister standard was made by initiating corrosion from the inside, using a strong acid. Four 'Color Standards' were also created, with random corrosion features placed on red, orange, white, and flat black drums. They were to be used to investigate inspection accuracy as a function of drum color.

SWAMI was received at Fernald in September 1995 and was released in late December, following its demonstration. A technical team from SRTC and LLNL completed system integration and operated the robot during the tests. Access requirements for workers were met with 24 hours of classroom safety training. Baseline functions met during the tests included navigation to straight aisles and through the facility, drum center finding, rotation at aisle ends, image acquisition, barcode reading, and night operation. Data upload rates were determined to be 1,000 drum records in 13.6 hours, and other user interface control and reporting goals were achieved. SWAMI can accommodate drum stacking error with its two linear motions per sensor pod.

Image analysis and geometric (dent) inspection could not be demonstrated as part of an integrated SWAMI system but good results were achieved using images collected during previous data collection exercises. Streak detection, imaging of dents, and rust detection were shown. Blister detection was considered a 'plus' item and has not been completed. Because the inspection software could not be integrated with the robot in time, the two key duration tests could not be conducted. However, SWAMI is expected to participate in the bake-off, at which time it will have an opportunity to be evaluated.

The IMSS and ARIES have both been demonstrated in mockup facilities within the last year and will complete their next developmental phase by the end of 1996.They have not yet been tested at Fernald, and they will have that opportunity this coming year. The step following that is the MWFA bake-off, a side-by-side comparison of the drum inspection robots. A new test plan, set of facility modifications, and success criteria will be developed for the bake-off with fresh input from the end-users, principle investigators, and project managers. The goal is to consolidate the best components from all development efforts into a single robust and practical container inspection robot. A new User's Group is being formed and will be a key contributor to the project. The group will provide guidance as to what functionality should be targeted for demonstration by technologists and a new and revised set of requirements for use at a typical DOE site. They will also be asked to contribute to the

development of both the test plan and the criteria used to judge success. The bake-off site will be selected from this group based upon the level of interest and the availability and suitability of facilities for the demonstration. Several sites have already expressed an interest in hosting the bake-off and working these machines into their long-term waste facility operations plans.

CONCLUSIONS

So far, each robot has presented unique capabilities and some shortcomings. Though developmental testing is not yet complete and projects are not at the exact same developmental phase, some comparison is possible based on early demonstrations. The IMSS currently inspects 3-high stacks and features dent detection. It is also the narrowest vehicle, and thus can be used at a greater range of facilities. Inspection results are expected to improve with the addition of the ABCD system, which will be tested on the IMSS during the bake-off. ARIES has done an excellent job in vision system development and is the only system currently inspecting 110-gallon drums and identifying blisters, in stacks up to 4-high. They have not yet addressed streaks and dents, however. SWAMI is very tolerant of real-world aisle, pallet and drum position variations and has multiple redundant systems for obstacle detection. It is also reporting the best results for inspection of glossy black drums and identification of dents on drum rims. SWAMI can only inspect 55 gallon drums currently, however, and presently its laser based inspection and drum centering do not work in bright light conditions.

The need for improvements in inspection accuracy, completeness and efficiency is still strong as is evidenced by interest from various sites. However, the application has proven to be more challenging than originally anticipated. The fact that individual subcomponents have been proven in the field does not imply that a machine full of them will work reliably and robustly in the first design iteration. Because of the diversity of the teams that have independently pursued this problem, solutions to most of the challenges in the application have been demonstrated by at least one team. However, none of them have yet progressed to pilot-scale level performance. With the bake-off site undetermined at this time, an appropriate final testing location will now be sought so that the system is first optimized for an end-use site. Flexibility and accommodation have been required to foster this new application, and will remain important. The path towards integration of system components and technical maturity will not be easy, but the value and potential for drum inspection robotics remains strong.

ABSTRACT

The Light Duty Utility Arm and Deployment System (LDUA) is being developed by Spar Aerospace Limited under contract to the Westinghouse Hanford company. This robotic system will be used for the characterization and removal of nuclear waste stored in underground storage tanks (UST) at many of the U.S. Department of Energy (DOE) nuclear weapons facilities. It will also be used to assess the structural integrity of the tank walls.

The design and development aspects of the LDUA system are described. An overview of the integration of the various subsystems into a system is provided as well as the methodology used to verify system performance. Lessons learned and problems encountered are identified.

INTRODUCTION

The Light Duty Utility Arm System (LDUAS) will be used to perform surveillance, inspection and characterization activities in support of the remediation of underground storage tanks containing hazardous, radioactive wastes. It may also be used to perform light utility tasks and remediation.

The Light Duty Utility Arm System (LDUAS) is illustrated in Fig. 1. It is a truck-mounted mobile system which is erected at a tank site. A telescopic mast inserts the seven-degree-of-freedom 13.5 ft-long manipulator through the tank's 12 inch diameter riser a distance of up to 47 ft. into the UST. Before entering the tank, one of many different end effectors is attached to the end of the arm. The arm is controlled from an operations trailer which can be located a distance of up to 950 ft. away. The system features automatic collision avoidance and a graphical user interface permits off line path planning and training as well as on line graphical visualization to augment CCTV views.

Fig. 1

The design and development of the LDUAS involved a number of challenges due to the operational requirements, dimensional constraints and harsh environment. Some of these requirements are listed below:

To deploy into the tank through a 12 in. Schedule 40 riser and to provide a reach envelope 47 feet deep x 13.5 feet horizontal radius (see Fig. 1).

To include dexterity and kinematic redundancy to reach around obstacles obstructing the reach envelope.

To provide good teleoperator/telerobotic operating characteristics, e.g., good resolved motion, minimal oscillation, smooth motion.

To supply a large number of utilities (power, signal, video, water, air) to a variety of user-supplied end effectors mounted on the tip of the arm.All components including utility lines tobe packaged within a sealed and purged enclosure to provide contamination protection, tolerance of aggressive decontamination processes and for explosion-proofing.

All in-tank components and materials to be radiation-resistant; all external components and materials to be corrosion resistant (to both acidic and alkaline environments).

All components to be accessible for inspection and maintenance.

Some of these requirements are potentially contradictory, e.g., the small access riser and the large reach envelope, the fully enclosed packaging and the accessibility. This paper discusses some design challenges arising from these requirements and how they were met. The integration and testing of the system is also described with emphasis on the main features of the test program. An important factor in the successful resolution of many issues was the cooperative and interactive approach adopted by Spar and its customer in the early stage of the project. This enabled problems to be solved quickly and efficiently by a combination of relaxing specification requirements and concept modifications.

DESIGN CAPABILITIES AND CHALLENGES

In the paragraphs below some special capabilities and the associated design challenges are discussed with specific reference to:

Vertical Positioning Mast
Manipulator Elbow Joints
Packaging and Enclosure
Purge System
Operator Interface

Vertical Positioning Mast

The Vertical Positioning Mast (VPM) is required to deploy through a riser which is nominally a 12-in-dia. Schedule 40 pipe x 10 feet long but in practice after deformations, intrusions and tolerances the available I.D. is approximately 11.0 in. yielding a specified maximum O.D. for our equipment of 10.5 in. Since the stowed length of the VPM with manipulator is limited to 35 feet, the vertical reach of 47 feet, involving a deployment stroke of 60 ft., can only be achieved by a telescopic mast (see Fig. 2). However, the annular space for a telescopic mast is extremely limited and this is compounded by the need for rolling element bearings to achieve smooth motion and the use of CRES 316 as the only available corrosion resistant tube material limits the contact stresses of rollers on the tube.

Fig. 2

The design solution is shown in Fig. 2. The use of large-diameter convex rollers with Verpel tires mounted to and penetrating the inner tube reduce the contact stresses on the outer tube. Neither of the contact surfaces (rollers or interior of outer tube) is exposed to the contaminated in-tank environment. Because of the high ratio of stroke to stowed length, a multi-tube configuration would normally be preferred but the annular space precludes the use of more than a total of two tubes. Fortunately the customer was able to extend the stowed length requirement

from 30 feet maximum to 35 feet maximum and this made a critical difference, allowing a reasonable tube overlap for a two-tube design.Nevertheless, the bearing stresses in the outer tube were high compared to the strength of the CRES 316 and careful optimization of the design was required.

This rather involved evolution of the concept has paid dividends because the result is a robust, free-moving, fully-sealed mast with a smooth and regular external profile which is easy to decontaminate.

Manipulator Elbow Joints

The LDUA is a seven-jointed manipulator and was illustrated in Fig. 1. Its two adjacent elbow joints give it excellent dexterity in terms of its ability to articulate the end effector and reach around obstructions, as illustrated in Fig. 3. Another advantage of the configuration is the short link length compared with the overall reach which enables the manipulator to deploy into a constrained workspace, e.g., within 6 feet headroom or less depending on the end effector size.

Fig. 3

The elbow joints are a special design which combines:

High torque capacity (up to 38000 in.lb.)

Large angular travel (100 deg.)

Small diameter (8.62 in.)

Free internal volume for routing the large bundle of end effector utility lines.

The use of linear actuators (hydraulic cylinders) housed inside the main structural boom provided the necessary torque capacity, while an articulating linkage maintained a high torque through the full range of travel. The novelty and high performance of this joint required an early development effort to mitigate risk. Firstly, a theoretical optimization of the linage geometry and the pivot loads was conducted. Secondly, a Proof of Principle (POP) Elbow Joint was constructed and tested. As a result of the testing the primary link and its mounting were reinforced and a suitable joint servo control strategy was developed.

The benefits of this careful development approach were realized when the real elbow joints were found to be stiff, backlash-free and readily-controllable.

Packaging and Enclosure

The LDUA packaging must accommodate the following requirement:

Strength and stiffness require closed structural sections.

Enclosure of all components for contamination protection and explosion proofing means that they must be mounted inside the structure.

Internal routing of the large utility harness which comprises power, signal, video, hydraulic, water and air lines to support a variety of end effectors as well as to operate the arm itself.

Access to all components is required for maintainability.

The outside diameter is limited to 9.0 in.

These requirements are rather contradictory. The solution is illustrated in Fig. 4 and includes the following important features:

Fig. 4

Fully-enclosed design with large, removable covers.Covers are structural elements strongly connected to arm sections topreserve section properties.

High-strength corrosion-resistant material (CRES 17-4 PH) and fasteners accommodate concentrated loads at the structural connections.

Very careful internal packaging of components, verified by full-scale mock-up.

Purge System

The purge system renders the LDUAS in-tank components explosion-proof and prevents the ingress of particulate or liquid contamination into the interior of the LDUA and VPM. It achieves this by maintaining a positive pressure within the LDUA body and VPM tubes relative to the tank atmosphere so that no explosive gases can migrate inside and come into contact with electrical devices or hot components. The purge system is required to conform to ANSI/NFPA 496 for Class l, Division l, Group B components.

The purge system schematic is shown in Fig. 5. The purge air or gas supply is connected to the purge air coupling on the VPM housing. Inside the VPM the supply pressure and flow are regulated and routed through the VPM and LDUA utility harnesses to the TIP. When an end effector is attached to the LDUA the purge air or gas flows through the TIP hose coupling into the end effector. The return flow is via the interior of the LDUA, through the VPM inner and outer tubes and into the VPM housing. The VPM housing will be maintained at a pressure which is positive relative to the tank atmosphere (to ensure positive pressure in the LDUA and VPM tubes) and negative relative to the ambient atmosphere (to ensure containment in the event of leaks). This is accomplished by permitting the purge air to exhaust to the TRIC since the TRIC pressure is controlled by the buyer's ventilation system to be positive relative to tank and negative relative to ambient.

Fig. 5

The LDUA and the VPM tubes are thus explosion-proof both because they are maintained at a positive differential pressure relative to the tank atmosphere and because there is a significant purging flow through them. The purge system ensures this by monitoring the internal pressure at the top of the VPM inner tube and the VPM housing relative to the tank. The differential pressure at each location is monitored by two independent sensors connected to independent control functions in the control subsystem. One sensor is connected to a hard-wired switching circuit which cuts off all power to the LDUA if the differential pressure falls below a certain threshold. The second sensor is monitored by the system software which performs the same function and provides an error signal to the operator. This arrangement ensures that no single or common-mode failures can prevent the de-energizing of the LDUA if it is not maintained at a positive differential pressure relative to the tank.

Operator Interface

Operation is normally from a Remote Control Trailer located outside the Tank Farm fence. The Spar equipment includes two workstations, which together with joysticks and video monitorsprovide full control of, and feedback from the system. The operator interface has been designed to be User Friendly so that operators can learn and become comfortable with the system as quickly as possible.

The main control console uses a Sun Workstation with intuitive graphical point and click screens to guide the operator through the start-up, deployment and shutdown phases. Telerobotic control of the LDUA is via two 3-degree-of-freedom joysticks (one rotational; one translational) which allow either single joint or resolved motion commands. Visual feedback is provided from the LDUA shoulder camera, one or more in-tank "overview" cameras, and various video or 3-D laser end effectors.

A second (Silicon Graphics) workstation running Spar's Supervisory Graphics Control Software (SGCS) and Deneb's IGRIP simulation package provides a 3-D kinematic model of the LDUA arm and VPM which can be moved around inside a "world model" of the tank interior derived from the customers' 3-D mapping of the tank. Complete inspection missions can be simulated and recorded, potential collisions between the LDUA and tank obstacles can be detected and alternate paths chosen to avoid collisions, and optimize the inspection task. The planned mission can then be implemented and the simulation observed in real time to supplement the visual information provided to the operator.

INTEGRATION AND TEST

The integration and test program provides a logical and structured flow from assembly and subsystem through to final integrated system testing. The main steps in this process are:

- Manipulator Performance Test
- LDUA System Acceptance Test
- LDUA Inspection System Test and Evaluation at the Hanford Cold Test Facility

Manipulator Performance Test

After verifying that the manipulator has achieved its basic mechanical functionality, the manipulator and controller are connected and subjected to a series of tests designed to characterize and tune the manipulator performance. The test arrangement is illustrated in Fig. 6

Fig. 6

The first step is to carry out joint servo loop tuning to optimize individual joint performance. In the second step, the arm is operated in its resolved motion modes to verify and optimize the arm level control (ALC). This involves adjusting parameters such as washout spheres, transition and position hold spheres input command filter characteristics, joint position limits, self-collision avoidance, elbow and torque limit avoidance and LDUA deflection compensation.

These tests also demonstrate that the arm can meet its specified reach envelope, velocity and payload requirements together with its budgeted repeatability and resolution.

Considerable care is required during these tests, particularly in the early stages when full controllability is not established, because loss of control or operator error can result in collision with the floor or the test fixture.

System Acceptance Test

The system-level testing requires a special facility because the total height of the fully-deployed system is nearly 100 ft. (See Fig. 1). The selected facility is a partially-completed and mothballed thermal generating electrical power station currently used primarily for storage. The main turbine-generator hall provides an indoor location where the system can be craned on to the upper level and the VPM-LDUA deployed down to ground level as shown in Fig. 7. The building itself is unheated but a heated office space is available on the mezzanine level where the remote control station (console subsystem) is set up.

Fig. 7

A sequence of tests is conducted which represent most of the operational situations of the system in use, including the following:

- Ability to deploy/retract through a tank riser.
- Resolved motion including the VPM and its deflection compensation.

Payload capacity, velocity, and repeatability and resolution at various locations within the reach envelope.

Smooth motion and minimal oscillations.

Purge system functions.

Failsafe braking, health monitoring, interlocks and other safety features.

LDUA Inspection System Test and Evaluation at WHC

After delivery to WHC, the LDUA System will be installed in their indoor Cold Test Facility which provides adequate headroom and allows the VPM to be fully deployed into a vault containing simulated waste and a partial tank mock-up. Here the Spar LDUA system will be integrated with various customer supplied end effectors and a supervisory control and data acquisition system to verify the operation of the complete tank inspection and characterization system.

This test set up will be used for ongoing sensor and controls development, to develop operational procedures, and to provide operational and maintenance training.

CONCLUSIONS

A number of design challenges and development problems have been experienced in the LDUA program. These were successfully resolved by a combination of innovative engineering, careful design and development testing conducted on breadboard, proof-of-principle and mock-up hardware. The patience and flexibility of the customer was also a key factor in obtaining technically acceptable, cost-effective solutions. The final verification of the solutions was obtained during subsystem and system testing with a test plan designed to be rigorous yet cost-effective.

The first LDUA system is expected to be delivered to the Hanford site in February, 1996. After delivery to Hanford, the system will undergo testing at the site and end effectors will be integrated in support of a deployment in an underground storage tank at Hanford in September, 1996. The versatility and dexterity of the LDUA are expected to assist DOE in obtaining vital waste characterization data regarding the chemical composition of thewaste in these tanks.

Additional LDUA system will be delivered to the Hanford, Idaho and Oak Ridge sites during 1996 and are expected to be used to characterize underground storage tanks at these sites in 1997.

ABSTRACT

The U.S. Department of Energy (DOE) has significant amounts of radioactive waste stored in underground single-shell storage tanks. Many of these storage tanks have reached their design life and are deteriorating structurally. The wastes are chemically and radiologically hazardous with radiation levels ranging from slightly above background to hundreds of rads/hr. The consistency of the waste ranges from pumpable liquids and slurries to thick sludges and large crystalline masses. A priority mission of the DOE is to retrieve the waste from its present storage and process it for final disposal. The Light Duty Utility Arm (LDUA), a robotic system being developed by the DOE's Office of Science and Technology, will be used to gather information about the waste and the tanks in which it is stored to better plan and execute the clean-up mission. The LDUA will become operational at the Hanford Site in 1996, making it the first robotic system to be deployed in a radioactive underground storage tank.

Sandia National Laboratories is developing both a Supervisory Control System (SCS) and a Supervisory Data Acquisition System (SDAS) for use on the LDUA. The SCS is based on graphical programming and model-based control which allow previewing of programmed robot motion by the operator before actual robot motion is performed; this advanced capability is needed for robot safety in the hazardous environment. The SDAS is an integral part of the robotic system; it collects data from several end-effectors and controls both video storage and end-effector operations. SDAS uses a client/server architecture which allows multiple programs to receive data in real time including an operator interface, an expert system, and a data logger. This paper discusses the design and architecture of both the SCS and SDAS systems.

INTRODUCTION

The high-level radioactive wastes created as by-products of plutonium production and nuclear power generation have been stored in underground storage tanks at various U.S. Department of Energy (DOE) sites for more than 40 years. For example, at DOE's Hanford site approximately 140,000 m3 (37 Mgal) of waste material now resides in 149 single-shell tanks which range in size from 208 m3 (55,000 gal) to 3,785 m3 (1 Mgal) in capacity (1). These tanks consist of a carbon steel liner surrounded by a reinforced concrete shell. Many of these tanks have exceeded their design life and some are leaking contaminants into the surrounding environment. Characterization and remediation of these waste tanks is a high priority for the DOE's environmental restoration program. Radiation levels are too high for human workers to enter the tanks; therefore, remote means of characterization and removal must be considered. In support of this

mission, the DOE's Office of Science and Technology is sponsoring the development of the Light Duty Utility Arm (LDUA) system. The LDUA is an integrated robotic deployment system which will perform inspection, surveillance, waste analysis, and small-scale retrieval tasks in underground storage tanks (2). Current characterization methods used at tank sites are limited to positioning sensors and instruments directly below access risers. The advanced technologies being developed under the LDUA program will allow critical characterization and inspection throughout the tank, not just below the access risers.

The Light Duty Utility Arm is a seven degree-of-freedom articulated robotic arm on the end of a telescoping vertical positioning mast. The arm is designed to deploy a variety of tools (end effectors) into the underground tanks. Its redundant degrees of freedom give the arm the ability to maneuver around obstacles in the tank. The robotic arm and subsystem controller are being designed and developed by Spar Aerospace Ltd. Detailed information on the LDUA design can be found in Ref. 3.

Supervisory control and data acquisition for the LDUA will be implemented in stages. The initial deployment of the LDUA will be video and photographic surveys of the tank and waste (4). The Supervisory Data Acquisition System (SDAS), developed by Sandia National Laboratories, will control and gather video from both overview and end effector cameras. Control of the LDUA will be performed using joysticks in a teleoperated mode. The Supervisory Control System (SCS) described in this paper will be implemented on the LDUA in later missions. The SCS will improve the operations efficiency and safety of the LDUA system by adding graphical previewing and collision checking, automated path planning, and point-and-click motion to the control system. Further advances include task-level automatic sequencing and automatic trajectory planning for collision free motion in the tank.

MODEL BASED CONTROL & GRAPHICAL PROGRAMMING

A world model is a three-dimensional computer model of the robot and its operating environment. In an underground storage tank, the world model is developed with computer drawings of known aspects of the tank as well as with sensor-developed models of the unknown aspects of the tank (i.e. the waste surface.) The purpose of the world model is to allow the operator to visualize the position and motion of the robot relative to other objects in its environment. Motions are planned and previewed within the world model to verify their correctness and freedom from collisions before they are executed. This planning and safety checking in a preview mode is termed Graphical Programming.

Graphical Programming uses three-dimensional animated graphics models as intuitive operator interfaces for the programming and control of complex robotic systems (5). In remote deployment of robotic systems, such as the LDUA, the operator cannot directly interact with or view the robot motions. In a purely teleoperated control mode, the operator must guide the robot motions with input from cameras at discrete locations in the tank. The development of collision-free paths is completely dependent on the ability of the operator and the viewing angles of the in-tank cameras. In an underground tank environment, collisions (especially collisions with the tank wall) can have catastrophic effects. Graphical programming and model-based control provide a means for ensuring collision-free motion as well as reducing operator error and fatigue.

In a graphical programming system, the graphic representation of the robot, its environment, and controls allow an operator who is not an

expert robot programmer to easily interact with the robot and command safe robot motions. The user interface has pop-up menus, displays, and the ability for "point-and-click" motion commands which intuitively guide the operator through robot control. Using these graphic operator inputs, the robot's supervisory control software:

Translates commanded tasks into graphical robot motions;

Simulates and analyzes robot motion to check for safety;

Commands the robot to execute motions that have been determined to be safe;

Monitors the robot's motion to verify task compliance;

Updates the graphics model as tasks are performed by the robot.

Simulation and monitoring are key functions of the graphical programming supervisor software. Robot tasks are simulated before they are performed and the simulation system's safety validation functions determine whether the tasks can be performed safely (5). For example, motion previewing of this type is used to avoid collisions with tank walls and other obstacles within the tank. While the motion or task is being performed, the supervisory software slaves the simulation system to the robot's actual motion and monitors to verify that the move was performed as simulated. The supervisory software can also interrupt robot motion that excessively deviates from previewed paths or results in entry into hazardous regions.

Model-based control of robots as described above is dependent on a model of the environment in which the robot is functioning. On the LDUA system, creation of the world model will begin with the tank structure and will be based on best existing knowledge of the tank (e.g., design drawings and external measurements) (6). A topographical mapping system will be used to map contours of the waste surface and any unrecorded objects in the tank. Sandia has developed world model building capabilities which will rapidly create models from these mapping subsystems. As the world model is reasonably, but not completely accurate, a minimum approach distance will be established for the world model based on an analysis of all sources of error (6). In a more ideal graphical programming system, the robot would be equipped with physical sensors to compensate for any errors in the world model. For example, a pipe cutting end effector would be instrumented with proximity sensors to accurately dock the cutter at the correct location (7) or the entire arm would be instrumented with proximately sensors to sense and avoid near collisions (8). These sensors could then be used to update and increase the accuracy of the world model. Ideally, in the future the LDUA will be instrumented with these types of sensors, thus increasing both the safety and the accuracy of the robotic system.

FLEXIBLE DATA ACQUISITION FOR ROBOTIC SYSTEMS

A data acquisition system for use in robotic characterization of underground storage tanks must be capable and robust, as well as easily adaptable to changing requirements. Fundamentally, the system should provide a single point from which data from various end effectors can be acquired, processed, displayed, and stored. An additional goal of the design of such a system is that it should provide an open architecture that easily accommodates new end effectors and adapts to new missions with little disruption to the existing system. Ideally, the system design should allow for further development like the addition of neural networks and artificial intelligence which could provide data analysis concurrent with collection to give the operator guidance concerning tank characterization.

LDUA CONTROL AND DATA ACQUISITION DESIGN

The LDUA system is designed to be run by two operators using workstations located in a remote trailer. One operator uses the graphical interface on the Supervisory Control System (SCS) to operate the arm using path previewing and collision avoidance. The other operator uses the Supervisory Data Acquisition System (SDAS) to operate end effectors and gather data. The two systems are linked by a robot position client and server which provide current arm positions from the subsystem controller to the SDAS. Both the LDUA control and data acquisition systems are designed with an open architecture using the client/server model to achieve maximum flexibility. The designs of both systems are detailed below.

Supervisory Control System

The LDUA control architecture is based on the Generic Intelligent System Controller (GISC) approach developed at SNL (9). The GISC-based design of the SCS is illustrated in Fig. 1. This system is composed of four basic software components: a graphical supervisor (Sancho), a commercial robot simulation package (IGRIPa), a device driver (LDUA Robot Server), and communication interfaces. Both the simulation package and the supervisor are processes which run on a Silicon Graphics, Inc. workstation. The device driver software executes on a separate CPU which is attached to a Versa Module Eurocard (VME) bus.Communication interfaces exist between the supervisor and the simulation package, between the supervisor and the device driver, and between the simulation package and the device driver.

The supervisory program, Sancho, is written in the C programming language. Users interact with Sancho through a graphical user interface (GUI) based on the XForms library for X-windows (10). Sancho drives the simulation package using IGRIP's Command Line Interface (CLI) commands (11). Nettools, a Deneb Robotic's interface based on TCP/IP communications, is used to pass CLI commands and values returned by CLI commands between the supervisor and the simulation package. Sancho commands and interrogates the LDUA Robot Server device driver through a generic set of commands based on the Robot Independent Programming Environment/ Robot Independent Programming Language (RIPE/RIPL) programming paradigm (12). The generic RIPL command set includes commands such as: SetSpeed, SetToolLength, MoveTo, LoadPath, and MoveAlongPath. In addition to issuing commands to the device driver, the supervisor can also respond to asynchronous events that are generated by the LDUA Robot Server. Examples of such subsystem events include the completion of a commanded move and an externally-generated emergency stop.

Communications between the supervisor process and the device driver is accomplished through the GENeralized Interface for Supervisor and Subsystems (GENISAS) (9) communications library. GENISAS provides a convenient way to link commands, queries, and data exchanges to the appropriate robot control functions and data transfer functions within the device driver. GENISAS also provides the mechanism by which asynchronous events (E-stops, move complete, etc.) from the device driver are associated with the appropriate functions within Sancho.

As shown in Fig. 1, two separate instances of the LDUA Robot Server are spawned on the VME CPU. These two servers are referred to as the Real Robot Server and the Simulated Robot Server, respectively. As their names suggest, one server controls and queries the state of the actual robot arm whereas the other server is used for generating simulated motion for the IGRIP simulation package. GENISAS connections exist between Sancho

and the Real Robot Server and between IGRIP and the Simulated Robot Server.

Fig. 1

Both of the robot servers communicate with the LDUA Subsystem Control software developed by Spar Aerospace Ltd, the manufacturer of the LDUA. This communication takes place through a set of library functions referred to as the GISC interface. The Subsystem Controller is responsible for servo control of the robot arm. In addition, it can be placed in state known as "simulation" mode. In simulation mode, the Subsystem Controller accepts motion commands as usual, but, instead of moving the arm, it simulates the move by generating a sequence of joint positions. The Simulated Robot Server only interacts with the Subsystem Controller when simulation mode is enabled, and, likewise, the Real Robot Server interacts with the Subsystem Controller when simulation mode is disabled and motion is enabled.

When an operator issues a motion command to the SCS, the motion is first previewed through IGRIP. During the preview phase, IGRIP uses Deneb's shared library functions to command the Simulated Robot Server which, in turn, issues commands to the Subsystem Controller. Collision checking is done inside of IGRIP. If a collision is detected, the command is terminated. Following the preview phase, the SCS then queries the operator to determine if the motion should be executed by the real robot arm. If the motion is to be repeated by the actual robot, the Sancho application sends commands to the Real Robot Server to initiate, control, and monitor the move. Sancho displays the monitored motion in the IGRIP simulation to provide real time feedback to the operator as the move is executed.

The menu-driven user interface to Sancho overlayed on the IGRIP display is shown in Fig. 2. The interface allows the user to command motion to a selected tag point or along a predetermined path. Scripts for more complex tasks, such as tool-exchange operations, can be executed and modified through the Sancho interface. A tool for generating paths and motions for scanning operations is also available. The user can easily change the view in the IGRIP workcell as well as enter and leave IGRIP user mode.

Fig. 2

Supervisory Data Acquisition System

The Supervisory Data Acquisition System (SDAS) for the Light Duty Utility Arm (LDUA) is a flexible data acquisition and control system. SDAS operates independently of the Supervisory Control System (SCS) and provides services that do not affect the robot controller. SDAS is a general system that allows quick changes in the operator interface and input/ouput (I/O) configuration.

SDAS is composed of two parts: a real-time server and an operator interface. The server portion handles the real-time aspects of data acquisition and control. The operator interface provides a graphical interface for the operator to view data and control non-robotic LDUA subsystems. Both aspects of the SDAS are discussed in more detail below.

The real-time server runs under the VxWorksb operating system on a VME bus architecture, supporting an extensible set of input and output (I/O) boards. The server is a collection of records in a database with each record holding a single real-time value. Records obtain values from hardware inputs (i.e., analog to digital converters (ADC), digital to analog converters (DAC), and digital output devices), operator inputs, or

from calculations. Records are "processed" whenever a new value is received. Whenever a record value is updated, the current time and robot position are stored with the record.

The server schedules records to be processed at regular intervals, in response to events, or simply due to normal flow within the database. When a record is processed, it may optionally schedule additional records for processing. For example, an ADC record may read a voltage in counts, this record would then cause a calculation record to process which converts the ADC counts into engineering units. Two types of records in the database control this flow of additional processing. The first type unconditionally schedules a list of records for processing each time it is processed. The second conditionally schedules a single record for processing based on an input index. The configuration of the server database is specified via a text file each time the server is started. This allows considerable flexibility when changing the system and/or adding additional capability.

The integration and addition of various input and output devices are handled with corresponding device drivers within the data acquisition system. Device driver objects are independent of the SDAS program and are liked and loaded at runtime. The text database configuration file discussed above allows records to be associated with device drivers at runtime. This allows system administrators to add devices to an existing SDAS installation without modifying the SDAS code. The current SDAS contains drivers for support of the standard Industrial Pack mezzanine, Opto-22, and RS-232 and RS-485 serial standards. However, the system is not limited to these I/O devices; new drivers can easily be incorporated into the system.

In the current data acquisition system, client applications to the server include the operator interface and an auxiliary interface for viewing data. Again, the system is not limited; future client applications may include historical log files, commercial databases, or expert systems. These client applications connect to the server over ethernet using TCP/IP socket connections. After establishing a connection, client applications open records for reading and writing on an individual basis. Whenever a record is processed, all clients who have opened the processed record receive the new data along with the time and position stamp. The client/server architecture allows several clients to connect to the server at any given time and have access to the same records. At the same time, a record may be locked by a client, thus allowing single point of control.

The SDAS operator interface is a graphical user interface based on National Instrument's LabVIEWc software. A copy of the highest level SDAS operator interface is shown in Fig. 3. The interface consists of a collection of LabVIEW Virtual Instruments (VIs) which control and monitor LDUA subsystems. A LabVIEW VI is composed of a front panel and an associated wiring diagram. The front panel contains buttons, graphs, charts, menus, and other user interface graphics. The wiring diagram controls the front panel using a visual programming paradigm. The operator interacts only with the front panel. In the example shown, selecting any of the displayed buttons brings up the control and data acquisition front panel for that particular subsystem. SDAS provides a library of sub-VIs which send data to and receive data from the SDAS server. The interactive building of the front panel and visual

programming of the wiring diagram allow the operator interface to be easily maintained and updated to reflect changes in the system.
Fig. 3
For the first deployment of the LDUA system at Hanford, SDAS controls the pan and tilt camera systems and video system. This is accomplished for the camera systems by using a single Relay 16 Industrial Pack by Systran Corporation and an RS-232 serial connection and for the video system (composed of a video switcher, two VCRs, two video titlers, and a video printer) through multiple serial connections. In addition to the video and camera systems, future deployments of the LDUA will include the collection of data from various sensor end effectors including an SNL developed "minilab" multi-sensor end effector (13).

FUTURE PLANS AND DEVELOPMENTS

The first deployment of the LDUA in a radioactive waste tank will be at the Hanford site in 1996. The Supervisory Data Acquisition System described above will be used to control and store video images from various end effector and overview cameras (4). The Supervisory Control System described in this paper will be implemented on later deployments of the LDUA arm. At that time, the graphical commands, path previewing, and collision checking capabilities within the SCS will be used to operate the LDUA in a telerobotic mode versus pure teleoperation. Automated path planning algorithms will also be implemented to allow the operator to easily perform a complete survey of a surface with video, camera, and/or sensor end effectors.

Future deployments of the LDUA will use end effectors that must operate in contact with or in close proximity to the surface of the waste or tank structures (6). To support this mode of operation, the SCS will be extended to read position and force feedback from sensors on the LDUA end effectors and modify the motion of the arm for surface following, compliant motion, and docking-type operations (7). The ability of the arm and end effectors to be controlled from task-level automatic sequencing will be added to the SCS in later deployments. Further developments include advanced trajectory planning algorithms that calculate collision-free paths in congested work spaces.

SUMMARY

This paper describes the development of both a Supervisory Control System (SCS) and a Supervisory Data Acquisition System (SDAS) that were designed specifically for use on robotic systems in waste storage tanks. The two systems will be implemented on the Light Duty Utility Arm (LDUA) system, an integrated robotic deployment system which will perform inspection, surveillance,waste analysis, and small-scale retrieval tasks in underground storage tanks. SDAS will be implemented on the LDUA in its first deployment at the Hanford site in 1996. SCS will be installed and used to control the arm in later deployments.

ACKNOWLEDGMENTS

The Light Duty Utility Arm System is being developed under the sponsorship of the DOE Office of Science and Technology's Tanks Focus Area (EM-50). The LDUA is being implemented by a consortium of DOE sites, national laboratories, and commercial partners. These include: Westinghouse Hanford Company, Sandia National Laboratories, Oak Ridge National Laboratories, Pacific Northwest Laboratory, the Savannah River Site, the Idaho National Engineering Laboratory, and Spar Aerospace, Ltd. The work performed at Sandia National Laboratories was supported by the

United States Department of Energy under contract number DE-AC04-76DP00789.

Session 57 -- PANEL - WASTE MANAGEMENT CHARGEBACK SYSTEMS IN THE DOE COMPLEX

Co-chairs: R. Piscitella, INEL/LITCO;
James Van Vliet, INEL

57-1

CHARGEBACK SYSTEMS IN THE DOE COMPLEX

The workshop conducted during this session addressed Chargeback Systems in the Department of Energy (DOE) Complex. The purpose of this workshop was to present and discuss successes and problems that are currently being encountered with implementation of chargeback systems for waste

management activities in the DOE Complex. The workshop was introduced by the two chairmen of the session: J. A. Van Vliet, Director of Waste Operations for Lockheed Idaho Technologies Company (LITCO) at the Idaho National Engineering Laboratory (INEL) and R. R. Piscitella, Low-Level Waste Type Manager also with LITCO at the INEL. As part of the introduction, current reviews by the National Academy of Science, the Environmental Management Advisory Board, and other reviewing organizations that suggest chargeback as a funding mechanism were discussed. A definition of chargeback was also presented as follows:
A charging system where the waste generator is either partially or totally billed for waste management activities that are directly related to the waste that the generator produces.
Following this introduction, short presentations were made. Questions from the audience were answered during the presentations. Abstracts of these presentations are given below in the order presented.
Idaho National Engineering Laboratory, Waste Operations Chargeback System -- R. R. Piscitella, Telephone Number: (208) 526-1137
Chargeback systems are being considered for implementation on the INEL for two primary reasons: To give the waste generator a strong economic incentive to reduce the amount and/or hazard of the waste generated, and to give INEL treatment, storage and disposal facilities a strong incentive to be competitive with comparable private business and other DOE laboratories. The current waste management system on the INEL does not support either of the objectives listed above.
The proposed system would continue to directly fund Waste Management treatment, storage and disposal (TSD) facilities for activities such as legacy waste and post-closure activities. However, waste generators would pay for waste management activities that directly relate to TSD activities for the wastes they produce. A chargeback pilot programthat addresses only low-level waste (LLW) processing and disposal is being completed in FY-96. This pilot program will modify waste tracking and accounting systems to allow "simulated" bills to be sent to LLW generators. The pilot program will be evaluated at the end of this fiscal year and, based on the results, future chargeback activities will be determined.
Sandia National Laboratory, Operational P2 Chargeback and New Chargeback System Development -- S. A Schrader, Telephone Number: (505) 848-0381
To support its Waste Minimization/Pollution Prevention Program, Sandia National Laboratories adds a surcharge to each unit of hazardous waste that is managed by the EM-30 Waste Management Program. While providing funding for Waste Minimization/Pollution Prevention activities, this also provides a financial incentive for organizations to reduce waste generation. It is not a full cost recovery system, but exemplifies a method of recovering costs from specific customers. The system relies on waste collection data to determine charges to customer organizations. Cost allocation is managed using a "Service Center" mechanism provided by Sandia's Corporate Financial Information System.
This year, Sandia's Sample Management Office (SMO) is implementing a full cost recovery system using the Service Center mechanism. Estimated budgets are used to predetermine cost allocations, which are adjusted each quarter to assure equitable distribution of actual costs among SMO customer organizations.
USDOE Albuquerque, Reorganized (Re-Engineered) Waste Management -- J. Orban, Telephone Number: (505) 845-4421

Results of an independent technical review of Lawrence Livermore National Laboratory, Los Alamos National Laboratory and Sandia National Laboratory waste minimization and management programs pointed out the fact that program drivers are fundamentally different when compared to the private sector. The only focus of a commercial waste minimization and management program is compliant, cost-effective management of the minimum waste. In contrast, DOE and the Laboratories treat waste minimization and managementas the commercial equivalent of a "profit center" rather that a support service. The primary program focus is on money management, not waste cost management. There is no Laboratory equivalent to the commercial profit "bottom Line" incentive for controlling waste streams, volumes, and program costs.

A DOE working group was established to take the result of this technical review and define alternatives for re-engineering DOE Waste Management. DOE Laboratory activities were divided into a Commercial Portion and Investment/Legacy Portion. The Commercial Portion would be a full cost recovery service center and would cover activities associated with treatment, storage and disposal of currently-generated waste. The Investment/Legacy portion would cover legacy storage, legacy workoffs, etc., and would be individually estimated as separate projects. Current implementation plans call for restructuring selected DOE sites into Commercial and Investment/Legacy in a pilot program in FY-97 with "real" billing occurring in FY-98. Other DOE sites would follow with a one- year delay.

Pacific Northwest National Laboratory, New Chargeback System Piloting and Implementation -- K. L. Peterson, Telephone Number: (509) 372-4540

The DOE-EM funded Pacific Northwest National Laboratory Inventory and Waste Management Chargeback design project was discussed. This project is coordinated through the PNNL Waste Management Division and is currently looking at a lab-wide chargeback system that would include: 1) Waste Management Chargeback, 2) Pollution Prevention Investment, 3) Inventory Control, and 4) Effluent Monitoring Costs. Chargeback costs would be divided into fixed costs that would be funded through the Activity Data Sheet (ADS) process and variable costs that would be funded by the waste generator. Implementation issues include: generator planning for FY-97, year-end closeout carryover, accrual of costs, and notification of generators.

Current schedule for implementation includes development of the system this fiscal year, with a waste generator chargeback system expected to be implemented in FY 1997.

Chem-Nuclear Systems, Inc., Chargeback in the Private Sector,
G.J. Antonucci, Telephone Number: (803) 758-1807

Chem-Nuclear Systems, Inc., (CNSI) operates the commercial LLW disposal facility at Barnwell, SC. CNSI conducted a study of LLW disposal at the INEL from the perspective of operating like a private business. Steps that would be followed in the establishment and operations of "running INEL LLW disposal like a private business" were discussed. These steps included: 1) develop and agree upon the real costs for LLW disposal operations, 2) make generators aware of the chargeback system and get their buy-in to participate, 3) develop waste forecasts, 4) establish rates and surcharges that apply to forecast waste streams, 5) treat, store, and dispose of waste at established rates, and 6) if disposed rates exceed forecasts by greater than 10%, either the generator stores the waste or a 30% increase in fee is applied.

Session 58 -- WASTE CHARACTERIZATION AND SPECIFICATION TO MEET REGULATORY REQUIREMENTS AND WASTE ACCEPTANCE CRITERIA

ABSTRACT

The goal of just-in-time characterization and certification, which is based on the just-in-time manufacturing process, is to streamline the certification process by eliminating redundant layers of oversight and establishing pro-active waste management controls. Just-in-time characterization and certification would rely on a waste management system in which wastes are characterized at the point of generation, precertified as they are generated (i.e., without iterative inspections and tests subsequent to generation and storage), and certified at the point of shipment, ideally the loading dock of the building from which the wastes are generated. Waste storage would be limited to accumulating containers for treatment, if necessary, or for cost-efficient offsite shipment only.

Just-in-time characterization and certification would be accomplished by establishing 1) a comprehensive waste management quality assurance (QA) program consisting of infrastructure controls and on-going verification measures that provide the overall confidence in data validity and waste package integrity to allow certification upon demand and 2) three essential functions of characterization at the point of generation, "precertification" (including necessary inspections, data validation, nonconformance control, and document compilation and review), and final waste package certification (i.e., a document package review ensuring that all applicable regulatory and disposal facility requirements are satisfied).

Just-in-time characterization and certification is most applicable to wastes generated by decontamination and decommissioning activities. However, implementation of the process can be phased, using other waste categories (e.g., environmental restoration waste, rejected waste, legacy waste, newly generated waste) to introduce the concept at the facility and for use in employee training.

INTRODUCTION

Transportation and disposal of wastes generated by Department of Energy (DOE) activities, including weapons production and decontamination and decommissioning (D&D) of facilities,require that wastes be certified as complying with various regulations and requirements. These certification requirements are typically summarized by disposal sites under specific waste acceptance criteria (WAC). Although a large volume of wastes has been generated by past activities and are presently in storage awaiting disposal, a significant volume of wastes, particularly from D&D projects,

has not yet been generated. To prepare wastes for disposal in an efficient manner, it is suggested that a program of just-in-time characterization and certification be adopted.

The concept of just-in-time characterization and certification is based on established just-in-time manufacturing practices, in which goods are produced as needed to fill customers' orders; parts and product inventories, and the storage needs for these inventories, are minimized to reduce costs. The linchpin of just-in-time manufacturing is a well-developed infrastructure that allows quick and dependable response to customer needs. The key to successful just-in-time characterization and certification is confidence derived from an effective characterization and waste management system, and the resultant ability to certify wastes as they are processed (i.e., without iterative inspections, tests, and re-evaluations subsequent to generation and storage).

The following description of the just-in-time characterization and certification concept is based on an evaluation of the waste certification program at the Rocky Flats Environmental Technology Site (RFETS) and experience at other DOE facilities, including the Los Alamos National Laboratory (LANL).

REGULATORY DRIVERS AND THE NEED FOR JUST-IN-TIME CHARACTERIZATION AND CERTIFICATION

Requirements for waste certification are derived from DOE Order 5820.2A, 10 CFR Part 71, 40 CFR Part 191, and 49 CFR Part 172 (1,2,3,4). These specifications require waste generators to assure waste treatment, storage, and disposal facilities that the regulatory requirements for the waste are met. This assurance includes the implementation of the controls and measures necessary to ensure compliance with the disposal facility WAC. Certification requirements are also present in the WAC for various disposal facilities, as follows:

- Envirocare of Utah, Material Acceptance Process Manual (5)
- Hanford Site, Hanford Site Solid Waste Acceptance Criteria (6)
- Nevada Test Site, Nevada Test Site Defense Waste Acceptance Criteria, Certification, and Transfer Requirements (7)
- Scientific Ecology Group (SEG), Waste Acceptance Criteria (8)
- Waste Isolation Pilot Plant, Waste Acceptance Criteria for the Waste Isolation Pilot Plant (9)

The specific certification requirements of DOE, U.S. Environmental Protection Agency (EPA), U.S.Department of Transportation (DOT), and different treatment, storage, and disposal facilities can result in multiple layers of oversight (Fig. 1). In turn, these multiple layers of oversight may increase the amount of bureaucracy, time and resources (i.e., personnel and budget) needed to get a waste shipment offsite, which reduces efficiency and increases costs. The goal of just-in-time characterization and certification is to streamline the waste characterization and certification processes. This can be accomplished by eliminating redundant levels of oversight and establishing pro-active controls rather than "final inspection quality" to achieve WAC compliance. The degree to which extended storage of waste can be reduced or eliminated is also fundamental to streamlining the waste disposal process.

Fig. 1

JUST-IN-TIME CONCEPT

The basic concepts inherent to the just-in-time operational management philosophy have direct application at DOE facilities. The goals of just-

in-time manufacturing are to reduce costs, increase efficiency, and increase the company's responsiveness to its customers. Eliminating overhead in the form of parts inventories, product inventories, and storage requirements associated with these inventories, reduces costs; in addition, process bottlenecks can be identified and corrected. Manufacturing products at the rate of demand improves the efficiency of the process. Because the products are manufactured at the same rate as demand, the time required for responding to shifting customer demands can be reduced.

These concepts can be applied to waste characterization and certification at DOE facilities. Rather than storing waste until it is ready to be shipped and incurring costs (e.g., inspections, utilities, building floor space) associated with this storage, the just-in-time process would ship wastes immediately after generation. In addition to reducing or eliminating storage costs, this process would enable DOE facilities to meet changing WAC as the wastes are generated, not as the packages are pulled from storage, which results in higher costs and delays in shipping because of the rework of the packages to meet the new acceptance criteria.

JUST-IN-TIME CHARACTERIZATION AND CERTIFICATION

Just-in-time characterization and certification at DOE facilities would allow wastes to be shipped from the generation location and eliminate the need for long-term storage. Wastes would be stored only for the purpose of accumulating enough waste packages to make shipment economically viable. Both characterization and certification would be required at or near the point of generation.

For certification on demand (e.g., as needed) to be a viable option, the entire process must be supported by a well-planned, comprehensive, and rigorous waste management QA program. Such a program provides the procedural infrastructure necessary to achieve confidence that all aspects of the waste management system are implemented in an effective manner. This procedural infrastructure includes the basic elements of the existing QA standards (e.g., NQA-1, DOE 5700.6c, ASQC-E4); therefore, the infrastructure provides for operations control through personnel qualification, procedural control of activities, nonconformance control, and planning and provides assurance of program effectiveness through systematic verification activities (i.e., inspection, surveillance, audit, and corrective action).

With such a program in place, demonstration of program effectiveness for external oversight or regulatory agencies becomes a relatively simple exercise. Also, confidence in the adequacy of waste characterization, such as characterization data and package integrity, is sufficient to allow certification based on existing data and without the intense scrutiny of individual packages commonly associated with programs plagued by suspect data, continuous external inspection, and audit findings. With such a program in place, a facility can concentrate on strengthening and streamlining the important functions of waste characterization, data validation, and documentation review that allow just-in-time certification. Such a program is depicted in Fig. 2.

Fig. 2

For characterization to support the just-in-time concept, the waste generated by an environmental restoration (ER) or D&D project must be characterized (i.e., sampled and analyzed as necessary, with complete analytical results) before the wastes are placed into containers. This

requires the characterization personnel to participate during the planning stages of a project. As the responsible manager and engineers are planning the process for performing the project, the characterization personnel would be reviewing the planning documents, designing the sampling plan, and performing initial sampling of materials that would be generated as wastes during the project. Initial sampling that is conducted during the planning stages of the project could also be applicable to the validation of process knowledge for future ER and D&D activities. The characterization plan should prescribe measures to be taken when anomalous results or unknown or unanticipated waste items are encountered. During the actual performance of the project, waste characterization personnel must be available, on an on-call basis, to resolve such issues so that they are not pushed aside to become uncharacterized backlog wastes that may cast aspersions on the validity of overall characterization data.

Wastes generated by the project would be certified at the point of shipment, similar to what currently occurs at many facilities. However, the wastes would be precertified at the point of generation. Precertification would entail verification of characterization and data validation completeness, waste package inspection, verification that characterization data is traceable to waste packages, and compilation of the documentation necessary to support certification. Precertification would be performed before containers are sealed and while the containers remain the responsibility of the generator, which allows any problems to be corrected while the waste is still easily accessible and while the generator can be held accountable for, and learn from, such problems. Final certification would primarily be a review to verify that the waste package meets disposal facility and transportation requirements, as opposed to the detailed scrutiny of paperwork common to facilities that cannot rely on the viability of the overall waste management system to produce a quality product.

PERSONNEL REQUIREMENTS

The adoption of just-in-time characterization and certification may require the realignment and refocus of waste management organizations. In addition to waste generation, just-in-time characterization and certification would require emphasis on three functions: characterization at the point of generation, waste precertification, and waste shipment certification.

Two requirements must be met for successful implementation of just-in-time characterization and certification. First, waste characterization and certification activities must be autonomous in terms of organizational structure and funding. The responsible organizations must carry the authority to resolve problems identified during the waste generation, packaging, and certification process.

Second, all personnel responsible for the characterization and certification process must be qualified in their disciplines and must be knowledgeable of the overall project. A fundamental precept of the International Atomic Energy Agency (IAEA) is applicable: personnel auditing, inspecting, or approving work must be at least as qualified as the personnel performing the work being overseen. A root cause for many problems in existing waste management organizations is deficiencies in personnel training and qualification. Such problems must be eliminated for just-in-time characterization and certification (or any waste management system) to function efficiently.

Waste Characterization

To provide for just-in-time characterization, the personnel responsible for this characterization must be available to the personnel generating and precertifying the waste. These characterization personnel must also be involved in the planning stages of the project. Waste characterization personnel would prepare characterization plans and procedures, implement and oversee sampling and analysis, ensure proper data validation, and prepare final characterization data packages, including regulatory justifications. The personnel would attest to the proper characterization of the waste being placed into the container and be available to provide guidance when sampling unknown or suspicious wastes as they are encountered by the personnel performing the waste generating activity. Guidance on the proper packaging of individual or unique wastes that are being generated would also be available from waste characterization personnel.

Waste Precertification

Under just-in-time certification, a detailed review of the container documentation would need to be performed during the process of waste generation. Although the waste precertification personnel's duties would be similar to that of a waste inspector performing in-process inspection of a waste package, the level of inspection detail is greater. This detailed review would be performed by waste precertification. The waste precertification function would also include verification that waste characterization data are complete and satisfactory, and compilation of all documentation required for the final certification.

Waste precertification would control access to the waste packages; ensure the proper setup of the container for the waste stream being generated (e.g., number and type of liners, presence of a carbon filter); ensure that generators placing waste into the package have current qualifications, and ensure that the wastes placed in the package are of the same, or compatible, waste types. In position and responsibility, the waste precertifier would be analogous to the package certifier described in NVO-325, Nevada Test Site Defense Waste Acceptance Criteria, Certification, and Transfer Requirements (7).

Waste Shipment Certification

When D&D and ER activities are undertaken at DOE facilities, the volume of wastes generated will increase dramatically over current generation rates. Consequently, the certification function will become important to managing waste and meeting overall project milestones. It is probable that certification staffing levels will have to increase significantly at many facilities.

In the just-in-time certification concept, final certification becomes a matter of ensuring that waste packages meet disposal facility and transportation requirements rather than a detailed scrutiny of all documentation on a package-by-package basis. The waste management QA program would control the accuracy and completeness of the documentation. The precertification function would control oversight and review. Thus, the waste shipment certification official would be freed from the checking function and can devote efforts to resolving larger issues. The waste shipment certification official would also have better communication with disposal facility officials and regulators. Consequently, personnel in this capacity will need to be of a senior level and must be knowledgeable of all disciplines involved in the waste generation, treatment, and disposal process. If the facility wishes to be

successful in processing the volumes of waste anticipated from the D&D and cleanup of DOE facilities, it will have to recognize the importance of this function, and staff and support it accordingly.

IMPLEMENTATION

Implementation of the just-in-time concept into a manufacturing operation typically involves five steps. Similarly, these just-in-time concepts can be adapted to waste management, characterization, and certification, as follows:

Cleaning up the Operations. Factors that prevent the certification and shipment of waste (e.g., procedural roadblocks, duplicative or competing activities) can be identified and eliminated or reduced by performing an evaluation of the existing process for waste generation and certification and a root cause analysis of problems diagnosed during this process.

Establishing a Comprehensive Waste Management QA Program. If the facility does not presently have an effective QA program, which is essential to the viability of the just-in-time concept, establishing such a program is essential, but is not a trivial undertaking. The process can be briefly described as evaluating the facility to determine the activities that are important to safety and waste quality, and then ensuring that all activities are proceduralized to ensure that they are performed adequately and that auditable documentation to demonstrate satisfactory performance is provided. Development of such a program must be the responsibility of senior, experienced personnel with the authority to institute necessary changes.

Effecting a Company-wide Culture Change. Because DOE facilities are in a period of transition from weapons manufacturing to ER and D&D, a facility-wide culture change might be necessary, particularly if a comprehensive waste management QA program is not currently in place. This would be an ideal opportunity to introduce the concept of just-in-time waste characterization and certification.

It is worth noting that cross-cutting cultural changes have been successfully accomplished in many troubled industries, both commercial and nuclear, over the last few decades. This process has been successful only where management was fully committed and where the responsible individuals were given full authority to make necessary changes. However, in those facilities that resisted such change, the process has in many cases been less than fruitful.

Preparing Logistics for Just-in-time. Procedures and processes for the certification of waste should be reviewed so that unnecessary or redundant requirements are eliminated. It may also be necessary to upgrade existing facilities that are used to ship the large amounts of waste expected to result from ER and D&D activities. Areas requiring logistical upgrades should be identified after a more detailed analysis of the facilities has been done.

Implementing the Program. Another aspect of preparing for just-in-time characterization and certification implementation is training personnel to the revised procedures and processes. Characterization, certification, and their associated quality assurance requirements should be pushed as far back in the waste generation process as possible, ideally to the point of generation.

Reviewing and Monitoring the System after Implementation. Specific measurable performance objectives should be established for each department or program that will be contributing to just-in-time characterization and certification. Ongoing verification of performance

by an autonomous organization will be necessary to establish the validity of the overall system and to demonstrate system viability to external oversight personnel.

It is recommended that any just-in-time certification process first be established as a pilot program. The intent of this program would be to introduce and develop the concept of just-in-time certification and to provide training for the required personnel (i.e., waste shipment certifiers, waste precertifiers, and waste characterizers). This training would be accomplished by rotating the personnel through the pilot program and then placing them into other waste generating buildings, at which time just-in-time characterization and certification would be implemented. By having such a centralized, hands-on training process, consistency in training could be achieved, personnel motivation enhanced, and lines of communication established. To ensure the certifiability of wastes generated during this pilot program, it is recommended that the waste packages in-process be inspected and certified using the existing certification system on a temporary basis, in parallel to the certification being performed under the just-in-time system.

To further the transition from the current waste generation and certification process to the just-in-time process, and to simplify it, present waste packaging procedures should be reviewed to identify those requirements absolutely necessary for the certification of wastes to the disposal facility WAC. Requirements that are not absolutely required should be eliminated. The procedures themselves should be simplified, combined, and rewritten so that one procedure would provide sufficient information for the proper packaging of waste.

As these procedures are revised, and as the just-in-time process is developed, it is also recommended that the responsibilities of the organizations involved in waste characterization and certification be reviewed and, as necessary, combined so that only those organizations absolutely necessary to the certification process are involved. Responsibilities of the retained organizations, and the lines of communication among those organizations, should also be defined as completely as possible to remove any ambiguity that may confuse or slow the process.

Finally, it should be recognized that no procedure or program should ever be implemented without clear specification of how existing waste will be viewed and addressed under the change and regulator and disposal facility endorsement, where required or appropriate.

SUMMARY

Just-in-time manufacturing and supply concepts work for many commercial enterprises. These concepts work where business programs and procedures are so well organized and reliable that the company can respond at a moments notice to changing customer needs. At DOE facilities, the customer is not only DOE (and, consequently, the public), but also project commitments and schedules. Just-in-time characterization and certification programs can help meet the accelerated disposal schedules anticipated for future D&D and ER activities. Our customers deserve the well organized and reliable waste management program that makes just-in-time concepts possible now.

DEVELOPMENT OF A LOW-LEVEL RADIOACTIVE WASTE ACCEPTANCE PROGRAM AT THE NEVADA TEST SITE

Michael B. Noland

Nevada Operations Office

ABSTRACT

The Nevada Test Site (NTS) accepts low-level radioactive waste from generators across the United States. The program utilizes multi-organizational concepts in the contracting of scientists and specialists. Personnel are involved with all facets of the program including the development of the Waste Acceptance Criteria, review of generator documentation, and assessment of generator programs. The development of the NTS low-level radioactive waste acceptance program has been through an evolution of regulatory drivers, policy, and expertise, resulting in a safe and effective waste management and disposal strategy.

HISTORY/OVERVIEW

The Nevada Test Site (NTS) has historically been the nuclear weapons test facility for the U.S. Department of Energy (DOE) and its previous agencies such as the U. S. Atomic Energy Commission. The NTS is located approximately 65 miles northwest of Las Vegas, Nevada, and encompasses 1,350 square miles. The NTS also serves as a major disposal facility for low-level radioactive waste (LLW) generated by DOE and other non-DOE installations throughout the United States.

Once the test ban treaty prohibiting the testing of atmospheric nuclear weapons was ratified, awareness for the need of clean-up and remediation of the atmospheric test debris and areas of testing at the NTS began to arise. As the process began, the research for disposal methods of low-level radioactive waste were initiated. With concerns for the safe and final disposal of LLW came the realization that criteria which address

geology, hydrology, and the climatic concerns of the disposal area must be established. At the same time, it was realized that consideration must also be given to safety, shipment methods, identification of waste content, Federal and state regulations, and radiological parameters. As preparations began to select and utilize an existing crater from a previous underground test, a plan was developed to address the subject criteria for the disposal of the LLW. Considered in this plan was the arid climate, deep aquifer,alluvial soil, and isolation from the public of the selected disposal site. This plan evolved into the "Operational Radioactive Defense Waste Management Plan for the Nevada Test Site," NVO-185.

In 1978, as waste disposal activities began, the development of criteria paralleled the disposal operations. Lessons were learned and the activity evolved. Researchers began to better understand the ideal attributes of the area and continued to develop techniques for safe and permanent disposal options for DOE's overburdening amounts of LLW. In January 1985, NVO-185 was revised for the fourth time to implement the technically evolving criteria for both on-site and off-site generators.

With the onset of increased Federal regulations such as the Resource Conservation and Recovery Act (RCRA) and the inclusive Land Disposal Restrictions (LDR), the DOE re-evaluated its program to manage the growing volumes of wastes being generated and stored at its various sites across the country. In September of 1988, DOE developed and implemented DOE Order 5820.2A, "Radioactive Waste Management." This order provided requirements and guidance to the operations and field offices for the management and disposal of their wastes.

Since the NTS was familiar with the regulatory issues and in anticipation of the new DOE Order being issued, the NTS began to utilize its NVO-185 Plan to develop waste acceptance criteria (WAC) that would incorporate additional lessons learned, the new and evolving RCRA requirements, and the anticipated DOE Order 5820.2A. In October 1988, NVO-325, "Nevada Test Site Defense Waste Acceptance Criteria, Certification, and Transfer Requirements," was formally issued, replacing NVO-185. The NTS was now disposing of waste in well-designed subsurface disposal trenches as well as in bulk crater sites. Many strides had been made in the utilization of disposal packaging, disposal techniques, waste characterization, and shipment mechanisms. This information was included in the new WAC.

As off-site DOE generators were attracted to the potential for shipping their LLW to the NTS and began to submit applications as required by the new criteria, the DOE Nevada Operations Office (DOE/NV) realized that professionals needed to be assigned to review these applications against the WAC and verify through assessment of the generator's site that the LLW met the NTS WAC.

Through the appointment of a DOE/NV Program Manager and the acquisition of additional needed technical expertise from the disposal site Management and Operating Contractor (M&O) and other contractors, DOE/NV developed a team of specialists that performed the needed functions. As the generator numbers and volumes increased, the NTS Program's team of specialists and scientists gained knowledge and experience. With the lessons learned and ever-evolving Federal and state regulations (including a very concerned state of Nevada), it was realized that the WAC needed to be revised to address these issues and to assure that the NTS, which is currently not permitted to dispose of LLW with RCRA regulated hazardous components (low-level mixed waste [LLMW]) was

complying with all applicable waste regulations. In June 1992, NVO-325, Revision 1, was issued.

This document describes the Acceptance Program responsible for developing, maintaining, and implementing the WAC. In addition it summarizes the current WAC being used by DOE/NV for the disposal of LLW at the NTS Area 3 and Area 5 Radioactive Waste Management Sites (RWMSs). Revision 2 to NVO-325 is currently being developed and is anticipated to be released in late 1996.

NTS WASTE DISPOSAL VOLUMES-CURRENT STATUS

In the first seventeen years of operation, the NTS Areas 3 and 5 RWMSs accepted and disposed approximately 17 million cubic feet of LLW. The NTS safely disposed of 752,644 cubic feet of LLW in Fiscal Year 1994 and 884,614 cubic feet in Fiscal Year 1995.

The NTS disposed of 85 percent of the DOE complex off-site LLW in 1993 and 1994. NTS disposal forecasts estimate receiving 1.1 million cubic feet of LLW in 1996 and 1 million cubic feet in 1997.

The NTS is the nation's largest volume LLW disposal site (commercial or DOE) and has fifteen approved on-site and off-site generating facilities. These facilities are listed in Table I. Currently, 24 LLW generators have received waste designation for potential use of the NTS disposal facilities. The NTS has two on-site LLW generators (contractors).

Table I

RADIOACTIVE WASTE ACCEPTANCE PROGRAM (RWAP)

The NTS disposal program, through the guidance of a single DOE Program Manager and the involvement of a team of M&O contractor personnel, continued to evolve. The synergy from active team participation in the program's development was quickly realized by DOE and the need for additional team expertise was recognized. As the program and generators evolved, a second Program Manager was assigned. These Program Managers developed the team approach and began to utilize expertise from the M&O and other contractor specialists. A unique team approach was implemented which allows active input and ideas, and encourages participation.

The RWAP program has developed a mission statement, instructions that provide guidelines for its operations, and uses on the job training with discipline specific training for its members. These DOE/NV instructions further detail the process followed in the RWAP program. These instructions are controlled and issued to all RWAP support organizations. Training is required in the instructions, as well as other areas, as applicable, to each team member's discipline. Development of the instructions was performed by the RWAP team and is an example of this unique team approach. Quality performance and a customer oriented approach are emphasized.

The RWAP team of active DOE and varied contractor personnel is encouraged to work and motivate as a single team unit and not as individual personnel or organizations. This unique approach has been very successful and currently allows multi-contractor personnel direct input into all operations and activities.

NVO-325, Revision 1, provides DOE/NV with the necessary waste management plans and policy guidelines regarding waste acceptance and transfer. The RWAP team applies these plans and guidelines through basic RWAP program elements.

The Program. As discussed above, the program utilizes a multi-contractor organization team of specialists under the direction of four DOE Program Managers who operate to finite, documented approaches and guidelines. The

team consists of sub-teams that perform audits and surveillances, site visits to assist generators, and technical issues such as criteria revision and problem solving. Often, waste generator organizations are invited to participate on the sub-teams, including audits of waste generator programs other than their own.

The Generator Approval Process. The process begins with a waste designation by DOE Headquarters. The generator then contacts DOE/NV WMD and requests to apply. If accepted, a current copy of NVO-325 is issued to the generator. In concert with the development of the application, the generator also develops and implements a waste certification program and process which includes the development of characterization and certification plans and procedures. If the generator is having difficulty with plan development or other portions of the program, RWAP personnel(the actual DOE/NV auditors) may be sent to assist the generator in understanding the program requirements. RWAP personnel will not set up the program but rather provide guidance and conduct a "mock" audit. These mock audits can be beneficial as they allow a generator to understand what the audit team will be looking for and identify deficiencies in the program without the need for formal corrective action and documentation. The generator then characterizes their waste and completes their waste application. Once the generator has completed the application to ship waste to the NTS, it is submitted to DOE/NV RWAP for review and comment. Upon completion of the application review and comment processes, DOE/NV schedules and conducts a programmatic and performance-based audit. Based on any deficiencies identified in the audit, the generator completes the corrective actions, and a follow-up surveillance is conducted to verify their accuracy and completion. Upon satisfactory closing of the corrective actions, the Manager of DOE/NV approves the generator for the waste streams reviewed, based on a recommendation from the responsible RWAP Program Manager.

Generator Facility Audits The RWAP audit teams evaluate all aspects of the LLW generator's waste management program including areas such as characterization, procurement, training, document control, traceability, and certification. The RWAP audit methods include checklists, document reviews, personnel interviews (large emphasis on field personnel), and visual evaluations of field activities such as the packaging of the waste. Typical teams consist of three areas. These areas are quality assurance, characterization, and traceability. Subject matter experts are sometimes used as needed. The quality assurance team utilizes one or two auditors and the Lead Auditor is always one of these individuals. Characterization and traceability can be comprised of one to four individuals each. The teams work independently of each other during the daily audit activities and then meet in a team meeting at the end of each day to compare conclusions and discuss discrepancies.

Generators are given as much guidance as possible; however, the human element of all programs result in mistakes, errors, and misunderstanding. Therefore, follow-up evaluations (surveillances) are conducted to verify that all deficiencies resulting from the audit are corrected, or that corrective action is being adequately implemented, before waste is approved for shipment to the NTS.

In the earlier years of the program, only one team of core audit personnel existed. Because of the high demand for audits and surveillances and the rigorous travel required (in some cases up to seven weeks in a row), as well as an increase in the volume of waste streams

and number of generating facilities, concerns for the team's ability to maintain performance at a acceptable technical level (individual burn-out) became a serious concern. In 1992, the development of two "core" teams, with additional matrix personnel that specialize in the various disciplines, was initiated. The matrix personnel are utilized as dictated by work load and schedules. By March 1995 two additional DOE Program Managers had been added for a total of four and the two RWAP audit and surveillance teams traveled to generator facilities approximately every other week of the calendar year. This doubled the amount of facilities that could be given RWAP attention at the same time and reduced the concern for "burn-out." The 1996 schedule has been developed to schedule audit trips for every third week of the calendar year based on available personnel and expertise.

NVO-325, NEVADA TEST SITE DEFENSE WASTE ACCEPTANCE CRITERIA, CERTIFICATION, AND TRANSFER REQUIREMENTS

NVO-325 provides waste acceptance guidelines for on-site and off-site generators for items such as characterization, certification, acquisition of analytical laboratories, and quality assurance activities for the RWAP. The criteria have evolved into comprehensive quantitative and qualitative guidelines for DOE/NV to provide oversight of waste generator compliance to the waste acceptance requirements through an application review and audit processes.

Although most DOE operations for the treatment, storage, and disposal of LLW are performed by contractors; official contact for waste designations, applications to ship waste, and final disposition of approvals and issues is between DOE/NV and each facility's DOE oversight office. All on- and off-site LLW generators are subject to the NVO-325 approval process. NVO-325 does not currently apply to the storage of on-site LLW, mixed waste, or transuranic (TRU) waste; all other criteria for disposal do apply.

THE WASTE ACCEPTANCE CRITERIA (WAC) - NVO-325

NVO-325 addresses the WAC and requires the LLW generator's application provide sufficient detail, as requested in Sections 3.0 through 8.0. NVO-325 does provide a formatting example to stipulate the requirement for the presentation of the LLW generating site's detailed data reflecting conformance of their waste to the WAC in their application. The following is a summary of the pertinent sections from NVO -325 (Rev.1):

Introduction (1.0) This section is offered to the generator to discuss the RWAP and WAC Purpose, Scope, Policy, implementation plan, and responsibilities.

Application Approval Process (2.0) Section 2.0 explains the defense designation requirements from DOE Headquarters, requirements for the generator's application format, the generator approval process (which includes the application review and comment), audit and surveillance process, and the annual program review and approval.

Generator Information and Application Requirements (3.0 - 9.0) Beginning with the following sections of NVO-325, the generator must address the required criteria in their application. By following the guidance in these sections, the generator should be able to develop an application which can be easily evaluated by the RWAP reviewers. These sections contain the minimum criteria for:

- application signatures and approvals,
- radioactive and hazardous waste characterization,

waste stream information which includes specific criteria for waste types, prohibited materials, parameters, shipping, packaging, and radiological requirements;

waste certification program development,

exemption requests,

direction on procedures and documentation, and waste transfer requirements.

Quality Assurance Requirements for Waste Certification Programs (NVO-325, Appendix C) The waste generator is required to define a management system to assure the quality of the desired results for waste certification activities. Appendix C provides specific interpretation of certain NQA-1 requirements for application to LLW certification programs. This Appendix follows the 18 criteria in ANSI/ASME, NQA-1 and adds a 19th. These quality criteria are identified as "Basic Requirements" and are listed in Table II.

Table II

CONCLUSION

The development of the NTS low-level WAC has been the result of practical experience, the evolution of regulatory drivers;political and scientific concerns from the State of Nevada and the local community; specific disposal site needs for operations, safety, and health; DOE Orders; characterization and identification of the wastes; disposal site performance assessment conclusions; environmental impact assessments; and a need for a quality process assuring safe transport and disposal of LLW. A disposal site's criteria are only as good as its enforcement program. Concerned members of the community and state where the site is located can only be assured that accepted criteria are adequate if there is documented evidence of the enforcement of the criteria. Through involvement in the development of the criteria and its enforcement, RWAP team members, under the direction of their respective DOE RWAP Program Managers provide this crucial step.

As the processes continue to evolve, so will the need for the NTS WAC to be revised. Such is the case with the development of NVO-325, Revision 2, to include all the elements necessary to continue to safely and effectively manage and dispose of the nation's radioactive low-level waste.

ABSTRACT
Process Knowledge can be a viable method for waste characterization when barriers such as personnel exposure (As Low As Reasonably Achievable [ALARA]), analytical laboratory limitations, waste matrices, and costs limit or exclude the use of sampling and analysis (1, 2). However, due to the lack of definitive regulatory requirements and specific definitions relative to process knowledge, waste generators have little guidance as to what level of documentation is needed to objectively demonstrate acceptable process knowledge.
Waste generators that ship waste to the Nevada Test Site (NTS) must demonstrate that each waste stream meets the criteria established in the "Nevada Test Site Defense Waste Acceptance Criteria, Certification and

Transfer Requirements," NVO-325, Revision 1 (June 1992). In order to demonstrate compliance with the criteria specific to waste characterization, generators must objectively demonstrate that methods and procedures have been developed and implemented that will ensure accurate determinations of the physical, chemical, and radiological properties of the waste (1, 3). Using a systematic approach for documenting process knowledge and incorporating pre- and postgeneration administrative controls can be effective in demonstrating adequate waste characterization.

INTRODUCTION

There are numerous activities involved in the generation and subsequent management of waste that have the potential to affect the physical, chemical, and radiological properties of the waste. The obvious activities that impact the properties of the waste are the type of materials used in the process, and the fate of those materials during the actual process that generates the waste. These are the areas that generators have historically concentrated on for process knowledge. However, to effectively demonstrate adequate characterization, especially the absence of hazardous wastes, other administrative controls and waste management activities must be utilized and documented. In most cases, by the time a waste is packaged, certified, and ready for disposal, numerous organizations have had some type of involvement related to the waste, either directly or indirectly. For the most part, documenting each organization's activities related to the waste lends itself to better demonstrating properties of the waste.

For the purposes of demonstrating adequate process knowledge to meet the waste characterization requirements encompassed in NVO-325, there exists a hierarchy of activities and information that must be documented.

Description of the characterization approach.

Description of the process generating the waste.

Identification of the procedures and/or other supporting documentation used in the process, materials used in the process, controls for segregation and handling of regulated materials, waste types (low-level, mixed, hazardous, etc.) to be generated, and methods used for determining constituent (chemical, radionuclide) concentrations in the waste.

Once the aforementioned aspects have been identified, a documented review of the information should be performed by personnel of appropriate expertise to ensure that proper waste determinations have been accomplished and adequate controls are in place to maintain the status of the waste characterization (1).

A good mechanism for developing a systematic approach for waste characterization via process knowledge is through the use of Data Quality Objectives (DQOs). By initially establishing DQOs, all of the parameters, inputs, decision rules, and documentation necessary to establish acceptable process knowledge can be identified (4). By documenting this approach, the reviewer is provided with an explanation of the data, decisions, and logic that went into the characterization of the waste.

A primary data collection source for process knowledge will be the actual person and/or organization that is responsible for the process that generates the waste. Depending on the specifics of the generator organization, and the regulatory requirements that must be met (Resource Conservation and Recovery Act [RCRA], Toxic Substances Control Act [TSCA], state regulations, Waste Acceptance Criteria, etc.), the characterization process should involve other organizational aspects such

as compliance, waste management, quality assurance, procurement, and training as necessary.

GENERATOR ACTIVITIES

For the purposes of this paper, the waste generator is a person or persons within the organizational group that is directly involved with the process that actually generates the waste. Because of its intimacy with the waste generating process, the waste generator can provide a wealth of information for establishing and documenting process knowledge. The generator can provide information relative to identifying and describing the actual process, procedures, logbooks, records, or other documentation used throughout the process. Depending upon the level of control involved in the process, the generator may also be able to provide detailed information about the identification of the actual waste components, any hazardous and/or other prohibited materials used in the process, associated concentrations, controls for segregation and handling of these materials, isotopes present and associated quantities, and the identification of all waste types that may be generated (low-level, hazardous, mixed waste). Other documentation that may not be directly related to the process, but that may provide good additional information,are things such as spill reports, occurrence reports, chemical inventories, abatement documentation, material tracking information, and purchase orders. Once the necessary information and documentation regarding the waste generation process has been obtained and the basis for waste characterization has been established, the information should then undergo a documented review by personnel of various expertise as appropriate (1).

ENVIRONMENTAL REVIEW

A documented review of information obtained from the waste generation activities can serve several purposes. First, it provides a mechanism for data verification; secondly, it strengthens the defensibility of the process knowledge by involving specific expertise in the waste characterization process. The unique aspects of individual processes and associated waste streams will dictate what type of expertise should be involved in reviewing and verifying the information supplied by the waste generator. For the purposes of demonstrating the absence of hazardous waste, personnel with expertise in RCRA, TSCA, the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), etc., should be involved in the review (1). Along the same line of reasoning, personnel with experience in health physics should be involved in evaluating and verifying the radiological aspects of the waste stream such as radionuclide identification and activity determinations. Environmental reviews should not be limited to documentation reviews. In addition to reviewing operating procedures, logbooks, etc., personnel should also evaluate the waste generating process(es), examine facilities where the waste is generated, and evaluate the adequacy of controls that are in place for waste segregation, packaging, and handling (1). The outcome of this review should be the verification of the waste types that will be generated, determination of the adequacy of waste handling/segregation controls, and the acceptable identification of waste components for each waste type. Through the environmental review, the determination will be made that either adequate information and documentation exists to meet the data needs defined by the DQO process, or that areas with insufficient data will be identified and can be addressed as necessary (4). The review process can also be used in the

evaluation of waste minimization practices that are currently in use and can help determine whether or not any improvements can be implemented. A documented environmental review that includes review of documents, evaluation of controls, verification of types of waste being generated, and identification of acceptable and unacceptable waste components then becomes a major component of the final package for demonstrating adequate process knowledge.

FINAL PRODUCT

The final product with regard to using process knowledge for waste characterization must be able to demonstrate through objective evidence (documentation) that the waste has been adequately characterized to ensure proper treatment, storage, and disposal (1). Using this approach, the final product can demonstrate acceptable process knowledge through a documented description of the waste generating process; a documented characterization approach that identifies data inputs, parameters, and justification for decisions; the identification of data used in the characterization determination; a documented review of the data used; identification of acceptable and unacceptable waste components for each waste stream; and the identification and evaluation of controls for waste handling (packaging, segregation, storage).

Often, there is a substantial amount of documentation that is used in the waste characterization process. Assimilating all of this information into one area may not be feasible, so it is important that some type of traceability is established between all of the associated documentation such that the data can be presented in an auditable fashion. The presentation of the characterization data can be as simple as a documentation package that includes a summary of the characterization approach, description of the waste stream and waste generating process, and the identification (reference list) of the documentation that substantiates characterization of the waste.

Under NVO-325, generators are required to maintain characterization information in waste stream-specific files. The basic format for these types of files includes an executive summary that describes the specific characterization approach used and references the documentation that was used in the characterization process to demonstrate the characteristics of the waste. Examples of documentation that should be referenced are process procedures, operating procedures, waste packaging procedures, historical analytical data, laboratory logbooks, purchase orders, documented environmental reviews as described above, chemical inventory records, waste handling procedures, and post characterization controls for maintaining characterization status.

CONCLUSION

The substance of acceptable process knowledge is the ability to objectively demonstrate what the physical, chemical, and radiological properties of the waste are. Acceptable process knowledge goes beyond statements like "solvents are not in this waste stream because they are not used in the process." It is the procedure, purchase order, inspection reports, etc., that identify solvents as being absent from the process that objectively demonstrates the absence of solvents.

Defining a systematic approach (DQOs) for characterizing waste by process knowledge should be one of the first steps in the characterization process. The benefits of the this type of approach is that a great deal of information is documented at the beginning of the characterization process. Information identified during this definition stage (what

requirements have to met, what was initially known about the waste, what additional information needed to be obtained, decision rules, and decision errors) is, in itself, good process knowledge documentation . Once this systematic approach has been defined, the waste generators and generating process should be a primary source for data collection. All data defined as inputs to the characterization decision should then undergo a documented review by appropriate experts. This review will verify that the information adequately supports the waste determinations and demonstrates compliance with identified requirements. When the characterization process is complete, the information should be assembled and maintained in a manner that ensures document traceability, is readily retrievable and auditable, and can objectively demonstrate the properties of the waste and the adequacy of the waste determination.

CHARACTERIZATION OF LOW-LEVEL MIXED WASTE FOR LAND DISPOSAL RESTRICTION COMPLIANCE CONSERVATIVE VS. REGULATORY APPROACH

INTRODUCTION

The Resource Conservation and Recovery Act (RCRA) was passed into law in 1976. This was the initial start of a nationwide movement to restrict the land disposal of hazardous wastes. These regulations appear in Title 40 of the Code of Federal Regulations (CFR), Parts 264 and 265. In 1984, Congress passed the Hazardous and Solid Waste Amendments (HSWA). This mandated new land disposal limitations. HSWA required the U. S. Environmental Protection Agency (EPA) to issue new regulations referred to as the land disposal restrictions (LDRs).

The land disposal restrictions apply to waste management activities controlled by two environmental laws, RCRA and the Safe Drinking Water Act (SDWA). SDWA controls waste injected in deep wells. All other waste disposal activities are regulated by RCRA. The LDR program is designed to discourage placing untreated waste in or on the land when a better treatment or immobilization technology exists.

The Rocky Flats Environmental Technology Site (RFETS) requires the following steps to be performed to characterize a waste form for land disposal:

1) Preliminary investigation and identification
2) Sampling and analysis plan development
3) Development of sampling methodology
4) Administrative and technical preparations
5) Sampling of waste
6) Laboratory analysis
7) Data validation
8) Waste characterization report and wrap-up

We are focusing on the cost associated with the 8 tasks listed above for characterizing specific RFETS waste forms. Currently, Saltcrete, Item Description Code (IDC) 804 is being shipped for disposal at Envirocare of Utah, Inc. (Envirocare), having completed all of the above steps. Saltcrete is cemented chloride, nitrate, and sulfate salts generated from process water through an evaporation and subsequent cementation. Four other low-level (LL) and low-level mixed (LLM) waste forms have been proposed to be characterized for future disposal at either the Nevada Test Site (NTS) or Envirocare (commercial disposal site). They are as follows:

1) LLMW form Cemented Composite Chips, classified as IDC 327. This waste form represents approximately 95 cubic meters of LLMW. The cemented composite chips waste form is a solid matrix consisting of metal machining chips and Portland cement.
2) LLMW form Pondcrete classified as IDC 805. This waste form represents approximately 5,700 cubic meters of LLMW; of this we expect to qualify 2,000 cubic meters without treatment for offsite disposal. The Pondcrete is a cemented sludge. The sludge was collected from the solar evaporation ponds. It was generated by mixing Portland cement, water and pond sludge.
3) LLMW form Roaster Oxide classified as IDC 069. This waste form represents approximately 66 cubic meters of LLMW. Roaster Oxide is generated from stabilizing Uranium turnings. The uranium metal was roasted (converted into an oxide) to remove the pyrophoric nature of uranium metal.
4) LLMW form Blacktop, Concrete, Dirt and Soil classified as IDC 374. This waste form represents approximately 400 cubic meters of LLMW. This waste form was generated from various cleanup and construction activities around site.

CASE STUDY

The Saltcrete waste form will be used for the case study, with the results being applied to the other four waste forms.

Saltcrete carries a number of RCRA hazardous waste codes (F codes only). The codes that take precedence are D002 and F039. D002 is applied to certain waste streams at the point of generation; F039 is applied to the interceptor trench water that is included in the saltcrete process. D002 and F039 waste codes invoke the underlying hazardous constituent rule [40 CFR-268.40(e)], which requires all underlying hazardous constituents must meet the Universal Treatment Standards (UTS) found in 40 CFR-268.48, Table UTS, prior to land disposal. Invoking the underlining hazardous constituent rule requires the waste generator to know the concentration of over 219 constituents in the waste (many compound families are included as one constituent (e.g., polychlorinated biphenyls [PCBs] only count as one). However, the rule only requires that the waste generator

know the concentrations for constituents that may reasonably be expected to be present. The waste generator is not required to analyze for all of the compounds in the UTS list.a To date, RFETS has required all of the organic compounds found in the UTS list be determined.

To reevaluate the waste forms, two data bases were reviewed: Wastren Chemical Data (a study performed by a contractor to determine all the chemicals onsite); and the Plant Chemical Tracking Data. Analytical data from seven waste types were evaluated. All nine sources of information were summarized. The Wastren Chemical Data was considered to be out of date. The current plant chemical tracking data base contains all of the compounds (over 10,000 entries) in active use on site.b The analytical data from the 7 waste types reflects all of the chemicals that have been used and disposed of in the past. This includes not only saltcrete data, but also surface water plant discharge and interceptor trench water. This data was mapped into the UTS List of Compounds.

After evaluation of the listed data sources, 63 compounds were determined to be probable compounds for analysis. These are listed in Table I. Twenty-eight of these compounds were found in the listed waste streams and waste types in Table I, the rest were from the Plant Chemical Tracking Data Base. Eight compounds were identified from the analysis of the waste form that are not found in the Plant Chemical Tracking Data Base. These compounds were probably used on the site in the past: the phthalates (3) as plasticizer, the cresols (2) as wood preservative, and it has not been determined where the nitriles (2) and nitrophenol have been used in the past.

Evaluating the amounts of material present on site, 20 of the 63 compounds were eliminated from the concern list due to the small amount of materials present on site. For these 20, we assume a worst case contamination scenario; all of the material in any building being poured into the process line at the same time and ending up in the brine solution for processing. Calculations show the levels of these materials in the saltcrete will still meet LDRs. (The brine solution that is being processed at any given time represents approximately 3 million gallons of process water, making approximately 20,000 pounds of saltcrete.) Three other compounds can be removed by regulation:

Table I

carbon disulfide, cyclohexanone and methanol.c Of the 40 compounds remaining, all may be determined by requesting the "normal" SW-846; 8260 and 8270 waste analytes suite of compounds.

Saltcrete shows that by considering all the aspects of the waste form, it is possible to reduce the cost of characterizing the waste for land disposal.

CONCLUSIONS

From the case study, evaluation of the eight steps required to characterize waste for land disposal, we see Step 1 increasing in cost by using a strict regulatory approach. This is due to the additional time required to evaluate the waste form and processes that generate it. However, the other seven steps have decreased in cost. The overall savings range from 20% to 30%. This is a significant decrease in costs. This is shown in Table II for saltcrete analytical cost.

Table II

The Base Line cost for pondcrete for six of the steps is shown in Table III. For these six steps, a decrease in costs of over 30% would be realized by following the regulatory approach.

Table III
Applying this to the four waste forms in the study (Table IV), we see a potential savings of $679,200.
Table IV
Although all 8 steps are required to be completed (we have not removed any requirements), by changing the emphasis on each step, a large cost savings can be realized. The overall results show a projected savings of 24% for these 4 projects.
There are a number of factors that have not been considered. These include faster completion of projects, reduced staffing, improved worker morale, etc. These factors should lower the cost further.

58-5
A TECHNICAL AND REGULATORY FOUNDATION FOR MIXED-WASTE DELISTING

ABSTRACT

The purpose of this paper is to propose a risk-based approach that can be used to identify mixed-waste streams that can be delisted from regulation under the Resource Conservation and Recovery Act (RCRA). The goal of this paper is to describe both the technical and regulatory foundations by which one can identify ostensibly mixed-waste streams for which the risk from the hazardous component of the waste stream is minimal, so that it can be treated as low-level radioactive waste. In addition, the approach described here may also be applicable to defining de minimis levels of purely hazardous or purely radioactive wastes.
First, an approach developed by the U.S. Environmental Protection Agency (EPA) for identifying de minimis levels of hazardous contamination in soils will be described. Second, it will be argued that an approach developed for unconfined soils can be used with great confidence at licensed low-level radioactive waste disposal facilities. Third, this approach will be argued to be legally equivalent to satisfying no-migration variance requirements under RCRA. Fourth, an approach will be proposed for establishing a formal procedure for carrying through analyses for delisting waste streams to be disposed at particular sites. Since the approach is founded on EPA-generated approaches and information, regulatory issues should be eased. Furthermore, the approach is consistent with an approach published by the U.S. Nuclear Regulatory Commission for defining acceptable levels of residual radioactive contamination. This means that the potential exists for developing a common framework for both minimally hazardous radioactive and minimally radioactive hazardous mixed waste streams.

INTRODUCTION

The purpose of this paper is to provide an initial assessment of an approach that can be used to identify de minimis levels of hazardous contamination in mixed waste streams. However, the approach described here is also applicable to waste that is only hazardous. The approaches and principles described in this report draw on numerous ongoing efforts in the area of mixed waste management. The National Council on Radiation Protection and Measurements (NCRP) has had a scientific committee (Scientific Committee 87-2) studying issues related to mixed waste risk

assessment for several years. The International Atomic Energy Agency (IAEA) has established an international program to study the issues associated with common risk assessments for the hazardous and radiological components of mixed waste. IAEA has been developing a first step toward developing a common risk assessment framework for assessing environmental impacts from different types of sources (1). This framework is intended to be a first small step toward addressing the mixed waste issue. The problems are recognized to be thorny, and nobody expects quick resolutions. Note that this is at the international level: the problems are not entirely rooted in regulatory differences between U.S. Government agencies. Nevertheless, it is generally recognized that a key component to resolving the mixed waste issue is to minimize the volumes of mixed waste by defining mixed waste to only include wastes in which there is truly both radioactive and chemical risk.

The goal of this paper is to identify ostensibly mixed waste streams, and demonstrate that the hazardous component of the waste stream is sufficiently minimal that it can be treated as low-level radioactive waste. The structure of this memo is as follows. First, an EPA-developed approach for identifying de minimis levels of hazardous contamination in soils will be described. Second, it will be shown how that approach can be used with confidence at low-level radioactive waste disposal facilities. Third, this approach will be shown to be equivalent to satisfying no-migration variance requirements under RCRA. Fourth, an approach is proposed that will establish a formal approach for carrying through analyses for delisting waste streams to be disposed at particular sites. Since the approach is founded on EPA-generated approaches and information, regulatory issues should be eased. Furthermore, the approach is consistent with an NRC-developed approach for defining acceptable levels of residual radioactive contamination. The means that the potential exists for developing a common framework for both minimally hazardous radioactive and minimally radioactive hazardous mixed waste streams.

DRAFT EPA SOIL SCREENING METHODOLOGY

In December 1994, EPA issued a draft approach for developing both generic and site specific Soil Screening Levels (SSLs) that are intended to be Administrative Improvements to the Superfund program (2). The idea behind the SSL approach was to define generically de minimis levels of hazardous contamination for Superfund sites. More importantly, the draft position provides a framework for developing site-specific SSLs if the generic SSL is found to be overly restrictive for a particular site.

A three-tiered approach is described in the SSL document. The approaches begin with simple, arguably conservative analyses and progress to less conservative,yet more complicated, analyses as shown in Fig. 1. At the first tier, soil concentrations are derived from screening models, argued to be generally conservative, that link the soil concentration to a health risk by exposure pathway models. If soil concentrations are less than this level, no further action of any kind need be taken. That is, they are effectively de minimis levels. At the second level, easily gathered site-specific information is used to modify parameters in the simple generic models to produce an alternative, less conservative, representation of the site. Concentration levels derived in this way are still considered to be de minimis levels, but represent site-specific de minimis. At the third level, a more detailed modeling approach is used, based on a more extensive collection of site-specific data. At this

stage, the level of effort needed for the analysis can be expected to approach the level of effort needed for low-level waste site performance assessments.

Fig. 1

It is interesting to note the dramatic similarity of this EPA approach with an independently developed approach from the NRC for the comparable soil-screening problem at decommissioning sites under NRC jurisdiction (3). The only significant differences between the two approaches are in the details of the models used for generic screening. It is also interesting to note the similarities between this evolutionary approach to site risk assessment and current low-level waste performance assessment guidance (see, e.g., Refs. 4, 5, and 6). This commonality suggests that there is the potential to develop common approaches for eliminating both minimally hazardous and minimally radioactive waste streams from the mixed-waste spectrum.

SOIL SCREENING LEVELS AND MIXED WASTE DISPOSAL

Let us now consider the significance of this approach for evaluating the risk of hazardous materials in soil relative to mixed-waste disposal. First, a variety of exposure pathways are considered in the SSL approach. Low-level waste assessments are usually dominated by the ground-water pathway, although ground water is not believed to be an important pathway at either the proposed Texas Compact site (7) or the Area 5 facility at the Nevada Test Site (8) because of low recharge, nor is it believed to be important at the Clive, Utah mixed-waste site because of high ground-water salinity (9). In any case, the SSL approach can be adapted for use in evaluating a low-level waste disposal facility, since it is a multiple pathway analysis. Nevertheless, for the majority of low-level waste facilities, a subset of the SSL methodology (the portion relating to potential groundwater contamination) will be adequate. Second, the SSLs relate to unconfined soils, not engineered disposal facilities. It seems safe to make a general statement that for the same level of contamination, the risks associated with engineered disposal facilities will be less than the risks associated with unconfined soil. Third, the provision exists in the methodology to make a more reasonable estimate of an acceptable soil concentration based on a more elaborate calculation. We can conclude from these arguments that the generic SSLs can be used to identify a de minimis level for the hazardous component of mixed waste. If the hazardous concentration of a waste stream is below the generic SSL, we need spend no more effort to delist the waste stream from RCRA, and can treat it solely as low-level radioactive waste. Furthermore, we can use the latter two stages of the SSL process to justify, on a site-specific basis, that higher levels of contamination can be considered de minimis. Again, the result should be that wastes identified in this way can be treated as strictly radioactive, and their hazardous component can be ignored from a risk basis. In its most extreme case, we might end up conducting calculations similar to the low-level waste performance assessments, which are rather detailed in scope, and using those calculations to justify a de minimis claim for relatively high concentrations of hazardous materials.

SOIL SCREENING LEVELS AND NO MIGRATION

RCRA contains the provision that "there will be `no migration' of hazardous constituents from the disposal unit or injection zone for as long as the waste remains hazardous." The demonstration that this is indeed the case for a particular disposal system is known as the "no-

migration variance." In 40 CFR 268 and 271, "EPA interprets this statutory language to require that petitioners demonstrate that hazardous waste constituents will not migrate from the land disposal unit in hazardous concentrations for as long as the wastes remain hazardous [emphasis added]." Davis et al. (10) noted that this means that "no migration" does not mean "zero release;" rather it says that releases are permissible as long as they do not exceed health-based standards. Davis et al. also noted that EPA incorporated this interpretation into its final rule making on underground injection wells under 40 CFR 148, and incorporated this interpretation into its reviews of "no migration" variances submitted under 40 CFR 268.6. This interpretation was upheld in Natural Resources Defense Council vs. EPA litigation (11). Draft EPA guidance for determining compliance with 40 CFR 268.6 also suggests that "model assumptions and input data should be conservative and tend toward overestimating rather than underestimating migration." (12). The SSL approach described above clearly follows this same philosophy.

There are precedents for conducting performance assessment analyses to demonstrate "no migration" under RCRA. Davis et al. (10) described the basis for a unified assessment approach for 40 CFR 191, DOE order 5820.2a, and RCRA no migration for the Greater Confinement Disposal (GCD) facility at the Nevada Test Site. The GCD facility contains high-activity low-level waste, transuranic waste, and hazardous components; consequently all three regulations needed to be addressed. They were able to show that each of these regulatory structures hold common themes and approaches, and that demonstration of compliance with one can be shown to be equivalent to compliance with the others. In the case of the GCD facility, they were able to show that demonstration of compliance with 40 CFR 191 would also show compliance with the other two regulations.

Anderson et al. (13) have described an approach being used to develop a no-migration variance for WIPP. The intent of this approach is to use the full probabilistic performance assessment model being developed to demonstrate compliance with 40 CFR 191 to establish (in a posterior sense) conservative parameter values. These are to be used in a deterministic analysis to attempt to demonstrate that under ordinary operating conditions, waste can be expected to be confined to the facility boundary.

Kincaid et al. (14) used their performance assessment to make a case that nitrate levels can be expected to be far below the MCL for nitrates as a result of disposal of liquid wastes in grout at the Hanford site. As part of the Tri-Party agreement, this disposal technology was abandoned in favor of vitrification of the waste. As a result, the approach proposed by Kincaid et al. has never undergone a full review. However, the approach is significant. The assessment is used to demonstrate that MCLs for groundwater are not exceeded now, nor can they be expected to be exceeded in the future. This is equivalent to establishing a risk limit for the chemical portion of the inventory.

A similar approach was used in the performance assessment of the Z-area Saltstone facility at the Savannah River Site. This performance assessment explicitly considered degradation of groundwater by the release of nitrates (15). The reason for including nitrates in the analysis was a special agreement with the state authorities, rather than any legal objective that had to be met. The Saltstone facility is used to dispose of a liquid waste high in 99Tc; the Tc is chemically fixed in

place by the nature of the Saltstone. Compliance with agreed standards for nitrates was the most stringent problem in this assessment.

Other performance assessments that are not considering chemical risks are (1) the Nebraska (Boyd County) commercial facility, (2) Oak Ridge (16), (3) the SRS E-area vaults (17), (4) the Hanford 218-W-5 disposal facility (18), and (5) the INEL radioactive waste management complex (19). It should be noted that there are no requirements to include chemical risks in these assessments, so this comment is not intended as a criticism of these assessments. There are serious issues related to analyzing the chemical risk from ordinary low-level waste streams. In particular, there are usually insufficient data available on the chemical inventory (developed from shipping manifests) to develop a satisfactory analysis.

PROPOSED APPROACH

The following tiered approach is proposed for substantiating a delisting of a waste stream using risk-based no-migration arguments. The first tier is to use the generic SSL concentrations for soil, and to apply them verbatim to mixed waste. Waste streams with concentrations below this level can be delisted and disposed of as purely radioactive waste with no further effort needed to justify the minimal importance of the hazardous component of the waste. The argument for doing this is that the engineered enhancements will lower the risk compared to the risk from contaminated soil. The SSL levels "generally correspond to a 10-6 risk level for carcinogens, and a hazard quotient (HQ) of 1 for noncarcinogens" (2). Consequently, the risk of carcinogenesis is lower by far than the permissible radiological risk from the same waste (Using current regulatory approaches, 15-25 mrem/yr is presumed to equate to about 5x10-4 risk of cancer fatalities. There is, of course, considerable uncertainty in the actual relationship between risk and dose.) The combination of improved packaging and extremely low risk levels makes a strong case that there is no appreciable risk from hazardous waste streams that meet the soil screening levels. The argument here is that "minimal risk" is equivalent to "no migration."

The second tier is to use the EPA models with some site-specific information to provide a less conservative estimate of acceptable levels of contamination in a disposal facility. At this tier, we are not taking credit for engineered barriers, containment, or immobilization. As a result, the results are still extremely conservative, and will therefore be easily defensible when presented to regulatory authorities. Nevertheless, it may still be possible to delist more waste streams in this way than were delisted in the first tier. In particular, if some site-specific information is introduced for the NTS Area 5 waste management facility, it is clear that less stringent concentrations can be shown to be acceptable, because of the extremely favorable conditions at that site.

The third tier is to conduct a more elaborate analysis using more site-specific information. At this tier, the analysis can include the influence of immobilization technologies, containers, vaults, covers, and other engineering enhancements of the facility. The basis for this analysis can be the existing performance assessments for the low-level waste sites at which the waste stream would be disposed. It is expected that since the performance assessments exist, at least in draft form, for all DOE low-level waste disposal facilities, the amount of effort that will need to be expended to conduct this analysis will be minimal. However, it should be understood that the difficulty of convincing the

regulator will be proportional to the complexity of the analysis. As more complexity is introduced, and as the analyst takes credit for more beneficial effects of the system, the regulator tends to scrutinize the analysis more. In the first two tiers, it should be very easy to make the case that the risk posed from the hazardous material is minimal.

We note in passing that Smith et al. (20) and Little et al. (21) have described a consistent framework for conducting health risk assessments of mixed waste using performance assessment methods. This approach, known as SACO, is under development in Europe for worldwide use. When completed, SACO may form a consistent basis for conducting risk assessments for hazardous materials, radioactive materials, or mixed materials.

SUMMARY

There is a common thread of an approach that exists in both CERCLA and RCRA for defining an acceptable risk level based on pathway and transport modeling. The approach for CERCLA has been made explicit in the draft Soil Screening Level (SSL) methodology. The approach for RCRA has not been formalized, but EPA's clear interpretation of "no migration" is that it refers to no migration above health-based limits. It does not mean "zero release." The SSL methodology is identical in concept both to the soil screening methodology developed independently by NRC for radionuclide contamination, and to the approaches used in performance assessments for low-level radioactive waste disposal facilities.

As a result, in this paper an approach is proposed for delisting the hazardous portion of mixed-waste streams that is identical in concept to the SSL approach. The tiers progress from more conservative to less conservative, from less complex to more complex, from generic to site specific, and from easily defensible to more complex to defend.

One flaw to this proposed approach is that the Soil Screening Limits are still only in draft form, and it is unclear when EPA will issue final guidance. However, while the specific concentration limits may change, and the details of the screening models may change, the general approach and philosophy is likely to remain the same. Consequently, the approach will be applicable to the level of detail that has been proposed here.

One of the most interesting concepts is the commonality of approaches between NRC's 10 CFR 20 Subpart I analyses to demonstrate the soil contaminations are minimally contaminated with radioactive materials, and the SSL approach, which does the same for hazardous materials. This raises the possibility for developing a common approach for both ends of the mixed-waste spectrum: both minimally radioactive hazardous waste and minimally hazardous radioactive waste.

DIFFICULT BUT NOT IMPOSSIBLE: MONITORING HIGHLY ACTIVE WASTES RETRIEVED FROM INTERIM STORAGE FACILITIES

ABSTRACT

Major national nuclear programs have resulted in a considerable number of storage facilities containing either highly active liquors or highly active solid wastes. The latter in many cases contain inhomogeneous mixtures of fuel, metal scrap and debris. In the UK major efforts are underway to retrieve these wastes for treatment and, ultimately, disposal. In order to conduct these operations safely, and to meet the inventory data requirements for ultimate disposal, it is essential to achieve a valid measurement of inventory in the early stages of the waste routing process. BNFL Instruments Ltd are playing an important role by providing this measurement capability to retrieval projects on the parent company's Sellafield site. Current measurement solutions are based on many years of operational experience which the company has accumulated in delivering special purpose waste monitoring instrumentation for process control as well as for inventory measurements. In spite of the difficulties of measuring the inventories of very variable retrieved wastes, in high dose rate environments, measurement systems are being provided which satisfy the demands of both the repository operators and national regulators.

INTRODUCTION

In common with the other nuclear powers, Britain has constructed and operated several generations of nuclear reprocessing facilities since the early 1950's. The Sellafield site, now operated by British Nuclear Fuels plc (BNFL), has seen the construction and operation of early fuel storage, reprocessing, product finishing and waste storage facilities which are now in varying stages of shutdown or decommissioning. Of particular concern are the very variable solid wastes which may be contaminated with a variety of fissile and radioactive nuclides. Interim storage facilities within the site boundary have contained these highly active wastes safely and with minimum environmental impact for several decades. Now as part of BNFL's overall waste management strategy, major efforts are underway to empty these stores and repackage and encapsulate

the waste prior to ultimate disposal. Once emptied the buildings themselves can be decommissioned.

In this paper the issue of measurement is placed in the context of the waste retrieval operations and the particular difficulties of adequately monitoring the radionuclide inventory and fissile content are highlighted. The solution to such problems can be shown to lie in the experience gained by close involvement throughout more recent reprocessing and waste treatment operations. BNFL Instruments Ltd, a wholly owned subsidiary company of BNFL plc, have supported the parent company's engineers and designers by developing specialized instrumentation for all new plants at Sellafield for over 25 years. In the course of this support, techniques have been developed which, for highly active waste, will enable operators to perform a non-destructive assay prior to encapsulation and to establish the detailed characterization of waste required to satisfy the disposal authority and the national regulator.

WASTE STORAGE AND RETRIEVAL

An overview of the material flow in reprocessing operations and the routes by which wastes arise at Sellafield are shown in Fig. 1.

Irradiated fuel has historically been stored in water filled ponds prior to reprocessing. Once sufficiently cooled for safe reprocessing, the fuel is taken for pre-treatment. For Magnox fuel, this consists of stripping off the outer cladding prior to dissolving the metal fuel in nitric acid. The de-cladding debris (known as swarf) is treated as intermediate level waste (ILW). Current arisings of swarf are being sent directly for cement encapsulation into 500 litre drums, at a plant commissioned in 1990. A second plant commissioned in 1992 is used to deal with the cladding residue from oxide fuel reprocessing in a similar way.

Fig. 1

Storage

Prior to the availability of the encapsulation plants, the cladding waste was sent to interim storage facilities. The first such facility was a dry silo, but from 1960 onwards new arisings were stored underwater. The silos were also often used to store scrap associated with the de-cladding process. The contents of the silo compartments filled in the early years of operation have corroded to a mixture of sludges and solids. The original fuel storage ponds, which are now redundant, also contain sludges, corroded fuel and fuel handling equipment.

Retrieval

As part of BNFL's overall waste management strategy, major efforts are underway to empty the redundant ponds and interim storage facilities and repackage and encapsulate the waste (1). Once emptied it will be possible to complete the decommissioning process by dismantling the building itself.

Safety and dose minimization are important issues in engineering a cost-effective retrieval process. Major problems to be overcome include: high dose environments, the need for containment to prevent the spread of contamination, chemical hazards, fire risks and other safety issues. Significant development work and plant trials have been undertaken to find the safest and most cost-effective means of retrieval. Purpose built machinery is being designed and constructed to facilitate retrieval and subsequent treatment of the stored waste into a form suitable for ultimate disposal. Several dedicated plants will be built to receive this waste. Sorting, screening, settling, packaging and drying prior to

encapsulation of the waste are all options either in operation or under consideration.

The retrieval of stored irradiated fuel bearing wastes has already begun on the Sellafield site and will continue well into the next century.

Measurement and Characterization

Detailed reviews including sampling, analysis and scrutiny of plant records have been carried out on the contents of the redundant storage facilities. This has enabled sufficient information on the stored materials to be determined for the selection of waste routing through to disposal.

The waste retrieval, treatment and repackaging process will generate waste packages which will require characterization on an individual basis. The sampling and plant records can often provide a good representation of the overall contents of the waste stores, however, the characterization requirements for the final waste product cannot be satisfied with this information alone. One of the major requirements is the provision of radionuclide inventory and fissile content information to satisfy disposal regulations and to ensure criticality safety.

Non-destructive assay (NDA) techniques can be used for measurement of each waste package prior to ultimate disposal. The requirements for NDA depend on the application. There are a number of general driving forces including safety, dose minimization, regulatory requirements, disposal authority requirements and process control.

The major function of waste product monitoring is the generation of an extensive radionuclide inventory including fission products, trans-uranic radionuclides and total fissile content of the waste, where applicable.

CHALLENGES FOR WASTE MEASUREMENT

In determining the optimum monitoring solution, physicists, engineers and designers have co-operated to find the most suitable waste retrieval strategy incorporating the required measurements. The technique used, location and physical arrangement of the system must fit in with the need to engineer a safe and cost-effective waste routing process through to disposal, taking into account the suitability of measurement at various possible locations.

Typically, waste is retrieved in batches, which contain a variable mixture of materials including highly active fuel residues, fuel cladding materials and miscellaneous operational scrap. Figure 2 illustrates a mock-up of typical retrieved wastes undergoing a sorting process.

Treatment, sorting and repackaging are often performed before the monitoring stage. The detailed inventories that have been prepared for the storage facilities themselves will generally provide only limited information for the waste measurement system to use (e.g. during calibration). These measurement conditions are also often complicated by the bulk quantities of waste involved and the inhomogeneous and variable nature of the materials.

Fig. 2

Further problems arise due to the high dose rates and potential for loose contamination associated with the waste treatment processes. This often leads to shielding, handling and containment requirements which makes the measurement more problematic.

Quality Assurance plays a key role throughout the entire process of providing plant operators with the solution to their measurement needs. The instrumentation must be capable of generating fully reproducible

results and must operate reliably and be capable of performing regular automated self checks.

MEASUREMENT TECHNIQUES

There are a variety of radiometric NDA techniques which can be used in waste monitoring. The basis of all such measurements is the quantification of certain properties of the sample based on the detection of some form of radiation. Due to the bulk quantities of materials encountered, the most suitable NDA techniques are based on either gamma or neutron measurements.

Gamma Ray Measurements

In order to obtain the maximum amount of information from a gamma ray measurement, High Resolution Gamma Spectrometry (HRGS), based on high purity germanium (HPGe) semiconductors, is preferred to low resolution spectrometry based on scintillation detectors. Within irradiated fuel, there are many gamma emitting nuclides. Due to the attenuation effects within the waste container, only higher energy gamma rays can be measured in large containers. In practice there are very few photopeaks in the spectrum of historic irradiated fuel bearing waste. This is mainly due to the long cooling times and Compton scatter interference effects from several high energy, high intensity gamma rays (mainly 137Cs and 60Co). Gamma ray detection can also be used by instrumentation at the retrieval facility and within the treatment and sorting facilities. Gamma ray imaging techniques have been developed which allow operators to identify `hot spots' of gamma activity on a contaminated wall, say, or at a sorting table. These instruments can include a coarse spectrometric capability which enables fuel to be discriminated from other items. This `gamma view' can be combined with the traditional optical image to assist in segregation of the waste and reduces operator dose uptake.

Passive Neutron Measurements

Passive neutron counting involves measuring the intrinsic fast neutron emission from the waste. This arises from two types of event: spontaneous fission and (,n) reactions. Typically 2 or 3 coincident neutrons will be emitted from each spontaneous fission event, whilst (,n) reactions (caused by the interactions of alpha particles with light elements such as oxygen) result in the emission of a single neutron. Maximum (,n) emission occurs when the alpha emitter is chemically linked to the light element as, for example, in corroded fuel.

Assay systems can utilize the detection of the total or coincident neutron emission. The latter may involve the detection of two time correlated neutrons (referred to as Passive Neutron Coincidence Counting PNCC) or multiple time correlated neutrons (Multiplicity Counting). Coincidence techniques allow the signal from spontaneous fission to be isolated from the (,n) signal. This is necessary when the chemical composition of the waste is poorly characterized such that the ratio of the (,n) to the total neutron emission can vary.

Active Neutron Interrogation

In contrast to passive methods, active neutron measurements rely on the detection of induced radiation. Neutrons from an interrogating source are introduced into a measurement chamber made up of moderating and shielding materials. Fast neutrons quickly slow down in the chamber by multiple elastic scattering in the moderating materials. In addition some moderation and absorption usually takes place in the measurement sample; the magnitude of which will depend on the matrix composition. The neutrons induce fission events in any fissile material present giving

rise to the emission of secondary fast neutrons and gamma rays. It is this secondary radiation that is detected to give a measurement of the total amount of fissile material present.

One method of active neutron interrogation is the differential die-away (DDA) technique. Short pulses of fast neutrons from a neutron generator are injected into the measurement chamber. This gives rise to a thermal neutron flux which persists for a few milliseconds. Fast neutrons arising from the induced fission events are then counted using fast neutron detector packages embedded in the chamber walls. These detector packages have much shorter characteristic neutron lifetimes than the chamber and this large difference in the die-away time makes the measurement possible. The measurement signal is used to quantify the mass of fissile material present.

EXPERIENCE IN WASTE MEASUREMENTS

Over the last 25 years, many special purpose waste monitoring systems have been developed to meet a wide variety of difficult measurement problems in the Sellafield reprocessing and waste treatment operations (2). As new generations of increasingly sophisticated plant have been commissioned and the demands of the regulators have become more stringent, several generations of instrumentation have been developed from concept through to commissioning, calibration and fully automated operation. Several examples are given here of such systems.

Swarf Tipping Monitors

One of the earliest measurements of highly active wastes was performed during the process of transferring the Magnox decanning waste to its interim store. A measurement of the uranium content of the waste was required in order to quantify carry-over of fuel from the decanning plant. The chosen measurement technique was based on detection of a distinctive high energy gamma ray from a short cooled gamma emitter which is only associated with irradiated fuel (the 2.18 MeV gamma ray from 144Pr was used).

Two low resolution NaI(Tl) gamma spectrometers viewed a swarf bin which was scanned past the detectors before and after tipping. Calibration was performed using fuel rods of known irradiation history and cooling time, placed in a supporting frame, at known positions in a bin full of water. The measurement enabled the reprocessing plant operators to gain confidence in the decanning process and was also of sufficient quality to contribute to the materials accountancy for the plant. A great deal of performance assessment work was carried out during and after commissioning of the instrument. This work has provided confidence in the accuracy of the declared data and provided valuable experience in the development of later generations of highly active waste assay instrumentation.

Swarf Inventory Monitor

The next generation of monitoring instrumentation was developed to improve on the original measurements carried out during swarf tipping. In 1985, the first high technology system (designed to quantify fuel carry-over), was installed in a new fuel handling plant. Subsequently a system was developed to provide improved measurements in parallel with the advent of swarf encapsulation. As previously noted, since 1990 arisings of waste from the Magnox decanning process have been encapsulated into 500 litre drums to await ultimate disposal. A requirement of the licensing and regulatory bodies is that an extensive radionuclide inventory must be provided for this waste. In addition, there is a

process control measurement requirement, to monitor for excessive quantities of uranium in the swarf prior to export to the encapsulation plant. The most appropriate measurement technique is HRGS, since the relatively short cooling time of this waste stream enables a wide variety of nuclides to be directly measured. This provides sufficient information to determine the irradiation history of the fuel from which it is possible to infer the uranium content as well as a variety of other non-measurable radionuclides.

Measurements on bulk quantities of swarf would be undesirable because of gamma absorption effects, so the swarf is measured in small batches. The Swarf Inventory Monitor (SIM), located in the decanning cell, is illustrated in Fig. 3 (a neighboring instrument for measuring the cooling time of the fuel is also shown here). For each batch, a HPGe detector views the waste and acquires a gamma ray spectrum. The activity of the gamma emitters is calculated from analysis of the spectrum. This calculation takes into account detection efficiency, background from the measurement tray and self-attenuation in pieces of uranium. The irradiation history of the fuel is derived from various ratios of the measurable gamma emitters. Uranium mass and the activity of other radionuclides can then be quantified using known relationships derived from the fuel inventory code, FISPIN (3).

Fig. 3

The HPGe detector is mounted in the cell roof on a precisely engineered movable table. The detector views the waste tray through a gamma ray collimator. The positioning of the detector is carefully monitored with an infra-red proximity sensor in order to ensure that the calibration arrangement remains valid during all subsequent measurements. An ultra high count rate capability (handling an input of up to 500,000 counts per second) is required to provide a wide dynamic range to cope with the variation in activity of monitored swarf. Advanced electronics are used to process the signal from the detector with accurate dead-time correction. Based on experience gained in using HPGe detectors in process plants, special mounting and screening is used on the detector and its electronics to overcome electrical and mechanical noise. Considerable effort was made to provide high quality diagnostics and to make the system `user friendly' for the plant operators and engineers.

The monitor has been operating since July 1990 and provides a reliable determination of uranium mass and radionuclide inventory. Detailed assessment work was performed after commissioning of the instrument in order to identify and eliminate potential biases. This has enabled the system's process parameters to be finely tuned to the actual measurement conditions that have been found to arise in the plant.

Fissile Material Detector

Current arisings of miscellaneous items of ILW from the Sellafield plant are stored in 3m3 boxes at a purpose built facility, the Miscellaneous Beta Gamma Waste Store (MBGWS). For criticality safety, it is necessary to quantify the fissile content of this waste prior to filling of the storage boxes. The technique employed for this measurement is the active neutron interrogation technique, DDA.

The Fissile Material Detector (FMD) is capable of measuring the wide variety of wastes consigned to the store. Various calibrations were performed for each type of waste classification during commissioning. The waste consigned to the plant includes miscellaneous mixtures of: steel, lead, concrete, graphite, cellulose and plastics. The total fissile

content is derived using the DDA measurement result, operator declared classification and the neutronic properties of the sample, determined during the measurement.

The measurement chamber consists of polyethylene and graphite, with neutron detectors and a pulsed neutron generator located in the walls. Lead shielding is used to reduce the gamma flux to the detectors from the waste. Regular automated checks on the system performance are performed using a source transfer system.

Hulls Monitor

The reprocessing of oxide fuel at the THORP plant generates another ILW stream. This consists primarily of the residues of fuel assemblies (hulls") which are the waste product from the dissolver after the shear/leach process. The hulls are exported from THORP to an encapsulation plant where they grouted and stored prior to ultimate disposal. Monitoring of the hulls (prior to export) is necessary in order to:-

Ensure criticality safety in subsequent handling.

Ensure that fuel retention complies with limits for interim storage and ultimate disposal or return to the customer.

Demonstrate that uneconomic fuel retention has not occurred.

Derive inventory information for customers and regulators.

Provide safeguards and materials accountancy data.

The Hulls Monitor, illustrated in Fig. 4, has been developed to satisfy these measurement requirements using a combination of neutron interrogation (DDA), passive neutron totals counting and HRGS. The application and development of these techniques to this measurement scenario represents a major measurement challenge.

Fig. 4

The residual fissile content of the leached hulls is determined from the DDA measurement. Total uranium content is derived using the fissile content, the measurement of passive neutron emission and information on the initial enrichment of the fuel batch provided by the reactor operators and from measurements (via a separate monitor) on the fuel before shearing. Additional inventory information is determined using HRGS, the passive neutron count, initial enrichment and cooling time of the fuel and FISPIN derived correlations.

The measurement is undertaken on a dissolver basket, 0.67m in diameter filled with hulls up to a depth of 2m. In addition to the hulls, the basket will contain additional fuel assembly hardware (such as end appendages) and a small amount of neutron poisoned dissolver liquor trapped within the hulls. During a measurement sequence, the basket is lowered into a re-entrant thimble in a monitoring cell below the basket handling area. Fast neutron detectors and the neutron generator are housed in a collar around the thimble. The collar is constructed of moderating materials designed for the DDA measurement. Plant ruggedised electronics have been developed to provide the detection systems with noise immunity, high count rate capabilities and fast recovery times essential for DDA measurements. The HRGS system is located outside the cell and views the basket through a collimator set into the cell wall above the neutron collar.

Comprehensive self-checking and back-up facilities have been designed into the instrument. Functionality of the neutron and gamma detection systems, and of the neutron generator is confirmed by standardization checks that are initiated by the basket handling cave control system at

regular intervals and before each measurement. Confirmation of a satisfactory standardization must be provided before a measurement can be carried out. In addition, real-time checks are continually performed by the software to confirm the absence of fault conditions.

The hulls monitor neutron system is capable of measuring residual fissile content with a lower limit of detection of 5-10 g 235U equivalent levels. Further work is underway to develop an advanced radiometric instrument to deal with the more challenging measurement of hulls from mixed oxide and higher burn-up uranium oxide fuels.

THE MEASUREMENT SOLUTION

Development work has been performed to adapt the existing waste measurement technologies to the challenge of monitoring highly active waste retrieved from interim storage facilities. One area in particular where considerable development work has been applied is in the application of neutron assay techniques. These measurements are often needed for criticality control and as supporting information for radionuclide inventory of waste packages prior to ultimate disposal.

Technique Development

The assay of trans-uranic elements in highly active waste presents a major measurement challenge. Passive techniques, in isolation, are of limited applicability. The gamma rays associated with the trans-uranic nuclides are often difficult to detect due to the low energy or low emission rates. For the measurement of irradiated fuel bearing wastes, there is usually no measurable gamma signal from any trans-uranic nuclide because of the interference from the intense gamma rays from fission and activation products. Passive neutron counting can be used on highly active wastes but this measurement can only quantify the total spontaneous fission neutron emission rate (due to emissions from even mass nuclides such as 238U, 240Pu and 244Cm). In isolation, this measurement cannot be used to quantify specific trans-uranic nuclides. To do this, additional parameters relating to the trans-uranic content of the waste need to be known or measured.

Active neutron interrogation enables the total fissile content of the waste to be measured (comprising the fissile nuclides 235U, 239Pu and 241Pu). For waste measurements, one of the most suitable forms of this technique is DDA. In the UK, as elsewhere in the world, the earliest applications of DDA have been the assay of low concentrations of fissile material in wastes that have low overall inventories of radioactive materials. In addition the materials presented for assay and the geometrical arrangements have traditionally been well characterized.

The adaptation of DDA to the highly active wastes retrieved from interim storage is complicated due to the following aspects of the measurement:-

Wastes can vary in composition. Materials that have very different neutronic properties (absorbers and moderators) are often found together. Examples include graphite, stainless steel, organics and sludges. Waste is heterogeneous. Frequently a container will contain voids and lumps of different materials.

Water is often present in the waste. For neutron measurements, the moderating effect of water is usually undesirable, particularly where the content is variable. Efforts can be made to design the waste retrieval process to present the waste in a dry state. However, safety or process limitations often lead to the presence of bound or free water in the waste stream.

Wastes can vary in density. Typical ranges that can be encountered are 0.5 to 5 g/cm3.

The wastes are poorly characterized. A methodology has been developed for measurements of mixed wastes, where the operator cannot define distinct `streams'.

The measurement container is large. Process and engineering requirements often mean that the waste can only be presented for measurement in large containers. This is undesirable from a measurement point of view as it increases the uncertainty in the measurement. Physicists have worked in close collaboration with plant designers to find the most appropriate measurement point in the process.

System Description

The conceptual measurement system for assay of highly active waste comprises a custom built chamber made up of polyethylene and graphite, suitable for both active and passive measurements (DDA and PNCC). Fast neutron detector packages are located in the walls of the chamber together with the pulsed neutron generator(s) for the active assay. Due to the gamma emissions associated with highly active materials, the chamber is lined with several centimetres of lead shielding to reduce the gamma flux to the detectors (which are sensitive to both gamma rays and neutrons).

Imaging and matrix corrections capabilities have been developed which allow accurate determination of the fissile content and spontaneous fission neutron emission rate of a variety of waste streams. It is possible to use these parameters to quantify individual trans-uranic nuclides (e.g. 239Pu) and fission products in the waste container. Sensitivities at or below gram levels of fissile material are achievable.

CONCLUSIONS

Characterizing a retrieved waste from an interim store which may have been operational thirty or more years ago represents a challenge to the instrument supplier. For a site such as the BNFL Sellafield facility, many such retrieved waste streams will be encountered as redundant facilities are cleaned out in preparation for decommissioning, each posing its own distinct set of problems. To all of this can be added the challenge of meeting the increasingly detailed requirements of the regulator and disposal site operator in terms of the degree of characterization required.

Detailed consideration of some of the needs for retrieved waste monitoring at Sellafield has demonstrated the value of utilizing instrumentation concepts and techniques originally developed in support of reprocessing and associated operations.

BNFL Instruments Ltd with its considerable experience of providing instrumentation systems for the characterization of spent fuel and freshly generated wastes, which have now been taken through several generations of increasing sophistication and reliability, has provided the parent company with the confidence to move forward in its waste retrieval program with the knowledge that tractable and economic solutions can be developed for all waste streams.

ABSTRACT

This paper presents a human health risk assessment methodology for a large site that includes multiple facilities with solid and liquid waste disposal sites, which contribute contamination through several media such as air, groundwater, soil, and surface water. Risk-based decision making is evaluated for agricultural, residential, industrial, and recreational land uses. Also evaluated are risk-based decision making as it pertains to Native American land uses. The methodology includes a risk presentation that is useful for communicating with interested groups and valuable for decision makers. The human health risk is presented in isopleths overlaid on the region of analysis. This region of analysis may be the region within the site boundary or the region outside of the site boundary as far as necessary.

The risk assessment methodology is applied as a decision making tool. Decisions on whether to undertake a remedial action are evaluated based on parameters such as the extent of remediation and restoration achieved compared to target risk, the amount of risk reduction at varying cost levels, and the risk from various land uses before and after remediation. Several examples of the human heath risk contours are presented. The high-risk areas within an isopleth are traced back to the media, source, and the constituents that cause the high risk. Comparisons of various alternatives versus cost are presented. Finally, the feasibility of a single or multipurpose land-use strategy is evaluated based on human health risk and ecological risk for several remedial alternatives.

INTRODUCTION

Increasingly, risk assessment is being applied to pollution control and remediation decisions, particularly in the context of cost-benefit analysis and land-use planning. While there are many advantages in using risk assessment to prioritize remedial actions and risk reduction strategies, there are several inherent limitations in their ability to

addresses simultaneously the impact on human health, the ecosystem, and social culture. Some of the limitation are 1)numerous source terms and release patterns; 2) various constituents and environmental media; and 3)endpoint receptors.

Most risk assessments are limited to a single waste site or a closely integrated site grouping, such as the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) operable units. Thus, most risk assessments can be modeled using a single release term for each individual waste site to multiple receptors, such as the maximally-exposed individual (MEI), a member of the public, or a land user. For a facility with 100 waste sites and a receptor, the risk from each site to the same receptor has to be calculated individually (100 times), then added to all the risk values to evaluate the overall risk to the individual from the facility. A change in any parameters or components of the risk such as the source, location, or exposure pathway will require complete recalculation of risk. The methodology described in this paper is based on the Modular Risk Assessment (MRA). The methodology allows overall risk from widely scattered release sites throughout an installation with areas of thousand of km2 to be calculated and displayed graphically. The change in risk over time and anticipated remediation and post-remediation land uses can be easily calculated and displayed graphically. While the MRA methodology is applicable to human heath, ecological, and cultural risk, this paper discusses only the human health risk. The application of MRA methodology to the ecological risk is described in Duke et al. (1995). The application of MRA to the cultural risk is reported in Harper (1995).

Briefly, the methodology described in this paper breaks the facility into smaller, more manageable sections or cells by superimposing a map of the facility with a grid. This methodology uses a discrete and modular approach. This methodology has been discussed in several publications (Nazarali et al. 1994 and Whelan et al. 1994) and applied in two major Hanford Site Environmental Impact Statements (EIS). The contaminations, as a module, are identified and quantified in each cell for each medium (i.e., groundwater, soil, surface water, and air) using existing databases and environmental surveillance data. There lease and transport of a unit concentration, as a module, through different media to the receptor is modeled for several time periods ranging from the present to 10,000 years in the future. The unit risk factor, as a module, is calculated by using a unit of concentration to calculate the risk for several land-use receptors. The overall risk is calculated by multiplying the source term by the unit transport factor, at the selected time, to obtain the concentration of the contaminants at the selected time available to the receptor. The product of this concentration and the unit risk factor results in the risk from the particular constituent at the certain time to the receptor of concern.

The most important part of this methodology is its ability to present the results and information for environmental restoration and waste management decisions. The presentation is in contour form, which provides a great deal of information in a graphic form that is easy to assimilate. This presentation assists in thorough decision making due to the illustrated overall picture of the results. A thorough decision requires incorporating all the variables that are the integral part of the decision. The more typical tabular presentation of the risk based on single site and single receptor for a large facility with multiple sites

will not display all the decision making variables in a manageable format. The relative risk from one or all of the sources through one or all media to one or several receptors, which is essential to the decision makers, would be tedious and almost impossible if the single site single risk evaluation method were applied. In addition, presenting the results in tabular form would make the analysis much harder because of the volume of the data. The estimated risk by the MRA methodology can be communicated with the interest groups in a simple and clear manner. Decisions regarding the remediation of a site, the whole facility, or selected constituent based on the target risk, regulatory standard, or the stack holder cleanup goal can be analyzed and compared efficiently and easily.

METHODOLOGY

The methodology is divided into two primary sections, risk calculation and risk presentation. The risk calculation is based on the MRA. The risk presentation is time and spacial dependent. The risk results are presented in graphical form for a selected time and specific location. The risk calculation and presentation are discussed in the following sections.

Risk Calculation Methodology

Modular Risk Assessment Approach

The multiple waste sites with different waste forms at different locations that require assessment demand a more flexible approach, which ensures that the important aspects of the assessment are not lost through gross aggregation. The MRA approach allows for evaluating regional risk by accounting for the effects of widely scattered waste sites. The approach becomes powerful and relatively easy to apply because the system is automated. The MRA is based on the independent evaluation of each module that is the component of the risk. These independent modules are source, transport, and exposure, which are shown in Fig. 1 and discussed in the following sections.

The first approach in applying the MRA is to establish a spacial configuration that addresses the location of the waste sites. The location of any object can be addressed by Cartesian, cylindrical (polar), and spherical coordinates. In this paper, the Cartesian coordinates are used for the MRA approach. The x-axis represents the east-west coordinates, and the y-axis represents the south-north coordinates. The z-axis (perpendicular to the xy plane) represents the magnitude of the source, concentration, or risk. The size of the grid cells in xy- plane depends on the size and configuration of the facility. For a large facility such as the Hanford Site, the 1.0-km by 1.0-km grid cell would be proportionate. Smaller facilities may use as small as 100-m by 100-m or 10-m by 10-m grid cells. Figure 2 shows the 1.0-km by 1.0-km grid cells superimposed over a map of the Hanford Site.

Fig. 1

Fig. 2

Source Module

The source module represents the source term, which refers to the inventory or concentration of the pollutants that are available for release within the media such as the soil (surface and subsurface), groundwater, surface water, and air. Each cell contains a table for the source at the present time, as shown in Table I. The pollutants are divided into three groups of radionuclides, carcinogenic chemicals, and non-carcinogenic chemicals. The groundwater column represents the

inventory or concentration of each constituent within the groundwater. The soil column displays the inventory or concentration of each constituents in the surface soil (Z1), subsurface soil (Z2), and total soil (Z). The surface water and air columns represent the inventory or concentration of each constituents in surface water and air, respectively. For cells that contain several waste forms, the aggregated source term or concentration is used.

Table I

Prior to collecting data that specifically describes the waste at each site, the environmental setting and grid system must be determined. The installation is divided into regions where the geology, hydrology, hydraulics, and meteorology are considered to be representative of the region. Data describing each environmental setting are collected and verified as being representative of the area by installation engineers and scientists.

Transport Module

A unit of each constituent in each media is transported into the environment using the transport code. The Multimedia Environmental Pollutant Assessment System (MEPAS) was used for the Draft Hanford Remedial Action EIS (HRA-EIS) risk assessment analyses. MEPAS was chosen because it includes the following elements. MEPAS 1) addresses radioactive, organic, and inorganic wastes; 2) provides user flexibility in describing the geology, hydrology, hydraulic, and meteorology at an installation by allowing the use of site-specific data; 3)performs calculations within the installation boundary and offsite; 4) is largely based on the solutions to the advective-dispersive equations for solute transfer; 5)includes atmospheric complex terrain, channeling of wind, fugitive dust emissions, wet and dry deposition, and gaseous and particulate releases; 6) addresses both active and inactive sites and releases; 7)allows for user or code specific time-varying (i.e., transient) source-term emission rates; and 8) addresses contaminated soils, pond sites, liquid discharges, injection wells, and point, line, and area sources.

The unit source term for each media from each cell that contains the source are transported to other cells using transport code. The comprehensive methodology and application of unit environmental transport assessment of contaminants is described in Whelan et al. (1995). For example, in the groundwater transport the source from one cell in some cases was transported to several hundred cells. Therefore, a fraction of the unit source from one cell may appear in one or several cells. The contribution of all the sources from one cell or several cells to a cell at a selected time are gathered in a file (table) as the unit transport factor (UTF). The data have the same format as the source term, as shown in Table I. The values in this table are the fraction of unit source or concentration of the constituent of concern within the media of concern at a selected time for the particular cell. Each cell contains its own table with the specific UTF.

Exposure Module

This module calculates and represents the risk to a certain receptor (life style or land use) from a unit of concentration in groundwater, soil, surface water, and air for each constituents. Four land-use receptors are analyzed in the Hanford Site Risk Assessment Methodology (HSRAM) document (DOE 1995). Each of these receptors' unit risk factor is calculated based on their activity and life style. The four receptors

(agricultural, residential, industrial, and recreational) unit risk factors for radionuclides, carcinogenic chemical, and noncarcinogenic chemicals for all the media (groundwater, soil, surface water, and air) are described and calculated (Strenge and Chamberlain 1995). For example, the agricultural receptor uses all the media. This receptor uses the groundwater for showering, drinking, watering the garden, crops, and animals. This receptor uses the soil (surface and sub-surface) for raising a garden, crops, and animals. The surface water and air are part of this receptor's pathway. The risk from a unit of the concentration within each medium are gathered in a file (table) as the unit risk factor (URF). The URF data have the same format as the source term and UTF, as shown in Table I. The URF values have unit of risk (cancer incidence or fatalities) per concentration.

Risk Result

Each cell will have one risk table for every exposure scenario and time. The product of the source term and the UTF results in the concentration of the pollutant in that medium. The product of this concentration and the URF results in the risk to the selected receptors at the selected time for the constituent of concern at the particular cell. The resultant data are gathered in a file (table) as risk. These data have the same format as the source term, UTF, and URF. An example of the risk output is shown in Table II. The consistency in the source, UTF, URF, and risk tables format is for computation purposes. The separation hazard categories (radionuclides, chemicals carcinogenic, and chemical noncarcinogenics) are for risk summation. The resultant risk can be summed for each media, each constituents, and each hazard category. For each receptor (land user) at the Hanford Site, there are total of 2,700 (53 km by 53 km) risk tables generated (a table per cell).

The mathematical risk calculation can be expressed by Eq. 1.

Eq. 1

Where R, S, U, and E represent the total risk, source term, unit transport factor, and unit risk (exposure) factor, respectively. The subscripts i, j, k, and t represent the constituent, medium, receptor, and time.

Risk Presentation Methodology

In most analytical calculations, the computation results are presented in tables or some type of graphical form such as a pie or bar chart. For the Hanford Site, a comprehensive risk assessment would include 2,700 risk tables for a selected time. The analyses usually evaluate the risk for several time frames, such as T0, T1, T2, and T3 for each receptor, which results in 10,800 individual risk tables (2,700 4) for each receptor and a total of 43,200 tables (10,8004) for all four receptors.

In this methodology, the value of the risk for each cell is plotted on the z-axis. Therefore, for the Hanford Site all the 2,700 risk tables for a selected receptor at a selected time can be presented on one graph. The four land-use receptors and the four time frames of interest will result in a total of 16(4by4) contour maps. Figure 3 presents the risk to a residential farmer for 4 selected time frames (T0, T1, T2, and T3,)

ANALYSES

The methodology can be applied to the baseline, remediation, and post-remediation human health and ecological risk analyses. The baseline risk represents the risk to a selected receptor from all the sources prior to any remediation or restoration or for the no action alternative for the National Environmental Policy Act (NEPA) EISs. The remediation risk

refers to the risk that corresponds to the remedial activities. The post-remediation or residual risk refers to the risk from the pollutants that are left in the environment after completing the remediation activities. The flexibility and capability of this methodology makes it possible to conduct analyses such as comparing the baseline, remediation, and post-remediation risk for a several land-use scenarios. By subtracting the post-remediation risk from the baseline risk, the reduction in risk to the receptors can be analyzed. This reduction in risk can be compared against the risk from the remediation itself for further analyses. The risk at different times may be reduced as the time goes by so that remediation may not be required at all or may be required only for a certain waste form or land-use scenario. The combination of several land uses over the region of interest is a process of analyzing that is possible by using this methodology.

Table II

Target Risk Analysis

The target risk mainly refers to the end point risk that is desired after completing remediation. For a selected target risk, a risk reduction factor (RRF) can be calculated by this methodology by comparing post-remediation risk with the baseline risk. For example, a typical tolerated exposure level for carcinogenic substance may increase the upper bound lifetime cancer risk from 1.0E-04 to 1.0E-06. This factor can be expressed as the ratio of the target risk to baseline risk as follows:

Eq. 2

The level of contamination remaining after remedial actions compared to the baseline can be expressed mathematically as a concentration reduction factor (CRF). This factor can be evaluated using target risk or target concentration. The RRF is directly proportional to the CRF, as follows:

Eq. 3

Decision Making

This methodology is a powerful tool for risk-based decision making. There are several ways to use this methodology as decision making tool. First, the processes of radioactive decay and biological degradation reduce the initial inventory of a contaminant over time. Therefore, presenting risk for different times in the future can communicate the need for remediation. Second, presenting the risk for the same time but different land uses such as unrestricted (agricultural and residential scenario), partially restricted (industrial scenario), and restricted (recreational scenario), can give enough information to the decision maker for selecting the remediation and extent of remediation that is necessary. Third, the combination of time and land use can assist the decision making processes, as this methodology demonstrates.

APPLICATION

This methodology has been applied in two major EISs at the Hanford Site.

Hanford Remedial Action Draft Environmental Impact Statement

The Hanford Remedial Action EIS evaluated and analyzed several alternatives regarding the remediation of over 1,100 past practice waste sites at the Hanford Site. In this EIS, a comprehensive baseline human health and ecological risk analysis was conducted. The risk assessment was performed using the methodology described in this paper. However, the remediation risk and the post-remediation risk were not the same as the methodology in this paper. The remediation assumed the complete removal of the all the sources and/or securing the waste sites by mean of

capping. This forced the analysis to assume that the post-remediation risk was nominal.

Tank Waste Remediation System Draft Environmental Impact Statement

The Tank Waste Remediation System EIS analyzed several alternatives for remediating 177 single and double-shell tanks. These tanks contain 56,000,000 gallons of high-level waste with total activity of 176,700,000 curies that have been generated from nuclear defense production activities. The post-remediation risk for this EIS uses this risk assessment methodology. The baseline risk was analyzed under the no action risk. This risk assessment methodology assisted in selecting a combination of alternatives for the Tank Waste Remediation System EIS.

ABSTRACT

This paper outlines the various steps pursued in performing a generic safety assessment of the various technologies considered for the low-level mixed waste (LLMW) "No-Flame" option in the U.S. Department of Energy (DOE) Waste Management Programmatic Environmental Impact Statement (WM PEIS). The treatment technologies for the "No-Flame" option differ from previous LLMW technologies analyzed in the WM PEIS in that the incineration and thermal desorption technologies are replaced by sludge washing, soil washing, debris washing, and organic destruction. A set of dominant waste treatment processes and accident scenarios were selected for analysis by means of a screening process. A subset of results (release source terms) from this analysis is presented.

INTRODUCTION

This paper presents a preliminary assessment of potential accidents for the "No-Flame" option leading to airborne releases at U.S. Department of Energy (DOE) sites. The assessment is being developed in support of the Programmatic Environmental Impact Statement (PEIS) for management of low-level mixed waste by the Environmental Management (EM) Office of DOE. An important consideration in the WM PEIS is the risk to human health of potential radiological releases from facility accidents. An evaluation of facility accidents is a necessary first step in evaluating the risk of accidents to the on-site and off-site populations at each of the sites. This risk evaluation is part of the process of comparing alternative management strategies in the WM PEIS. These strategies include decentralization, regionalization, and centralization of waste treatment activities.

Low-level mixed waste contains both radioactive and Resource Conservation and Recovery Act (RCRA)-controlled substances. LLMW is generated, projected to be generated, or stored, at 37 DOE sites as a result of research, development, and production of nuclear weapons. It is projected that waste management activities will require management of an estimated 226,000 m3 of LLMW over the next 20 years.

A variety of treatment methods and processes for LLMW were considered in the WM PEIS. For difficult-to-treat LLMW containing organic material, two thermal treatment methods were analyzed: incineration, which EPA considers the best demonstrated available technology for organic waste, and thermal desorption, which bakes the waste at temperatures lower than those used in incineration. A "No-Flame" treatment process is being considered that replaces thermal treatment (incineration and thermal desorption) with sludge washing, soil washing, debris washing, and organic destruction technologies.

The safety documentation that exists for the washing and organic destruction technologies were reviewed to establish which technology may significantly contribute to the overall risk of waste treatment. The technologies were also examined to determine if one or more of the following accident conditions could exist:

1) Conditions which could result in large-scale damage or overpressurization of the various pieces of equipment, tanks, or vessels for each technology;

2) Ignition of flammable gases (including liquids and aerosols) that are always present or ignition after release of retained flammable gas/liquid/aerosol;

3) Process equipment failures which could result in an energetic release of radioactive material;
4) Suspension of radioactive materials by sprays, etc.

Based on the above criterion, it was determined that the accident analysis would focus on Organic Destruction (ORD), due to the potential of overpressurization (point 1), combustibility of the input waste stream (point 2), and energetic releases upon reactor rupture (point 3).

The organic destruction technology is similar to wet-air oxidation except that the organic concentration in the waste feed is significantly higher (greater than 50 percent). Organic destruction is the aqueous-phase oxidation of concentrated organic and inorganic wastes in the presence of oxygen at elevated temperature and pressure. Pressure in the range of 300 to 3,000 psi is used to maintain water in its liquid state, which allows oxidation to progress at lower temperatures than would be required for open-flame combustion. Water serves to moderate the oxidation rate by absorbing excess heat of reaction. Reactor temperatures typically range from 350o to 610oF (4,6). The layout of an ORD conceptual facility is presented in Fig. 1, based on (6)

Fig. 1

OVERVIEW OF FACILITY ACCIDENT ANALYSIS

The source term associated with an accident is the amount of radioactive material that is released to the immediate environment and is the product of four factors that vary for each radionuclide within the inventory affected by the accident:

Eq. 1

The material-at-risk (MAR) is defined as the inventory of waste impacted by an accident. The damage fraction is defined as the volumetric fraction of the MAR actually susceptible to airborne release. The RARF is the fraction of the total available radioactive material that is released and rendered airborne from primary confinement in a readily dispersible form. The LPF accounts for the reduction of the amount of airborne material due to containment, high-efficiency particulate air (HEPA) filtration, deposition, etc.

Determination of the Material-at-Risk (MAR)

The material-at-risk for the conceptual ORD facility is given by the summation of the major equipment and process piping:

Eq. 2

The various pieces of process equipment and their operating conditions were reviewed to establish which accident conditions would result in the largest airborne release, based on the present state of knowledge concerning the operation of the technology, potential failure modes, and radionuclide quantity present at the presumed time of failure. The material-at-risk associated with the process lines, heat exchangers, and other pieces of process equipment is neglected in this analysis, due to the presumed low volume of material associated with these items. The same argument is applied to the material-at-risk in the separator, due to the low-temperatures and pressures employed in this unit, as well as low volatility of the treated wastes.

The calculation of material-at-risk for the reactor and feed mix tank takes the following form:

Eq. 3

where TR is the treatment throughput rate (m3/yr) of the ORD facility, CONCi is the concentration of radionuclide "i" in the feed (Ci/m3), and t is the space time (residence time) of the reactor and the feed mix tank.

The treatment throughput rate and radionuclide concentration of the feed are obtained from the WASTE_MGMT computational model (1) and are a function of DOE site, treatment technology, and alternative site configuration.

LLNL (4) indicates that an organic destruction reactor would require a capacity of 540 gallons for a throughput of 5,177 kg feed per week, resulting in a space time of 33 hours (treactor ~ 33 hour). The space time for the feed mix tank is estimated based on equipment size data for a similar wet-air oxidation system (3) which indicates that comparable volumes of waste are contained within the reactor and feed mix tank. To assure a continuous flow of waste as feed to the reactor, the space time of the feed mix tank must be similar to that of the reactor (tfeed mix tanks ~ 33 hour) and therefore the material-at-risk for the feed mix tank is equivalent to that postulated for the reactor. The material-at-risk for the ORD facility is given by:

Eq. 4

based on 4,032 hours of operation per year.

DEVELOPMENT OF ACCIDENT SEQUENCES

A spectrum of accidents that occur during treatment were developed based on the waste's physical and radiological characteristics in conjunction with the technology specifications. They range from operational events (i.e., an overpressurization in the reactor chamber) to facility fires to external events (i.e., natural phenomenon events and airplane crashes). The accidents considered are discussed below.

Rupture of a Single ORD Reactor (accident sequence WAX)

Due to the similarity in processes between organic destruction and wet-air oxidation (WAO), the limited safety literature for the WAO process was reviewed to determine which accident sequences have been postulated to be risk-dominant. The worst-case internally-generated accident generally involved the rupture of the WAO reactor resulting from overpressurization and/or equipment failure (2). The ORD reactor operates at a pressure and temperature of approximately 250 psi and 260oC, respectively (4). If the reactor fails, the solution will flash to steam. The steam will be assumed to condense into particles of less than respirable size (10 micron AED) and be transported out of the ORD facility. The release to the atmosphere will be limited as the release is not energetic enough to breach the facility containment.

A review of the literature for tank and/or connecting pipe failures indicate that the failure rates depend primarily on 1) the design standard or basis when considering specific damage mechanisms, and 2) the inherent conservatism involved. As an example, large high-pressure vessels have a lower failure rate than low-pressure storage tanks. Failure rates between 1 x 10-4 to 1.3 x 10-3 / yr have been reported for various pressure vessels with a median value of 1 x 10-3 / yr. In this analysis, it is assumed that a failure rate of 1 x 10-3 / yr applies to breaches of the ORD reactor that could result in significant releases. The damage fraction for this sequence is based on the contents of a single ORD reactor. The contents of the three ORD reactors constitute 50% of the facility MAR, so that the contents of a single ORD reactor is about 16.7% of the facility MAR (one-third of 50%).

The respirable airborne release fraction (RARF) is the product of the airborne release fraction (ARF) and the respirable fraction (RF). The RARF for free-fall spill of the superheated aqueous solution in the ORD reactor is determined assuming isentropic expansion. The amount of the

ORD reactor contents that will flash to steam upon release was determined from the following:

Eq. 5

where HL1 is the enthalpy of the feed stream (1,265 Btu/lb at 250 psi and 260oC), HL2 is the enthalpy of the liquid (water) after release (180 Btu/lb at 1 atm and 100oC) and DHvap is the heat of vaporization at the release temperature and pressure (970 Btu/lb at 1 atm and 100oC). The mole fraction of vapor flashed is estimated from the above equation to be approximately 100%. Thus, all of the solution would flash (evaporate) to steam. The release factor from pressurized releases of superheated aqueous liquid solutions is given by (7):

Eq. 6

Based on a vapor mole fraction of 100%, the RARF is estimated to be 0.33. It should however be noted that this relatively high release fraction would be mitigated by the presence of double banks of HEPA filtration and moisture-condensing systems such as demisters, condensers, etc.

The characteristics of the WAX accident sequence are given in Table I. The value of the RARF shown in the above table only applies to nonvolatile particulate solid radionuclides (such as U-235, Pu-238 and other transuranics, etc.); a release fraction of unity is applied to noble gases and halogens.

Table I

Facility Fire (accident sequence WAF)

The ORD facility is designed to process organic and inorganic semi-solid and adsorbed materials and to destroy soluble materials such as heavy organic oils and emulsions (including chlorosolvents) produced during washing of sludges, soil, and debris. The high organic feed streams are diluted to 5 percent organic or less prior to injection into the reaction vessel. A low-order detonation of the organic waste and oxidant has been postulated to occur; however, the reaction chamber would be designed to avoid detonation (4). In this analysis, it is postulated that a fire occurs outside the ORD feed mix tank following leakage. A fire caused by ignition of combustible solvent would disperse radioactive particulates in the immediate area of the fire and would last for a short period because the amount of combustible material is limited. Due to the high structural integrity of the ORD reactor as well as the dilute aqueous nature of its contents, it is assumed that its contents would be unaffected (i.e., not released in significant quantities) by this accident sequence. (However it may be expected that its continued operation would be impaired.) The accident is presumed to be initiated by failure of the feed mix tank resulting in a large pool of organic liquid, fine particulates, etc. on the ground. This leakage from the feed mix tank is ignited by an electrical short, etc. It is conservatively assumed that all of the tank contents are spilled and burn. The release to the atmosphere will be limited due to the fire protection capabilities of the facility and the assumption that the release would not be energetic enough to breach the facility containment.

A wide range of initiating fire frequencies has been reported in recent NEPA literature, ranging from 7 x 10-4 to 2.0 x 10-2 / yr with a median value of 5 x 10-3 / yr. In this analysis, it is assumed that an initiating frequency of 5 x 10-3 / yr applies to a fire in the ORD feed mix tanks that could result in significant releases.

The damage fraction for this sequence is based on the contents of a single ORD feed mix tank. The contents of the ORD feed mix tank constitute 50% of the facility MAR, leading to a damage fraction of 50%. The input feed to the ORD reactor is stated to be diluted to 5 percent organic or less. The feed to the ORD facility has been categorized in the WM PEIS as an Organic Combustible Solution in an Aqueous Solution. Because a large percentage of the input liquid is aqueous in nature, the behavior of the feed mix tank contents upon application of a thermal stress was considered to be consistent with that of a boiling Aqueous Solution with droplet formation, for a RARF of 1 x 10-2 (7). The characteristics of the WAF accident sequence are given in Table II.

Table II

External Events

External challenges to the ORD facility include airplane impacts and natural phenomenon. The representative natural phenomenon analyzed is a seismic event because of its potential to affect the entire facility. A seismic event is postulated to rupture fittings/connections to the ORD reactors, resulting in aerosol formation. It was however not assumed that this would result in a small fire affecting the facility MAR. The contribution associated with the feed mix tank was neglected as a beyond-design basis seismic event could fracture the concrete footings under the holding tanks, allowing any spilled material to be absorbed by the soil, with negligible atmospheric releases. The accident frequency for seismic events is estimated on the performance goal for a Moderate Hazard facility, as defined in DOE guidelines.

Aircraft impacts were also analyzed as potential man-made external events. Aircraft accident frequencies are site dependent and were obtained from aviation statistics and the locations of DOE sites with respect to major airports and aviation routes.

Functional event trees specific to the organic destruction technology were developed to track the progression of the external accident initiators out to the point of airborne release. Initiating accident frequencies and conditional probabilities of the various event tree branches were determined from applicable safety literature where possible. Further information on development of the external event sequences is available in (5). The assumed characteristics of the various external accident sequences are given in Table III.

Table III

RESULTS AND DISCUSSION

The results of the accident analysis were obtained in the form of a detailed source term and an associated estimated annual frequency. The accidents have been grouped into four categories on the basis of their estimated frequency, with the categories ranging from anticipated (frequency higher than 10-2 per year) to extremely unlikely (frequency less than 10-6 per year) events.

Table IV provides a sample results with detailed information about the risk-dominant accidents summed over all radionuclides released, including the volume of the material-at-risk (VMAR., in m3), the material-at-risk (MAR, in Ci), total release fraction (TRF), source term (in Ci), accident frequency, and frequency class. The total release fraction is the product of the leak path factor(LPF), damage fraction (DF), and the respirable airborne release fraction (RARF). Only one WM PEIS alternative, number 36, which involves treatment at 12 sites, is shown because of space restrictions.

Table IV

The results in the table suggest that, in general, the risk of releases from the ORD facilities due to accidental causes would be low. Preliminary screening estimates confirmed that the risks to human health involved in LLMW management for the "No-Flame" option would be relatively low. Generally, releases of large amounts of radioactivity are associated with a very low estimated frequency, while more frequent events potentially result in small releases. The relatively low health impacts are the result of a number of factors including less severe operating conditions, absence of a fuel source such as natural gas used in incineration, and dilution with water of the product stream from organic destruction. All these factors may be expected to contribute to a lower health impact in comparison with incineration.

ABSTRACT

This paper describes the Waste Management Facility Accident Analysis (WASTE_ACC) software, which was developed at Argonne National Laboratory (ANL) to support the U.S. Department of Energy's (DOE's) Waste Management (WM) Programmatic Environmental Impact Statement (PEIS). WASTE_ACC is a decision support and database system that is compatible with Microsoft Windows. It assesses potential atmospheric releases from accidents at waste management facilities. The software provides the user with an easy-to-use tool to determine the risk-dominant accident sequences for the many possible combinations of process technologies, waste and facility types, and alternative cases described in the WM PEIS. In addition, its structure will allow additional alternative cases and assumptions to be tested as part of the future DOE programmatic decision-making process. The WASTE_ACC system demonstrates one approach to performing a generic, systemwide evaluation of accident risks at waste management facilities. The advantages of WASTE_ACC are threefold. First, the software gets waste volume and radiological profile data that were used to perform other WM PEIS-related analyses directly from the WASTE_MGMT system. Second, the system allows for a consistent analysis across all sites and waste streams, which enables decision makers to understand more fully the trade-offs among various policy options and scenarios. Third, the system is easy to operate; even complex scenario runs are completed within minutes.

INTRODUCTION

This paper builds on earlier work that developed the computational framework for identifying risk-dominant accident sequences (1,2). Only atmospheric releases are considered, and risk is assessed in terms of the airborne source terms, measured in Ci, along with the frequency of the associated accident sequence. The framework employs a probabilistic analysis for potential radiological accidents at DOE facilities that manage low-level waste (LLW), low-level mixed waste (LLMW), transuranic waste (TRUW), and high-level waste (HLW). The framework considers both waste storage and waste treatment, as well as treatment technology options including incineration, vitrification, and wet-air oxidation. In addition, it considers internally initiated industrial-type accidents that may occur during waste management activities (e.g., breaching a waste drum during handling and rendering a portion of the contents airborne) and externally initiated accidents (e.g., earthquakes or airplane strikes). The WASTE_ACC system implements this framework to provide policy analysts and researchers with an easy-to-use tool.

The WASTE_ACC system generates a consistent evaluation of accident risks across all 52 potential waste management sites within the purview of the WM PEIS and across the various waste streams (i.e., LLW, LLMW, HLW, and TRUW). Many of the input and process parameters used by WASTE_ACC were developed specifically for the WM PEIS, and these data reside in comprehensive generic databases that are an integral part of the WASTE_ACC system. The WASTE_ACC software uses a state-of-the-art database that incorporates the latest accident information from DOE safety documents. To date, no other system can provide the consistent analysis across sites and waste streams required in the WM PEIS. Furthermore, no other model utilizes site-specific waste volumes and radiological profiles, as developed through ANL's WASTE_MGMT system.

Although WASTE_ACC was developed to support the WM PEIS, any site contemplating processing radioactively contaminated waste could use the system to obtain at least a first-cut analysis. All that would be required to perform site-specific analyses is further development of supplemental site-specific databases. Besides being used for waste treatment facilities, WASTE_ACC's probabilistic approach could be used for other types of facilities, such as hazardous waste incinerators or chemical processing plants, and for other types of facility accidents.

WASTE_ACC CAPABILITIES

WASTE_ACC can be used to:

- Determine the risk-dominant accident sequence as a function of treatment site, waste management alternative, and waste type;
- Perform preliminary calculations of the health effects of the postulated accident sequence for four receptors: off-site maximally exposed individual (MEI), off-site population, on-site MEI, and on-site population;
- Develop the progression of accident sequences for external initiators (such as seismic events or airplane crashes) and calculate the probabilities of accident progression along various event tree branches;
- Print records associated with the risk-dominant accident sequences to standard or laser printers; and
- Generate ASCII text output files containing airborne release data by nuclide for risk-dominant accident sequences.

The sections below describe the WASTE_ACC software.

WASTE_ACC DEVELOPMENT

The programming challenge was to construct an easy-to-use PC-based system with the capacity to process large amounts of data and the flexibility to accommodate various waste management alternatives, waste streams, and site-specific information. The solution implemented an application shell (based on the Microsoft FoxPro for Windows database system) around the framework that had been developed earlier. This solution has two main advantages. First, FoxPro provided the software tools necessary to develop a Windows-compatible graphical user interface, thereby enabling a user to manipulate the model by means of a familiar metaphor. Second, the development of an application shell around the framework integrated several stand-alone modules that previously constituted the accident analysis system into a single application. The system can now be run from a single screen with a few mouse clicks, and run-time has been reduced by more than 75%.

WASTE_ACC REQUIREMENTS

The system requires a DOS-compatible computer running Microsoft Windows 3.1, a microprocessor equivalent to a 33 MHz 486SX or greater, and at least 4 MB of RAM. The software itself requires about 2 MB of disk space for installation (beyond that required for FoxPro). The WASTE_MGMT input data files can take up to 500 MB for all alternatives and waste types. Furthermore, the system can require as much as 300 MB of additional free disk space to run. Scenario runs generally take between 1 and 10 minutes on a PC powered by a 90-MHz Pentium, depending on the waste type and the complexity of the alternative being considered. Decentralized cases require more computational time and disk space than centralized alternatives because they have more sites to be analyzed. LLMW alternatives require longer execution times because they have more waste subtypes.

WASTE_ACC OPERATION

Figure 1 presents WASTE_ACC's welcome screen. After clicking on the Continue button, the system's main screen appears, as presented in Fig. 2. These screens illustrate the latest improved user interface. Buttons, list boxes, and text fields are conveniently and logically arranged on the screen. These input mechanisms address the information requirements for running an alternative clearly and in the English language. All information is requested before a model run begins. In contrast, earlier versions used menus that popped up on the screen while the program was running. These menus required the user to have considerable knowledge of the executing module to select the correct option.

Fig. 1

Fig. 2

Besides the user interface, the model's structure has also been updated. The updated version of WASTE_ACC integrates numerous stand-alone modules into a single application that runs to completion at the click of a button. Stand-alone modules had been necessary to cope with the extremely large data files and complex data manipulation steps inherent in the model. However, improved computer resources and streamlined code enabled the system to be integrated into a single application. The integration greatly reduced processing turn-around time and improved the system's integrity and reliability. A run that used to require four separate programs and some human intervention can now be completed with a few mouse clicks in a fraction of the time. The next few paragraphs describe the main screen in more detail, and discuss how to run WASTE_ACC.

User Input

The screen displayed in Fig. 2 is divided roughly into three parts top, middle, and bottom. In the top part of the screen, the user selects which waste stream and alternative to run and the desired output options. The middle of the screen contains an area that displays which module is running so the user can monitor a run's progress. It also contains buttons to start model execution or to exit the program. A check box labeled "Batch" enables the user to set up a series of runs all at once. In the bottom part of the screen, users can tell WASTE_ACC where to find input files and where to locate working (scratch) disk space. The top part is described first.

In the first field, under the phrase "Waste Stream:," the user can select a waste stream to be analyzed from a list box. This box provides a complete list of the possible choices, from which the user selects one. The waste stream choices are: High Level Waste, Low Level Waste, ER Low Level Waste, Low Level Mixed Waste, ER Low Level Mixed Waste, Transuranic Waste, and ER Transuranic Waste. In the field below, labeled "Alternative:," the user selects from another list box containing the possible alternatives for the selected waste stream.

After the alternative has been selected, the user can choose output options. Regardless of the options selected, WASTE_ACC always produces a summary data file that is sent to the output directory. If the "Summary Reports" check box is selected, as it is in Fig. 2, the system sends a formatted summary report to the printer and to the screen, as shown in Fig. 3. If the "Site/Nuclide Reports" check box is selected, the program prints reports that detail source terms by site and nuclide for each risk-dominant accident sequence. Finally, if the "Source Term Files" check box is selected, a source terms data file is sent to the output directory.

Fig. 3

The user provides file location information by clicking on the appropriate button in the lower part of the screen. When the user clicks on the "Data" button, a standard Windows file-open dialog box appears. The user selects a directory to tell WASTE_ACC where to find various support and input files, except for the WASTE_MGMT data (as of Version 4.3 in October 1995). Similarly, by clicking on the "Output" button, the user can tell the program where to put the output files. Files can be directed to any available drive, and not all the drives need to be the same. The user can select the "Scratch" or temporary drive, where temporary files will be placed. In most cases, this should be the user's own hard drive to minimize network traffic and increase processing speed, but the extremely large capacity needed to run the model (more than 300 MB free space) may prevent this. As an added feature, the user does not have to select a button to specify a drive but may instead type the directory name directly into the field. Finally, the user tells the system where to find the WASTE_MGMT files by typing a drive letter next to the phrase "Network Drive for WASTE_MGMT files:". This drive may be the user's own hard drive (i.e., C), but because the size of the WASTE_MGMT files needed by WASTE_ACC is so large (more than 500 MB), the drive is most likely to be that of a file server.

Performing Scenario Runs

WASTE_ACC can perform runs one at a time, sequentially, or grouped together in a batch. To run a single alternative, the user simply makes the appropriate waste stream, alternative, and directory choices and then clicks on the "Run" button. As the model runs, small message windows appear on the screen to indicate WASTE_ACC's progress. Besides messages, WASTE_ACC displays the name of the executing module in the main screen next to the word "Module:" to tell the user exactly which stage the model is executing. Then, when an alternative has finished processing, WASTE_ACC alerts the user with a beep and a message. The user has the option to either quit the program or make additional (sequential) model runs.

When several alternatives must be run, the user may elect to group them together in a "batch" run to significantly reduce processing time. To initiate a batch run, the user clicks on the "Batch" check box, and a screen similar to that shown in Fig. 4 appears. The user chooses which alternatives to run by typing a "T" in the "T/F" (last) column of the screen. Then, when the model runs, WASTE_ACC processes all of the designated alternatives and places the resulting source term files in the output directory as specified on the main screen.

Fig. 4

After the user has clicked on the Run button, WASTE_ACC sets up the work space, which in this context means it closes any files that may be open from earlier model runs. Next, the system locates necessary input files for the waste stream of the scenario being processed. When all the files are located, the computations begin. First, the quantity and characteristics of the material at risk (MAR) are calculated. After the MAR file is built, the system assigns unit dose conversion factors (DCFs), provided by Oak Ridge National Laboratory, to the MAR on the basis of its characteristics. Next, the system develops the accident parameters (such as accident frequency,damage fraction, and conditional probability) for each site, accident initiator, and sequence. These accident parameters are then linked to the MAR, and the model computes releases, doses, risks, and consequences for all of the accident

sequences. Finally, the system ranks accident sequences by risk and then constructs a file to contain radiological source terms for sequences with the largest impacts. The system writes this file to the output directory, and the computations are complete.

If the model is processing a single run, the system displays the results in a series of report screens (see Fig. 3). After all of the results have been presented, the application returns to the main screen so the user can choose the next action. For batch runs, the system does not present results on the screen since this would interrupt the program's operation. Instead, as the program loops though each of the designated alternatives, it writes the results to the output file described above. When all of the alternatives are done, the main screen appears, and the user regains control.

Output

The final outputs of WASTE_ACC are site-specific atmospheric source term results and accident summaries. One type of source term result is on the amount of radioactivity released to the atmosphere per radionuclide of each accident initiator's risk-dominant sequence. The accident summaries (partially shown in Fig. 3) provide detailed information about the risk-dominant accidents, summed over all radionuclides released, which include data on the:

- Volume of material at risk (m3),
- Material at risk (Ci),
- Air-release source term (Ci),
- Dose to the off-site MEI (person-rem),
- Cancer risk of the off-site MEI (incidents/yr),
- Risk to the off-site MEI (rem/yr),
- Doses to off-site population (person-rem),
- Number of excess latent cancer fatalities in the off-site population,
- Accident frequency (incidents/yr), and
- Frequency class.

Future Development

Although WASTE_ACC has come a long way toward becoming an easy system to use, much work remains. The system focuses primarily on DOE Waste Management issues and capabilities, but with some data development, it could perform accident analyses for other systems, such as hazardous waste incinerators or chemical processing plants. Moreover, the large and complex databases that support WASTE_ACC could have tools, such as input screens and preprocessing routines, that would make data collection and entry easier and less error-prone. The system could be adapted to perform detailed analyses on sites by using even more site-specific data than are available or appropriate for a nationwide analysis. Finally, the system could be adapted to quantify the uncertainty for the computed risk values. The model would account for uncertainties in the input data and process parameters, so instead of computing a point estimate, the model would produce a probability distribution reflecting the uncertainty of the system.

A PROPOSED ALTERNATIVE APPROACH FOR PROTECTION OF INADVERTENT HUMAN INTRUDERS FROM BURIED DEPARTMENT OF ENERGY LOW LEVEL RADIOACTIVE WASTES*

John R. Cochran,
Sandia National Laboratories

ABSTRACT

The burial of radioactive wastes creates a legacy. To limit the impact of this legacy on future generations, we establish and comply with performance objectives. The most controversial of these performance objectives is the requirement to protect possible future inadvertent human intruders (IHIs). This paper summarizes the regulatory approaches designed to protect future IHIs from buried radioactive wastes and proposes an alternative approach for protecting the IHI.

Standard exposure scenarios for the burial of U.S. Department of Energy (DOE) low-level radioactive wastes (LLW) assume that inadvertent human intrusion will occur, i.e., the probability of intrusion is one. A number of events must proceed inadvertent exposure to buried waste, including loss of active site control, loss of knowledge of the site, loss of site characteristics (the burial site must not resemble a burial site), loss of waste characteristics (the waste must not resemble waste), and inadvertent intrusion must occur.

Assuming that the probability of inadvertent intrusion is one is conservative, but does not account for important site characteristics. Site characteristics are included in the proposed alternative approach which is based on the "expected dose" to the IHI. The expected dose is the product of the consequence of intrusion and the probability of intrusion. For example, if the consequence of intrusion is calculated to be 125 millirem per year chronic dose and the probability of intrusion is assessed at 0.65, the expected chronic dose to the IHI is 81 millirem per year. All aspects of calculating the consequence of human intrusion are identical to calculating the consequence under DOE 5820.2A; the only new element is the derivation of the probability of intrusion.

Consequence is calculated using the long-standing exposure scenarios for intrusion. The probability of intrusion, where probability is a reasoned belief, can be assessed a number of ways and the expert elicitation process is recommended. A site-specific assessment of the probability of inadvertent intrusion allows credit to be taken for favorable site characteristics, such as site aridity, depth to water, and past site use, that are not explicitly accountable when the probability of intrusion is assumed to be one.

INTRODUCTION

The burial of radioactive wastes creates a legacy. To limit the impact of this legacy on future generations, we establish and comply with performance objectives. This paper reviews performance objectives for the long-term isolation of buried radioactive wastes; identifies regulatorly-defined performance objectives for protecting the inadvertent human intruder (IHI) from buried low-level radioactive waste (LLW); (3) discusses a shortcoming of the current approach; and (4) offers an alternative approach for protecting the IHI. This alternative approach is written specifically for the burial of U.S. Department of Energy (DOE)

wastes at the Nevada Test Site (NTS), although the approach might be applied at other DOE burial sites.

PERFORMANCE OBJECTIVES FOR BURIAL OF LLW

There are typically three performance objectives for the isolation of buried radioactive wastes:

- the long-term protection of human health from wastes that might migrate from the disposal site;
- the long-term protection of individuals that might inadvertently intrude into the disposal site (e.g., water well drillers);
- the long-term stability of the disposal site after closure to eliminate the need for active maintenance.

A possible fourth objective, protection of deliberate intruders, is typically considered infeasible (15).

In summary, performance objectives are defined to keep the wastes from getting to people and keep people from inadvertently getting to the wastes. These goals are expressed as two types of performance objectives: protection of the Member of Public (MOP) and protection of the IHI. This paper addresses protection of the IHI.

There are three categories of measures to protect the IHI from buried LLW: 1) active institutional controls, such as fences and guards; 2) passive institutional controls, such as deed restrictions, long-term government ownership, and long-lived markers; and 3) engineered barriers, such as special waste forms, burial depth, and special materials incorporated into the site closure system (15).

There are many who believe that DOE will maintain control of DOE disposal sites forever, thereby eliminating the possibility of an inadvertent human intrusion. The intent of the U.S. government is to maintain control of its high-level radioactive waste (HLW) burial sites forever (35 FR 17533) and there are formal discussions of maintaining control of the LLW burial and cleanup sites in perpetuity. However, there is significant concern that over the next few thousand years, control will be (at least temporarily) lost. For example:

- The U.S. Environmental Protection Agency (EPA) "... believes that passive institutional controls can never be assumed to eliminate the chance of inadvertent and intermittent human intrusion ..." (40 CFR 191, Appendix B);
- From guidance developed for the U.S. DOE "...survival of engineered systems may not be credible over time frames beyond 1 or 2 millennia." (15, p. 10);
- The National Research Council stated in 1995 that: "... it is not reasonable to assume that institutional controls can be maintained for more than a few centuries, we also conclude that there is no scientific basis for assuming that human activity can be prevented from occurring in an exclusion zone ..." (7, p. 122);
- The U.S. Nuclear Regulatory Commission (NRC) stated that: "... inadvertent human intrusion into a closed disposal facility at some point after closure of the disposal facility is likely." (9, p. 4-53).

With the failure of these protective mechanisms, the future may include IHIs receiving high doses of radiation from buried radioactive wastes. If future conditions could be anticipated, it would be possible to protect future generations. However, future conditions are uncertain. Despite this uncertainty, it is still possible to make intelligent decisions to protect the IHI. Regulations governing the protection of IHI typically define a set of hypothetical conditions. As a society (i.e., by

rulemaking), this country has established that compliance with these hypothetical conditions is protective of the IHI.

REGULATORY BACKGROUND

Several standards govern the disposal of radioactive waste in this country, and each of these standards establishes a different set of requirements that address the IHI. However, each standard has the same underlying assumption; that future generations maintain current living habits. This assumption is probably incorrect for the next 10,000 years; in just the last 60 years, our children have migrated from the yards and creeks to the video arcades and malls.

In the U.S., three major standards set requirements for the disposal of radioactive waste:

Commercial LLW is governed by 10 CFR 61; DOE-titled LLW, and other DOE radioactive wastes, are governed by DOE Order 5820.2A; and

40 CFR 191 sets requirements for the disposal of transuranic (TRU) wastes, HLW, and spent nuclear fuel.

The disposal of TRU wastes at the Waste Isolation Pilot Plant (WIPP) is governed by 40 CFR 191 with site-specific requirements set by 40 CFR 194. For the disposal of spent nuclear fuel and HLW, the WIPP Land Withdrawal Act exempted Yucca Mountain from the requirements of 40 CFR 191, and the Energy Policy Act of 1992 directed the U.S. EPA to establish site-specific standards for Yucca Mountain. These site-specific standards will define a fourth major regulation and are currently under development (60 FR 47172). These three standards (10 CFR 61, DOE Order 5820.2A, and 40 CFR 191) are briefly discussed as below.

Standards for Commercial LLW Burial

The NRC's 10 CFR 61 sets licensing requirements for the shallow-land burial of commercial LLW. In developing 10 CFR 61, the NRC recognized that the greatest risk of inadvertent exposure to buried LLW will be far in the future. If the nature of possible future exposures were knowable, specific measures could be taken to protect future intruders. However, the nature of any future exposure is uncertain. To proceed in the face of this uncertainty, the NRC chose to define surrogate, or hypothetical, IHI exposure scenarios. Protection of the IHI under the conditions defined in these hypothetical exposure scenarios would, by legal definition, be protective of future IHIs.

Defining the characteristics of the surrogate IHI exposure scenarios cannot be accomplished by science alone and requires policy judgments. NRC formalized these policy judgments through the rulemaking process. NRC held a series of four regional workshops, worked with the EPA and public input, developed draft and final Environmental Impact Statements (EIS) (9,10), and corresponding proposed rule (8) and final rule (10 CFR 61). Because the NRC was setting disposal standards for LLW burial sites not yet defined, it chose to protect the IHI by developing a generic set of waste classes. These classes are termed generic, because they were developed independent of disposal site characteristics and are based on a standard set of exposure scenarios defined through the rulemaking process. A similar approach is currently being taken by the EPA to set cleanup standards for federally-owned sites contaminated with radioactive materials (13).

The NRC's generic analysis was based on the following set of beliefs or concerns:

The potential for inadvertent human intrusion is likely. Extensive intrusion activities (such as major apartment construction) are unlikely.

There is a limited time (e.g., 500 years) in which natural and engineered barriers can be expected to last.

As long as the waste is structurally stable (i.e., is recognizable as waste), extensive inadvertent human intrusion is not considered credible. Based on these beliefs, the NRC established performance objectives to protect the MOP from contaminated groundwater and to protect the IHI. Establishment of these performance objectives was complicated and required consideration of five elements:

The length of institutional control;

The time at which the intrusion would occur;

An appropriate dose standard for the IHI;

The probability of the intrusion occurring; and

The specific exposure scenario(s) for the IHI.

Performance objectives are an interrelated "package deal." Altering one of the components may change the overall protectiveness of the rule. A short summary of each of these five objectives is provided below.

Length of Institutional ControlThe NRC selected 100 years. "...the Commission believes that it is not a question of how long the government can survive, but how long they should be expected to provide custodial care." (10, vol. 1, p. 5-27)

The Time at Which the Accidental Intrusion Would OccurNRC made the conservative assumption that knowledge of the site would be lost when the cognizant government control was relinquished (100 years after closure). This loss of knowledge was assumed to be a temporary, bureaucratic error.

An Appropriate Dose Standard for the IHIThe NRC selected 25 millirem (mrem) per year as the dose standard for the MOP and 500 mrem/year as the dose standard for the IHI. Setting an IHI standard 20 times greater the MOP dose standard was justified, because the MOP standard assumes continuous exposure to radionuclides by populations, whereas the IHI would not be routine and would only involve a few people.

The Probability of Intrusion OccurringIn the draft of 10 CFR 61, the NRC assumed that the probability of IHI is one (IHI will occur). The assumption was conservative (i.e., easy to defend) and not costly (i.e., the final 10 CFR 61 allows the shallow land burial of 99% of the commercial LLW (52 FR 5999)).

In response to the draft rule, many reviewers were concerned that the probability of an intrusion occurring was too high (i.e., not reflective of what the future would probably bring), and that the probability of intrusion should be incorporated into the calculation. The NRC had several responses. First, it is very difficult to set a numerical value on the probability that an intrusion event will occur, and to estimate the extensiveness of the intrusion. Second, in the final EIS, the NRC responded by increasing (liberalizing) the concentration-based limits on Class C wastes by an order of magnitude (from 10 to 100 nanocuries per gram) to "eliminate unnecessarily conservative assumptions." Additionally, the IHI is based on reasonably conservative scenarios (discussed below), and finally, the dose standard for the IHI is 20 times higher than that for the MOP. So, rather than attempt to assign a probability to the IHI, the NRC "loosened" other components of the regulatory package.

Specific Exposure ScenariosThe NRC developed three generic waste classes, Classes A, B, and C. The NRC states "[t]he (IHI) events are conservatively assumed to occur based on consideration of typical human

activities. NRC has assumed reasonably conservative (but not overly conservative) actions on the part of the intruder" (10, Vol. 1, p. 4-13). The exposure scenarios included the intruder-construction scenario and the intruder-agriculture scenario. The intruder-construction scenario involves the hypothetical exposure of workman involved in the construction of a house, with a basement, directly on the disposal facility, contacting and dispersing the waste. The intruder-agriculture scenario involves individuals that live in the house constructed in the intruder-construction scenario, who consume food grown in a small on-site garden which contains some of the soil from the basement excavation. These scenarios are described in great detail (cubic yards excavated,percentage of excavated soil used in the garden, etc.) in the Draft EIS, Vol. 4, beginning on page G-57 (9).

For each of the two intruder scenarios, for each of the four hypothetical, regional disposal sites, three sets of assumptions were made, corresponding to the three classes of wastes. Analysis of these exposure scenarios does not consider site-specific factors that might reduce the probability of the intrusion occurring and/or might increase the probability of the waste being recognized as waste.

In summary, 10 CFR 61 regulations apply to the burial of commercial LLWs and define generic classes of wastes where the waste classification is defined to protect the hypothetical IHI. The regulations not take into consideration site-specific burial site characteristics.

DOE Order 5820. 2A

DOE Order 5820.2A sets policy for DOE's management of radioactive wastes. Like the NRC's 10 CFR 61, DOE chose to establish separate dose standards for protection of the MOP and the IHI from buried LLW.

To protect the IHI, the original versions of 5820.2A had a classification system similar to the NRC's Classes A, B, and C, with some exceptions. However, DOE did not adopt the NRC system, because 1) the DOE waste streams were different from the NRC's commercial LLW streams; 2) in some cases, the DOE standard would be inconsistent with the NRC standard; and 3) the NRC standard was generic, not site-specific. Because DOE already knew the locations of its active, LLW disposal sites, DOE chose to require site-specific performance assessments to demonstrate protection of the IHI, as well as the MOP.

The boundary between standardized assumptions and site-specific considerations is not defined in DOE Order 5820.2A. General guidance is provided by the DOE Performance Assessment Task Team (14,15) and the DOE Performance Assessment Peer Review Panel. The Performance Assessment Task team recommends that "standardized" DOE exposure scenarios include (15):

An acute construction scenario and a chronic agricultural (homesteader) scenario involving excavation into disposal units, mixing exhumed waste in an intruder's vegetable garden, and permanent residence in a home on top of disposal units;

An acute discovery scenario and a chronic residential scenario involving an attempted excavation into disposal units, which is assumed to be precluded by the presence of intact engineered barriers, and

An acute drilling scenario and a chronic post-drilling scenario involving drilling a water well through a disposal units and mixing the drilling wastes in an intruder's vegetable garden.

Like the NRC's generic scenarios, DOE Performance Assessments (PAs) have not taken site-specific credit for the probability of IHI and have assumed the probability of intrusion is one. In summary, DOE's Order

5820.2A governs the disposal of DOE radioactive wastes, and the specific performance objectives for disposal of LLW are similar to the NRC's 10 CFR 61, with some important exceptions.

Regulations for Disposal of Spent Nuclear Fuel, HLW, and TRU Wastes

The EPA's 40 CFR 191 sets standards for the management and disposal of spent nuclear fuel, HLW, and TRU radioactive wastes. Subpart B of 40 CFR 191 contains one requirement (assurance) and three performance objectives: protection of the individual, protection of groundwater, and containment.

Protection of the individual and protection of groundwater are both "undisturbed performance" standards and specifically exclude the IHI. The containment standard (40 CFR 191.13) requires the assessment of all events and processes that may disturb the disposal system, including inadvertent human intrusion.

The containment standard is a 10,000-year, probabilistic standard. The containment standard is based on an abstracted ratio between the original inventory of buried TRU radionuclides and the inventory of radionuclides that might move beyond the controlled area (a legally defined term). The containment standard does not consider the dose to the IHI; only the abstracted ratio is important. A repository might pass the containment standard even if the IHI hypothetically received a lethal dose from an "industrial accident."

In a PA for TRU wastes, a "scenario" is a mutually exclusive combination of features, events, and processes, which is very different from an "exposure scenario" as used in an LLW PA. The EPA requires the assessment of site-specific scenarios for disposal sites governed by 40 CFR 191. The EPA recognized there would be uncertainty in assessing features, events, and processes for the next 10,000 years, and offered significant guidance in Appendix B of 40 CFR 191.

" ... inadvertent and intermittent intrusion by exploratory drilling for resources ... can be the most severe intrusion scenario assumed by the implementing agencies...the Agency assumes that the likelihood of such inadvertent and intermittent human drilling need not be taken to be greater than 30 boreholes per square kilometer of repository area per 10,000 years for geologic repositories in proximity to sedimentary formations, or 3 boreholes per square kilometer in other geologic formations."

In summary, 40 CFR 191: 1) applies to TRU, HLW, and spent nuclear fuel wastes; 2) does not specifically attempt to protect an intruder; 3) requires the assessment of the probabilities of all future events and processes; and (4) offers significant EPA guidance concerning the probability of future inadvertent human intrusion.

ALTERNATIVE APPROACH FOR PROTECTION OF INADVERTENT HUMAN INTRUDERS

The previous sections of this paper highlighted the development of the IHI standard. In this section, important assumptions are reviewed, consequences of these assumptions are discussed, and an alternative approach is proposed.

The NRC and the DOE make the generic assumption that inadvertent intrusion will occur. This assumption is predicated on the simultaneous occurrence of at least five events:

- institutional control is lost;
- knowledge of the site's history is lost;
- the disposal site is unrecognizable as a disposal site;
- the waste is indistinguishable from soil; and

the population and well drilling densities are high enough to result in a random drilling into a burial cell.

Despite the conservative nature of these generic assumptions, most DOE LLW meet the IHI criteria. However, some long-lived wastes (e.g., thorium) fail the IHI standard, independent of the location and the depth of burial. For example, for a given disposal configuration, burial of LLW in metropolitan Washington, DC and burial at the NTS result in the same (calculated) dose to the IHI, using the well drilling scenario. The calculated dose using the well drilling scenario is also independent of the depth of burial. Burial under 3 m. of cover and burial under 30 m. of cover results in the same calculated dose to the IHI. Clearly, the probability of intrusion is greater in a large metropolitan area than at the NTS, and burial under 30 m. of soil, as opposed to 3 m., should reduce the probability of intrusion.

For DOE's LLWs that fail the existing IHI standard, independent of the depth of burial, an alternative approach is proposed which assumes that the probability of IHI varies with disposal facility. This alternative approach is within the flexibility allowed by DOE Order 5820.2A and takes credit for the NTS's arid environment and the fact that wastes will be recognizable for long time periods.

Alternative Approach

The alternative approach is based on several premises. The first is that protection of the IHI is an appropriate goal for the burial of LLW. The approach also accepts the IHI standard in DOE's 5820.2A as appropriate for most LLW. It presumes that LLW with characteristics of HLW (wastes that fail the IHI exposure scenarios, independent of the depth of burial) require an alternative approach, and finally, that the probability of IHI is different for different locations.

The alternative approach continues using the IHI standard found in DOE Order 5820.2A, as interpreted by Wood et. al. (15) and the DOE Peer Review Panel. For wastes that fail the IHI standard, independent of the depth of burial, the "expected dose" should be calculated. The expected dose is the product of the consequence of the intrusion times the probability of the intrusion. For example, if the consequence of intrusion is calculated to be 125 mrem/year chronic dose and the probability of intrusion is assessed at 0.65, the expected chronic dose to the IHI is 81 mrem/year. All aspects of calculating the consequence of human intrusion are identical to calculating the consequence under DOE 5820.2A; the only new element is the derivation of the probability of intrusion.

The expected dose could then be compared to (a) the IHI dose standard (100 mrem/year chronic and 500 mrem acute), or to (b) the MOP dose standard of 25 mrem/year. To compare the IHI expected dose to the 25 mrem/year MOP standard would be inconsistent with the existing DOE Order. However, there is concern that comparing the expected dose to the 100 mrem/year standard may not be appropriate, because the 100 mrem standard was set higher than the 25 mrem/year standard to compensate for the intrusion being "...not...routine" and involving only a few people. The higher IHI standard was set to partially compensate for the low probability of occurrence. With the formal inclusion of the probability of inadvertent intrusion, the higher dose standard may not be appropriate. This portion of the alternative approach is not currently resolved.

The proposed approach of assessing the expected dose to the IHI will allow the inclusion of important, site-specific characteristics in the decision making process. For burial at Area 5 of the NTS, these include:

Consideration of the very slow rate of waste decomposition (the long time required for the wastes to become unrecognizable as wastes) caused by the aridity of the site, which receives approximately 10 cm of precipitation annually;

Consideration of the depth to the water table, requiring the drilling of water wells over 230 m. deep;

Consideration of the past use of the NTS for testing nuclear weapons (knowledge of the past use of the NTS will be very difficult to lose because of the hundreds of large craters which will probably survive tens of millennia), and

Consideration of the very low population densities (and possibly low future population densities).

The question is how to derive a probability of intrusions which considers the site-specific characteristics of the disposal site. The NRC stated that it is very difficult to set a numerical value on the probability that an intrusion event will occur and to estimate the extensiveness of the intrusion. However, to develop 10 CFR 61, the NRC did estimate the extensiveness of intrusion by developing the standard exposure scenarios. This paper advocates using those same long-standing exposure scenarios, coupled with the site-specific assessment of the probability of occurrence, which is addressed in the following sections.

Probability

The use of this alternative approach requires assessing the site-specific probability of an individual inadvertently drilling a water well through buried LLW. Of importance is the definition of probability. There are two schools of thought concerning the definition of probability (6). The frequentists believe that probability is the result of repetitive experiments or observations. In this paper, we call this frequency. Subjectivists believe that probability is a state of knowledge or state of confidence. In this paper, we call this probability.

When there are insufficient data, the subjective probability is the only probability. Often, a numerical value can be assigned to this state of belief, e.g., "there's a 75% probability that inflation will return to double digits by the year 2000." Using this definition, probability is a "soft" number and may vary with the individual.

The assessment of probability is a key component of risk analysis, where risk is typically defined as RISK = PROBABILITY x CONSEQUENCE. Mathematically, RISK can also be thought of as the "expected value." With this definition of probability, the next question is how to derive a probability of inadvertently drilling at a specific location at the NTS over the next 10,000 years.

Determining the Probability of IHIs

There are a number of ways to assess probability (where probability is a state of knowledge or reasoned belief). A formal, defensible approach is the expert elicitation process. The process typically requires a trained facilitator, panelists (experts and/or stakeholders), some preliminary exchange of information, the formal elicitation process, and follow up activities. Bonano et al. (2) discusses many of the advantages and disadvantages of the formal elicitation process. The advantages include improved accuracy of judgment, well-thought-through design of elicitation, consistency of procedures, scrutability, communication, and

fewer delays. The cited disadvantages can include high cost, time, and flexibility.

There are seven standardized steps for a formal probabilistic elicitation. They are:

- Development of an issue statement (define the event of concern);
- Panel identification and selection;
- Presentation of the issue statement and process definition;
- Organization of the panel;
- Review of literature pertinent to the elicitation;
- Elicitation; and
- Documentation of elicitation.

The event would be divided into components and the panelists would assign probabilities to each component. For example, the issue statement might be "What is the probability of an individual inadvertently drilling a water well through a buried LLW cell at the NTS's Area 5?" The event could be divided into components such as:

- the probability that institutional control will be lost;
- the probability that knowledge of the past use of the NTS will be lost;
- the probability that wastes will become unrecognizable as wastes;
- the probability of drilling a water well in Area 5 of the NTS; and
- the probability of drilling though a buried waste cell.

Panelists would be asked to provide the probability of each component occurring and the reasoning for each numerical estimation.

The elicitation process is subjective. However, the assessment of probability is used daily for decisions of far greater consequence than assessing the probability of an IHI. For example, medical opinions typically employ probabilities, and U.S. economic policy (e.g., to raise or lower the prime interest rate) is based on indices and subjective probability.

SUMMARY

For the burial of LLW, we want to keep the wastes from getting to people and we want to keep people from inadvertently getting to the wastes (i.e., to protect the IHI). This paper addresses protection of the IHI. If the future could be anticipated, current society could define the specific measures to protect future intruders. However, the future is uncertain and society has established that demonstrating compliance using specific exposure scenarios is, by definition, protective of the IHI. For buried LLW wastes, the probability of inadvertent intrusion has been assumed to be one: intrusion will occur. This paper proposes incorporation of the site-specific probability of intrusion. For burial of LLW at the NTS, incorporation of this probability will allow the consideration of favorable site characteristics such as aridity, the slow decay of wastes, the great depth to water, and (possible) low future population densities. This proposed alternative is identical to the existing interpretation of DOE Order 5820.2A, except that the probability of intrusion is included as a site-specific characteristic.

ABSTRACT
The team of the Harry Reid Center for Environmental Studies (HRC) at the University of Nevada Las Vegas and the firm of E. J. Bentz & Associates (EJB&A) of Springfield, VA are conducting a risk assessment and risk management evaluation of environmental management activities in Nevada. The NRAMP is part of a national effort by the DOE Office of Science and Technology Policy (EM-52) to develop new sources of information and approaches with public involvement to risk assessment, risk management, risk communication and public outreach as these objectives relate to the ecological and human health effects of radioactive and hazardous waste management and site remediation activities. Implementation of this process has not yet been demonstrated at any site.
This program is currently eight months into a 21 month schedule. Conclusions to date are primarily based on the development of a public working group, literature surveys, collection of DOE national and site-specific data and a state-wide public opinion survey. Members of the public have been successfully organized into a "working group" to augment public involvement in coordination with the NTS Community Advisory Board. The scope of NRAMP activities differs from past DOE risk assessments in Nevada by integrating risks from all major contaminants, consideration of geologic time periods and by incorporating the project goal of "making a difference".

INTRODUCTION
The team of the Harry Reid Center for Environmental Studies (HRC) at the University of Nevada Las Vegas and the firm of E. J. Bentz & Associates (EJB&A) of Springfield, VA was awarded in April 1995 a cooperative agreement by the US Department of Energy Environmental Management Program Office of Science and Technology Policy (EM-52) to conduct a $2.8 million, 21 month risk assessment and risk management evaluation of environmental management activities in Nevada and to transfer this experience to other sites. The NRAMP is part of a national effort by the DOE to develop new sources of information and approaches with public involvement to risk assessment, risk management, risk communication and public outreach as these objectives relate to the ecological and human health effects of radioactive and hazardous waste management and site remediation activities.
Specific objectives of the NRAMP are to be accomplished by; 1) Working closely with stakeholders to develop credible independent assessments of risks at radioactive and hazardous waste sites in Nevada and other states; 2) Evaluating and prioritizing options in Nevada for waste site restoration and future land use from the perspective of stakeholders, and; 3) Transferring risk assessment/management results and methods from Nevada to stakeholder groups in other states as well as utilizing, from

other states, appropriate methods, tools and results for the evaluation of Nevada sites.

APPROACH

Specific tasks of the NRAMP implement a risk assessment process with public involvement as described in the National Research Council's report, Building Consensus Through Risk Assessment and Management of the Department of Energy's Environmental Remediation Program. Implementation of this process has not yet been demonstrated at any site. This process, if successful, holds great promise to reaching clearly defined, defendable and lasting agreements between the DOE, regulatory agencies and the general public on appropriate and sustainable strategies for site restoration, future site operations and waste management.

DOE operations in Nevada are an appropriate place for the development of risk analysis and risk management techniques because of the timing of this program and ongoing DOE needs for the NTS. NRAMP is timely to EM activities in Nevada because:

The NRAMP activities will generate greater public interest in ongoing NEPA activities in Nevada

The Community Advisory Board (EM's Site Specific Advisory Board in Nevada) is developing in Nevada and can benefit from access to the independent technical resources available through the NRAMP

There has been limited public involvement in risk-related work conducted in Nevada to date

The NTS is a multi-program site. The Nevada Test Site will continue to play an important role for the US DOE in the completion of defense, environmental and alternative energy missions

The Congress and the DOE have advocated the development and use of a risk-based programmatic approach to achieve human health goals for EM activities in a cost effective manner.

The NRAMP is demonstrating the application of risk assessment and risk management techniques with direct stakeholder involvement. The methods to be applied under this program are graphical to facilitate direct active participation of stakeholders in the application of the risk assessment model, assumptions and data. Value-impact assessment techniques developed by the US Nuclear Regulatory Commission will be used in the NRAMP to systematically consider risk, cost and judgmental factors in the stakeholder identification and prioritization of options for site restoration.

Five principle means will be used to accomplish the objectives of developing credible, broadly-accepted risk assessments and improving decision-making processes for Nevada and other states such that they reflect the priorities and concerns of all stakeholders:

First, using the principles of consensus building, develop a Working Group consisting of stakeholders to work towards a consensual agreement.

Second, supplement the meetings of the Working Group with systematic and extensive opportunities for stakeholder participation in developing a detailed scope of work and conducting the risk assessment/management evaluations.

Third, development of quality products through the adaptation of risk management, value/impact processes and technical computer tools.

Fourth, include extensive independent technical reviews.

Fifth, collaborate with other national sites to transfer results and include applicable results from other sites in the NRAMP.

RESULTS TO DATE

This program is currently ten months into an 21 month schedule. Task 1, Development of a working group has been completed. The NRAMP working group consists of 70 individuals who began meeting in May 1995 to learn about the Nevada Test Site and identify issues for the NRAMP team. The NRAMP team also established relationships with the NTS Community Advisory Board and the Nevada Operations Office. Results of these discussions and relationships included the development of a risk assessment scoping matrix which is the basis for the development of the technical portion of the NRAMP, a state-wide public opinion poll and a summary of risk related activities by site-specific advisory boards at all DOE sites. A work plan for the development of a preliminary risk assessment of DOE sites in Nevada is under development.

NRAMP Working Group Development

Primary methodologies used to develop the NRAMP working group included working closely with the Nevada Test Site Community Advisory Board (CAB) - whose composition carefully mirrors public demographics, local governments, and involved agencies - and forming a Working Group with much broader public involvement to ensure inclusion of all stakeholders. The NRAMP Working Group has several responsibilities: providing a list of their priorities for future NTS land uses, reviewing this Work Plan to ensure stakeholder issues have been appropriately included, providing input and reaction to Preliminary Risk Assessment data, and accepting or rejecting the conclusions of the Baseline Risk Assessment and prioritization of site restoration activities. By analyzing insights gained from interactions with this Working Group, the NRAMP team will construct a stakeholder model for use at similar DOE sites across the nation.

Stakeholder identification was Milestone I for the NRAMP and several methods were applied to reach it. The project was first presented to the NTS CAB. Although the CAB was initially concerned about duplication of effort, it was strongly swayed toward cooperation by the concept that NRAMP provided an independent research team to accomplish studies the CAB did not have resources to complete. As a result, two members were appointed to attend the Working Group meetings and to coordinate CAB and NRAMP activities. This kind of cooperation with existing groups is an important component of the developing interaction model.

Using the CAB mailing list and a similar list from DOE/NV Environmental Management, letters of personal invitation were mailed to persons who had shown previous interest in the NTS. General public announcements were aired on local radio and television stations, and large advertisements were run in local newspapers. Everyone who responded was included in the NRAMP Working Group, and no attempt was made at representative demographic sampling.

However, at the same time, a statewide telephone survey* was conducted to validate Working Group input by comparing it with general Nevada interests and attitudes toward the NTS. The survey questions also provided insight into the general level of public knowledge about the NTS and its possible future uses. By design, the survey deliberately over sampled Nevada's rural areas. Four hundred miles separate the state's two major population centers of Las Vegas and Reno/Carson City. Nye County, which includes most of the NTS, lies between these two centers and is almost totally rural in nature. The NRAMP Survey collected 400 opinions from the Las Vegas area, 400 from Reno/Carson City, and 400 from rural Nevada.

Survey results show that the public perceives very high risk from transportation of high-level radioactive waste (71.9%), storage of radioactive waste (67.7%), transportation of hazardous waste (60.8%), worker exposure to radioactivity (55.3%), groundwater contamination (54.8%), ecosystem damage as a result of soil contamination (53.3%), atmospheric releases of radioactive materials (53.0%), and, in general, to their personal safety and well-being (52.1%). The same public supports the following future uses in descending order of popularity: alternative energy research and development (79.6%), environmental restoration research (78.2%), nuclear emergency response and safety technology development (65.6%), weapons disassembly (52.9%), hazardous waste management (50.5%), nuclear materials management and technology development (49.5%), open air nuclear age museum (48.5%), maintenance of current uses (33.4%), return to public land inventory (29.1%), and nuclear fuel storage (21.3%).

Initial surveys among the Working Group show generally similar results; however, survey issues are currently being studied by the group and interesting comparisons will be drawn at the conclusion of the NRAMP education effort (see below).

Working Group Interactions

Because of the state's geography, two separate groups have been formed: the Las Vegas or Southern Working Group and the Reno or Northern Working Group. (A third group, the Nye County Working Group, is still being organized.) The Southern Working Group met for the first time in May 1995 and collected a good representation of 45 local citizens, agency representatives, and pre-existing groups who appeared willing to work together in learning and using the risk-based process. Seven persons attended the first meeting of the Northern Working Group one week later in June. Attendees at both meetings were interested in knowing why they should devote time and effort to still another public meeting, questioned how their input would be used, and wondered whether they could truly have a significant impact on DOE decisions.

To answer these questions, the NRAMP team chose a meeting model based on three focus areas: 1) response to recorded stakeholder issues from previous meetings, 2) educational presentations, and 3) group input activities. As an example, the second meeting was planned to begin with an education segment, a presentation on plutonium contaminated soils. A response to stakeholders was prepared to address group issues such as reasons for supporting the NRAMP and its opportunities for input. And, to close, an input activity, a group reading and revision of the public opinion survey, was conducted.

Stakeholder issues identified in the June meetings included plutonium contamination inside and outside the NTS, the extent of environmental damage, mutations in animals, the State's cancer rates, contaminated ground water, the Ruby Valley Treaty, and the DOE decision not to attempt clean-up of underground contamination. In addition, both groups requested more information about the NRAMP, including its time line and its procedures.

In an attempt to bring the two Working Groups together, the NRAMP team moved to videoconferencing for the third, or August, meeting. The technology proved very effective and provided a venue for presenting the NRAMP Risk Assessment Matrix, the near-term opportunities for Working Group input to DOE, and a review of all issues raised by the group, as well as the NRAMP responses to those issues.

The Risk Assessment Matrix identifies five general categories of hazards (underground contamination, surface contamination, industrial sites, waste disposal, and transportation-related issues), maps them across their possible receptors based on land use, determines the time period under consideration, identifies subjects at risk, and explores the trade-offs in costs and opportunities. The NRAMP will provide stakeholders with an in-depth look at the identified categories and, in the Baseline Risk Assessment, ask the Working Group to prioritize future land uses based on what has been learned.

At the same time, the Working Group will provide input to DOE documents currently in preparation and on DOE actions in progress such as the Federal Facility Agreement and Consent Order, the NTS Resource Management Plan, the EM Risk Report, the Waste Management PEIS, the NTS EIS, and the Federal Facility Compliance Act.

The NRAMP is carefully tracking and responding to all issues raised in Working Group meetings. Major issues include

Short- and long-term risks to the public and the environment from above-ground test residuals (Response: include in risk assessment)

Describe the various forms of potential waste for storage (Response: schedule for Working Group presentation)

Land ownership is an open dispute with Native Americans (Response: acknowledge in NRAMP reports and document input)

The NTS is a potential museum to the atomic age (Response: include in list of future land uses)

Cultural resources should be considered in the risk assessment (Response: develop maps of NTS locations and review current status during risk assessment)

NRAMP should provide input to the NTS EIS, Resource Management Plan and Compliance Agreement (Response: include in risk assessment, write letters requesting formal participation, invite presentations by DOE officials, and develop group comments in writing)

A finding of "no risk" based on current low population density is unacceptable (Response: include future potential populations and workers in the risk assessment)

Consider cumulative risks from storage, waste management, and past testing (Response: include in Matrix to extent possible)

The working group will decide about decision making and facilitation processes(Response: allow groups to develop most effective process for individual circumstances)

Consider the effect of teleconferencing on group decision making (Response: encourage group to experiment with new technologies)

Include more rural and Native American representatives (Response: hold Nye County meeting, create new press releases, present Native American contributions included in NTS EIS)

Working Group should control of NRAMP agenda (Response: agree)

Several general problems remain to be overcome. Some group members are still distrustful of NRAMP motivations and purposes because of project links to DOE. Many are still struggling to grasp the whole NRAMP concept and exactly how it can make a difference. Frictions and differences in opinion and interest exist between working group members. However, several NRAMP successes with group interactions can be plainly seen even at this point. A dedicated group of stakeholders has been formed without resort to the lengthy and complicated "keystone" process. Interesting uses of technology have been applied: the telephone poll has helped to

compensate for the vast distances of a sparsely populated state, and videoconferencing has begun to coordinate the efforts of two geographically separated groups. In addition, the Working Group has committed itself to an action-oriented approach which appears more aggressive than that of site advisory boards in general. The NRAMP Working Group is clearly geared toward making a difference.

Working Group Education

The NRAMP team believes that stakeholder input must go hand-in-hand with education, and team efforts will include training in group processes, instruction in basic scientific data collection and analysis, and information about current risk management theory and practice.

In an effort to learn from experience with other stakeholders, the NRAMP Team Member, E. J. Bentz and Associates, Inc., conducted a study of existing DOE advisory boards. Their report, Risk-Related Activities Currently Being Performed by DOE Site Specific Citizens' Advisory Boards, provides narrative profiles of advisory boards at Fernald, Hanford, Idaho National Engineering Laboratory, Monticello, Pantex, Rocky Flats, and Savannah River. Specifically, it addresses each site's tools for consensus building and communication, future land use options, management and remediation options, risk approaches/methodologies, and perceived cost benefits. Data from the report are being used to suggest new policies and approaches for NRAMP participants. The Working Group's most pressing need in the process area is decision-making, and the facilitator will develop several alternatives for selection by the group.

The crucial point to be made above and beyond all of these activities is that forging "groups" into "teams" appears to be the pivotal component for success with stakeholders. The Working Group need to develop enough confidence in themselves and in the NRAMP team to work through difficult, but necessary, decisions. They also need enough information about risk management to judge the efforts of the NRAMP team and to understand the basics of the scientific data which underlie the risk management process. One of many insights gleaned from the NRAMP process is that formation of such stakeholder teams should begin long before attempting consensus on such complex choices as future land uses of the NTS.

Working Group Participation

Successful stakeholder participation is occurring through the Working Group in several identifiable areas. Comments in behalf of the group have been submitted to the EM-6 Risk Report to Congress and the group has requested information about or inclusion in NTS activities such as the NTS EIS, the Resource Management Plan, the Federal Facility Agreement and Consent Order, the Yucca Mountain Project, and the Nevada Department of Environmental Protection. Areas of study have been identified, and a matrix for understanding the risk process has been prepared.

Although the Working Group have not yet fully formulated their position on future land uses, they will review the general modeling procedures described in this Work Plan. The NRAMP team intends to continue consensus building while conducting the Preliminary Risk Assessment. The Working Group will study the issues being modeled, and it is hoped that stakeholders will be ready to examine and state their priorities in relation to the models of both the Preliminary and the Baseline Risk Assessments.

Specifically, then, stakeholders will be expected to play the following important roles through participation in the Working Group:

1. input to major working documents

2. identification of future NTS land uses 3. acceptance or rejection of the preliminary integrated risk analysis
4. addition of specific areas of concern for concentrated modeling
5. evaluation of cost effectiveness of alternatives based on the Baseline Risk Assessment
6. endorsement of specific future land uses with full knowledge of risk and cost analysis.

Preliminary Risk Assessment Work Plan

The Preliminary Risk Assessment (PRA) that is currently under development is intended to be a screening assessment of present and future risks to the public, workers and the environment from existing, and anticipated environmental management program activities in Nevada. This plan is currently under review by the NRAMP Working Group and the NRAMP peer review team. The PRA has the primary objective to "identify the holes" in understanding the NTS relative to the scope of a risk assessment discussed with the working group, to facilitate further discussions with the working group on acceptable risk levels and to obtain comment from the NRAMP peer review group on the general approach to the assessment of NTS risks. The PRA will form the basis for evaluating the value of planned site remediation activities as part of the baseline risk assessment, development of additional risk management concepts during the risk management task, and the identification of data and model needs to better understand and manage risks from DOE activities in Nevada.

MEETING NEW AIR STANDARDS WITH A VOLATILE ORGANIC TREATMENT TRAIN

John Bowers
David Dennison
Glenn May*
Lawrence Livermore National Laboratory
Hazardous Waste Management Division
P.O. Box 808, L-621 Livermore, CA 94550

ABSTRACT

The U.S. Environmental Protection Agency (EPA) issued the second phase of the organic air emission standards for hazardous waste treatment, storage, and disposal facilities (TSDFs) and hazardous waste generators in December 1994. These standards (referred to as the Subpart CC standards) are designed to further reduce organic air emissions from hazardous waste management activities. Lawrence Livermore National Laboratory (LLNL) is evaluating a modification of its existing Waste Water Treatment Tank Farm (hereafter called Tank Farm) with a volatile organic removal and destruction treatment train in order to comply with these new air standards.

LLNL's Tank Farm consists of six, 7,000-L open-top tanks used to store and treat aqueous low-level radioactive, mixed, and hazardous waste. The

aqueous waste has elevated volatile organic constituent (VOC) concentrations while stored and treated in the tanks. According to the Subpart CC standards, tanks handling waste with similar VOC concentrations must be retrofitted with a cover and an emission control device for cover openings; the installed emission control devices must achieve at least a 95% reduction in the total organic content of the vented gas stream. LLNL concluded that the removal and destruction of VOCs from waste before they enter the Tank Farm would demonstrate compliance with the Subpart CC standards more effectively and be more cost effective than the installation of air emission control devices on the Tank Farm. LLNL has designed this removal and destruction technique to consist of an air stripper, high-efficiency particulate air (HEPA) filter, catalytic oxidizer, scrubber, and mist eliminator.

INTRODUCTION

LLNL operates a waste water treatment tank farm for the treatment of aqueous low-level radioactive, mixed and hazardous waste. Federal air emission standards promulgated under RCRA will restrict LLNL from treating waste exceeding 100 mg/kg VOC concentration in the open-top design of the tank farm. LLNL has evaluated several compliance options and selected a preferred option in order to continue treating its aqueous waste streams.

LEGAL REQUIREMENTS

The Resource Conservation and Recovery Act (RCRA) directs the EPA to promulgate regulations for monitoring and controlling air emissions from TSDFs as may be necessary to protect human health and the environment. Two phases of the congressional directive are complete. The first phase includes the promulgation of standards that control organic emissions vented from certain hazardous waste treatment processes (i.e., distillation, fractionation, thin-film evaporation, solvent extraction, steam stripping, and air stripping) as well as from leaks in certain ancillary equipment used for hazardous waste management processes. The second phase includes the promulgation of emission standards designed to further reduce organic emissions from hazardous waste management activities associated with tanks, surface impoundments, containers, and miscellaneous units operated at TSDFs. This second phase is referred to by EPA as the Subpart CC standards.

In reference to tanks managing hazardous waste, the Subpart CC standards apply when the waste exceeds a VOC concentration of 100 mg/kg; the VOC concentration of a waste is determined at the point of waste origination. The blending of VOC-ladened wastes with other aqueous wastes to lower the VOC concentration is not permitted as a means to avoid subjection to the standards. If a tank manages waste exceeding the regulatory VOC concentration, the regulations require the installation and operation of one of the following air emission control systems on the tank:

- A cover that is connected through a closed-vent system to a control device
- A fixed-roof type cover with an internal floating roof
- An external floating roof
- A pressure system that allows the tanks to operate as a closed system.

In specific cases, the Subpart CC standards allow the use of a fixed-roof-type cover without additional controls. The specific cases include tanks which do none of the following:

- Mix, stir, agitate, or circulate waste using a process that results in splashing, frothing, or visible turbulent flow on the waste surface

Heat the waste except to prevent the waste from freezing or to maintain adequate waste flow conditions

Treat waste using a waste stabilization process or a process that produces an the exothermic reaction

Exceed a defined maximum organic vapor pressure.

The type of air emission control device incorporated into a tank design modification is not specified by the performance-based standards of Subpart CC. TSDFs have the flexibility of choosing an air emission control device best suited for the characteristics of the organic emissions. However, the installed air emission control device must achieve at least a 95% reduction in the total organic content of the vapor stream vented to the device or, in the case of an enclosed combustion device, a reduction of the total organic content of the vapor stream to a level less than or equal to 20 mg/kg on a dry basis corrected to 3% oxygen.

The Subpart CC standards provide an alternative to the installation and operation of air emission control systems. TSDFs are allowed to remove or destroy organics in the waste by a treatment process that significantly reduces the volatile organic concentration so that storage and treatment units operated downstream of the treatment process in the waste management sequence do not have to use air emission controls. This alternative does not require the owner or operator to perform volatile organic concentration waste determinations for the hazardous wastes prior to treatment, yet still accommodates the blending of wastes that have different volatile organic concentrations.

The Subpart CC standards are temporarily deferred for systems solely managing mixed wastes (waste that contains both hazardous waste and source, special nuclear, or byproduct material subject to the Atomic Energy Act of 1954). EPA provided the deferral because the air emission control equipment required by the Subpart CC standards may conflict with certain radioactive waste management requirements under the Nuclear Regulatory Commission. The Subpart CC standards will be effective in December of 1995.

TANK FARM

LLNL's onsite activities generate a variety of aqueous hazardous and mixed waste. Many of the waste streams contain VOCs such as tetrachloroethylene (PCE), methyl chloroform, and methylene chloride. The organic concentration of each waste stream ranges between 0 mg/kg and 10,000 mg/kg. The VOC-containing waste streams are generated at a rate of approximately 586,000 L/y.

The aqueous waste streams are initially accumulated at the point of generation in various size containers ranging from 19 L carboys to 3785 L portable tanks. The containers are transported from the onsite activities to the treatment facility and placed in storage as destined for treatment. Treatment of the waste begins with the transfer of waste from a select number of containers in a predetermined sequence to one of the tanks of the Tank Farm. The sequence of blending is established to moderate reactions and dissipate heat of reactions. The blended waste within a tank is subsequently treated using one or more of several different treatment techniques. The treatment techniques are selected to achieve a desired treatment objective. The types of treatments potentially performed on a batch of blended waste within a tank include:

Neutralization/pH adjustment

Oxidation/reduction

Cyanide destruction
Precipitation
Chelation/flocculation
Ion exchange
Adsorption
Separation.

Treated waste may be shipped offsite for disposal or discharged to the City of Livermore Water Reclamation Plant via the sanitary sewer in accordance with established discharge limits.

The Tank Farm consists of six, 7,000-L tanks with ancillary equipment such as piping and pumps. Piping system of the six tanks allow for the transfer of wastes to and from each tank, to and from a filtration system, and to and from portable tanks and containers. Each tank is a vertical, open-top, cylindrical tank. A roof, constructed of metal sheeting on steel supports, partially protects the tanks from precipitation and weathering. The tanks are equipped with high-level alarms, high-level interlocks, pH probe, treatment reagent lines, and mixers. A diagram of a 7,000-L tank is presented in Fig. 1.

Prior to the blending process, wastes to be treated in the Tank Farm have average volatile organic concentrations equal to or greater than 100 mg/kg. The treatment methods employed in LLNL's Tank Farm create exothermic reactions and prevent LLNL from qualifying for the special case variance. Consequently, the Subpart CC standards will require either the open-top design of the tanks in the Tank Farm to be modified or a change in LLNL's hazardous waste management operations.

The simplest and least costly modification of the Tank Farm design to comply with the Subpart CC standards is the installation of a fixed-roof cover connected through a closed-vent system to an air emission control device. The organic emissions from the Tank Farm result from the evaporation of VOCs at the liquid surface of the waste and their dispersal into the atmosphere by displacement during tank filling, diffusion, or wind. The rate of the organic emissions depends on the physical and chemical characteristics of the waste, temperature of the waste, tank design, tank condition, and operational characteristics. Although mixing and exothermic reactions within the tanks increase mass transfer rates, the blending of the waste reduces both the VOC concentrations and the overall organic emission rate while the waste remains in the tank. The low organic emission rates create difficulty in the identification of an air emission control device for LLNL's Tank Farm that achieves the Subpart CC performance-based standards. The Subpart CC standards suggest two air emission control systems to achieve the performance standards: adsorption systems and thermal destruction. Adsorption systems work best on air emissions that are below the economic threshold for thermal oxidation. Adsorption systems include adsorbents that may be either polar or nonpolar. Polar sorbents have a high affinity for water vapor and are ineffective in air streams that have any appreciable humidity, but most air streams associated with waste treatment are humid. Nonpolar adsorption, like activated carbon, is effective at removing all but the most volatile compounds associated with waste treatment systems. Adsorption capacity of an adsorbent is directly proportional to the concentration of the adsorbate. Thus, all else being equal, more adsorbent is required to remove a lower concentration contaminant with equal efficiency than to remove the same contaminant at higher concentrations. EPA suggests that the minimum air stream VOC

concentration for carbon adsorption to economically achieve a 95% removal efficiency of VOCs is 1,000 mg/kg by volume.
Fig. 1
If LLNL were to use carbon adsorption technology on a Tank Farm design modification to achieve the performance-based standards, the fixed-roof cover would require an actively vented system connection to the carbon adsorption air emission control device. A passively vented system on the Tank Farm may maintain low organic emissions in the air stream, but the amount of carbon necessary to meet the performance-based standard would be impractical. However even with an actively vented system, it is difficult to achieve the 95% removal efficiency using a carbon adsorption system. Adsorbers that operate periodically or where the concentration of the contaminate varies greatly, such as in batch operations with varying waste streams, can be quickly impaired. In addition, an actively vented system on a tank containing aqueous waste will create a high humidity gas stream. Excessive humidity in the gas stream can reduce the effectiveness of adsorption systems. Gas streams close to saturation can cause capillary condensation, which occupies potential adsorption sites and blocks access to the carbon pores.
Thermal destruction of vented organics can achieve the Subpart CC performance standards using flares or other thermal oxidation units. However, LLNL has had extreme difficulty in obtaining a permit with the State of California for direct-fire or flame techniques. LLNL speculates that this difficulty is a result of poor public opinion on these techniques. Use of other thermal oxidation units as air emission control devices are economically impractical for the low organic emission rates associated with LLNL's Tank Farm operations.
The difficulties in using available technologies for air control emission devices on the tank system forced LLNL to evaluate the alternative provided by the Subpart CC. In particular, LLNL investigated the removal of VOCs from the aqueous wastes before the wastes are introduced into the Tank Farm. LLNL's preferred option to remove VOCs from the waste is air stripping, but the volatile organic removal or destruction method following the air stripping poses similar problems for an air emission control device installed with a fixed-roof cover.
Using effective air stripping of LLNL's aqueous wastes, the worst case VOC concentrations (typically methyl chloroform, PCE, and methylene chloride) in the gas stream exiting the air stripper will be 1-10% organics. Condensation following air stripping has potential rewards, and LLNL will evaluate them further; however, the condensed organics will require treatment prior to disposal. Because many of the wastes have radionuclides, solvent recovery was not considered. Carbon adsorption systems are prohibitively expensive for removal of VOCs in the gas stream from the air stripper because of the high organic concentrations. LLNL did not evaluate direct-fired or flame destruction techniques because of the difficulty in obtaining a permit with the State of California these techniques.
The methods LLNL investigated to destroy the VOCs in the gas stream exiting the air stripper included ozonation and catalytic oxidation. Ozonation uses ozone to oxidize organic contaminants in two ways:

- By direct oxidation with ozone gas
- By the generation of free radical intermediates, such as hydroxyl radicals.

Contaminants most amenable to direct oxidation by ozone include aromatics such as polycyclic aromatic hydrocarbons and chlorinated ethenes. The major concerns with using ozone are that it is not good with low-molecular-weight chlorinated organics and the concentrations of the gas stream expected by LLNL are extremely high for cost-effective systems. Catalytic oxidation is well suited for the destruction of VOCs in vent gas streams, especially when the hydrocarbon concentrations are 25% or less of their lower explosive limit with flow rates ranging from 14 standard m3/min to over 2,800 m3/min. Catalytic oxidation systems are normally designed for destruction efficiencies that range from 90-98%. The destruction efficiency for chlorinated hydrocarbons is typically quite low; however, recent catalyst developments have produced products that can effectively destroy chlorinated hydrocarbons. For example, in a joint venture of King, Buck & Associates Inc. (KBA) in San Diego, California and Catalytic Combustion Corp. in Bloomer, Wisconsin, a catalytic oxidizer system demonstrated the capability of treating 5.7 m3/min of chlorinated VOCs at a concentration of more than 2,000 mg/kg.

Proposed Modifications

Based on the potential of catalytic oxidation, LLNL's selected preferred option for compliance with the Subpart CC standards includes an air stripper followed by nonflame catalytic oxidation using a halocarbon destruction catalyst as a removal and destruction system. The specific design of the system consists of an air stripper followed by a heat exchanger, preheater, catalytic oxidizer, and scrubber. A diagram of the unit is provided in Fig. 2.

The catalytic oxidizer system will be operated on a batch basis as needed. Typical waste management activities will require the system to operate six hours per week. As waste streams are transported from the onsite activities in various containers, the containers will be incorporated into a blending sequence. The blending sequence will be developed to optimize the volatile content of a blended waste stream for air stripping. In addition, the blending sequence will be designed to limit reactions and dissipate reaction heat.

According to the determined blending sequence, up to four containers will be emptied using a vacuum pump. The pumped waste will be blended via a pipe manifold system. The blended waste stream will then be piped to an air stripper at controlled flow rates up to 57 L/min based on the volatile content of the blended waste stream. As containers are emptied, they will be replaced manually with containers containing waste according to the blending sequence schedule.

The air stripper will be designed to remove at least 95% of the VOC content from the blended waste streams. An air stream of approximately 14 m3/min will strip the VOCs from the blended waste streams. The stripped aqueous waste stream will be pumped to a 4,200-L portable tank with a condenser installed on the vent line or to one of the open-top tanks of the Tank Farm. The actual location to which the aqueous waste stream will be pumped will depend on the precautions necessary to ascertain that the system has adequately stripped the blended aqueous waste stream. The stripped aqueous waste stream will have a concentration less than 50 mg/kg in order to comply with the Subpart CC standards.

Fig. 2

The VOC concentration of the gas stream exiting the air stripper will range between 300-50,000 mg/kg. The gas stream will be directed to a duct heater to elevate the temperature of the air stream from ambient

temperature to 38C. The gas stream will then enter a blower followed by a HEPA filter to remove radionuclides associated with the mixed wastes. After filtration, the gas stream will enter a hot catalytic oxidizer to oxidize the organics. The catalytic oxidizer will contain approximately 0.28 m3 (10 ft3) of a halogenated hydrocarbon destruction catalyst capable of achieving greater than 99% destruction efficiency. The air stream exiting the oxidizer, typically at a temperature between 370-540C, will then be quenched and neutralized using a sodium carbonate solution in a quench column. The quench column will scrub the acid gas generated during oxidation. The neutralizing solution can be recycled or treated in LLNL's Tank Farm. The gas exiting the quench column will be demisted and exhausted to the atmosphere.

The capital cost of the system is approximately $350,000. Electrical power requirements are largely required for the pumps, duct heater, and hot catalytic oxidizer. The power costs will be approximately $15 per hour of operation. The catalyst will have to be replaced, but since the system is only operated periodically, catalyst replacement should only be necessary once every six years at an approximate cost of $85,000.

STATUS AND PLANS

The VOC removal and destruction system will require permitting under RCRA and the Clean Air Act. Regulators from both the Bay Area Air Quality Management District and California Department of Toxic Substances Control support catalytic oxidizer systems which are not direct fired. Based on preliminary discussions, the regulatory agencies support LLNL preferred option for compliance with the Subpart CC standards.

LLNL is currently completing a specification package on the catalytic oxidizer system design. The system will not be on-line before December, 1995; therefore, an implementation schedule for installation of the equipment will be developed and placed in the facility operating records in order to comply with the Subpart CC standards.

ABSTRACT
The Clean Air Act (CAA) and its associated regulatory requirements represent one of the most complex environmental programs in the U.S. The program involves consideration not only of specific pollutants and processes associated with the generation of those pollutants, but also the application of mathematical modeling, periodic and possibly continuous emissions monitoring, analytical meteorology, source-receptor relationships, human health and ecological risk assessments, control techniques and management plans, reporting, and recordkeeping. These considerations can be compounded by the complexity of facility processes and the geographic siting of a facility. Meeting the applicable CAA requirements can be a complex task even for the most experienced DOE facility manager.
Using Technical Area 53 (TA-53), the Los Alamos Neutron Scattering Center (LANSCE), within the U.S. Department of Energy's (DOE) Los Alamos National Laboratory (LANL) as an example, this paper summarizes steps that were successfully taken to bring a complex facility into compliance with the radioactive air emissions requirements of the Clean Air Act (CAA).
Additionally, several other issues related to the Radionuclide NESHAP Memorandum of Understanding (MOU) between the USEPA and DOE for complex-wide application, as well as the USEPA's self-policing policy, will be covered briefly.
OBJECTIVES AND APPROACH
The primary objective of this paper is to examine how the LANSCE facility located at LANL successfully implemented new management techniques to demonstrate compliance with radioactive air emissions requirements after receiving U.S. Environmental Protection Agency (USEPA) citations for nonattainment. Secondarily, it suggests several additional air quality management program factors that might be considered by DOE and other facilities in seeking to address issues and opportunities associated with the management of facility air emissions. These represent factors that were not in place when the Notice of Noncompliance for radioactive air emissions was received.
INTRODUCTION
At the outset, it is important to recognize that three major portions of the Clean Air Act (CAA) Amendments of 1990 (P.L. 95-95) are most applicable to facilities managed by DOE: Titles I, V, and VI. Title I contains requirements associated with Attainment and Nonattainment Areas (107); National Ambient Air Quality Standards, or NAAQS (109); State Implementation Plans, or SIPs (110; Hazardous Air Pollutants, or HAPs (112); and the Prevention of Significant Deterioration, or PSD (160-169). Title V contains requirements to fulfill the Operating Permit Program (501-507), and Title VI contains requirements associated with Stratospheric Ozone Protection (601-618).Some of the specific CAA regulatory drivers that relate to DOE sites include the following recordkeeping and monitoring requirements:
  Requirements applicable to stationary sources that emit air pollutants for which a NAAQS is in effect to maintain records concerning the nature

and amount of these emission(s), along with air sampling data and other information deemed necessary to determine compliance with applicable emission limitations listed on the site's permit. These records must be kept a minimum of two years (40 CFR 51).

Requirements for stationary sources that emit HAPs involve the maintenance of monitoring data records, monitoring system calibration checks, and the occurrence and duration of any period during which the monitoring system is malfunctioning or inoperative; records of emissions test results from stack sampling that are used to determine total emissions; and records of concentrations at all sampling sites and other data needed to determine such concentrations. All these records must be held a minimum of two years (40 CFR 61).

Historically, most States and the Air Quality Management Districts (AQMDs) within them have issued air permits for individual non-radioactive emissions units under the applicable State Implementation Plan (SIP). Accurate and documented monitoring is the key to accountability and compliance under this regulatory approach. Continuous Emissions Monitoring (CEM) systems are referenced in 504 under Title V of the CAA. The entire CEM system must be installed and certified before it can be used for compliance, and a written quality assurance/quality control (QA/QC) plan must accompany the permit application. The CEM system utilized by a particular site would be dependent on the compounds of interest and the monitoring requirements based on the CAA.

DISCUSSION

Los Alamos National Laboratory (LANL, or "Lab") is a nuclear research lab located in northern New Mexico, immediately adjacent to Bandelier National Monument (Fig. 1) operated by the Board of Regents of the University of California. The Laboratory must meet the requirements of over 20 major environmental laws. Under the CAA, LANL is concerned with the National Emission Standards for Hazardous Air Pollutants (NESHAP) for radionuclides, asbestos, and beryllium; the NAAQS; and the New Mexico Air Quality Control Regulations. In addition, because Bandelier National Monument is adjacent to LANL, the air quality requirements associated with PSD also must be considered. The Air Quality and Meteorology Section of LANL's Environmental Protection Group (ESH-17) has responsibility for air quality services to LANL, including monitoring, surveillance, meteorology service, emergency response, and environmental assessment for ambient and facility need.

Fig. 1

New Mexico State ambient air quality standards are more stringent than the National standard for all items, and the Laboratory has been in compliance with all nonradiological ambient air quality standards for the past several years. LANL has a site-wide Air Quality permit application for non-radioactive emissions submitted to the New Mexico Environmental Department (NMED) under the Title V program. There is no permit, as such, for radioactive emissions; however, these are covered specifically under 40 CFR 61 Subpart H, which sets 10 mrem/year as the dose limit for DOE facilities.

TA-53, the Meson Physics Facility (Fig. 2) is used for physics research, and is the site for a linear particle accelerator for research in areas of basic physics, materials studies, and isotope production, the Ground Test Accelerator, the Proton Storage Ring, and the Los Alamos Neutron Scattering Center (LANSCE), formerly known as the Los Alamos Meson Physics Facility (LAMPF). By accelerating protons to an energy of 800 Mev

into graphite and tungsten targets, this facility produces a variety of sub-atomic particles. Over 25 radioisotopes are currently produced at LANSCE, primarily for a variety of medical and research procedures, and are distributed world-wide. A variety of radioactive materials are therefore generated at LANSCE by radioactivation, among them radioactive air emissions. The air that passes through the proton beams, as well as material used in the beam stops and experimental area, becomes activated while the beams are on. The radionuclides thus produced include Ar-41, Be-7, Br-82, C-10, C-11, N-13, N-16, O-14, O-15, Ta-182, and H-3.
Fig. 2
LANSCE operates approximately 3000 hrs/yr, or about 29% of the total number of available annual hours. Although LANSCE personnel would like to operate 7000 hrs/yr (80%), the overriding concern is that LANSCE contributes over 98% of the total allowed radionuclide emissions for the entire Lab.
As indicated earlier, accurate and effective monitoring is the primary method of assessing accountability and compliance, and CEMs are EPA's stated method of choice. At LANL, several systems are in place, designed to monitor both point and non-point sources as well as both radioactive and non-radioactive emissions. Radioactive air emissions at the Laboratory are evaluated primarily against 40 CFR Part 61, Subpart H, National Emission Standards for Emissions of Radionuclides Other Than Radon From Department of Energy Facilities, as well as DOE/EH-0173T, Environmental Regulatory Guide for Radiological Effluent Monitoring and Environmental Surveillance.
The Laboratory operates monitors to routinely measure primary pollutants, beryllium, acid precipitation, and visibility.
Radioactive Air Emissions. Based on self-reporting, in 1991 DOE notified EPA that it could not demonstrate full compliance with certain requirements under 40 CFR 61. As a result, the USEPA Region VI issued two Notices of Noncompliance (NONs). The first NON documented deficiencies in LANL's identification and evaluation of release sources, lack of stack monitoring equipment on all point release sources, inadequate quality assurance programs, and incomplete reporting. The second NON was issued for using a method that was not approved by EPA for calculating the emissions dose that resulted in exceeding the 10 mrem standard for calendar year 1990. The issuance of the NON immediately presented concerns to DOE and the University of California. DOE and EPA commenced negotiations for a Federal Facility Compliance Agreement to establish the framework for demonstration of site-wide compliance with NESHAPs requirements
Working with the EPA Region VI office in Dallas, Texas, DOE and the University of California-operated Lab made a concerted effort to correct these air program deficiencies. Procedures to more closely monitor the stack emissions were implemented. Four additional ambient air monitors co-located with LANL monitors in Los Alamos and nearby White Rock are used to verify LANL measurements, and to help quantify nonstack-type emissions.
As indicated, LANSCE contributes in excess of 98% of the Lab's total radioactive emission allowance. These products are very short-lived, as indicated in the isopleth (Fig. 3) which also illustrates the locations of LANSCE, monitoring sites, and the potentially Maximally Exposed Individuals (MEIs).
Fig. 3

Following receipt of the NON, measures were implemented at LANSCE to bring radioactive air emissions into compliance. In May 1995, the "LANL Radioactive Air Emissions Management Plan for LAMPF, TA-53" modified a 1993 plan ("LAMPF Compliance with Laboratory Radioactive Air Emissions Limits") in several ways. Two important changes of the new Air Emissions Management Plan: 1) although annual emissions reports to USEPA Region VI, as required by regulation, will continue, these reports will be filed internally monthly, making it easier to maintain running 12-month mrem totals; and 2) graded frequencies of data analyses and reporting of environmental exposure were replaced by more real-time management decision making, increasing assurances and administrative controls to achieve NESHAP compliance and providing more useful, defensible data. Other specified actions were also outlined in the new Air Emissions Management Plan. One of these, an Air Quality Group procedure, the "Monthly Curie Limit Projection for LAMPF", was developed to construct the monthly curie release limit used in tracking LANSCE releases, using CAP-88 modeling. This limit is imposed for any month following a month in which the running 12-month dose-to-date from LANSCE exceeds 7.0 mrem. This information is crucial, in that LANL needs to know the total of the previous 12 months' dose is as it approaches the 10 mrem/yr limit. A comparison of the total discharged Curies vs. the allowed total is graphed, such as this actual example from the month of November 1995 (Fig. 4).

Another change in the Air Emissions Management Plan was that the original agreement had called for automatic cessation of radionuclide-emitting Lab operations at 8.5 mrem; now the LANL/DOE management team meet when the accumulated total is 8.0 mrem, and agree on action to be taken when the total reach 8.5 mrem, dependent on current and pending conditions of activity. One other important change was the use of meteorological data during actual operating period, rather than using annual average meteorology data, as allowed by NESHAP regulations (by implication). Monthly projections will be modeled, using realistic but conservative meteorological data for the site. The intent is for projections to be conservative.

Fig. 4

Table I illustrates the new process for managing and reporting radioactive air emissions at LANSCE, from the inception of operations resulting in radioactive air emissions through actions to be taken should levels be projected to reach 8.5 mrem within the next month. Table II enumerates the steps taken to estimate emissions from LANSCE.

Table I

Table II

The appropriateness and accuracy of these procedures has been confirmed through off-site environmental monitoring results and doses calculated from measured stack emissions, as off-site doses have now been determined to be less than 10 mrem/yr, the Federal limit.

Additional Air Program Considerations. The above summarizes how LANL successfully implemented a management strategy for demonstrating compliance with radioactive air emissions requirements. It indicates not only how radionuclide emissions can be estimated and monitoring procedures implemented, but also how various operational, compliance, and management personnel can work together to demonstrate compliance at a complex facility. By nature, however, the steps that were summarized are retrospective. It is also useful to explore several program

considerations that have been put in place following issuance of the NON. These are summarized in the following with regard to the DOE/EPA MOU concerning NESHAPs for radionuclide emissions at DOE sites across the country, and the final USEPA policy on self-policing. In suggesting these approaches, the intent is to assist future compliance efforts by offering for consideration additional elements for meeting regulatory requirements. Not considered in the following are such approaches as the Risk Management Plan under 112(r) of the CAA, and the Environmental Management System under the voluntary ISO 14000 standard; while useful, they may be somewhat outside the scope of this paper.

Subsequent to the development of an air emissions management plan for LANSCE, the USEPA and DOE finalized a Radionuclide NESHAP MOU. This MOU serves to clarify provisions of 40 CFR Part 61, Subpart H, I, Q and T as they apply to DOE facilities. The MOU notes that in some instances where DOE facilities cannot demonstrate compliance that CEM requirements may present technical and procedural difficulties which necessitate significant effort and resources to resolve. Faced with these circumstances, the DOE facility and appropriate USEPA Regional Office can determine the most efficient compliance measures including consideration of alternative monitoring methods under 40 CFR 61.93(b)(3).

In addition to alternative monitoring methods, the MOU also indicates that engineering calculations and/or representative measurements may be used to comply with periodic confirmatory measurement requirements. This option may be applicable to those DOE facilities which have large numbers of minor release points and that have similar emissions and controls. DOE facility managers can use their best professional judgment, knowledge of the radionuclides and quantities being used in plant operations, and their potential for release to determine when representative measurements should be made and/or engineering calculations utilized.Under this MOU, DOE facilities (with prior USEPA approval) can also implement continuous monitoring procedures that differ from 40 CFR 61.93(b) reference methods; reasons for utilizing different reference methods include site-specific conditions as well as engineering, economic, health and safety considerations. In addition, the MOU allows for the use of environmental monitoring as an alternative to air dispersion calculations at critical receptor locations in order to demonstrate compliance with the radionuclide NESHAP; this assumes that the criteria contained in 6193(b)(5) are met and that the USEPA grants prior approval.

In addition to the USEPA/DOE Radionuclide NESHAP MOU, the USEPA issued on 22 December 1995 (60 FR 66706) a final self-policing policy, "Incentives for Self-Policing: Discovery, Disclosure, Correction and Prevention of Violations", aimed at encouraging the adoption of a voluntary approach to protecting the environment and public health. The policy which became effective on 22 January 1996 arose for several reasons including the realization that government enforcement efforts alone cannot achieve environmental compliance.

In implementing this self-policing policy, the USEPA has identified nine conditions that must be met in order to avoid gravity-based penalties (viz., the punitive portion of the penalty and not that portion which represents the economic gain from non-compliance). If all nine conditions are met, gravity-based penalties will not be sought. If all conditions are met except for the voluntary discovery of the violation through a formal environmental audit or due diligence, then the USEPA will reduce the gravity penalty by 75%.

The other conditions are:

Voluntary discovery other than through a legally mandated monitoring and sampling requirement that is required by law, regulation, permit, judicial or administrative order, or consent agreement. For example, the policy does not apply to:

- Violations discovered through CEM where such monitoring is required;
- Violations of NPDES discharge limits detected through sampling and monitoring; and
- Violations discovered through a compliance audit required by a consent order or settlement agreement.

Prompt disclosure in writing to the USEPA within 10 days of the specific violation.

Discovery and disclosure independent of government or third party plaintiff.

Correction of the violation with 60 days of disclosure.

Written agreement to prevent the future recurrence of the violation.

The USEPA self-policing policy indicates that criteria for determining due diligence can be met by a variety of compliance management programs. According to the policy, due diligence can be demonstrated through the systematic application of all of the following:

Identify how compliance policies, standards and procedures can meet the requirements of laws, regulations and permits.

Assignment of overall and specific responsibility for overseeing compliance with policies, standards and procedures.

Mechanisms for systematically assuring that compliance activities are being carried out.

Communication efforts with employees and others.

Compliance performance incentives for managers and employees.

Procedures for prompt and appropriate correction of violations.

The USEPA notes that this is a policy (not a regulation) which they expect USEPA employees to follow; however, the agency reserves the option of issuing a rulemaking at some later date if greater consistency and predictability are needed. Finally, within three years the USEPA will conduct a study to determine the effectiveness of this self-policing policy.

Both of these measures - the USEPA/DOE Radionuclide NESHAP MOU and the USEPA self-policing policy - add important new considerations to the facility management of air emissions control. Through these steps as well as others the complex and difficult task of achieving and maintaining facility compliance with the requirements of the CAA will be made more flexible and cost-effective.

CONCLUSIONS

The CAA is a very complex legal and regulatory framework, with interlocking and rigorous requirements. When LANL received two NONs for radioactive air emissions in 1991 from USEPA, DOE and LANL reacted by implementing a management plan to gain control of the Lab's radioactive air emissions program through a series of steps, including increased monitoring and reporting and actions to be taken at appropriate milestones. As the LANSCE facility within TA-53 contributes over 98% of the Lab's total radioactive air emissions, the majority of these steps were aimed specifically at LANSCE's emissions. This "Success Story" can serve as a guideline for other sites with similar problems, and other solutions/considerations that were not available at the time of TA-53's solution were covered in brief.

ABSTRACT
This paper presents a generalized approach to conducting performance assessments for low-level radioactive waste disposal facilities. It defines the components of the disposal system (the natural site, the engineered facility, and the waste disposed) and identifies characteristics of the components that are important to performance assessments. It presents and explains the sequence of performance assessment activities and also discusses the application of the performance assessment process in various stages of disposal facility development.

OVERVIEW

The extent of radiological performance assessment undertaken in the development of a low-level radioactive waste (LLW) disposal facility depends heavily upon the regulatory framework within which the facility must be developed. Radiological performance assessment is prescribed by regulations that control LLW disposal facility licensing, namely Title 10

of the Code of Federal Regulations, Part 61, (1,2) and compatible state regulations.

Regulations for LLW disposal facilities state general performance objectives, list technical requirements, and require that members of the general public, potential inadvertent intruders, and workers at the disposal facility be protected from radiation. Design features and operating procedures must be prepared that support these general performance objectives and the more detailed technical requirements. However, advance assurance that potential radiation exposures to members of the general public, inadvertent intruders, and facility workers will meet the performance objectives can only be provided through assessment of the facility's radiological performance.

Performance assessment involves systematically evaluating a disposal system to determine the likely extent of compliance with specific performance objectives.(3,4) The process consists of a sequence of technical activities, shown in Fig. 1, that are coordinated to generate estimates of the potential impacts of the disposed waste on human health and safety. The following are the major steps involved in assessing the performance of an LLW disposal facility:

Characterize the disposal system (i.e., waste, natural site, and disposal facility).

Identify potential radiation exposures (i.e., potential receptors and exposure scenarios).

Develop conceptual exposure models (i.e., contaminant release mechanisms, transport pathways, and uptake modes).

Develop calculational tools (i.e., mathematical models and computer codes).

Estimate and evaluate potential radiation exposures (i.e., baseline results, sensitivity analyses, uncertainty analyses, and review of results).

Revise inputs, models, and assumptions as appropriate.

Fig. 1

Radiological performance assessment should be an ongoing and iterative process, as depicted in Fig. 1. Early in the process, assumptions must be made about some characteristics that may not be known with confidence. However, as the development process continues, reliance on assumptions should decline while confidence in actual characteristics should strengthen. Furthermore, as the process continues, the results of previous assessments should be reviewed to ascertain whether key components of the assessment should be revised to reflect the improved knowledge of the disposal system characteristics. The six major steps in the performance assessment process are described below.

CHARACTERIZE THE DISPOSAL SYSTEM

The principal elements of the disposal system (the waste to be disposed, natural site, and disposal facility) should be as fully characterized as possible each time performance is assessed. Characterizing the waste element of the disposal system involves describing the types and quantities of waste to be disposed of in the LLW disposal facility.(2,4,5) Important components of this element include the annual disposal volume, radionuclide concentrations, physical and chemical characteristics, container characteristics, leaching characteristics, gas generation characteristics, and external gamma radiation levels.

Actual waste stream characteristics will be available only after disposal facility operations begin. Prior to that time, information must be

collected from the expected waste generators to develop the best possible estimates of the types and quantities of waste that will require disposal. These estimates should be updated as appropriate to maintain an accurate understanding of the waste. Figure 2 shows a sample format for presenting these data, although other formats may also be suitable.
Fig. 2
To characterize the natural site element, the abiotic and biotic conditions in the region selected for development of the LLW disposal facility must be described.(2,4,5) Key components of the natural site include the following:

- Prominent manmade and natural features in the area.
- Population distribution around the site.
- Meteorological and climatological characteristics.
- Geologic characteristics and resources.
- Seismic characteristics.
- Surface water and groundwater hydrologic characteristics.
- Geotechnical characteristics.
- Geochemical characteristics.
- Water resource utilization patterns.
- Biotic features.

Finally, characterizing the disposal facility element involves describing the disposal units, temporary holding facilities, buildings, equipment, and other engineered features (2,4,5) within the disposal (natural) site which are used for disposing of LLW. The descriptions of principal design features should include textual descriptions, engineering drawings, design calculations, construction procedures, and operating procedures.

IDENTIFY POTENTIAL RADIATION EXPOSURES

The next major step is the identification of potential receptors and definition of applicable exposure scenarios, as shown in Fig. 1. Potential receptors include

- Persons residing or who may reside at or near the boundary of the disposal facility during and following disposal operations.
- Persons who may inadvertently intrude into the stabilized disposal facility (whether or not into the waste itself) following the assumed loss of institutional control, nominally 100 years after facility closure.

Because of human persistence and creativity, protecting against intentional intrusion through passive means is extremely difficult if not impossible. Therefore, assessment of intentional intrusion should be considered optional.
Once the potential receptors have been identified, situations in which persons may be exposed to the waste or to releases from the disposal facility should be characterized. These situations, or exposure scenarios, should be broad enough in scope to provide reasonable assurance that no individual will receive radiation exposures greater than those received by the individuals posited in the assessment. They should also address the potential for both acute and chronic exposures. Exposure scenarios considered in a performance assessment should include offsite resident, intruder-drilling, intruder-construction, intruder-discovery, and intruder-agriculture scenarios.
The exposure scenarios developed should be internally consistent and reasonable, that is, their assumed events and activities should not involve conditions that could not logically occur.

DEVELOP CONCEPTUAL EXPOSURE MODELS

A conceptual model should be developed for each exposure scenario. The conceptual models define the release mechanisms, transport pathways, and modes of uptake that result in the postulated exposures.

All phenomena that control or influence the release of radionuclides from the disposal unit should be identified, described, and characterized. These may include water infiltration, container degradation, leaching, gas generation, and intrusion into the waste.

The pathways by which contaminants released from the disposal unit may be transported away from the disposal unit should be identified, described, and characterized.(2) These include groundwater, surface water, atmospheric diffusion and dispersion, gaseous releases through cover system, and food chain transport.

All phenomena that control or influence the exposure of humans to external radiation or the uptake of contaminants by humans should be identified, described, and characterized. These include water ingestion, food ingestion, inhalation, external radiation, and dermal absorption.

DEVELOP CALCULATIONAL TOOLS

Once a conceptual exposure model is developed, the Applicant should determine appropriate mathematical representations of each model component, as shown in Fig. 1. This process involves identifying models available for each phenomenon, evaluating model characteristics and abilities, comparing model characteristics and abilities to represent the most important aspects of the phenomena, and selecting the preferred model.

In general, several mathematical representations or models exist for each release mechanism, transport pathway, and uptake mode. Some models of a given phenomenon are simpler than others, and each has its own data requirements. The ability of each model to represent the actual phenomenon should be evaluated considering the limitations and strengths of each.

Most models of release mechanisms, transport pathways, and uptake modes have been implemented as computer codes and are widely available. Existing codes may require modification to adequately represent the phenomena at the disposal facility. When such modifications are necessary or preferable, care should be taken to ensure that the resulting code is properly implemented and documented. The code should be benchmarked and validated to the extent practical.

As a general rule, the model(s) used should not be more sophisticated than is necessary to adequately represent the actual phenomenon. Furthermore, the sophistication of the model(s) used in the performance assessment should be consistent with the level of detail of data available for input.

ESTIMATE AND EVALUATE POTENTIAL RADIATION EXPOSURES

As depicted in Fig. 1, after the first four major steps of the performance assessment have been completed, the performance of the disposal facility can be assessed. The assessment will demonstrate the extent to which the disposal facility satisfies radiological performance objectives, identify parameters significant to the analysis, and examine the effects of uncertainty on the projected results. Following the assessment, the results should be reviewed for reasonability and consistency with data collected during characterization efforts.

The base-case performance assessment indicates the extent of compliance with the performance objectives and technical requirements using the actual or expected conditions at the facility. Under many circumstances,

the actual conditions will be represented by making simplifying assumptions. When simplifying assumptions are necessary, they should be conservative (i.e., that the exposure results will not be understated), but also realistic. Extreme levels of conservatism may not be useful.

A significant element of the performance assessment is the analysis of sensitivities and uncertainties in the assessment.(6,7) Sensitivity analyses are conducted to identify important elements and parameters of the system, and involve estimates of changes in performance measures produced by changes in the variables of the system. Uncertainty analyses are conducted to identify uncertainties associated with the important elements and parameters of the system, and to understand the impacts these uncertainties have on the conclusions drawn from the calculated performance measures.

Sensitivity analyses typically involve perturbing each model parameter while keeping all other parameters at their nominal values. The relative effect of the perturbation on the model prediction is quantified; the parameters having the greatest influence on the model projections are designated as the most sensitive parameters in the model. Sensitivity analyses, then, focus on identifying the model parameters of greatest consequence to the projected results.

The need for uncertainty analyses arises from the fact that all environmental and dose assessment models are inherently uncertain. Uncertainties have been categorized as a)uncertainty in conceptual and mathematical models (model uncertainty); b)uncertainty about the future state of the site (scenario uncertainty); and c)uncertainty in the input data used in the models (parameter uncertainty).(7)

The results of all performance assessment calculations should be reviewed to ensure that they are reasonable and internally consistent. The results should be compared with assumed conditions to ensure that no logical contradiction exists. If calculated results infer a condition that is different from an assumed condition, the contradiction should be pursued to determine whether the assumed condition should be revised, or whether more fundamental aspects of the modeling process should be questioned. The process of judging the reasonability of calculated results requires knowledge of the sensitivities and uncertainties, as well as the perspective they provide.

REVISE INPUTS, MODELS, ASSUMPTIONS

Upon reviewing the results of the performance assessment, the need for revisions to the modeling process should be determined, as shown in Fig. 1. The extent of revisions may be as superficial as revising selected input values. However, the review of the results may also reveal that the entire performance assessment process should be revised. This may be the case, for example, if additional site-specific data indicate that the site conceptual model used in the performance assessment was inappropriate.

The potential effects that any data revisions may have on performance assessment results should be considered. If the revisions are expected to have important effects, the assessment should be revised to make it consistent with the data revisions. The revised performance assessment results should receive scrutiny similar to that received by the original results to ensure it is reasonable and internally consistent.

Revisions in the performance assessment process may be made within a particular stage of the facility life or as the facility evolves from one stage to the next. If the revisions are made within a single facility

stage, they may be made to virtually any step in the performance assessment process, as shown in Fig. 1. If the facility is progressing from one stage to the next, consideration should be given to reviewing all steps in the process and evaluating previous decisions according to the most recent and complete information available.

CUSTOMIZING PERFORMANCE ASSESSMENT TO EVOLVING NEEDS

The important stages of the disposal facility development process during which the radiological performance should be assessed are the following:

- Site screening.
- Site characterization and selection.
- Facility design and licensing.
- Facility operations.
- Facility closure and decommissioning.
- Facility postclosure and monitoring.
- Long-term care and license termination.

The objectives of assessing radiological performance and the nature of such assessments change significantly throughout the facility life. Early on, the extent of knowledge about the waste, site, and facility is relatively limited and superficial compared to that existing following facility closure. Differences in the extent of knowledge that exists over time should influence the methodology used to assess radiological performance and the emphasis placed on the results of such assessments. In early stages of the facility development process, the results of performance assessments should be used to influence (but not dictate) decision making. Later, performance assessments should be used to confirm earlier projections of facility performance and to identify appropriate monitoring and management approaches.

WORKSHOP -- HOW CLEAN IS CLEAN

Co-Chairs: J. S. Devgun, Consultant; D. LeMone, UTEP

WORKSHOP SUMMARY
"HOW CLEAN IS CLEAN?"
D&D AND RELEASE CRITERIA
J. S. Devgun, Ph.D.
1018 Rain Tree Dr.
Bolingbrook, IL 60440

This workshop was the fourth in the "How Clean is Clean?" series. The workshop focused on the important topic of release criteria for decontamination and decommissioning. The number of facilities and sites requiring D&D and cleanup runs into thousands, and the cleanup costs are projected to be in hundreds of billions of dollars. In the DOE complex alone about 6,000 facilities have been declared surplus and targeted for D&D. A number of nuclear power reactors have also been decommissioned worldwide and many other projects are currently underway. With D&D gaining momentum both in the federal and the private sector, the objective this year was to focus discussion specifically on the release criteria relevant to D&D projects.

A panel of experts was convened to discuss and debate the issues related to the theme of the workshop. The panel included representatives from the U.S. Department of Energy (DOE), U.S. Nuclear Regulatory Commission (NRC), Atomic Energy of Canada Limited (AECL), Los Alamos National Laboratory (LANL), Scientific Ecology Group (SEG), and the two workshop Co-Chairs.

Workshop format included presentations by the panelists followed by breaking out into two focus groups and then reconvening for a general discussion. Each focus group was led by two discussion leaders. The topics for group discussion were:

1) Risk-based criteria vs.generic concentration limits (site-specific criteria, pathways modeling, ALARA)
2) Criteria, cost and the need for BRC or de minimus.

Jas Devgun provided an overview of the D&D in the nuclear power industry and in the federal sector along with a very brief summary of the international projects. He also summarized the relevant national regulations and the international guides. NRC's proposed D&D criteria of 15 mrem/yr TEDE was also discussed.

Anthony Kluk of DOE discussed the DOE Order 5400.5 which lists the release guidelines used by DOE for decontamination of equipment, structures, and sites, implementation of these guidelines presented in DOE/CH 8901 report, application of RESRAD, and field examples from the Santa Susana Field Laboratory D&D project. Recent guidance from DOE/EH is that limit for soil should be selected such that ALARAis used and documented and that individual dose to a member of the public is less than 25 mrem/yr. Margaret Federline represented the NRC and provided an overview of the existing NRC criteria and guidance. Summary of the proposed rule was presented along with a detailed discussion of the public comments. The proposed rule provides a limit of 15 mrem/yr plus ALARA for unrestricted release.

The EPA representative or alternate were not able to attend. Notes presented by the EPA representative at the second workshop (Anthony Wolbarst) were considered relevant to D&D and were made available to the participants.

Robert Pollock of AECL presented the Canadian perspective on D&D and the release criteria. Regulatory Guide R-85 provides the policy statement.

The document provides radiation protection prerequisites for the exemption of certain radioactive materials from further licensing upon transferral for disposal.

Patrick LaFrate discussed the decontamination and decommissioning of surplus facilities at LANL. Lessons learned from these projects were discussed. The metal from D&D operations was recycled at SEG's facilities in Oak Ridge. James Nicolosi of SEG describes a processor's perspective and discussed the metal recycle facilities now available in Oak Ridge. David LeMone (UTEP) summarized the international developments in the D&D and the BRC area. Decommissioning plans recommended by the International Atomic Energy Agency were discussed as were the activities categories for radioactive scrap metal.

The discussion groups were led by Matthew Kozak, Mahmoud Haghighi, and the two Co- Chairs. The panelists also participated in the discussion groups. Each group presented their key points when all participants reconvened for a general discussion. Risk-based cleanup criteria were generally favored by the participants rather than the generic limits. Release criteria remain in flux. There is a need on the part of the federal agencies to come to a consensus on the acceptable dose criteria. Two recent events in this area are significant. One is the formation of Interagency Steering Committee on Radiation Standards (ISCORS) in April 1995. The other is the Multi-Agency Radiological Site Survey and Investigation Manual (MARSSIM) that is expected to be issued in mid-1996 in the draft form.

Approximately 70 people participated in the workshop. A package of papers, notes, and view graphs was provided to each participant. In the evaluations, a majority of the participants rated the workshop in the "good" to "very good" category.

Call For Papers
March 2-7, 1997
"HLW, LLW, Mixed Wastes and Environmental Restoration-Working Towards a Cleaner Environment"

WM'97, will be held March 2-7, 1997 at the Tucson Convention Center, Tucson, Arizona. Organized by WM Symposia, Inc., an Arizona non-profit corporation, the conference is hosted by the University of Arizona. Sponsoring organizations include the University of Arizona, the American Nuclear Society, the U.S. Department of Energy, New Mexico State University with the Waste-management Education and Research Consortium (WERC), and the American Society of Mechanical Engineers. The conference is organized in cooperation with the International Atomic Energy Agency. To assist international participation, we have added the names of contact people outside the US for as many topics as possible. The topics selected for WM'97 will have invited and contributed papers involving research, development and operational experience in nuclear waste, mixed waste, mill tailings, environmental restoration, waste management, and decommissioning. Papers concerning national and international agreements and regulations governing these topics as well as the impact of these activities on the environment are also solicited. Interested contributors to the meeting are invited to submit extended summaries on a 3 1/2 inch diskette and three hard copies. A single copy by fax will be accepted but the 3 1/2 diskette and three hard copies must follow by overnight mail. The disk is necessary for publishing to the World Wide Web (WWW), which we are considering in order to make the abstracts available to the Program Advisory Committee before the Paper Review. The Program Advisory Committee will be provided with an access code so that only they will be able to access this information two weeks prior to the Paper Review. The authors will be required to approve placing their summary on the WWW. Such approval has no influence on acceptance of the summary.

The summaries must show clearly 1) Topic (what paper is about), 2) Basis for originality, 3) or audience interest, 4) Conclusions. Summaries not meeting the above criteria will not be considered by the Program Advisory Committee (PAC). The fully completed attached form must accompany the extended summary for it to be considered. If you do not receive an acknowledgment within 10 days of your mailing, call (520) 624-8573. The approved papers will be assigned to either oral, poster or workshop sessions by the Technical Program Chairman with the advice of the PAC. The criteria for assignment is to assure that each paper is presented in the method of presentation best suited for its content, format and anticipated interaction with its audience. The publication of both the poster and oral papers will be identical.

The summaries will undergo critical technical review by the PAC to determine if they meet the criteria of technical content, significance and subject. The summary should be long enough to convey to the committee the substance of your proposed paper and its meeting of the stated criteria. Summaries submitted after due date may not be considered. Concerns about the quality of some papers which could be attributed to inadequate preparation led to our new policy of requiring that full papers be written and reviewed before the presentation. This process will also permit much earlier publication.

The full papers will be published on CD's and on the WWW. We also plan to put each full paper on the WWW as it is completed. This will provide much earlier distribution of your work, limited only by your submission schedule. WM'95 was our first use of CD's and some special considerations were granted which will not be possible for WM'97. We expect that many papers will be on the net before the conference but they will be

available only to the early registrants who have paid. Wouldn't you like for your paper to be one of the first available?
Please follow the schedule listed below:

Summary due by	August 16, 1996
Paper Review	September 16, 1996
Draft Full Papers	November 15, 1996
Reviewer Comments to Author	December 15, 1996
Final Approved Papers Due	February 3, 1997

Please mail abstracts to: WM Symposia, Inc.

Note: If you do not receive an acknowledgment card by September 13, 1996, please call and verify that your abstract was received. An abstract that has not been acknowledged will not be accepted after the paper review for late addition to the program.
WM'97 Topics
Topics are listed under "Tracks" designed to highlight specific interests. There is no longer a need for the words US or International since all sessions are open to papers from all countries and are limited only by technical content and relevance. In the event that an entire session deals with a given International group then we will identify the group doing the organization of the session. All topics include Regulatory, Standards, Technology, QA, Risk Assessment, Fate and Transport Modeling and Monitoring where appropriate.

GENERAL SESSIONS

1.0 Nuclear Waste Policies and Programs-Lawrence Harmon, MACTEC, V-(301)353-9444, F-(301)353-9447; Edward J. Bentz, Jr., E.J. Bentz & Assoc., Inc., V-(703)455-7469, F-(703)-912-6578

1.1 Plenary-Roy G. Post, WM Symposia, Inc., V-(520)624-8573, F-(520)792-3993, E-mail-wmsym@basix.com (*rgp@wmsym.org; Morton E. Wacks, U of AZ, V-(520)624-8573, F-(520)792-3993, E-mail-wmsym@basix.com (*mew@wmsym.org)
*address will be changing soon

1.2 Programs and Progress-Lawrence Harmon, MACTEC, V-(301)353-9444, F-(301)353-9447; Pierre Barber, ANDRA, V-33-1-46-11-8068, F-33-1-46-11-8268

1.3 Regulatory Compliance-Edward J. Bentz, Jr., E.J. Bentz & Assoc., Inc., V-(703)455-7469, F-(703)-912-6578; Donald E. Wood, WHC, V-(509)376-7832, F-(509)372-1033, E-mail-Donald_E_Wood@rl.gov

1.4 Health and Safety Issues-Carol A. Peabody, USDOE, (202)586-0201, F-(202)586-0916

2.0 High-Level-(Including Spent Fuel), Transuranic- and Long-Lived-Waste-Marshall J. Anderson, BDM Federal, Inc., V-(301)601-5382, F-(301)601-5426, E-mail- manderso@bdm.com; Jim W. Voss, Golder Associates International, V-(206)556-5590, F-(206)556-5595; Leif G. Erikkson, Advanced Sciences, Inc.,V-(505)887-1079, F-(505)887-5494; Joachim Fleisch, WAK, V-49-7247-88-2230, F-49-7247-88-2144

2.1 Status-Myron Kaczmarsky, Raytheon Engineers & Constructors, V-(212)839-3296, F-(212)839-3269; Warren Bodily, Westinghouse Electric Corp., V-(505)234-8990, F-(505)887-2116; Leif G. Erikkson, Advanced Sciences, Inc., V-(505)887-1079, F-(505)887-5494; Jurg Schneider, NAGRA, V-011-41-56-4371111, F-011-56-4371207

2.2 Concepts under Investigation (Including Environmental Studies)-Harry Babad, Westinghouse Hanford Co., V-(509)373-2897, F-(509)373-3198, E-mail-harry_babad@rl.gov; John Mathieson, UK Nirex, V-44-1235-825606, F-44-1235-825459, E-mail-100661.3164@compuserve.com

2.3 High Level Tank Waste Remediation*-Harry Babad, Westinghouse Hanford Co., V-(509)373-2897, F-(509)373-3198, E-mail-harry_babad@rl.gov; Ray D. Walton, Jr., Argonne National Lab., V-(301)948-0698 x-24, F-(301)990-1929; Ted McIntosh, USDOE, V-(301)903-7189, F-(301)903-8506

3.0 Low/Intermediate Level (Including Very Low Level Waste) and Mixed Waste Treatment Stabilization & Disposal-Lloyd McClure, Lockheed-Martin IdahoTechnologies Co., V-(208)526-1170, F-(208)526-5142; M. Jorda, ANDRA, V-33-1-46-118367, F-33-1-46-11-83-48; Leon C. Borduin, LANL, V-(505)667-3150, F-(505)665-2897; Radovan Kohout, Kohout & Associates, V-(416)488-9466, F-(416)488-2007

3.1 Status-Gary Benda, Consultant, V-(803)345-2170, F-Same; K.W. Han, IAEA, V-43-1-2060-22672, F-43-1-20607, E-mail-hank@nepo1.iaea.or.at

3.2 New Stabilization and Disposal Concepts under Investigation (Including Vitrification)-Paul Kalb, Brookhaven National Lab., V-(516)344-7644, F-(516)344-4486, E-mail-kalb@bnl.gov; A. Jouan, CEA, Marcoule, V-33-66-79-63-76, F-33-66-79-60-30, E-mail-milhes@cea.fr

3.3 State Compacts Status*-David E. Stewart, Bechtel Savannah River, V-(803)208-0541, F-(803)208-8117; Ali Yazdi, Bechtel Environmental Inc., V-(423)220-2340, F-(423)220-2103, E-mail-axyazdi@am@ornl; Holmes Brown, Afton Associates, V-(202)547-2620, F-(202)547-1668

4.0 Transportation and Packaging (Including Control)-H. Richard Yoshimura, Sandia National Labs., V-(505)845-8181, F-(505)844-0244, E-mail-hryoshi@ttd.sandia.gov; Carole B. Bentz,
E. J. Bentz & Assoc., Inc., V-(703)455-7469, F-(703)912-6578; B. Kirchner, Transnucleaire, V-33-1-4069-7678, F-33-1-40-69-7701

4.1 High Level and Transuranic Waste-Warren Bodily, Westinghouse Electric Corp., V-(505)234-8990, F-(505)887-2116; C.F. Wu, Westinghouse Electric Corp., V-(505)234-8384, F-(505)885-4562; Carole B. Bentz, E. J. Bentz & Associates, Inc., V-(703)455-7469, F-(703)912-6578

4.2 Low/Intermediate Level Waste-Al Grella, Grella Consulting Inc., V-540-972-2538, F-Same, E-mail-algrella@pc-central.com; F. DeCamps, ONDRAF/NIRAS, V-32-2-2121060, F-32-22-185165

4.3 New Concepts under Investigation-Richard Rawl, IAEA, V-43-1-2060-21260, F-43-1-20607; Lawrence Harmon, MACTEC, V-(301)353-9444, F-(301)353-9447

5.0 Environmental Restoration-Gary Benda, Consultant, V-(803)345-2170, F-Same; A. Freitag, Bechtel Hanford Inc., V-(509)375-9687, F-(509)372-9117

5.1 Status-A. Scott Dam, BNFL Inc., V-(703)385-7100, F-(703)385-7128

5.2 New Concepts Under Investigation-Edward L. Helminski, Exchange Monitor Publications, V-(202)296-2814, F-(202)296-2805; K. Komorowski, BMBF,V-49-228-57-3758 (or 3759), F-49-228-57-3605; Don Clark, IAEA, V-43-1-2060-26102, F-43-1-20607, E-mail-Clarkd@NEP01.IAEA.OR.AT

5.3 Decontamination and Decommissioning-A. Freitag, Bechtel Hanford, Inc., V-(509)375-9687, F-(509)372-9447; A. Sheil, BNFL UK Group, V-019467 74830, F-019467 71193; S. Halaszovich, KFA, V-49-2461-61-3207, F-49-2461-61-2460

6.0 Utility Waste Management-C. Clint Miller, Pacific Gas & Electric Co., V-(805)545-4582, F-(805)545-3459

6.1 At Reactor and Away From Reactor Fuel Storage-C. Bonnet, SGN, V-33-1-30-587498, F-33-1-30-587628; Ramesh Dayal, Ontario Hydro, V-(416)207-6049, F-(416)207-6094, E-mail-dayalr@rd.hydro.on.ca

6.2 Low/Intermediate Level Waste Processing-C. Clint Miller, Pacifc Gas & Electric Co., V-(805)545-4582, F-(805)545-3459; A. Scott Dam, BNFL Inc., V-(703)385-7100, F-(703)385-7128

6.3 Low/Intermediate Level Waste Storage-Larry C. Oyen, Sargent & Lundy, V-(312)269-6750, E-mail-Larry.c.oyen@slchicago.infonet.com A. Rex Meeden, APS, V-(602)393-6582, F-(602)393-5285

6.4 New Concepts in Utility Waste Management under Investigation-A. Rex Meeden, AZ Public Service, V-(602)393-6582, F-(602)393-5285; Thomas L. Nauman, ComEd, V-(815)942-2920 ext. 2841, F-(815)942-0579

6.5 Reactor Decontamination and Decommissioning-A. Freitag, Bechtel Hanford, Inc., V-(509)375-9687, F-(509)372-9447; Jas S. Devgun, Consultant, V-(708)985-9386, F-Same; Michele Laraia, IAEA, V-43-1-2060-26105, F-43-1-20607, E-mail-Laraia@NEP01.IAEA.OR.AT

6.6 NPP Waste Minimization Techniques-C. Clint Miller, Pacific Gas & Electric Co., V-(805)545-4582, F-(805)545-3459; Jas S. Devgun, Consultant, V-(708)985-9386, F-Same; E. Tarnuzzer, Consultant, V-(508)897-8512

6.7 Toxic & Hazardous Waste Management AT NPP-Jas S. Devgun, Consultant, V-(708)985-9386, F-Same; M. Mauzy, Roy F. Weston, Inc., V-(505)884-5050, F-(505)837-6870

7.0 Public Communication, Participation, Education and Training-Linda Ulland, Minnesota Pollution Control Agency, V-(218)828-6115, F-(218)828-2594; Ginger King, OCI Inc., (703)616-5307, F-(703)416-0007; Carol Worth, Words Worth Publishing & Communications, V-(703)742-0017, F-(703)742-0059, E-mail-Carolworth@aol.com

7.1 Impact of Information Technology on Community Outreach, Environmental Sciences and Public Acceptability-Ginger King, OCI Inc., V-(703)616-5307, F-(703)416-0007

7.2 Indigenous People-Merv L. Tano, Council of Energy Resource Tribes, V-(303)297-2378, F-(303)296-5690, E-mail-mervtano@ix.netcom.com;Michelle Rehmann, Energy Fuels Nuclear Inc., V-(303)899-5647, F-(303)595-0930

7.3 New Concepts under Investigation-Connie Callan, The University of New Mexico, V-(505)277-7750, F-(505)277-7833; Ron Bhada, WERC, V-(505)646-1510, F-(505)646-4149

7.4 Spent Fuel Storage and MRS Concepts*- Merv. L. Tano, Council of Energy Resource Tribes, V-(303)297-2378, F-(303)296-5690, E-mail-mervtano@ix.netcom.com

8.0 Infrastructure in Waste Management-Lowell Snow, Consultant, V-(703)690-3545, F-Same

8.1 Cost Effectiveness (Cost/Benefit) Analysis-Lloyd McClure, LIMTCO, V-(208)526-1170, F-(208)526-5142; John Mathieson, UK Nirex, V-44-1235-825606, F-44-1235-825459, E-mail-100661.3164@compuserve.com

8.2 Data Management-Jorma Heinonen, Lappeenranta Univ. Of Technology, V-358-53-621-2602, F-358-53-621-2699; Marshall J. Anderson, BDM Federal, V-(301)601-5382, F-(301)601-5426; H-J. Engelmann, DBE, V-49-5171-917710, F-49-5171-917740; Carlos Torres, IAEA, V-431-2060-21428, F-431-20607

8.3 Project Privatization and Outsourcing of Waste Services-J. Ed Day, ADTECHS, V-(703)713-9000, F-(703)713-9101; William Greenman, GTS-Duratek, V-(410)290-7078, F-(301)621-8211; Edward L. Helminski, Exchange Monitor Publications, Inc., V-(202)296-2814, F-(202)296-2805

9.0 Other Waste Problems, e.g. Mill Tailings-Morton E. Wacks, U of AZ, V-(520)624-8573, F-(520)792-3993, E-mail-wmsym@basix.com (*mew@wmsym.org); Werner Lutze, The University of New Mexico, V -(505)277-7964, F-(505)277-5433

WORKSHOPS

1. "HOW CLEAN IS CLEAN" --- JAS S. DEVGUN, CONSULTANT, V-(708)985-9386, F-Same

2. "UTILITY ROUND TABLE" --- C. CLINT MILLER, PACIFIC GAS & ELECTRIC CO., V-(805)545-4582, F-(805)545-3459

3. "ADVANCES IN REMOTE SENSING AND ENVIRONMENTAL SURVEILLANCE" --- JOE ANGELO, JR., CONSULTANT, V-(407)779-1313, F-(407)773-5866

4. "EFFECTIVE UTILIZATION OF NEWS MEDIA--HOW ARE WE DOING??"---CAROL WORTH, WORDS WORTH PUBLISHING & COMMUNICATIONS, V-(703)742-0017, F-(703)742-0059

SPECIAL SESSIONS

1. "MULTINATIONAL REPOSITORIES" --- JIM W. VOSS, GOLDER ASSOCIATES INTERNATIONAL, V-(206)556-5590, F-(206)556-5595; H. FUCHS, GNS, V-49-201-109-1502, F-49-201-109-1135

2. "MANAGEMENT OF PLUTONIUM" --- LLOYD MCCLURE, LOCKHEED-MARTIN IDAHO TECHNOLOGIES CO., V-(208)526-1170, F-(208)526-5142; JEAN-CLAUDE GUAIS, NUSYS, V-33-1-40 69 7600, F-33-1-47 20 85 96; NOBORU OI, IAEA, V-43-1-2060-22766, F-43-1-20607, E-MAIL-Oi@NEP01.IAEA.OR.AT

3. "METAL RECYCLE, FACILITY REUSE, AND ASSET RECOVERY" --- JOHN KENNERLY, LOCKHEED MARTIN ENERGY SYSTEMS, V-(423)241-3939, F-(423-574-9538; M. SAPPOK, SIEMPELKAMP, V-49-2151-894-205, F-49-2151-894-455

4. "POLLUTION PREVENTION/WASTE MINIMIZATION" --- DAVID A. ZIGELMAN, WESTINGHOUSE SAVANNAH RIVER CO., V-(803)557-6325, F-(803)557-6306; STEPHAN HALASZOVICH, KFA-JLICH, V-49-2461-61-3207, F-49-2461-61-2460

5. "ON-SITE STORAGE/DISPOSAL OF REMEDIATION ILW/LLW" --- J. ERICH EVERED, JACOBS ENGINEERING GROUP INC., V-(803)641-4400, F-(803)641-4414

6. "TRANSURANIC WASTE - WILL WIPP END THE ISSUE?*" --- MICHAEL P. MAUZY, ROY F. WESTON INC., V-(505)884-5050, F-(505)837-6870; LEIF G. ERIKKSON, ADVANCED SCIENCES, INC., V-(505)887-1079, F-(505)887-5494

7. "ENVIRONMENTAL JUSTICE IN MINORITY AND LOW-INCOME POPULATIONS" (EXECUTIVE ORDER 12898)* --- MICHELLE REHMANN, ENERGY FUELS NUCLEAR INC., V-(303)899-5647, F-(303)595-0930

8. "ROBOTICS" --- JOSEPH A. ANGELO, JR., CONSULTANT, V-(407)779-1313, F-(407)773-5866

9. "MARKET DRIVEN RECYCLING" ---MICHAEL GRESALFI, LOCKHEED-MARTIN, V-(301)742-2566, F-(301)916-8699; JACK MCELROY, GEOSAFE CORP., V-(509)375-0710, F-(509)375-7721

10. "WEST VALLEY AND SAVANNAH RIVER PLANT (DWPF) VITRIFICATION*" --- MYRON KACZMARSKY, RAYTHEON ENGINEERS & CONSTRUCTORS, V-(212)839-3296, F-(212)839-3269

11. "HYDROGEOLOGIC AND GEOCHEMICAL ASPECTS OF WASTE DISPOSAL" --- R.L. BASSETT, U OF AZ, V-(520)621-6215, F-(520)621-1422; ADRIAN BATH, GOLDER ASSOCIATES, UK Ltd., V-44-115-945-6544, F-44-115-945-6540

12. "DEFENSIBILITY OF RISK ASSESSMENT IN THE LEGAL SYSTEM" --- EVARISTO J. BONANO, BETA CORPORATION INTL., V-(505)822-1968, F-(505)822-1959; EDWARD J. BENTZ, JR., E.J. BENTZ & ASSOCIATES, INC., V-(703)455-7469, F-(703)912-6578

13. "END OF SEGREGATED MARKET FOR WASTE DISPOSAL*" --- EDWARD L. HELMINSKI, EXCHANGE MONITOR PUBLICATIONS, INC., V-(202)296-2814, F-(202)296-2805

14. "ADVANCES IN NON-INTRUSIVE INSPECTION AND WASTE CHARACTERIZATION" --- JOE ANGELO JR., CONSULTANT, V-(407)779-1313, F-(407)773-5866; R. ODOJ, KFA, V-49-2461 616190, F-49-2461 612450

15. "WASTE STREAMS ASSOCIATED WITH THE DISMANTLING OF NUCLEAR WEAPONS" --- JOE ANGELO JR., CONSULTANT, V-(407)779-1313, F-(407)773-5866

16. "ADVANCED ENVIRONMENTAL EDUCATION BY DESIGN APPLICATION"---RON BHADA, WERC, V-(505)646-1510, F-(505)646-4149; ABBAS GHASSEMI, WERC, V-(505)646-1719, F-(505)646-4149

17. "BUILDING ON THE FFCA MODEL - A NEW WAY OF DOING BUSINESS IN THE DEPARTMENT OF ENERGY*"---LAWRENCE HARMON, MACTEC, V-(301)353-9444, F-(301)353-9447

18. "ISO 14000 ENVIRONMENTAL MANAGEMENT SYSTEMS STANDARD*"---JO-ANN HOLST, THE S.M. STOLLER CORPORATION, V-(303)449-7220, F-(303)443-1408; LARRY STIRLING, USDOE, V-(202)586-2417, F-(202)586-0955

* INDICATES A SESSION OF SPECIAL INTEREST TO THE UNITED STATES OF AMERICA, PAPERS FROM OTHER COUNTRIES CONCERNING SIMILAR INTERESTS WILL BE CONSIDERED WITH THESE WHEN APPROPRIATE.
